Moore and Weller (2013) considered four models in their analysis but they based final inferences on what they termed Model 2B. Here, we use Model 2A instead. Models 2A and 2B are similar. The difference is that for Model 2A, the conditional probability of a non-PCFG whale being a WNP (rather than ENP) whale is simply based on the ratio of WNP:ENP population size. This is an intuitive estimator, though it does rely on the assumption that WNP and ENP animals migrating together are using the same migration corridors and behaving similarly. For Model 2B, this assumption is relaxed and we allow for broader uncertainty by stating that the conditional probability varies uniformly from zero (if the WNP whales do not migrate through the Makah area at all) to some maximum value that is based on (but not equivalent to) the ratio of WNP:ENP population size. However, it is difficult to define that maximum value, and allowing a lower probability of zero is not precautionary and arguably should not be considered without supporting evidence.

Model 2 (A and B) makes use of the mixing proportion/sightings data for the Makah hunt area, as well as WNP and ENP abundance estimates. WNP whales are assumed to be moving with the ENP migrants, so that the marginal probability of a WNP whale being struck is the probability that the struck whale is a migrant, P_{mig} (i.e., probability of not being a PCFG whale), multiplied by the conditional probability of being a WNP whale given that it is a migrant ($P_{WNP|mig}$). Thus, $P_{WNP} = P_{mig}P_{WNP|mig}$.

P_{mig} is defined as 1 – P_{PCFG}, where P_{PCFG} is given by an informative prior: P_{PCFG} ~ Beta (5.3648, 13.7952) which has a mean of 0.28 and SD of 0.1 (IWC 2018).

We assume that the per-capita likelihood of a migrating (non-PCFG) whale in the hunt area being a WNP whale (i.e., $P_{WNP|mig}$) is simply given by the proportion of the migrating population made up of WNP whales. This proportion depends on what fraction of the WNP population migrates along the U.S. West Coast, which we call *m*, and the relative size of the WNP to the ENP population. Thus, $P_{WNP|mig} = mN_{WNP}/(mN_{WNP} + N_{ENP})$. Let m ~ Uniform (0.37, 1), based on Cooke *et al.* (2015). N_{WNP} and N_{ENP} are treated as lognormally distributed variables with means and CVs as given above.

Estimation

Earlier analyses (Moore and Weller, 2013) used Bayesian estimation. In the current exercise, analysis was conducted using OpenBUGS software, but estimation is not strictly Bayesian because there are no new data updating the informative prior inputs. Rather, the present analysis is essentially a Monte Carlo procedure, with distributions for the parameters of interest (e.g., probability of striking a WNP whale) being derived from random draws from informed prior distributions for the input parameters. Derived parameter distributions are summarized from two MCMC chains, each 25,000 samples in length (50,000 samples total).

Derived parameters

The key parameter of interest is the per-strike probability of striking a WNP whale. Derived from this parameter are the probabilities of striking at least one WNP out of 3 gray whale strikes (i.e., the annual probability of striking a WNP whale, for the even-numbered years) or out of 15 gray whale strikes (i.e., probability for the whole 10-year period). These are calculated as $P(x > 0) = 1 – (1 – P_{WNP})^X$, where X is 3 or 15. Additionally, we can derive the expected number of WNP strikes as $E(x) = P_{WNP}X$. Using data collected during previous hunts (NMFS, 2015), the following two assumptions were used to calculate analogous estimates for vessel approaches and unsuccessful strike attempts: (1) there will be 353 vessel approaches per year (3530 across all 10 years)[3], and (2) there will be 6 unsuccessful strike attempts for every strike in an even-year hunt[4].

RESULTS

Parameter estimates

Estimated parameters from all model sets are in Table 1. Figure 2 shows the distribution for P_{WNP}. It is straightforward to integrate across the uncertainty in P_{WNP} to obtain a single probability estimate. We did this for the probability of striking ≥ 1 WNP whale over the entire 10-year hunt period (i.e., out of 15 strikes). This probability was 0.058.

Table 1. Distribution summaries for key model parameters. "Prob(WNP)" is the probability of at least 1 WNP animal being struck or subjected to unsuccessful strike attempts or vessel approaches given the specified number of events.

Parameter	Posterior mean	2.5% CRI	Posterior median	97.5% CRI
Prob(WNP) for a single interaction, i.e., P_{WNP}	0.004	0.002	0.004	0.007
Prob(WNP|3 strikes in 1 yr)	0.012	0.006	0.012	0.019
Prob(WNP|15 strikes in 10 yrs)	0.058	0.030	0.057	0.093
Prob(WNP|18 unsuccessful strike attempts in 1 yr)	0.070	0.036	0.069	0.110
Prob(WNP|90 unsuccessful strike attempts in 10 yrs)	0.299	0.167	0.298	0.442
Prob(WNP|353 approaches in 1 yr)	0.735	0.511	0.751	0.899
Prob(WNP|3530 approaches in 10 yrs)	~ 1.0	0.999	~ 1.0	~ 1.0
Expected WNP|3 strikes in 1 yr	0.012	0.006	0.012	0.019
Expected WNP|15 strikes in 10 yrs	0.060	0.030	0.059	0.097
Expected WNP|18 unsuccessful strike attempts in 1 yr	0.072	0.036	0.071	0.116
Expected WNP|90 unsuccessful strike attempts in 10 yrs	0.361	0.182	0.353	0.582
Expected WNP|353 approaches in 1 yr	1.416	0.714	1.386	2.283
Expected WNP|3530 approaches in 10 yrs	14.160	7.141	13.860	22.830

[3] This number is conservative because it assumes that all approaches (hunting and training) in both even and odd years occur during the winter/spring period when WNP whales may be present. Realistically we would expect a substantial number of approaches to occur outside this period, i.e., during the summer when ocean conditions are more favorable and, in odd years, when hunting approaches are restricted to July - October.

[4] We expect zero in odd years because the draft proposal limits training strikes (which count as unsuccessful strike attempts) to the summer-fall hunting season, when WNP whales are not expected to be present.

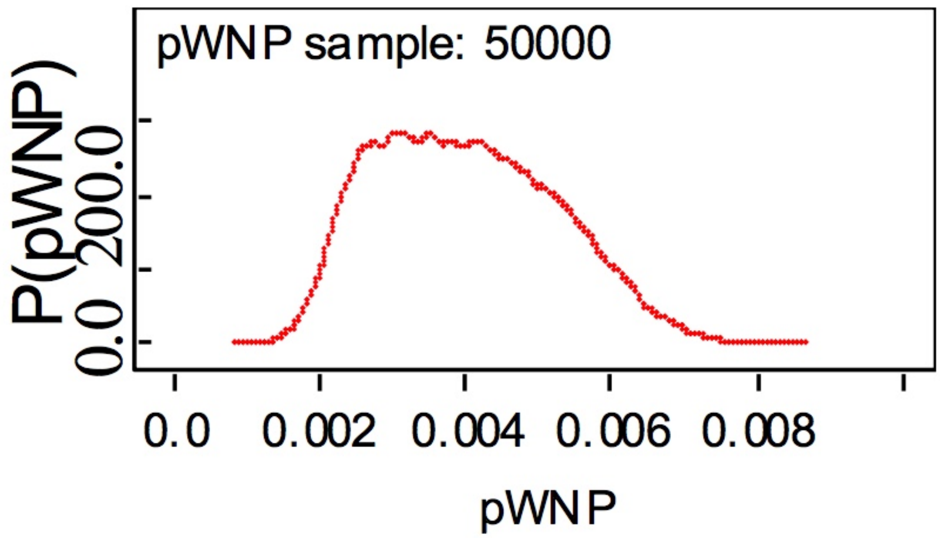

Figure 2. Posterior distribution for probability that any given strike is a WNP whale.

DISCUSSION

Estimates from our analysis may be precautionary since they assume that the Makah hunt will achieve proposed maximum strike limits, and because the assumption of Model 2A is that WNP whales are homogenously mixed with ENP whales. The likelihood of striking a WNP whale is overestimated if fewer total animals are struck or if in reality the WNP animals use a different migration corridor and are less likely to travel through the Makah hunt area. Given uncertainties associated with the model and scenario assumptions, these results serve as a rough approximation of the potential for WNP gray whales to be subjected to strikes, unsuccessful strike attempts and vessel approaches during a Makah hunt operating under a draft proposal currently being considered by NOAA Fisheries.

NOAA Technical Memorandum NMFS

The National Marine Fisheries Service's Alaska Fisheries Science Center uses the NOAA Technical Memorandum series to issue informal scientific and technical publications when complete formal review and editorial processing are not appropriate or feasible. Documents within this series reflect sound professional work and may be referenced in the formal scientific and technical literature.

The NMFS-AFSC Technical Memorandum series of the Alaska Fisheries Science Center continues the NMFS-F/NWC series established in 1970 by the Northwest Fisheries Center. The NMFS-NWFSC series is currently used by the Northwest Fisheries Science Center.

PREFACE

On 30 April 1994, Public Law 103-238 was enacted allowing significant changes to provisions within the Marine Mammal Protection Act (MMPA). Interactions between marine mammals and commercial fisheries are addressed under three new sections. This new regime replaced the interim exemption that has regulated fisheries-related incidental takes since 1988. Section 117, Stock Assessments, required the establishment of three regional scientific review groups to advise and report on the status of marine mammal stocks within Alaska waters, along the Pacific Coast (including Hawaii), and the Atlantic Coast (including the Gulf of Mexico). This report provides information on the marine mammal stocks of Alaska under the jurisdiction of the National Marine Fisheries Service.

Each stock assessment includes, when available, a description of the stock's geographic range; a minimum population estimate; current population trends; current and maximum net productivity rates; optimum sustainable population levels and allowable removal levels; estimates of annual human-caused mortality and serious injury through interactions with commercial, recreational, and subsistence fisheries, takes by subsistence hunters, and other human-caused events (e.g., entanglement in marine debris, ship strikes); and habitat concerns. The commercial fishery interaction data will be used to evaluate the progress of each fishery towards achieving the MMPA's goal of zero fishery-related mortality and serious injury of marine mammals.

The Stock Assessment Reports should be considered working documents, as they are updated as new information becomes available. The Alaska Stock Assessment Reports were originally developed in 1995 (Small and DeMaster 1995). Revisions have been published for the following years: 1996 (Hill et al. 1997), 1998 (Hill and DeMaster 1998), 1999 (Hill and DeMaster 1999), 2000 (Ferrero et al. 2000), 2001 (Angliss et al. 2001), 2002 (Angliss and Lodge 2002), 2003 (Angliss and Lodge 2004), 2005 (Angliss and Outlaw 2005), 2006 (Angliss and Outlaw 2007), 2007 (Angliss and Outlaw 2008), 2008 (Angliss and Allen 2009), 2009 (Allen and Angliss 2010), 2010 (Allen and Angliss 2011), 2011 (Allen and Angliss 2012), 2012 (Allen and Angliss 2013), 2013 (Allen and Angliss 2014), 2014 (Allen and Angliss 2015), and 2015 (Muto et al. 2016). Each Stock Assessment Report is designed to stand alone and is updated as new information becomes available. The MMPA requires Stock Assessment Reports to be reviewed annually for stocks designated as strategic, annually for stocks where there is significant new information available, and at least once every 3 years for all other stocks. New information for all strategic stocks (Western U.S. Steller sea lions, northern fur seals, Cook Inlet beluga whales, AT1 Transient killer whales, harbor porpoise, sperm whales, humpback whales, fin whales, North Pacific right whales, and bowhead whales) was reviewed in 2015-2016. This review, and a review of other stocks, led to the revision of the following stock assessments for the 2016 document: Western U.S. and Eastern U.S. stocks of Steller sea lions; northern fur seals; bearded seals; ringed seals; Cook Inlet beluga whales; narwhals; Eastern North Pacific (ENP) Alaska Resident, ENP Gulf of Alaska, Aleutian Islands, and Bering Sea Transient, and AT1 Transient stocks of killer whales; Southeast Alaska, Gulf of Alaska, and Bering Sea stocks of harbor porpoise; sperm whales; Western North Pacific and Central North Pacific stocks of humpback whales; fin whales; North Pacific right whales, and bowhead whales. The Stock Assessment Reports for all stocks, however, are included in this document to provide a complete reference. Those sections of each Stock Assessment Report containing significant changes are listed in Appendix 1. The authors solicit any new information or comments which would improve future Stock Assessment Reports.

The U.S. Fish and Wildlife Service (USFWS) has management authority for polar bears, sea otters, and walruses. Copies of the stock assessments for these species are included in Appendix 8 of this NMFS Stock Assessment Report for your convenience.

Ideas and comments from the Alaska Scientific Review Group (SRG) have significantly improved this document from its draft form. The authors wish to express their gratitude for the thorough reviews and helpful guidance provided by the Alaska Scientific Review Group members: Karl Haflinger, Lloyd Lowry (Chair from 2012 to 2016), Beth Mathews, Craig Matkin, Mike Miller, Grey Pendleton, Robert Small, Kate Stafford, Robert Suydam, David Tallmon, and Kate Wynne. We would also like to acknowledge the contributions from the NMFS Alaska Region and the Communications Program of the Alaska Fisheries Science Center.

The information contained within the individual Stock Assessment Reports stems from a variety of sources. Where feasible, we have attempted to utilize only published material. When citing information contained in this document, authors are reminded to cite the original publications, when possible.

CONTENTS*

*NMFS Stock Assessment Reports and Appendices revised in 2016 are in boldface.

STELLER SEA LION (*Eumetopias jubatus*): Western U.S. Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Steller sea lions range along the North Pacific Rim from northern Japan to California (Loughlin et al. 1984), with centers of abundance and distribution in the Gulf of Alaska and Aleutian Islands (Fig. 1). Large numbers of individuals disperse widely outside of the breeding season (late May-early July), probably to access seasonally important prey resources. This results in marked seasonal patterns of abundance in some parts of the range and potential for intermixing in foraging areas of animals that were born in different areas (Sease and York 2003). Despite the wide-ranging movements of juveniles and adult males in particular, exchange between rookeries by breeding adult females and males (other than between adjoining rookeries) is low, although males have a higher tendency to disperse than females (NMFS 1995, Trujillo et al. 2004, Hoffman et al. 2006).

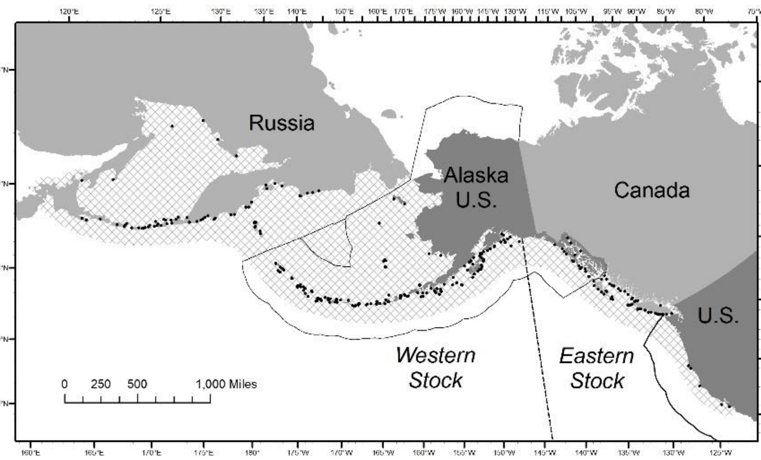

Figure 1. Generalized distribution (crosshatched area) of Steller sea lions in the North Pacific and major U.S. haulouts and rookeries (50 CFR 226.202, 27 August 1993), as well as active Asian and Canadian (British Columbia) haulouts and rookeries (points: Burkanov and Loughlin 2005; S. Majewski, Fisheries and Oceans Canada, pers. comm.). Black dashed line (144°W) indicates stock boundary (Loughlin 1997) and solid black line delineates U.S. Exclusive Economic Zone.

Loughlin (1997) considered the following information when classifying stock structure based on the phylogeographic approach of Dizon et al. (1992): 1) Distributional data: geographic distribution continuous, yet a high degree of natal site fidelity and low (<10%) exchange rate of breeding animals among rookeries; 2) Population response data: substantial differences in population dynamics (York et al. 1996); 3) Phenotypic data: differences in the length of pups (Merrick et al. 1995, Loughlin 1997); and 4) Genotypic data: substantial differences in mitochondrial DNA (Bickham et al. 1996). Based on this information, two separate stocks of Steller sea lions were recognized within U.S. waters: an Eastern U.S. stock, which includes animals born east of Cape Suckling, Alaska (144°W), and a Western U.S. stock, which includes animals born at and west of Cape Suckling (Loughlin 1997; Fig. 1). However, Jemison et al. (2013) summarized that there is regular movement of Steller sea lions from the western Distinct Population Segment (DPS) (males and females equally) and eastern DPS (almost exclusively males) across the DPS boundary.

Steller sea lions that breed in Asia are considered part of the western stock. Whereas Steller sea lions seasonally inhabit coastal waters of Japan in the winter, breeding rookeries outside of the U.S. are currently only located in Russia (Burkanov and Loughlin 2005). Analyses of genetic data differ in their interpretation of separation between Asian and Alaska sea lions. Based on analysis of mitochondrial DNA, Baker et al. (2005) found evidence of a genetic split between the Commander Islands (Russia) and Kamchatka that would include Commander Island sea lions within the Western U.S. stock and animals west of there in an Asian stock. However, Hoffman et al. (2006) did not support an Asian/western stock split based on their analysis of nuclear microsatellite markers indicating high rates of male gene flow. Berta and Churchill (2012) concluded that a putative Asian stock is "not substantiated by microsatellite data since the Asian stock groups with the western stock." All genetic analyses (Baker et al. 2005; Harlin-Cognato et al. 2006; Hoffman et al. 2006, 2009; O'Corry-Crowe et al. 2006) confirm a strong separation between western and eastern stocks, and there may be sufficient morphological differentiation to support elevating the two recognized stocks to subspecies (Phillips et al. 2009), although a recent review by Berta and Churchill (2012) characterized the status of these subspecies assignments as "tentative" and requiring further attention before their status can be determined. Recent work by Phillips et al. (2011) addressed the effect of climate change, in the form of glacial events, on the evolution of Steller sea lions and reported that the effective population size at the time of the event determines the impact of change on the population. The results suggested that during historic glacial periods, dispersal events were correlated with historically low effective population sizes, whereas range fragmentation type events were correlated with larger effective population sizes. This work again reinforced the stock delineation concept by noting that ancient population subdivision likely led to the sequestering of most mtDNA haplotypes as DPS or subspecies-specific (Phillips et al. 2011).

In 1998, a single Steller sea lion pup was observed on Graves Rock just north of Cross Sound in Southeast Alaska, and within 15 years (2013) pup counts had increased to 551 (DeMaster 2014). Mitochondrial and microsatellite analysis of pup tissue samples collected in 2002 revealed that approximately 70% of the pups had mtDNA haplotypes that were consistent with those found in the western stock (Gelatt et al. 2007). Similarly, a rookery to the south on the White Sisters Islands, where pups were first noted in 1990, was also sampled in 2002 and approximately 45% of those pups had western stock haplotypes. Collectively, this information demonstrates that these two most recently established rookeries in northern Southeast Alaska have been partially to predominately established by western stock females. While movements of animals marked as pups in both stocks support these genetic results (Jemison et al. 2013), overall the observations of marked sea lion movements corroborate the extensive genetic research findings for a strong separation between the two currently recognized stocks. O'Corry-Crowe et al. (2014) concluded that the results of their study of the genetic characteristics of pups born on these new rookeries "demonstrates that resource limitation may trigger an exodus of breeding animals from declining populations, with substantial impacts on distribution and patterns of genetic variation. It also revealed that this event is rare because colonists dispersed across an evolutionary boundary, suggesting that the causative factors behind recent declines are unusual or of larger magnitude than normally occur." Thus, although recent colonization events in the northern part of the eastern DPS indicate movement of western sea lions into this area, the mixed part of the range remains small (Jemison et al. 2013), and the overall discreteness of the eastern from the western stock remains distinct. Hybridization among subspecies and species along a contact zone such as now occurs near the stock boundary is not unexpected as the ability to interbreed is a primitive condition whereas reproductive isolation would be derived. In fact, as stated by NMFS and the U.S. Fish and Wildlife Service (USFWS) in a 1996 response to a previous comment regarding stock discreteness policy (61 FR 47222), "*The Services do not consider it appropriate to require absolute reproductive isolation as a prerequisite to recognizing a distinct population segment*" or stock. The fundamental concept overlying this distinctiveness is the collection of morphological, ecological and behavioral, and genetic evidence for stock differences initially described by Bickham et al. (1996) and Loughlin (1997) and supported by Baker et al. (2005), Harlin-Cognato et al. (2006), Hoffman et al. (2006, 2009), O'Corry-Crowe et al. (2006), and Phillips et al. (2009, 2011).

POPULATION SIZE

The western stock of Steller sea lions decreased from an estimated 220,000 to 265,000 animals in the late 1970s to less than 50,000 in 2000 (Loughlin et al. 1984, Loughlin and York 2000, Burkanov and Loughlin 2005). Since 2000, the abundance of the western stock has increased, but there has been considerable regional variation in trend (Sease and Gudmundson 2002, Burkanov and Loughlin 2005, Fritz et al. 2013). The most recent comprehensive aerial photographic and land-based surveys of western Steller sea lions in Alaska were conducted during the 2014 and 2015 breeding seasons (Fritz et al. 2015a, 2015b). Western Steller sea lion pup and non-pup counts in Alaska in 2015 were estimated to be 12,492 (95% credible interval of 11,480-13,612) and 38,491 (34,377-42,634), respectively, using agTrend (Johnson and Fritz 2014) and survey results through 2015 (Fritz et al. 2015a, 2015b). Demographic multipliers (e.g., pup production multiplied by 4.5) and proportions of each age-sex class that are hauled out during the day in the breeding season (when aerial surveys are conducted) have been proposed as methods to estimate total population size from pup and/or non-pup counts (Calkins and Pitcher 1982, Higgins et al. 1988, Milette and Trites 2003, Maniscalco et al. 2006). However, there are several factors which make using these methods problematic when applied to counts of western Steller sea lions in Alaska, including the lack of vital (survival and reproductive) rate information for the western and central Aleutian Islands, the large variability in abundance trends across the range (see Current Population Trend section below and Pitcher et al. 2007), and the large uncertainties related to reproductive status and foraging conditions that affect proportions hauled out (see review in Holmes et al. 2007).

Methods used to survey Steller sea lions in Russia differ from those used in Alaska, with less use of aerial photography and more use of skiff surveys and cliff counts for non-pups and ground counts for pups. The most recent counts of non-pup Steller sea lions in Russia were conducted in 2007-2011 and totaled ~12,700 (V. Burkanov, NMFS-AFSC-MML, pers. comm.). The most recent estimate of pup production in Russia is available from counts conducted in 2011 and 2012, which totaled 6,021 pups. Analysis of data collected in 2013 and 2015 is ongoing and results will be included in a future Stock Assessment Report.

Minimum Population Estimate

Because of the uncertainty regarding the use of a pup multiplier or haulout rate to estimate N, we will use the best estimate of the total count of western Steller sea lions in Alaska as the minimum population estimate (N_{MIN}). Western Steller sea lion pup and non-pup counts in 2015 in Alaska were estimated to be 12,492 and 38,491, respectively (Fritz et al. 2015b), which total 50,983 and will be used as the N_{MIN} for the U.S. portion of the western stock of Steller sea lions (Wade and Angliss 1997). This is considered a minimum estimate because it has not been corrected to account for animals that were at sea during the surveys.

Current Population Trend

The first reported trend counts (sums of counts at consistently surveyed, large sites used to examine population trends) of Steller sea lions in Alaska were made in 1956-1960. Those counts indicated that there were at least 140,000 (no correction factor applied) sea lions in the Gulf of Alaska and Aleutian Islands (Merrick et al. 1987). Subsequent surveys indicated a major population decrease, first detected in the eastern Aleutian Islands in the mid-1970s (Braham et al. 1980). Counts from 1976 to 1979 totaled about 110,000 sea lions (no correction factor applied). The decline appears to have spread eastward to Kodiak Island during the late 1970s and early 1980s, and then westward to the central and western Aleutian Islands during the early and mid-1980s (Merrick et al. 1987, Byrd 1989). During the late 1980s, counts in Alaska overall declined at ~15% per year (NMFS 2008) which prompted the listing (in 1990) of the species as threatened range-wide under the Endangered Species Act (ESA). Continued declines in counts of western Steller sea lions in Alaska in the 1990s (Sease et al. 2001) led NMFS to change the ESA listing status to endangered in 1997 (NMFS 2008). Surveys in Alaska in 2002, however, were the first to note an increase in counts, which suggested that the overall decline of western Steller sea lions stopped in 2000-2002 (Sease and Gudmundson 2002).

Johnson and Fritz (2014) estimated regional and overall trends in counts of pups and non-pups in Alaska using data collected at all sites with at least two non-zero counts, rather than relying solely on counts at "trend" sites (also see Fritz et al. 2013). Using data collected through 2015, there is strong evidence that non-pup and pup counts of western stock Steller sea lions in Alaska increased at ~2% y^{-1} between 2000 and 2015 (Table 1; Fritz et al. 2015b). However, there are strong regional differences across the range in Alaska, with positive trends east of Samalga Pass (~170°W) in the Gulf of Alaska and eastern Bering Sea and negative trends to the west in the Aleutian Islands (Table 1; Fig. 2).

Regional differences in pup trends cannot be explained by movement of pups during the breeding season. However, slower growth in pup counts in the central Gulf of Alaska than in the surrounding regions east of Samalga Pass could be due to movement of adult females out of the region (suggesting some level of permanent emigration), indicating that sea lions may have responded to meso-scale (on the order of 100s of kilometers) variability in their environment (O'Corry-Crowe et al. 2014).

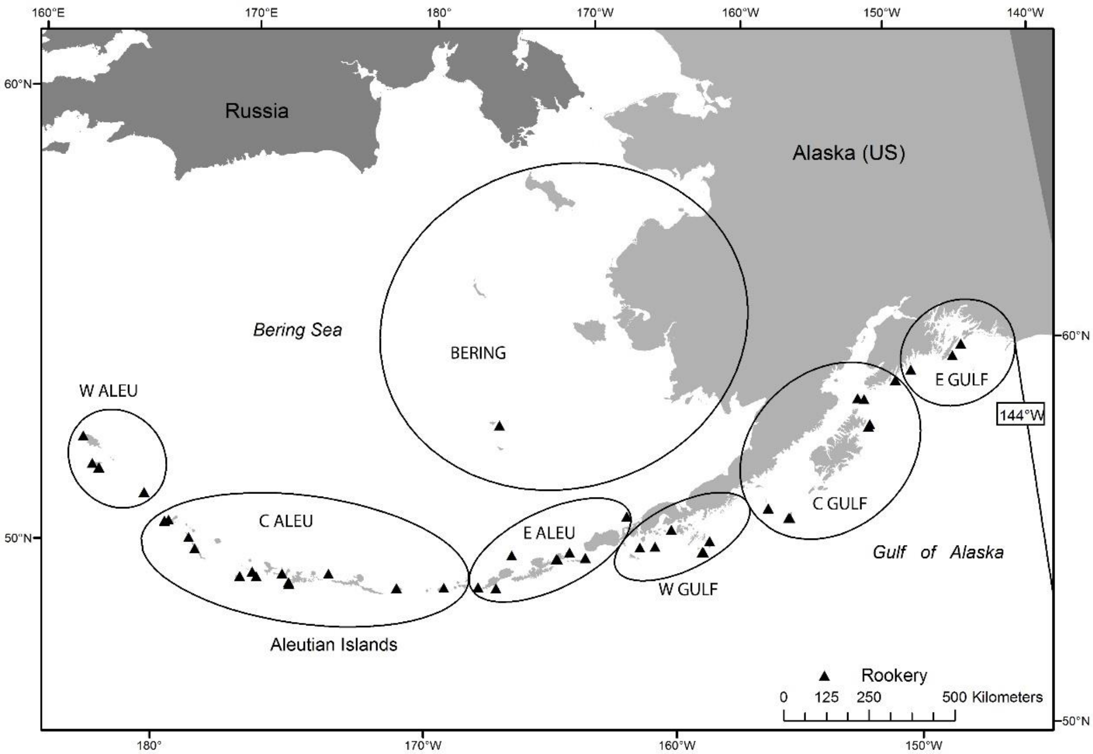

Figure 2. Regions of Alaska used for western Steller sea lion population trend estimation. E GULF, C GULF, and W GULF are eastern, central, and western Gulf of Alaska regions, respectively. E ALEU, C ALEU, and W ALEU are eastern, central, and western Aleutian Islands regions, respectively.

Table 1. Trends (annual rates of change expressed as % y^{-1} with 95% credible interval) in counts of western Steller sea lion non-pups (adults and juveniles) and pups in Alaska, by region, for the period 2000-2015 (Johnson and Fritz 2014; Fritz et al. 2013, 2015a, 2015b).

		Non-pups				**Pups**		
Region	**Latitude Range**	**Trend**	**-95%**	**+95%**		**Trend**	**-95%**	**+95%**
Western Stock in Alaska	144°W-172°E	1.94	1.35	2.58		1.87	1.30	2.40
E of Samalga Pass	144°-170°W	3.28	2.55	4.10		3.30	2.61	3.98
Eastern Gulf of Alaska	144°-150°W	5.07	2.35	7.87		4.31	2.54	6.00
Central Gulf of Alaska	150°-158°W	2.68	1.53	3.73		2.82	1.39	4.24
Western Gulf of Alaska	158°-163°W	3.95	2.75	5.11		3.28	1.86	4.61
Eastern Aleutian Islands	163°-170°W	2.08	0.69	3.44		3.35	2.29	4.37
W of Samalga Pass	170°W-172°E	-1.82	-2.62	-0.97		-1.62	-2.45	-0.82
Central Aleutian Islands	170°W-177°E	-0.84	-1.69	0.05		-0.68	-1.58	0.23
Western Aleutian Islands	172°-177°E	-8.71	-10.65	-6.83		-8.88	-10.00	-7.73

The distribution of sightings of branded animals during the breeding season indicates an average annual net movement of adult and juvenile sea lions from the central to the eastern Gulf of Alaska (Fritz et al. 2013). This could have depressed non-pup trend estimates in the central Gulf (2.68% y^{-1} between 2000 and 2015) and increased them in the eastern Gulf (5.07% y^{-1}; Table 1). Although less is known about inter-regional movement west of Samalga Pass, including Russia, sea lion dispersal during the breeding season may have had a smaller influence on non-pup trends here than in the eastern-central Gulf of Alaska given the much larger area over which regional non-pup (and pup) trends are declining (see discussion of Russia below).

The net magnitude of Steller sea lion movements during the breeding season between the eastern and western stocks appears to be relatively small and would have a negligible impact on non-pup trend estimates in either area (Fritz et al. 2013, Jemison et al. 2013). However, there were significant differences by sex in cross-boundary movements: for females, there was a net increase of ~600 in the east and very few moved from east to west, while males moved in both directions but with a net increase of ~500 males in the west. This pattern of movement is supported by mitochondrial DNA evidence that indicated that the newest rookeries in northern Southeast Alaska (eastern stock) were colonized in part by western females (Gelatt et al. 2007, O'Corry-Crowe et al. 2014).

Burkanov and Loughlin (2005) estimated that the Russian Steller sea lion population (pups and non-pups) declined from about 27,000 in the 1960s to 13,000 in the 1990s and increased to approximately 16,000 in 2005. Data collected through 2012 (V. Burkanov, NMFS-AFSC-MML, pers. comm.) indicate that overall Steller sea lion abundance in Russia increased back to levels observed in the 1960s (~27,100 based on life table multiplier of 4.5 on the most recent total pup count of 6,021). However, just as in the U.S. portion of the stock, there are significant regional differences in population trend in Russia, with increasing abundance in the Sea of Okhotsk and Kuril Islands and stable or declining trends in eastern Kamchatka, the Commander Islands, and the western Bering Sea. The largest decline in Steller sea lions in Russia has been in the western Bering Sea (which has no rookeries), where non-pup counts declined 98% between 1982 and 2010. Regions in Russia that have either stable or declining counts of pups and non-pups are adjacent to regions in the U.S. with similar trends (Aleutian Islands west of 170°W). Results from surveys conducted in 2013 and 2015 will be available soon and included in a future Stock Assessment Report.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

There are no estimates of the maximum net productivity rate for Steller sea lions. Hence, until additional data become available, it is recommended that the theoretical maximum net productivity rate (R_{MAX}) for pinnipeds of 12% be employed for this stock (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the potential biological removal (PBR) is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: $PBR = N_{MIN} \times 0.5R_{MAX} \times F_R$. The recovery factor ($F_R$) for this stock is 0.1, the default value for stocks listed as endangered under the ESA (Wade and Angliss 1997). Thus, for the U.S. portion of the western stock of Steller sea lions, PBR = 306 animals (50,983 × 0.06 × 0.1).

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Detailed information (including observer programs, observer coverage, and observed incidental takes of marine mammals) for federally-managed and state-managed U.S. commercial fisheries in Alaska waters is presented in Appendices 3-6 of the Alaska Stock Assessment Reports.

Between 2010 and 2014, mortality and serious injury of western Steller sea lions was observed in the following 8 fisheries of the 22 federally-regulated commercial fisheries in Alaska that are monitored for incidental mortality and serious injury by fisheries observers: Bering Sea/Aleutian Islands Atka mackerel trawl, Bering Sea/Aleutian Islands flatfish trawl, Bering Sea/Aleutian Islands Pacific cod trawl, Bering Sea/Aleutian Islands pollock trawl, Bering Sea/Aleutian Islands Pacific cod longline, Gulf of Alaska Pacific cod trawl, Gulf of Alaska Pacific cod longline, and Gulf of Alaska sablefish longline fisheries (Table 2; Breiwick 2013; MML, unpubl. data).

Observers also monitored the Alaska State-managed Prince William Sound salmon drift gillnet fishery in 1990 and 1991, recording two mortalities in 1991, extrapolated to 29 (95% CI: 1-108) for the entire fishery (Wynne et al. 1992). No mortality or serious injury was observed during 1990 for this fishery (Wynne et al. 1991), resulting in a mean annual mortality rate of 15 (CV = 1.0) sea lions for 1990 and 1991. It is not known whether this incidental mortality and serious injury rate is representative of the current rate in this fishery.

Combining the mortality and serious injury estimates from the Bering Sea/Aleutian Islands groundfish trawl, Bering Sea/Aleutian Islands longline, Gulf of Alaska groundfish trawl, and Gulf of Alaska longline fisheries (15) with the estimate from the Prince William Sound salmon drift gillnet fishery (15) results in an estimated mean annual mortality and serious injury rate of 30 sea lions from this stock in observed U.S. commercial fisheries (Table 2).

Table 2. Summary of incidental mortality and serious injury of Western U.S. Steller sea lions due to U.S. commercial fisheries in 2010-2014 (or the most recent data available) and calculation of the mean annual mortality and serious injury rate (Wynne et al. 1991, 1992; Breiwick 2013; MML, unpubl. data). N/A indicates that data are not available. Methods for calculating percent observer coverage are described in Appendix 6 of the Alaska Stock Assessment Reports.

Fishery name	Years	Data type	Percent observer coverage	Observed mortality	Estimated mortality	Mean estimated annual mortality
Bering Sea/Aleutian Is. Atka mackerel trawl	2010 2011 2012 2013 2014	obs data	100 99 99 99 99	1 0 0 0 0	1 0 0 0 0	0.2 (CV = 0.05)

Prince William Sound salmon drift gillnet	1990 1991	obs data	4 5	0 2	0 29	15 (CV = 1.0)
Minimum total estimated annual mortality						30 (CV = 0.50)

[a]Total mortality and serious injury observed in 2010: 4 sea lions in sampled hauls + 1 sea lion in an unsampled haul.
[b]Total estimate of mortality and serious injury in 2010: 4 sea lions (extrapolated estimate from 4 sea lions observed in sampled hauls) + 1 sea lion (1 sea lion observed in an unsampled haul).
[c]Mean annual mortality and serious injury for fishery: 5.8 sea lions (mean of extrapolated estimates from sampled hauls) + 0.2 sea lions (mean of number observed in unsampled hauls).
[d]Total mortality and serious injury observed in 2012: 7 sea lions in sampled hauls + 1 sea lion in an unsampled haul.
[e]Total estimate of mortality and serious injury in 2012: 7 sea lions (extrapolated estimate from 7 sea lions observed in sampled hauls) + 1 sea lion (1 sea lion observed in an unsampled haul).
[f]Mean annual mortality and serious injury for fishery: 6.3 sea lions (mean of extrapolated estimates from sampled hauls) + 0.2 sea lions (mean of number observed in unsampled hauls).

Reports from the NMFS Alaska Region stranding network of Steller sea lions entangled in fishing gear or with injuries caused by interactions with gear are another source of mortality and serious injury data (Table 3; Helker et al. 2016). During 2010 to 2014, there were five reports of a Steller sea lion in poor body condition with a flasher lure hanging from its mouth and, in each case, the animal was believed to have ingested the hook (Table 3). An additional animal was hooked by longline gear and two animals were entangled in unidentified fishing gear. Fishery-related strandings in these unknown (commercial, recreational, or subsistence) fisheries during 2010-2014 resulted in a minimum mean annual mortality and serious injury rate of 1.6 animals from this stock (Table 3). This estimate is considered a minimum because not all entangled animals strand and not all stranded animals are found or reported. Additionally, since Steller sea lions from parts of the western stock are known to travel to parts of Southeast Alaska to forage, and higher rates of entanglement of Steller sea lions have been observed in this area (e.g., Raum-Suryan et al. 2009), estimates based solely on stranding reports in areas west of 144°W longitude may underestimate the total entanglement of western stock animals in fishery-related and other marine debris.

Table 3. Summary of Western U.S. Steller sea lion mortality and serious injury, by year and type, reported to the NMFS Alaska Region marine mammal stranding network and Alaska Department of Fish and Game in 2010-2014 (Helker et al. 2016).

Cause of injury	2010	2011	2012	2013	2014	Mean annual mortality
Hooked by Gulf of Alaska longline gear*	1	0	0	0	0	0.2
Hooked by Southcentral Alaska salmon troll gear*	0	1	0	0	1	0.4
Hooked by Alaska Peninsula troll gear*	0	0	0	1	0	0.2
Hooked by troll gear*	0	0	2	0	0	0.4
Entangled in unidentified fishing gear*	0	0	1	0	1	0.4
Entangled in marine debris	5	1	2	0	3	2.2
Struck by arrow	0	0	0	1	0	0.2
Entangled in commercial Kodiak salmon hatchery net	0	0	0	1	0	0.2
*Total in unknown (commercial, recreational, or subsistence) fisheries						1.6
Total in marine debris						2.2
Total due to other causes (arrow strike, entangled in hatchery net)						0.4

NMFS studies using satellite-tracking devices attached to juvenile and adult female Steller sea lions suggest that these two age/sex classes rarely go beyond the U.S. Exclusive Economic Zone into international waters (Merrick and Loughlin 1997; Lander et al. 2009, 2011a, 2011b). Little is known about the at-sea distribution of sub-adult and adult males, however, since there have been no satellite-tracking devices attached to them. In the 1980s and 1990s, Steller sea lions of unknown sex and age were observed in international waters of the North Pacific Ocean and Bering Sea, but it is unclear how important these areas are for foraging (Himes-Boor and Small 2012).

The minimum average annual estimated mortality and serious injury rate incidental to U.S. commercial fisheries is 30 Steller sea lions. The minimum average annual mortality and serious injury rate for all fisheries, based on observer data (30 sea lions) for commercial fisheries and stranding data (1.6 sea lions) for unknown (commercial, recreational, or subsistence) fisheries is 32 western Steller sea lions. Observer data for state fisheries are from 1990-1991; however, these are the best data available to estimate takes in these fisheries. No observers have been assigned to several fisheries that are known to interact with this stock, thus, the estimated mortality and serious injury is likely an underestimate of the actual level.

Alaska Native Subsistence/Harvest Information

Information on the subsistence harvest of Steller sea lions comes via two sources: the Alaska Department of Fish and Game (ADF&G) and the Ecosystem Conservation Office (ECO) of the Aleut Community of St. Paul. The ADF&G conducted systematic interviews with hunters and users of marine mammals in approximately 2,100 households in about 60 coastal communities within the geographic range of the Steller sea lion in Alaska (Wolfe et al. 2005, 2006, 2008, 2009a, 2009b). The interviews were conducted once per year in the winter (January to March) and covered hunter activities for the previous calendar year. As of 2009, annual statewide data on community subsistence harvests are no longer being consistently collected. Data are being collected periodically in subareas. Data were collected on the Alaska Native harvest of Western U.S. Steller sea lions for 7 communities on Kodiak Island in 2011 and 15 communities in Southcentral Alaska in 2014. The Alaska Native Harbor Seal Commission (ANHSC) and ADF&G estimated a total of 20 adult sea lions were harvested on Kodiak Island in 2011, with a 95% confidence range between 15 and 28 animals (Wolfe et al. 2012), and 7.9 sea lions (CI = 6-15.3) were harvested in Southcentral Alaska in 2014, with adults comprising 84% of the harvest (ANHSC 2015). These estimates do not represent a comprehensive statewide estimate; therefore, the best available statewide subsistence harvest estimates for a 5-year period are those from 2004 to 2008. Therefore, the most recent 5 years of data available (2004-2008) will be retained and used for calculating an annual mortality and serious injury estimate for all areas except St. Paul. Data from St. Paul are still being collected and will be updated with the most recent 5 years of data available. The ECO collects data on the harvest in near real-time on St. Paul Island and records hunter activities within 36 hours of the harvest (Lestenkof 2011). Information on subsistence harvest levels is provided in Table 4; data from ECO (e.g., Lestenkof 2011) are relied upon as the source of data for St. Paul Island and all other data are from the ADF&G (e.g., Wolfe et al. 2005). The most recent 5 years of data from St. Paul are from 2010 to 2014 (Lestenkof 2011, 2012).

The mean annual subsistence take from this stock for all areas except St. Paul in 2004-2008 (172) combined with the mean annual take for St. Paul in 2010-2014 (29) is 201 western Steller sea lions (Table 4).

Table 4. Summary of the subsistence harvest data for Western U.S. Steller sea lions. As of 2009, data on community subsistence harvests are no longer being consistently collected. Therefore, the most recent 5 years of data (2004-2008) will be retained and used for calculating an annual mortality and serious injury estimate for all areas except St. Paul. Data from St. Paul are still being collected and will be updated with the most recent 5 years of data available (2010-2014). N/A indicates that data are not available.

	All areas except St. Paul Island			St. Paul Island

Other Mortality

Reports from the NMFS Alaska Region stranding network of Steller sea lions entangled in marine debris or with injuries caused by other types of human interaction are another source of mortality and serious injury data. From 2010 to 2014, 11 animals were observed entangled in marine debris, 1 animal was struck by an arrow, and 1 entangled in a commercial Kodiak salmon hatchery net (Table 3; Helker et al. 2016). The minimum mean annual mortality and serious injury rate from these sources of human interactions in 2010-2014 is 2.6 sea lions from this stock.

Mortality and serious injury may occasionally occur incidental to marine mammal research activities authorized under MMPA permits issued to a variety of government, academic, and other research organizations. In 2011, there were two reports of mortality incidental to research on the Western U.S. stock of Steller sea lions (Division of Permits and Conservation, Office of Protected Resources, NMFS, 1315 East-West Highway, Silver Spring, MD 20910), resulting in a mean annual mortality and serious injury rate of 0.4 sea lions from this stock in 2010-2014.

STATUS OF STOCK

The current mean annual U.S. commercial fishery-related mortality and serious injury rate (30 sea lions) is less than 10% of the PBR (10% of PBR = 31) and, therefore, can be considered insignificant and approaching a zero mortality and serious injury rate. Based on available data, the total estimated annual level of human-caused mortality and serious injury (236 sea lions) is below the PBR level (306) for this stock. The Western U.S. stock of Steller sea lions is currently listed as endangered under the ESA and, therefore, designated as depleted under the MMPA. As a result, the stock is classified as a strategic stock. However, the population previously declined for unknown reasons that are not explained by the documented level of direct human-caused mortality and serious injury.

HABITAT CONCERNS

Many factors have been suggested as causes of the steep decline in abundance of western Steller sea lions observed in the 1980s, including competitive effects of fishing, environmental change, disease, contaminants, killer whale predation, incidental take, and illegal and legal shooting (Atkinson et al. 2008, NMFS 2008). Potential threats to Steller sea lion recovery are shown in Table 5. A number of management actions have been implemented since 1990 to promote the recovery of the Western U.S. stock of Steller sea lions, including 3 nautical mile no-entry zones around rookeries, prohibition of shooting at or near sea lions, and regulation of fisheries for sea lion prey species (e.g., walleye pollock, Pacific cod, and Atka mackerel; see reviews by Fritz et al. 1995, McBeath 2004, Atkinson et al. 2008, NMFS 2008).

Table 5. Potential threats and impacts to Steller sea lion recovery and associated references. Threats and impacts to recovery as described by the Revised Steller Sea Lion Recovery Plan (NMFS 2008). Reference examples identify research related to corresponding threats and may or may not support the underlying hypotheses.

Threat	Impact on Recovery	Level of Uncertainty	Reference Examples
Environmental variability	Potentially high	High	Trites and Donnelly 2003, Fritz and Hinckley 2005
Competition with fisheries	Potentially high	High	Fritz and Ferrero 1998, Hennen 2004, Fritz and Brown 2005, Dillingham et al. 2006
Predation by killer whales	Potentially high	High	Springer et al. 2003, Williams et al. 2004, DeMaster et al. 2006, Trites et al. 2007
Toxic substances	Medium	High	Calkins et al. 1994, Lee et al. 1996, Albers and Loughlin 2003
Incidental take by fisheries	Low	High	Wynne et al. 1992, Nikulin and Burkanov 2000, Perez 2006
Subsistence harvest	Low	Low	Haynes and Mishler 1991, Loughlin and York 2000, Wolfe et al. 2005
Illegal shooting	Low	Medium	Loughlin and York 2000, NMFS 2001
Entanglement in marine debris	Low	Medium	Calkins 1985
Disease and parasitism	Low	Medium	Burek et al. 2005
Disturbance from vessel traffic and tourism	Low	Medium	Kucey and Trites 2006
Disturbance or mortality due to research activities	Low	Low	Calkins and Pitcher 1982, Loughlin and York 2000, Kucey 2005, Kucey and Trites 2006, Atkinson et al. 2008, Wilson et al. 2012

STELLER SEA LION (*Eumetopias jubatus*): Eastern U.S. Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Steller sea lions range along the North Pacific Rim from northern Japan to California (Loughlin et al. 1984), with centers of abundance and distribution in the Gulf of Alaska and Aleutian Islands (Fig. 1). Individual sea lions disperse widely outside of the breeding season (late May-early July), probably to access seasonally important prey resources. This results in marked seasonal patterns of abundance in some parts of the range and potential for intermixing of eastern and western stock sea lions in foraging areas (Sease and York 2003). Despite the wide-ranging movements of juveniles and adult males in particular, exchange between rookeries by breeding adult females and males (other than between adjoining rookeries) is low, although males have a higher tendency to disperse than females (NMFS 1995, Trujillo et al. 2004, Hoffman et al. 2006, Jemison et al. 2013). A northward shift in the overall breeding distribution has occurred, with a contraction of the range in southern California and new rookeries established in Southeast Alaska (Pitcher et al. 2007).

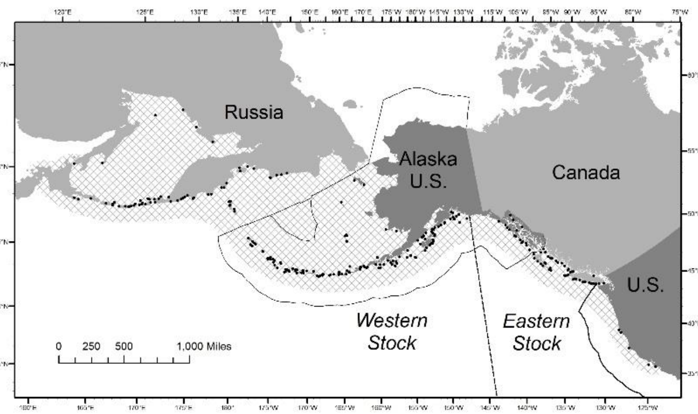

Figure 1. Generalized distribution (crosshatched area) of Steller sea lions in the North Pacific and major U.S. haulouts and rookeries (50 CFR 226.202, 27 August 1993), as well as active Asian and Canadian (British Columbia) haulouts and rookeries (points: Burkanov and Loughlin 2005; S. Majewski, Fisheries and Oceans Canada, pers. comm.). Black dashed line (144°W) indicates stock boundary (Loughlin 1997) and solid black line delineates U.S. Exclusive Economic Zone.

Loughlin (1997) considered the following information when classifying stock structure based on the phylogeographic approach of Dizon et al. (1992): 1) Distributional data: geographic distribution continuous, yet a high degree of natal site fidelity and low (<10%) exchange rate of breeding animals among rookeries; 2) Population response data: substantial differences in population dynamics (York et al. 1996); 3) Phenotypic data: differences in the length of pups (Merrick et al. 1995, Loughlin 1997); and 4) Genotypic data: substantial differences in mitochondrial DNA (Bickham et al. 1996). Based on this information, two separate stocks of Steller sea lions were recognized within U.S. waters: an Eastern U.S. stock, which includes animals born east of Cape Suckling, Alaska (144°W), and a Western U.S. stock, which includes animals born at and west of Cape Suckling (Loughlin 1997; Fig. 1). However, Jemison et al. (2013) summarized that there is regular movement of Steller sea lions from the western Distinct Population Segment (DPS) (males and females equally) and eastern DPS (almost exclusively males) across the DPS boundary. Most of this movement, but not all, is likely to access seasonally available, but important, prey resources as discussed above.

All genetic analyses (Baker et al. 2005; Harlin-Cognato et al. 2006; Hoffman et al. 2006, 2009; O'Corry-Crowe et al. 2006) confirm a strong separation between western and eastern stocks and there may be sufficient morphological differentiation to support elevating the two recognized stocks to subspecies (Phillips et al. 2009). However, a recent review by Berta and Churchill (2012) characterized the status of these subspecies assignments as "tentative" and requiring further attention before their status can be determined. Phillips et al. (2011) addressed the effect of climate change, in the form of glacial events, on the evolution of Steller sea lions and reported that the effective population size at the time of the event determines the impact of change on the population. The results suggested that during glacial periods, dispersal events were correlated with historically low effective population sizes, whereas range fragmentation type events were correlated with larger effective population sizes. This work again reinforced the stock delineation concept by noting that ancient population subdivision likely led to the sequestering of most mtDNA haplotypes as DPS or subspecies-specific (Phillips et al. 2011).

In 1998, a single Steller sea lion pup was observed on Graves Rock just north of Cross Sound in Southeast Alaska, and within 15 years (2013) pup counts had increased to 551 (DeMaster 2014). Mitochondrial and microsatellite analysis of pup tissue samples collected in 2002 revealed that approximately 70% of the pups had mtDNA haplotypes that were consistent with those found in the western stock (Gelatt et al. 2007). Similarly, a rookery to the south on the White Sisters Islands, where pups were first noted in 1990, was also sampled in 2002 and approximately 45% of those pups had western stock haplotypes. Collectively, this information demonstrates that these two most recently established rookeries in northern Southeast Alaska have been partially to predominately established by western stock females. While movements of animals marked as pups in both stocks support these genetic results (Jemison et al. 2013), overall the observations of marked sea lion movements corroborate the extensive genetic research findings for a strong separation between the two currently recognized stocks. O'Corry-Crowe et al. (2014) concluded that the results of their study of the genetic characteristics of pups born on these new rookeries "demonstrates that resource limitation may trigger an exodus of breeding animals from declining populations, with substantial impacts on distribution and patterns of genetic variation. It also revealed that this event is rare because colonists dispersed across an evolutionary boundary, suggesting that the causative factors behind recent declines are unusual or of larger magnitude than normally occur." Thus, although recent colonization events in the northern part of the eastern DPS indicate movement of western sea lions into this area, the mixed part of the range remains small (Jemison et al. 2013) and the overall discreteness of the eastern from the western stock remains distinct. Hybridization among subspecies and species along a contact zone such as now occurs near the stock boundary is not unexpected as the ability to interbreed is a primitive condition whereas reproductive isolation would be derived. In fact as stated by NMFS and the U.S. Fish and Wildlife Service (USFWS) in a 1996 response to a previous comment regarding stock discreteness policy (61 FR 47222), "*The Services do not consider it appropriate to require absolute reproductive isolation as a prerequisite to recognizing a distinct population segment*" or stock. The fundamental concept overlying this distinctiveness is the collection of morphological, ecological and behavioral, and genetic evidence for stock differences initially described by Bickham et al. (1996) and Loughlin (1997), and supported by Baker et al. (2005), Harlin-Cognato et al. (2006), Hoffman et al. (2006, 2009), O'Corry-Crowe et al. (2006), and Phillips et al. (2009, 2011).

POPULATION SIZE

The eastern stock of Steller sea lions has historically bred on rookeries located in Southeast Alaska, British Columbia, Oregon, and California. However, within the last several years a new rookery has become established on the outer Washington coast (at the Carroll Island and Sea Lion Rock complex), with >100 pups born there in 2015 (R. DeLong and P. Gearin, NMFS-AFSC-MML, pers. comm.). Counts of pups on rookeries conducted near the end of the birthing season are nearly complete counts of pup production. The dates of the most recent aerial photographic and land-based surveys of eastern Steller sea lions have varied by region. Southeast Alaska was surveyed in June-July 2015 (Fritz et al. 2015), while counts used in population analyses for the contiguous U.S. (i.e., Washington, Oregon, and California) are from 2013 surveys and counts from Canada (i.e., British Columbia) are from the 2010 survey effort (NMFS, Fisheries and Oceans Canada, Oregon Department of Fish and Wildlife, Washington Department of Fish and Wildlife, unpubl. data). For trend and population estimates, we used agTrend (Johnson and Fritz 2014) to augment missing counts in order to estimate 2015 counts. The 2015 estimated total eastern stock pup count is 19,423 (95% credible interval of 16,318-23,309). The 2015 estimated total eastern stock non-pup count is 52,139 (95% confidence interval of 45,428-59,711); this estimate does not account for animals at sea.

Minimum Population Estimate

Because of the uncertainty regarding the use of a pup multiplier or haulout rate to estimate N, we use the best estimate of the total count of eastern Steller sea lions as the minimum population estimate (N_{MIN}). The agTrend (Johnson and Fritz 2014) total count estimate of pups and non-pups for the entire eastern stock of Steller sea lions in 2015 is 71,562 (52,139 non-pups plus 19,423 pups). The estimated U.S. total count of the eastern stock of Steller sea lions is 41,638 (30,917 non-pups plus 10,721 pups; Table 1) and it will be used as the N_{MIN}. These counts are considered minimum estimates of population size because they have not been corrected for animals that are at sea during the surveys.

Current Population Trend

Using agTrend, we modeled the most recent count data to estimate annual trends from 1989 to 2015. This model indicates the eastern stock of Steller sea lions increased at a rate of 4.76% per year (95% confidence intervals of 4.09-5.45%) between 1989 and 2015 based on an analysis of pup counts in California, Oregon, British Columbia, and Southeast Alaska (Table 1, Figs. 2 and 3). A similar analysis of non-pup counts in the same regions plus Washington yielded an estimate of population increase of 2.84% per year (95% confidence intervals of 2.36-3.33%). Pitcher et al. (2007) reported that the Eastern U.S. stock increased at a rate of 3.1% per year during a 25-year time period from 1977 to 2002; however, they used a slightly different method to estimate population growth than the methods reported in NMFS (2013). The Eastern U.S. stock increase has been driven by growth in pup counts in all regions (NMFS 2013).

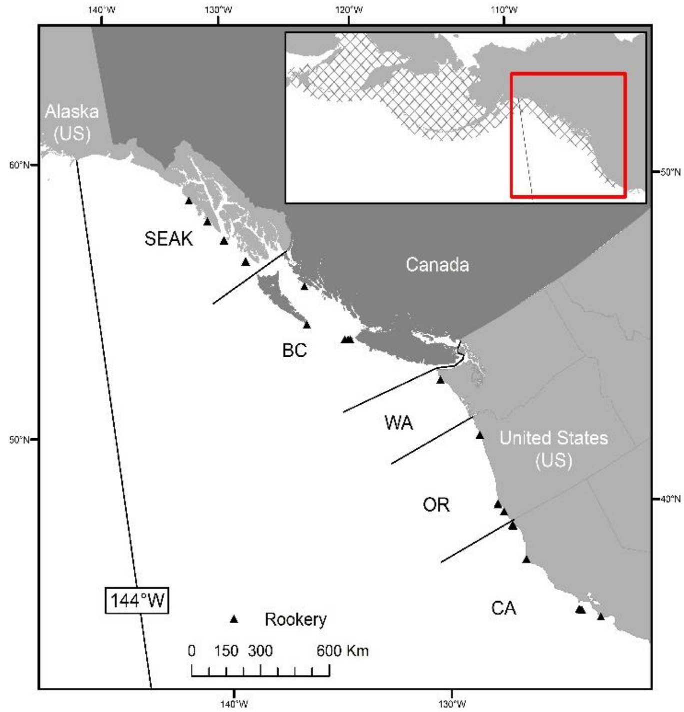

Figure 2. The eastern Steller sea lion rookery sites by region: SEAK (Southeast Alaska), BC (British Columbia, Canada), WA (Washington State), OR (Oregon State), and CA (California State).

Table 1. Trends (annual rates of change expressed as % y^{-1} with 95% credible interval) in estimated counts of eastern Steller sea lion non-pups (adults and juveniles) and pups, by region and total population, for the period 1989-2015 (Johnson and Fritz 2014, Fritz et al. 2015). The agTrend estimated counts of non-pups and pups by region and the overall counts in 2015 are also shown. Total eastern stock counts are slightly greater than the sums of the regional counts due to the modeling process.

	Non-pups					**Pups**			
Region	**Trend**	**-95%**	**+95%**	**2015**		**Trend**	**-95%**	**+95%**	**2015**
California, U.S.	1.95	0.36	3.53	3,120		3.82	2.47	5.05	936
Oregon, U.S.	2.39	1.08	3.54	5,634		3.80	2.58	5.03	1,946
Washington, U.S.*	8.77	6.00	11.37	1,407					
British Columbia, Canada	3.43	2.64	4.22	20,689		7.89	6.22	9.61	8,630
Southeast Alaska, U.S.	2.33	1.54	3.07	20,756		3.20	2.59	3.82	7,838
Total Eastern Stock	2.84	2.36	3.33	52,139		4.76	4.09	5.45	19,423
Total U.S. Eastern Stock				30,917					10,721

*NMFS has never observed Steller sea lion pups born on known sites in Washington except within the last several years. A new rookery has become established on the outer Washington coast (at the Carroll Island and Sea Lion Rock complex), with a confirmed count of 45 pups in 2013 and >100 pups born there in 2015 (R. DeLong and P. Gearin, NMFS-AFSC-MML, pers. comm.).

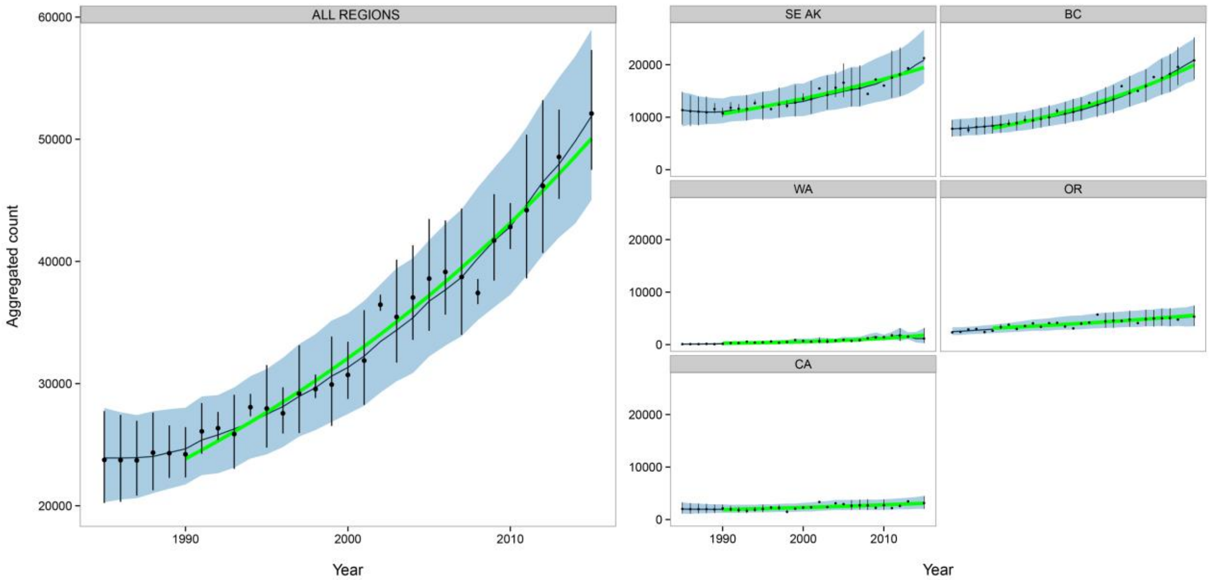

Figure 3. Estimated counts (modeled with agTrend) of eastern Steller sea lion non-pups (adults and juveniles) for the period from 1989 to 2015, with estimated trend (green line) from 1990 to 2015 for all regions and for the five separate regions: Southeast Alaska (SEAK), British Columbia (BC), Washington (WA), Oregon (OR), and California (CA) (Johnson and Fritz 2014, Fritz et al. 2015).

While the eastern stock of Steller sea lions has been increasing in all regions from 1990 to 2015, the most significant growth has been observed in Southeast Alaska and British Columbia, Canada (Fig. 3). These two regions comprise almost 85% of the total eastern stock count. Non-pups in Oregon and Washington have been increasing since 1990, though at a lower rate. Non-pup counts in California ranged between 4,000 and 6,000 with no apparent trend from 1927 to 1947 but subsequently declined. At Año Nuevo Island off central California, a steady decline in abundance began in 1970, and there was an 85% reduction in the breeding population by 1987 (LeBoeuf et al. 1991). Non-pup counts increased slightly from 1989 to 2015, ranging from approximately 2,000 to 3,100.

The net magnitude of Steller sea lion movements during the breeding season between the eastern and western stocks appears to be relatively small and would have a negligible impact on non-pup trend estimates in either area (Fritz et al. 2013, Jemison et al. 2013). However, there were significant differences by sex in cross-boundary movements: for females, there was a net increase of ~600 in the east and very few moved from east to west, while males moved in both directions but with a net increase of ~500 males in the west. This pattern of movement is supported by mitochondrial DNA evidence that indicated that the newest rookeries in northern Southeast Alaska (eastern stock) were colonized in part by western females (Gelatt et al. 2007, O'Corry-Crowe et al. 2014).

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

There are no estimates of the maximum net productivity rate for Steller sea lions. Pitcher et al. (2007) observed a rate of population increase of 3.1% per year for the eastern stock but concluded this rate did not represent a maximum rate of increase. NMFS (2013) estimated that the eastern stock increased at rates of 4.18% per year using pup counts and 2.99% per year using non-pup counts between 1979 and 2009. Here, we estimated that counts of pups and non-pups increased at rates of 4.76% and 2.84% per year, respectively, between 1989 and 2015 (Table 1). Until additional data become available, it is recommended that the theoretical maximum net productivity rate (R_{MAX}) for pinnipeds of 12% be employed for this stock (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the potential biological removal (PBR) is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: $PBR = N_{MIN} \times 0.5R_{MAX} \times F_R$. On 4 December 2013, the eastern stock of Steller sea lions was removed from the list of threatened species under the Endangered Species Act (ESA; 78 FR 66140, 4 November 2013). NMFS' decision to delist this species was based on the information presented in the Status Review (NMFS 2013), the factors for delisting in section 4(a)(1) of the ESA, the biological and threats-based recovery criteria in the 2008 Recovery Plan (NMFS 2008), the continuing efforts to protect the species, and information received during public comment and peer review. NMFS' consideration of this information led to a determination that the eastern population has recovered and no longer meets the definition of a threatened species under the ESA. As recently noted within the humpback whale ESA listing final rule (81 FR 62259, 8 September 2016), in the case of a species or stock that achieved its depleted status solely on the basis of its ESA status, such as the eastern stock of Steller sea lions, the species or stock would cease to qualify as depleted under the terms of the definition set forth in MMPA Section 3(1) if the species or stock is no longer listed as threatened or endangered. Therefore, NMFS considers this stock not to be depleted; the recovery factor is 1.0 (recovery factor for a stock within its Optimum Sustainable Population), and the PBR = 2,498 (41,638 × 0.06 × 1.0).

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Detailed information (including observer programs, observer coverage, and observed incidental takes of marine mammals) for federally-managed and state-managed U.S. commercial fisheries is presented in Appendices 3-6 of the Alaska Stock Assessment Reports (for fisheries in Alaska waters) and Appendix 1 of the U.S. Pacific Stock Assessment Reports (for fisheries in Washington, Oregon, and California waters).

During 2010-2014, no incidental mortality or serious injury of eastern Steller sea lions was observed in the 22 federally-regulated commercial fisheries in Alaska monitored for incidental mortality by fisheries observers (Breiwick 2013; MML, unpubl. data).

U.S. West Coast groundfish fishery observers monitored three federally-regulated commercial fisheries in 2010-2013 in which Steller sea lions from this stock were taken incidentally: the Washington/Oregon/California (WA/OR/CA) groundfish bottom trawl, WA/OR/CA groundfish midwater trawl (shoreside hake sector), and WA/OR/CA midwater trawl (at-sea hake sector) fisheries, resulting in a mean annual mortality and serious injury rate of 14 Steller sea lions from this stock (Table 2; Jannot et al. 2016).

The estimated mean annual mortality and serious injury rate incidental to U.S. commercial fisheries is 14 eastern Steller sea lions, based on observer data for 2010-2013 (Table 2). Due to limited observer program coverage, no data exist on the mortality of marine mammals incidental to Canadian commercial fisheries (i.e., those similar to U.S. fisheries known to take Steller sea lions). As a result, the number of Steller sea lions taken in Canadian waters is not known.

Table 2. Summary of incidental mortality and serious injury of Eastern U.S. Steller sea lions due to U.S. commercial fisheries in 2010-2013 (Jannot et al. 2016) and calculation of the mean annual mortality and serious injury rate.

Fishery name	Years	Data type	Percent observer coverage	Observed mortality	Estimated mortality	Mean estimated annual mortality
WA/OR/CA groundfish (bottom trawl)[a]	2010 2011 2012 2013	obs data	18 100 100 100	7 20 7 5	7[b] 20 7 5	9.8
WA/OR/CA groundfish (midwater trawl - shoreside hake sector)[c]	2011 2012 2013	obs data	100 100 100	1 0 0	1 0 0	0.3
WA/OR/CA groundfish (midwater trawl - at-sea hake sector)	2010 2011 2012 2013	obs data	100 100 100 100	9 2 1 2	9 2 1 2	3.5
Minimum total estimated annual mortality						14

[a]The bottom trawl fishery was a limited entry fishery in 2010 and a catch shares fishery in 2011-2013.
[b]The observed mortality and serious injury for this fishery will be used until published estimates are available.
[c]Fishery observers began monitoring the shoreside hake sector of the fishery in 2011.

Reports to the NMFS Alaska Region stranding network and the Alaska Department of Fish and Game (ADF&G) of Steller sea lions entangled in fishing gear or with injuries caused by interactions with gear provide additional information on fishery-related mortality and serious injury (Table 3; Helker et al. 2016). During 2010-2014, one Steller sea lion interaction with a recreational Southeast Alaska salmon troll fishery was reported, resulting in a minimum mean annual mortality and serious injury rate of 0.2 Steller sea lions per year in recreational troll fisheries. An additional 154 Steller sea lion interactions with troll fisheries were reported in 2010-2014 (including 11 that occurred in the Southeast Alaska salmon troll fishery and 99 that occurred in unidentified Southeast Alaska troll fisheries). In each case, animals had either ingested troll gear or were hooked in the mouth; however, it is not clear whether these interactions involved recreational or commercial components of the fisheries. Three of the animals that were seriously injured in the Southeast Alaska troll fisheries had dependent pups, so the pups were also considered seriously injured. Other fishery-related mortality and serious injury of eastern Steller sea lions in 2010-2014 was due to interactions with longline gear, monofilament gear, trawl gear, and unidentified fishing gear. The minimum mean annual mortality and serious injury rate due to all non-commercial fishery interactions reported to the NMFS Alaska Region and ADF&G in 2010-2014 is 38 eastern Steller sea lions: 0.2 in recreational fisheries + 38 in unknown (commercial, recreational, or subsistence) fisheries (Table 3; Helker et al. 2016). Estimates of fishery-related mortality and serious injury from stranding data are considered minimum estimates because not all entangled animals strand, and not all stranded animals are found or reported.

An additional four Steller sea lions initially considered seriously injured in a Yakutat salmon set gillnet (1 in 2011), Southeast Alaska pot gear (1 in 2012), Southeast Alaska salmon drift gillnet (1 in 2012), and marine debris (1 in 2014) were disentangled and released with non-serious injuries in Alaska waters, and one Steller sea lion pup with serious injuries caused by human harassment was rehabilitated and released with non-serious injuries in Washington waters in 2014 (Helker et al. 2016). None of these animals were included in the average annual mortality and serious injury rate for 2010-2014.

Table 3. Summary of Eastern U.S. Steller sea lion mortality and serious injury, by year and type, reported to the NMFS Alaska Region marine mammal stranding network and ADF&G in 2010-2014 (Helker et al. 2016).

Cause of injury	**2010**	**2011**	**2012**	**2013**	**2014**	**Mean annual mortality**
Hooked by recreational SE Alaska salmon troll gear	0	0	0	0	1	0.2
Hooked by Gulf of Alaska longline gear*	1	0	0	0	0	0.2
Entangled in SE Alaska halibut longline gear*	0	1	0	0	0	0.2
Entangled in SE Alaska longline gear*	0	1	0	0	0	0.2
Hooked by SE Alaska salmon troll gear*	0	0	0	3	8	2.2
Hooked by SE Alaska troll gear*	42	30	27	-	0	25[a]
Dependent pup of animal seriously injured by SE Alaska troll gear*	2	0	1	-	0	0.8[a]
Hooked by troll gear*	0	0	0	3	41	8.8
Entangled in SE Alaska monofilament gear*	1	1	0	0	0	0.4
Entangled in trawl gear*	0	0	0	0	1	0.2
Hooked by unidentified fishing gear*	0	0	2	0	0	0.4
Entangled in marine debris	25	32	24	-	26	27[b]
Dependent pup of animal seriously injured by marine debris	0	1	0	-	3	1[b]
Entangled in foreign high-seas gillnet	1	0	0	0	0	0.2
Gunshot[c]	-	-	15	16	14	15[d]
Struck by arrow	0	0	0	1	0	0.2
Explosives	0	0	0	0	1	0.2

Cause of injury	2010	2011	2012	2013	2014	Mean annual mortality
Total in recreational fisheries						0.2
*Total in unknown (commercial, recreational, or subsistence) fisheries						38
Total in marine debris						28
Total due to other sources (gunshot, arrow, foreign gillnet, explosives)						16

[a]A 4-year average (using the 2010-2012 and 2014 data) was calculated for this category, since we did not receive data on mortality and serious injury due to flasher entanglement (which is primarily assigned to SE Alaska troll gear) from the ADF&G in 2013. Although the NMFS Alaska Region did not assign any mortality and serious injury to SE Alaska troll gear in 2014, this mortality and serious injury is accounted for in the more general category of "troll gear" in 2014.
[b]A 4-year average (using 2010-2012 and 2014 data) was calculated for this category, since we did not receive data on mortality and serious injury due to marine debris entanglement from the ADF&G in 2013.
[c]Only animals reported to the NMFS West Coast Region are included in this table because animals reported to the NMFS Alaska Region are likely accounted for as "struck and lost" in the Alaska Native harvest.
[d]A 3-year average (using the 2012-2014 data) was calculated for this category, since we do not have gunshot data for 2010 and 2011.

The minimum estimated mean annual mortality and serious injury rate incidental to all fisheries in 2010-2014 is 52 Steller sea lions: 14 in U.S. commercial fisheries + 0.2 in recreational fisheries + 38 in unknown (commercial, recreational, or subsistence) fisheries.

Alaska Native Subsistence/Harvest Information

Information on the subsistence harvest of Steller sea lions is provided by the ADF&G. The ADF&G conducted systematic interviews with hunters and users of marine mammals in approximately 2,100 households in about 60 coastal communities within the geographic range of the Steller sea lion in Alaska in 2005-2008 (Wolfe et al. 2006, 2008, 2009a, 2009b). The interviews were conducted once per year in the winter (January to March) and covered hunter activities for the previous calendar year. Approximately 16 of the interviewed communities lie within the range of the Eastern U.S. stock. As of 2009, annual statewide data on community subsistence harvests are no longer being consistently collected. Data are being collected periodically in subareas. During 2010-2014, monitoring occurred only in 2012 (Wolfe et al. 2013), when one animal was landed and eight animals were struck and lost. Therefore, the most recent 5 years of data (2005-2008 and 2012) will be retained and used for calculating an annual mortality and serious injury estimate. The average number of animals harvested plus struck and lost is 11 animals per year during this 5-year period (Table 4).

An unknown number of Steller sea lions from this stock are harvested by subsistence hunters in Canada. The magnitude of the Canadian subsistence harvest is believed to be small (Fisheries and Oceans Canada 2010). Alaska Native subsistence hunters have initiated discussions with Canadian hunters to quantify their respective subsistence harvests, and to identify any effect these harvests may have on management of the stock.

Table 4. Summary of the subsistence harvest data for Eastern U.S. Steller sea lions in 2005-2008 and 2012. As of 2009, data on community subsistence harvests are no longer being consistently collected at a statewide level. Therefore, the most recent 5 years of data (2005-2008 and 2012) will be retained and used for calculating an annual mortality and serious injury estimate.

Year	Number harvested	Number struck and lost	Estimated total number taken
2005	0	19	19[a]
2006	2.5	10.1	12.6[b]
2007	0	6.1	6.1[c]
2008	1.7	8.0	9.7[d]
2012	1	8	9[e]
Mean annual take (2005-2008 and 2012)	1.0	10	11

[a]Wolfe et al. (2006); [b]Wolfe et al. (2008); [c]Wolfe et al. (2009a); [d]Wolfe et al. (2009b); [e]Wolfe et al. (2013).

Other Mortality

Illegal shooting of sea lions in U.S. waters was thought to be a potentially significant source of mortality prior to the listing of sea lions as threatened under the ESA in 1990. (Note: the 1994 amendments to the MMPA made intentional lethal take of any marine mammal illegal except for subsistence hunting by Alaska Natives or where imminently necessary to protect human life).

Steller sea lions were taken in British Columbia during commercial salmon farming operations. Preliminary figures from the British Columbia Aquaculture Predator Control Program indicated a mean annual mortality of 45.8 Steller sea lions from this stock over the period from 1999 to 2003 (Olesiuk 2004). Starting in 2004, aquaculture facilities were no longer permitted to shoot Steller sea lions (P. Olesiuk, Pacific Biological Station, Canada, pers. comm.). However, Fisheries and Oceans Canada (2010) summarized that "illegal and undocumented killing of Steller Sea Lions is likely to occur in B.C." and reported "[s]everal cases of illegal kills have been documented (Department of Fisheries and Oceans, Canada, unpubl. data), and mortality may also occur outside of the legal parameters assigned to permit holders (e.g., for predator control or subsistence harvest)" but "…data on these activities are currently lacking."

Steller sea lion mortality and serious injury caused by gunshot wounds is reported to the NMFS Alaska Region and the NMFS West Coast Region. During 2012-2014, 45 animals with gunshot wounds were reported to the NMFS West Coast Region stranding network, resulting in a minimum average annual mortality and serious injury rate of 15 Steller sea lions from this stock (Table 3; Helker et al. 2016). An additional two animals with gunshot wounds were reported to the NMFS Alaska Region in 2010. Although it is likely that illegal shooting does occur in Alaska, these events are not included in the estimate of the average annual mortality and serious injury rate due to gunshot wounds because it could not be confirmed that the deaths were due to illegal shooting and were not already accounted for in the estimate of animals struck and lost in the Alaska Native subsistence harvest. Other non-fishery human-caused mortality and serious injury reported to the NMFS Alaska Region stranding network in 2010-2014 (and the resulting minimum mean annual mortality and serious injury rates) were due to entanglement in marine debris (27), dependent pups of animals seriously injured by marine debris (1), entanglement in foreign gillnet (0.2), arrow strike (0.2), and explosives (0.2) (Table 3; Helker et al. 2016). These estimates are considered a minimum because not all stranded animals are found, reported, or cause of death determined (via necropsy by trained personnel), and human-related stranding data are not available for British Columbia.

Mortality and serious injury may occasionally occur incidental to marine mammal research activities authorized under MMPA permits issued to a variety of government, academic, and other research organizations. Three mortalities occurred incidental to research on the Eastern U.S. stock of Steller sea lions in 2011 (Division of Permits and Conservation, Office of Protected Resources, NMFS, 1315 East-West Highway, Silver Spring, MD 20910), resulting in a mean annual mortality and serious injury rate of 0.6 sea lions from this stock in 2010-2014.

The minimum mean annual human-caused mortality and serious injury rate in 2010-2014 from sources other than fisheries or Alaska Native harvest is 45 eastern Steller sea lions.

STATUS OF STOCK

Based on currently available data, the minimum estimated mean annual U.S. commercial fishery-related mortality and serious injury rate for this stock (14 sea lions) is less than 10% of the calculated PBR (10% of PBR = 250) and, therefore, can be considered to be insignificant and approaching a zero mortality and serious injury rate. The total estimated annual level of human-caused mortality and serious injury (108 sea lions) does not exceed the PBR (2,498) for this stock. The Eastern U.S. stock of Steller sea lions is currently not listed under the ESA and is not considered depleted under the MMPA. This stock is classified as a non-strategic stock. Because the counts of eastern Steller sea lions have steadily increased over a 30+ year period, this stock is likely within its Optimum Sustainable Population (OSP); however, no determination of its status relative to OSP has been made.

HABITAT CONCERNS

Unlike the Western U.S. stock of Steller sea lions, there has been a sustained and robust increase in abundance of the Eastern U.S. stock throughout its breeding range. In the southern end of its range (Channel Islands in southern California), it has declined considerably since the late 1930s and several rookeries and haulouts south of Año Nuevo Island have been abandoned. Changes in the ocean environment, particularly warmer temperatures, may be factors that have favored California sea lions over Steller sea lions in the southern portion of the Steller's range (NMFS 2008). The risk of oil spills to this stock may increase in the next several decades due to increased shipping, including tanker traffic, from ports in British Columbia and possibly Washington State (COSEWIC 2013, NMFS 2013, Wiles 2014) and LNG facility and pipeline construction (COSEWIC 2013).

NORTHERN FUR SEAL (*Callorhinus ursinus*): Eastern Pacific Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

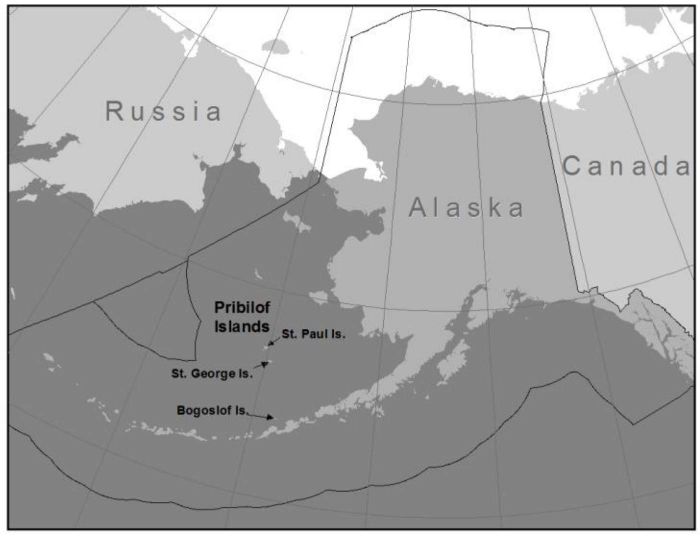

Figure 1. Approximate distribution of northern fur seals in the eastern North Pacific (dark shaded area).

Northern fur seals occur from southern California north to the Bering Sea (Fig. 1) and west to the Okhotsk Sea and Honshu Island, Japan. During the summer breeding season, most of the worldwide population is found on the Pribilof Islands in the southern Bering Sea, with the remaining animals on rookeries in Russia, on Bogoslof Island in the southern Bering Sea, on San Miguel Island off southern California (Lander and Kajimura 1982, NMFS 1993), and on the Farallon Islands off central California. Non-breeding northern fur seals may occasionally haul out on land at other sites in Alaska, British Columbia, and on islets along the west coast of the United States (Fiscus 1983).

During the reproductive season, adult males usually are on shore during the 4-month period from May to August, though some may be present until November (well after giving up their territories). Adult females are ashore during a 6-month period (June-November). Following their respective times ashore, fur seals of both genders then move south and remain at sea until the next breeding season (Roppel 1984). Adult females and pups from the Pribilof Islands move through the Aleutian Islands into the North Pacific Ocean, often to the waters offshore of Oregon and California. Adult males generally move only as far south as the Gulf of Alaska in the eastern North Pacific (Kajimura 1984) and the Kuril Islands in the western North Pacific (Loughlin et al. 1999). In Alaska, pups are born during summer months, leave the rookeries in the fall, on average around mid-November but ranging from late October to early December, and generally remain at sea for 22 months before returning to their rookery of birth. There is considerable interchange of individuals between rookeries.

Two separate stocks of northern fur seals are recognized within U.S. waters based on the distribution and population response factors of the Dizon et al. (1992) phylogeographic approach: 1) Distribution: continuous during non-breeding season and discontinuous during the breeding season, high natal site fidelity (DeLong 1982, Baker et al. 1995); 2) Population response: substantial differences in population dynamics between the Pribilof Islands and San Miguel Island (DeLong 1982, DeLong and Antonelis 1991, NMFS 1993); 3) Phenotypic differentiation: unknown; and 4) Genotypic differentiation: little evidence of genetic differentiation among breeding islands (Ream 2002, Dickerson et al. 2010). Thus, an Eastern Pacific stock and a California stock are recognized. The California stock is reported separately in the Stock Assessment Reports for the U.S. Pacific Region.

POPULATION SIZE

The population estimate for the Eastern Pacific stock of northern fur seals is calculated as the estimated number of pups born at rookeries in the eastern Bering Sea multiplied by a series of different expansion factors determined from a life table analysis to estimate the number of yearlings, 2-year-olds, 3-year-olds, and animals 4 or more years old (Lander 1981). The resulting population estimate is equal to the pup production estimate multiplied by 4.5. Juvenile northern fur seals are pelagic and are not included in the rookery counts. The expansion factor is based on a sex and age distribution estimated after the harvest of juvenile males was terminated. Coefficients of variation (CVs) are unavailable for the expansion factor. As the great majority of pups are born on St. Paul and St. George Islands, pup surveys are conducted biennially on these islands. Counts are available less frequently on Sea Lion Rock (adjacent to St. Paul Island) and Bogoslof Island (Table 1). The most recent estimate for the number of fur seals in the Eastern Pacific stock, based on pup counts on Sea Lion Rock (2014), on St. Paul and St. George

Islands (mean of 2010, 2012, and 2014), and on Bogoslof Island (2011), is 626,734 (4.47 × 140,209) northern fur seals.

Table 1. Estimates and/or counts of northern fur seal pups born on the Pribilof Islands and Bogoslof Island. Standard errors for pup estimates at rookery locations and the CV for total pup production estimates are provided in parentheses (direct counts do not have standard errors). The " symbol indicates that no new data are available for that year and, thus, the most recent prior estimate/count was used in determining total annual estimates.

	Rookery location				
Year	**St. Paul**	**Sea Lion Rock**	**St. George**	**Bogoslof**	**Total**
1992*	182,437 (8,919)	10,217 (568)	25,160 (707)	898 (N/A)	218,712 (0.041)
1994	192,104 (8,180)	12,891 (989)	22,244 (410)	1,472 (N/A)	228,711 (0.036)
1996	170,125 (21,244)	"	27,385 (294)	1,272 (N/A)	211,673 (0.10)

*Incorporates the 1990 estimate for Sea Lion Rock and the 1993 count for Bogoslof Island.

Minimum Population Estimate

A CV(N) that incorporates the variance of the correction factor is not available. Consistent with a recommendation of the Alaska Scientific Review Group (SRG) in October 1997 (DeMaster 1998) and recommendations contained in Wade and Angliss (1997), a default CV(N) of 0.2 was used in the calculation of the minimum population estimate (N_{MIN}) for this stock. N_{MIN} is calculated using Equation 1 from the potential biological removal (PBR) guidelines (Wade and Angliss 1997): $N_{MIN} = N/\exp(0.842\times[\ln(1+[CV(N)]^2)]^{½})$. Using the 3-year mean population estimate (N) of 626,734 and the default CV (0.2), N_{MIN} for the Eastern Pacific stock of northern fur seals is 530,474.

Current Population Trend

Estimates of the size of the Alaska population of northern fur seals increased to approximately 1.25 million in 1974 after the termination of commercial sealing on St. George in 1972 and pelagic sealing for science in 1974; commercial sealing on St. Paul continued until 1984. The population then began to decrease with pup production declining at a rate of 6.5-7.8% per year into the 1980s (York 1987). By 1983, the total stock estimate was 877,000

(Briggs and Fowler 1984). Annual pup production on St. Paul Island remained stable between 1981 and 1996 (Fig. 2; York and Fowler 1992). There has been a decline in pup production on St. Paul Island since the mid-1990s. Pup production at St. George Island had a less pronounced period of stabilization that was similarly followed by decline. However, pup production appeared to stabilize again on St. George Island beginning around 2002 (Fig. 3). During 1998-2014, pup production declined 4.25% per year (SE = 0.48%; P < 0.01) on St. Paul Island and 1.42% per year (SE = 0.54%; P = 0.04) on St. George Island. The estimated pup production in 2014 was below the 1917 level on both St. Paul and St. George Islands (MML, unpubl. data). Northern fur seal pup production at Bogoslof Island has grown at an exponential rate since the 1990s (Towell and Ream 2012). Despite continued growth at Bogoslof Island, recent estimates of pup production indicate that the rate of increase may be slowing. Between 2005 and 2011, pup production at Bogoslof Island increased 9.9% per year. Incorporation of the 2014 estimates from the Pribilofs shows a small and insignificant decline in pup production on the Pribilof Islands since 2010. Temporary increases in the overall stock size are observed when opportunistic estimates are conducted at Bogoslof, but declines at the larger Pribilof colony (specifically St. Paul) continue to drive the overall stock estimate down over time.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

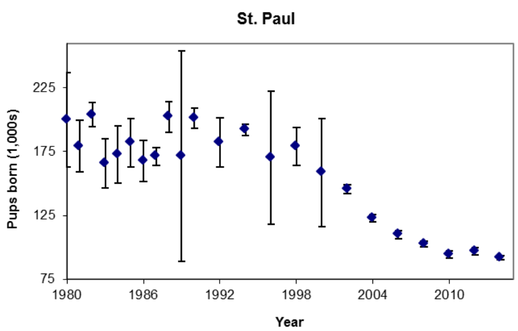

Figure 2. Estimated number of northern fur seal pups born on St. Paul Island, 1980-2014.

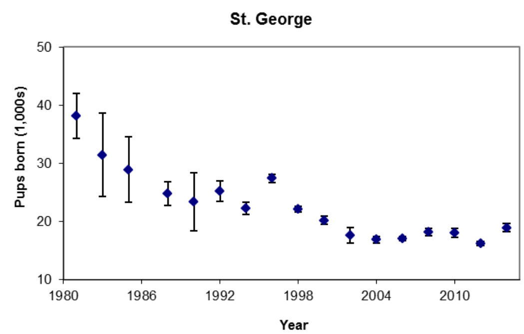

Figure 3. Estimated number of northern fur seal pups born on St. George Island, 1980-2014.

Pelagic sealing led to a decrease in the fur seal population; however, a moratorium on fur seal harvesting and termination of pelagic sealing resulted in a steady increase in the northern fur seal population during 1912-1924. During this period, the rate of population growth was approximately 8.6% (SE = 1.47) per year (A. York, NMFS-AFSC-MML (retired), unpubl. data), the maximum recorded for this species. This growth rate is similar and slightly higher than the 8.1% rate of increase (approximate SE = 1.29) estimated by Gerrodette et al. (1985). Though not as high as growth rates estimated for other fur seal species, the 8.6% rate of increase is considered a reliable estimate of R_{MAX} given the extremely low density of the population in the early 1900s.

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the PBR is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: $PBR = N_{MIN} \times 0.5R_{MAX} \times F_R$. The recovery factor ($F_R$) for this stock is 0.5, the value for depleted stocks under the MMPA (Wade and Angliss 1997). Thus, for the Eastern Pacific stock of northern fur seals, PBR = 11,405 (530,474 × 0.043 × 0.5) animals.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Detailed information on U.S. commercial fisheries in Alaska waters (including observer programs, observer coverage, and observed incidental takes of marine mammals) is presented in Appendices 3-6 of the Alaska Stock Assessment Reports.

During 2010-2014, incidental mortality and serious injury of northern fur seals was observed in the following 3 fisheries of the 22 federally-regulated commercial fisheries in Alaska monitored for incidental mortality and serious injury by fisheries observers: Bering Sea/Aleutian Islands flatfish trawl, Bering Sea/Aleutian Islands pollock trawl, and Bering Sea/Aleutian Islands Pacific cod longline fisheries (Table 2; Breiwick 2013; MML, unpubl. data). The estimated mean annual mortality and serious injury rate in these fisheries in 2010-2014 is 1.1 northern fur seals.

Observer programs for Alaska State-managed commercial fisheries have not documented any mortality or serious injury of northern fur seals (Wynne et al. 1991, 1992; Manly 2006, 2007).

Table 2. Summary of incidental mortality and serious injury of Eastern Pacific northern fur seals due to U.S. commercial fisheries in 2010-2014 and calculation of the mean annual mortality and serious injury rate (Breiwick 2013; MML, unpubl. data). Methods for calculating percent observer coverage are described in Appendix 6 of the Alaska Stock Assessment Reports.

Fishery name	Years	Data type	Percent observer coverage	Observed mortality	Estimated mortality	Mean estimated annual mortality
Bering Sea/Aleutian Is. flatfish trawl	2010 2011 2012 2013 2014	obs data	99 100 99 99 99	0 (+1)[a] 0 0 0 1	0 (+1)[b] 0 0 0 1	0.2 (+0.2)[c] (CV = 0.04)
Bering Sea/Aleutian Is. pollock trawl	2010 2011 2012 2013 2014	obs data	86 98 98 97 98	2 0 0 0 0	2.0 0 0 0 0	0.4 (CV = 0.07)
Bering Sea/Aleutian Is. Pacific cod longline	2010 2011 2012 2013 2014	obs data	64 57 51 67 64	1 0 0 0 0	1.4 0 0 0 0	0.3 (CV = 0.52)
Minimum total estimated annual mortality						1.1 (CV = 0.17)

[a]Total mortality and serious injury observed in 2010: 0 fur seals in sampled hauls + 1 fur seal in an unsampled haul.
[b]Total estimate of mortality and serious injury in 2010: 0 fur seals (extrapolated estimate from 0 fur seals observed in sampled hauls) + 1 fur seal (1 fur seal observed in an unsampled haul).
[c]Mean annual mortality and serious injury for fishery: 0.2 fur seals (mean of extrapolated estimates from sampled hauls) + 0.2 fur seals (mean of number observed in unsampled hauls).

Entanglement studies on the Pribilof Islands are another source of information on fishery-specific interactions with fur seals. Based on entanglement rates and sample sizes presented in Zavadil et al. (2003), an average of 1.1 fur seals per year on the rookeries were entangled in pieces of trawl netting and an average of 0.1 fur seals per year were entangled in monofilament net. Zavadil et al. (2007) determined the juvenile male entanglement rate for 2005-2006 to be between 0.15 and 0.35%. The mean entanglement rate in this 2-year period for pups on St. George Island was 0.06-0.08%, with a potential maximum rate of up to 0.11% in October prior to weaning. Female entanglement rate on St. George Island increased during the course of the 2005-2006 breeding seasons, reaching a rate of 0.13% in October; this rate increase coincided with the arrival of progressively younger females on the rookery throughout the season (Zavadil et al. 2007).

Entanglements of northern fur seals have been observed on St. Paul, St. George, and Bogoslof Islands. Since 2011, there has been an increased effort to include entanglement reports in the NMFS Alaska Region stranding database. A summary of entanglements in fishing gear that were reported in 2010-2014 is provided in Table 3 (Helker et al. 2016).

Three northern fur seals entangled in commercial Bering Sea/Aleutian Islands halibut longline gear and nine northern fur seals entangled in commercial Bering Sea/Aleutian Islands trawl gear were reported to the NMFS Alaska Region stranding network in 2010-2014, resulting in minimum mean annual mortality and serious injury rates of 0.6 and 1.8 fur seals, respectively, in these fisheries (Table 3; Helker et al. 2016).

An additional seven northern fur seals were initially considered to be seriously injured due to entanglement in commercial Bering Sea/Aleutian Islands trawl gear (2 in 2011, 2 in 2012, and 1 in 2014) and unidentified net (1 each in 2011 and 2012); however, since these animals were disentangled and released with non-serious injuries (Helker et al. 2016), they were not included in the mean annual mortality and serious injury rate for 2010-2014.

The total mean annual mortality and serious injury rate incidental to U.S. commercial fisheries in 2010-2014 is 3.5 northern fur seals (1.1 from observer data + 2.4 from stranding data).

The minimum mean annual mortality and serious injury rate due to entanglement in fishing line (0.2), pot gear (0.2), gillnet (0.2), and unidentified fishing net (0.8) in Alaska waters in 2010-2014 is 1.4 northern fur seals (Table 3; Helker et al. 2016). These entanglements cannot be assigned to a specific fishery, and it is unknown whether commercial, recreational, or subsistence fisheries are the source of the fishing debris. More thorough reporting of events has occurred since 2011, and there is significantly higher observation effort on the rookeries during the years of pup production (even years) than during odd numbered years, so this difference in the level of effort most likely affects estimates of entanglement based on opportunistic reports.

The Eastern Pacific stock can occur off the west coast of the continental U.S. in winter/spring; therefore, any mortality or serious injury of northern fur seals reported off the coasts of Washington, Oregon, or California during December through May will be assigned to both the Eastern Pacific and California stocks of northern fur seals. During 2010-2014, three northern fur seal entanglements in trawl gear occurred off the U.S. west coast in December through May (Carretta et al. 2016), resulting in an average annual mortality and serious injury rate of 0.6 Eastern Pacific northern fur seals in these waters (Table 3). An additional northern fur seal that stranded with a serious injury, due to an unidentified fishery interaction, in May 2012 in California was treated and released with a non-serious injury (Carretta et al. 2016); therefore, it was not included in the mean annual mortality and serious injury rate for 2010-2014.

Table 3. Summary of mortality and serious injury of Eastern Pacific northern fur seals, by year and type, reported to the NMFS Alaska Region (Helker et al. 2016) and NMFS U.S. West Coast Region (Carretta et al. 2016) marine mammal stranding networks in 2010-2014. Only cases of serious injuries are reported in this table; animals that were disentangled and released with non-serious injuries have been excluded.

Cause of injury	2010	2011	2012	2013	2014	Mean annual mortality
Entangled in commercial Bering Sea/Aleutian Is. halibut longline gear	0	0	0	0	3	0.6
Entangled in commercial Bering Sea/Aleutian Is. trawl gear	0	2	1	0	6	1.8
Entangled in Bering Sea crab pot gear*	0	1	0	0	0	0.2
Entangled in Bering Sea/Aleutian Is. monofilament hook and line gear*	0	1	0	0	0	0.2
Entangled in gillnet*	0	0	0	0	1	0.2
Entangled in unidentified net*	0	0	3	0	1	0.8
Entangled in trawl gear*	0	1[a]	0	0	2[a]	0.6
Entangled in marine debris	0	10	4	1	11	5.2
Entrained in power plant intake	0	0	1[a]	0	0	0.2
Sum of 2011, 2012, and 2014 events[b]		15	9		24	16
Total in commercial fisheries						2.4
*Total in unknown (commercial, recreational, or subsistence) fisheries						2.0
Total in marine debris						5.2
Total due to other sources (power plant entrainment)						0.2

[a]Mortality or serious injury that occurred off the coasts of Washington, Oregon, or California in December through May was assigned to both the Eastern Pacific and California stocks of northern fur seals.

[b]An increase in the number of reports is not necessarily an indication of an increase in occurrence of entanglements but rather is a reflection of more thorough reporting of these events in the NMFS Alaska Region stranding database as of 2011. The average of the sum of mortality/serious injury (M/SI) events reported in 2011, 2012, and 2014 may be a more accurate number of annual M/SI for management purposes due to more thorough reporting for those years.

Alaska Native Subsistence/Harvest Information

Alaska Natives residing on the Pribilof Islands are allowed an annual subsistence harvest of northern fur seals, with a 3-year take range based on historical local needs. Typically, only juvenile males are taken in the subsistence harvest, which results in a much smaller impact on population growth than a harvest that includes females. However, accidental harvesting of females and adult males does occur. Only juvenile males were harvested in 2010; no females were reported as accidentally killed. A single female was killed during the harvest on St. Paul Island in 2011 (Lestenkof et al. 2011), one female was killed on St. George Island in 2012 (Lekanof 2013), three females were killed on St. Paul in 2013 (Lestenkof et al. 2014), and four females were killed on St. Paul (Melovidov et al. 2014) and one was killed on St. George (Kashevarof 2014b) in 2014. During the inaugural pup harvest on St. George Island in 2014, 54 pups were killed (M. Williams, NMFS, Alaska Regional Office, Anchorage, AK, pers. comm). During 2010-2014, an average of 426 northern fur seals were harvested each year in the subsistence harvest on the Pribilof Islands (Table 4).

Table 4. Summary of the Alaska Native subsistence harvest of northern fur seals on St. Paul and St. George Islands in 2010-2014.

Year	St. Paul	St. George	Total harvested
2010	357[a]	78[b]	435
2011	323[c]	120[d]	443
2012	383[e]	64[f]	447
2013	301[g]	80[h]	381
2014	266[i]	158[j, k]	424
Mean annual take (2010-2014)			426

Other Mortality

Intentional killing of northern fur seals by commercial fishers, sport fishers, and others may occur, but the magnitude of that mortality is unknown. Such shooting has been illegal since the species was designated as depleted in 1988.

Since the Eastern Pacific and California stocks of northern fur seals overlap off the west coast of the continental U.S. during December through May, non-fishery mortality and serious injury reported off the coasts of Washington, Oregon, or California during that time will be assigned to both stocks. The mean annual mortality and serious injury rate due to entanglement in marine debris in Alaska waters in 2010-2014 is 5.2 Eastern Pacific northern fur seals (Table 3; Helker et al. 2016). A northern fur seal mortality in 2012 due to entrainment in the cooling water system of a California power plant resulted in an additional mean annual mortality and serious injury rate of 0.2 Eastern Pacific northern fur seals in 2010-2014 (Table 3; Carretta et al. 2016).

An additional 14 northern fur seals that were initially considered seriously injured due to entanglement in marine debris (3 in 2011, 7 in 2012, and 4 in 2014) were disentangled and released with non-serious injuries (Helker et al. 2016); therefore, these animals were not included in the mean annual mortality and serious injury rate for 2010-2104.

Mortality and serious injury may occasionally occur incidental to marine mammal research activities authorized under MMPA permits issued to a variety of government, academic, and other research organizations. In 2010-2014, no research-related mortality or serious injury was reported for the Eastern Pacific stock of northern fur seals (Division of Permits and Conservation, Office of Protected Resources, NMFS, 1315 East-West Highway, Silver Spring, MD 20910).

STATUS OF STOCK

Based on currently available data, the minimum estimate of the mean annual U.S. commercial fishery-related mortality and serious injury rate for this stock (3.5 fur seals) is less than 10% of the calculated PBR (10% of PBR = 1,140) and, therefore, can be considered to be insignificant and approaching a zero mortality and serious injury rate. The total estimated annual level of human-caused mortality and serious injury (437 fur seals) does not exceed the PBR (11,405) for this stock. However, given that the population is declining for unknown reasons, and this decline is not explained by the relatively low level of known direct human-caused mortality and serious injury, there is no reason to believe that limiting mortality and serious injury to the level of the PBR will reverse the decline. The northern fur seal was designated as depleted under the MMPA in 1988 because population levels had declined to less than 50% of levels observed in the late 1950s (1.8 million animals; 53 FR 17888, 18 May 1988) and there was no compelling evidence that carrying capacity (K, assumed to be 1.8 million animals) had changed substantially since the late 1950s. The Eastern Pacific stock of northern fur seals is classified as a strategic stock because it is designated as depleted under the MMPA.

HABITAT CONCERNS

Northern fur seals forage on a variety of fish species, including pollock. Some historically relevant prey items, such as capelin, have disappeared entirely from the fur seal diet and pollock consumption has increased (Sinclair et al. 1994, 1996; Antonelis et al. 1997). Analyses of scats collected from Pribilof Island rookeries during 1987-2000 found that pollock (46-75% by frequency of occurrence, FO) and gonatid squids dominated in the diet and that other primary prey (FO>5%) included Pacific sand lance, Pacific herring, northern smoothtongue, Atka mackerel, and Pacific salmon (Zeppelin and Ream 2006). These analyses also found that diets associated with rookery complexes reflected patterns associated with foraging in the specific hydrographic domains identified by Robson et al. (2004). Comparison of ingested prey sizes based on scat and spew analysis indicate a much larger overlap between sizes of pollock consumed by fur seals and those caught by the commercial trawl fishery than was previously known (Gudmundson et al. 2006). Call et al. (2008) found northern fur seals had three types of individual foraging route tactics at the rookery, which is important to consider in the context of adaptation to changes in environmental conditions and prey distributions.

Fishing effort displaced by Steller sea lion protection measures may have moved to areas important to fur seals; recent tagging studies have shown that lactating female fur seals and juvenile males from St. Paul and St. George Islands forage in specific and very different areas (Robson et al. 2004, Sterling and Ream 2004). From 1982 to 2002, pup production declined on St. Paul and St. George Islands (Figs. 2 and 3). However, it remains unclear whether the pattern of declines in fur seal pup production on the two Pribilof Islands is related to the relative distribution of pollock fishery effort in summer on the eastern Bering Sea shelf. Adult female fur seals spend approximately 8 months in varied regions of the North Pacific during winter, and forage in areas associated with eddies and the subarctic-subtropical transition region (Ream et al. 2005). Thus, environmental changes in the North Pacific could potentially be affecting abundance and productivity of fur seals breeding in Alaska.

There is concern that a variety of human activities other than commercial fishing, such as an increase in vessel traffic in Alaska waters and an increased potential for oil spills, may impact northern fur seals. A Conservation Plan for the Eastern Pacific stock was released in December of 2007 (NMFS 2007). This plan reviews known and potential threats to the recovery of fur seals in Alaska.

HARBOR SEAL (*Phoca vitulina richardii*)

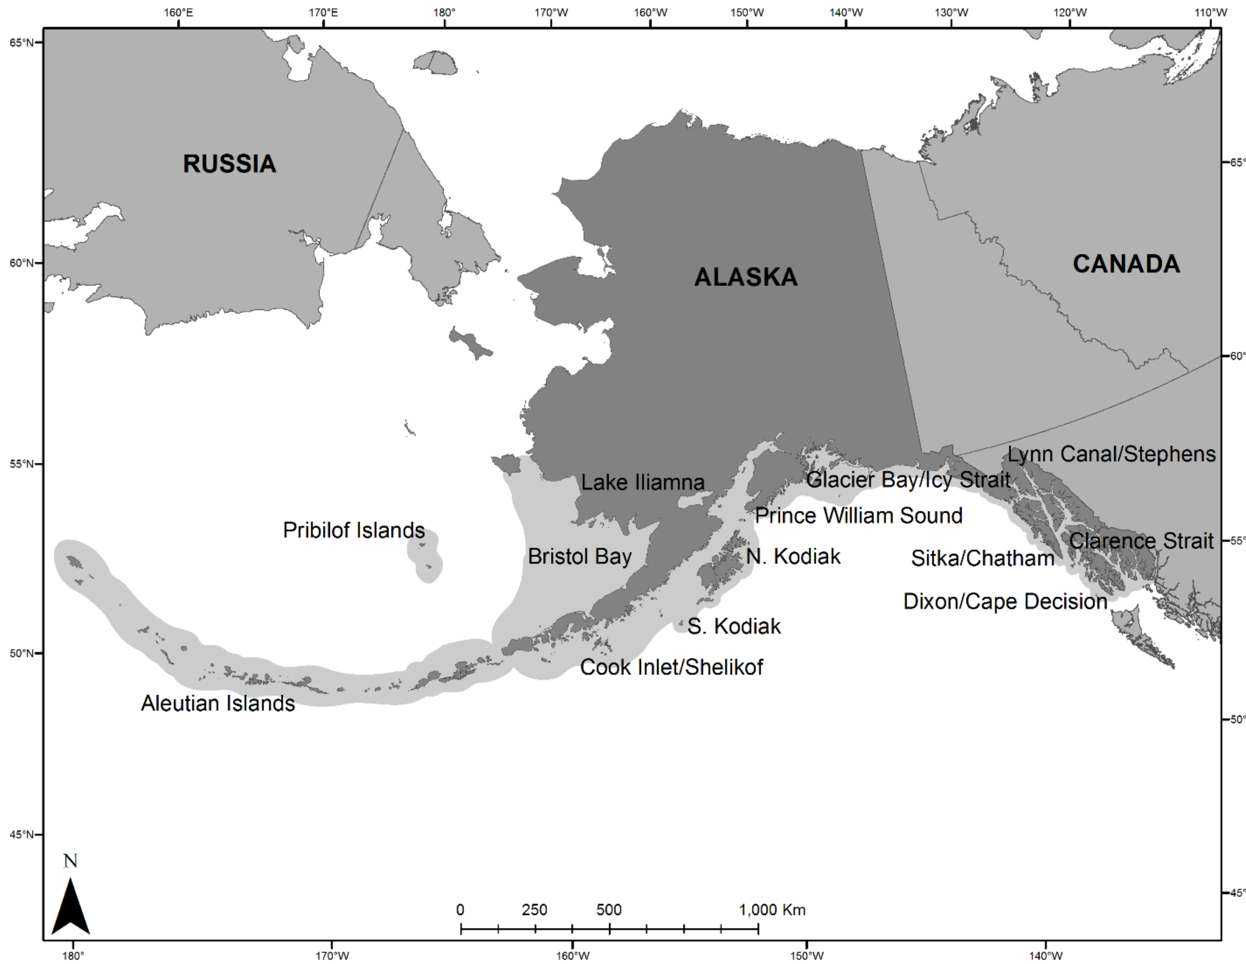

Figure 1. Approximate distribution of harbor seals in Alaska waters (shaded coastline area).

STOCK DEFINITION AND GEOGRAPHIC RANGE

Harbor seals inhabit coastal and estuarine waters off Baja California, north along the western coasts of the United States, British Columbia, and Southeast Alaska, west through the Gulf of Alaska and Aleutian Islands, and in the Bering Sea north to Cape Newenham and the Pribilof Islands. They haul out on rocks, reefs, beaches, and drifting glacial ice and feed in marine, estuarine, and occasionally fresh waters. Harbor seals generally are non-migratory, with local movements associated with such factors as tides, weather, season, food availability, and reproduction (Scheffer and Slipp 1944; Fisher 1952; Bigg 1969, 1981; Hastings et al. 2004). The results of past and recent satellite-tagging studies in Southeast Alaska, Prince William Sound, Kodiak Island, and Cook Inlet are also consistent with the conclusion that harbor seals are non-migratory (Swain et al. 1996, Lowry et al. 2001, Small et al. 2003, Boveng et al. 2012). However, some long-distance movements of tagged animals in Alaska have been recorded (Pitcher and McAllister 1981, Lowry et al. 2001, Small et al. 2003, Womble 2012, Womble and Gende 2013). Strong fidelity of individuals for haul-out sites during the breeding season has been documented in several populations (Härkönen and Harding 2001), including some harbor seal stocks in Alaska such as South Kodiak Island, Prince William Sound, Glacier Bay/Icy Strait, and Cook Inlet (Pitcher and McAllister 1981, Small et al. 2005, Boveng et al. 2012, Womble 2012, Womble and Gende 2013).

Local or regional trends in harbor seal numbers have been monitored at various time intervals since the 1970s, revealing diverse spatial patterns in apparent population trends. Where declines have been observed, they seem generally to have been strongest in the late 1970s or early 1980s to the 1990s. For example, counts of harbor seals declined by about 80% at Tugidak Island in the 1970s and 1980s (Pitcher 1990), and numbers at Nanvak Bay in northern Bristol Bay also declined at about the same time (Jemison et al. 2006). In Prince William Sound, harbor seal numbers declined by about 63% overall between 1984 and 1997, including a 40% decline prior to the *Exxon Valdez* oil spill that occurred in 1989 (Frost et al. 1999, Ver Hoef and Frost 2003). Harbor seal counts in Glacier Bay National Park, where the majority of seals haul out on floating ice calved from glaciers, declined by roughly 60% between 1992 and 2001 and continued to decline through 2008 (Mathews and Pendleton 2006, Womble et al. 2010). At Aialik Bay, a site in Kenai Fjords National Park where harbor seals also haul out on ice calved from a glacier, harbor seal numbers declined by 93% from 1979 to 2009 (Hoover-Miller et al. 2011). In the Aleutian Islands, counts declined by 67% between the early 1980s and 1999, with declines of about 86% in the western Aleutians (Small et al. 2008). Although there is evidence for recent stabilization or even partial recovery of harbor seal numbers in some areas of long-term harbor seal decline, such as Tugidak Island and Nanvak Bay (Jemison et al. 2006), most have not made substantial recoveries toward historical abundances. But these areas of declines in harbor seals contrast strongly with other large regions of Alaska where harbor seal numbers have remained stable or increased over the same period: trend monitoring regions around Ketchikan and the Kodiak area increased significantly in the 1980s and 1990s and were stable in around Sitka and Bristol Bay (Small et al. 2003). Differences in trend across the various regions of Alaska suggest some level of independent population dynamics (O'Corry-Crowe et al. 2003, O'Corry-Crowe 2012).

Westlake and O'Corry-Crowe's (2002) analysis of genetic information from 881 samples across 181 sites revealed population subdivisions on a scale of 600-820 km. These results suggest that genetic differences within Alaska, and most likely over their entire North Pacific range, increase with increasing geographic distance. New information revealed substantial genetic differences indicating that female dispersal occurs at region specific spatial scales of 150-540 km. This research identified 12 demographically independent clusters within the range of Alaskan harbor seals; however, significant geographic areas within the Alaskan harbor seal range remain unsampled (O'Corry-Crowe et al. 2003).

In 2010, NMFS and their co-management partners, the Alaska Native Harbor Seal Commission, identified 12 separate stocks of harbor seals based largely on genetic structure; this represents a significant increase in the number of harbor seal stocks from the three stocks (Bering Sea, Gulf of Alaska, Southeast Alaska) previously recognized. Given the genetic samples were not obtained continuously throughout the range, a total evidence approach was used to consider additional factors such as population trends, observed harbor seal movements, and traditional Alaska Native use areas in the final designation of stock boundaries. The 12 stocks of harbor seals currently identified in Alaska are 1) the Aleutian Islands stock – occurring along the entire Aleutian chain from Attu Island to Ugamak Island; 2) the Pribilof Islands stock – occurring on Saint Paul and Saint George Islands, as well as on Otter and Walrus Islands; 3) the Bristol Bay stock – ranging from Nunivak Island south to the west coast of Unimak Island and extending inland to Kvichak Bay and Lake Iliamna; 4) the North Kodiak stock – ranging from approximately Middle Cape on the west coast of Kodiak Island northeast to West Amatuli Island and south to Marmot and Spruce Islands; 5) the South Kodiak stock – ranging from Middle Cape on the west coast of Kodiak Island southwest to Chirikof Island and east along the south coast of Kodiak Island to Spruce Island, including the Trinity Islands, Tugidak Island, Sitkinak Island, Sundstrom Island, Aiaktalik Island, Geese Islands, Two Headed Island, Sitkalidak Island, Ugak Island, and Long Island; 6) the Prince William Sound stock – ranging from Elizabeth Island off the southwest tip of the Kenai Peninsula to Cape Fairweather, including Prince William Sound, the Copper River Delta, Icy Bay, and Yakutat Bay; 7) the Cook Inlet/Shelikof Strait stock – ranging from the southwest tip of Unimak Island east along the southern coast of the Alaska Peninsula to Elizabeth Island off the southwest tip of the Kenai Peninsula, including Cook Inlet, Knik Arm, and Turnagain Arm; 8) the Glacier Bay/Icy Strait stock – ranging from Cape Fairweather southeast to Column Point, extending inland to Glacier Bay, Icy Strait, and from Hanus Reef south to Tenakee Inlet; 9) the Lynn Canal/Stephens Passage stock – ranging north along the east and north coast of Admiralty Island from the north end of Kupreanof Island through Lynn Canal, including Taku Inlet, Tracy Arm, and Endicott Arm; 10) the Sitka/Chatham Strait stock – ranging from Cape Bingham south to Cape Ommaney, extending inland to Table Bay on the west side of Kuiu Island and north through Chatham Strait to Cube Point off the west coast of Admiralty Island, and as far east as Cape Bendel on the northeast tip of Kupreanof Island; 11) the Dixon/Cape Decision stock – ranging from Cape Decision on the southeast side of Kuiu Island north to Point Barrie on Kupreanof Island and extending south from Port Protection to Cape Chacon along the west coast of Prince of Wales Island and west to Cape Muzon on Dall Island, including Coronation Island, Forrester Island, and all the islands off the west coast of Prince of Wales Island; and 12) the Clarence Strait stock – ranging along the east coast of Prince of Wales Island from Cape Chacon north through Clarence Strait to Point Baker and along the east coast of Mitkof and Kupreanof Islands north to Bay Point, including Ernest Sound, Behm Canal, and Pearse Canal (Fig. 1). Individual stock distributions can be seen in Figures 2a-l.

POPULATION SIZE

The Alaska Fisheries Science Center's National Marine Mammal Laboratory routinely conducts aerial surveys of harbor seals across their entire range in Alaska. Prior to 2008, Alaska was divided into five survey regions, with one region surveyed per year. In 2010, the survey sites were prioritized based on the newly defined harbor seal stock divisions, and annual aerial surveys attempt to sample the full geographic range of harbor seals in Alaska, with a focus on sites that make up a significant portion of each stock's population every year; sites with fewer seals are flown every 3 to 5 years. This site specific survey approach is designed to provide the counts necessary to estimate stock specific population abundance and trend for all 12 stocks annually. To derive an accurate estimate of population size from these surveys, a method was developed to address the influence of external conditions on the number of seals hauled out on shore, and counted, during the surveys. Many factors influence the propensity of seals to haul out, including tides, time of day, and date in the seals' annual life-history cycle. A statistical model defining the relationship between these factors and the number of seals hauled out was developed. Based on those models, the survey counts for each year were adjusted to the number of seals that would have been ashore during a hypothetical survey conducted under ideal conditions for hauling out (Boveng et al. 2003). In a separate analysis of radio-tagged seals, a similar statistical model was used to estimate the proportion of seals that were hauled out under those ideal conditions (Simpkins et al. 2003). The results from these two analyses were combined for each region to estimate the population size of each stock in Alaska.

Abundance Estimates and Minimum Population Estimates

The current statewide abundance estimate for Alaskan harbor seals is 205,090 (Boveng et al. in press a), based on aerial survey data collected during 1998-2011. See Table 1 for abundance estimates of the 12 stocks of harbor seals in Alaska. The minimum population estimate (N_{MIN}) for 11 of the 12 stocks of harbor seals in Alaska is calculated as the lower bound of the 80% credible interval obtained from the posterior distribution of abundance estimates. This approach is consistent with the definition of potential biological removal (PBR) in the current guidelines (Wade and Angliss 1997). The abundance estimate and N_{MIN} for the remaining stock, the Pribilof Islands stock, is simply the number counted in the most recent survey of this very small group.

Table 1. Abundance and 5-year trend estimates, by stock, for harbor seals in Alaska, along with respective estimates of standard error. The probability of decrease represents the proportion of the posterior probability distribution for the 5-year trend that fell below a value of 0 seals per year.

Stock	Year of last survey	Abundance estimate	SE	5-year trend estimate	SE	Probability of decrease	N_{MIN}
Aleutian Islands	2011	6,431	882	75	220	0.36	5,772
Pribilof Islands	2010	232	n/a	n/a	n/a	n/a	232
Bristol Bay	2011	32,350	6,882	1,209	1,941	0.25	28,146
North Kodiak	2011	8,321	1,619	531	590	0.16	7,096
South Kodiak	2011	19,199	2,429	-461	761	0.72	17,479
Prince William Sound	2011	29,889	13,846	26	3,498	0.56	27,936
Cook Inlet/Shelikof Strait	2011	27,386	3,328	313	1,115	0.38	25,651
Glacier Bay/Icy Strait	2011	7,210	1,866	179	438	0.40	5,647
Lynn Canal/Stephens Passage	2011	9,478	1,467	-176	388	0.71	8,605
Sitka/Chatham Strait	2011	14,855	2,106	411	568	0.23	13,212
Dixon/Cape Decision	2011	18,105	1,614	216	360	0.29	16,727
Clarence Strait	2011	31,634	4,518	921	1,246	0.21	29,093

Current Population Trend

Aerial surveys of harbor seal haulout sites throughout Alaska have been conducted annually and provide information on trends in abundance. The most current estimates of trend (Table 1) were estimated as the means of the slopes of 1,000 simple linear regressions over the most recent eight annual estimates in each of the 1,000 Markov Chain Monte Carlo (MCMC) samples from the posterior distributions for abundance. Thus, they are in units of seals per year, rather than the typical annual percent growth rate. There is no appropriate method for converting these estimates of trend to annual percent growth rate. As a reflection of uncertainty in trend estimates, the proportion of the posterior distribution for each stock's trend that lies below the value of 0 is used as an estimate of the probability that a stock is currently decreasing (Table 1). This allows a probabilistic determination of the qualitative trend status: a value greater than 0.5 means the evidence suggests that the stock is decreasing; less than 0.5 means the stock is increasing. Because there will typically be a 2-3 year lag between the most recent surveys and the Stock Assessment Report update, a 5-year interval was used for estimating trend. This ensures trend estimates are based on data no more than about 8 years old, which is considered to be the approximate threshold of reliability for Marine Mammal Protection Act (MMPA) stock assessment data. One caveat of this approach is that, due to the skewness inherent in the posterior distribution, it is possible for a stock to exhibit a positive trend while also having a probability of decrease greater than 0.5. The following summarizes historical and recent information on the population trend for each of the 12 stocks.

Aleutian Islands: A partial estimate of harbor seal abundance in the Aleutian Islands was determined from skiff surveys of 106 islands from 1977 to 1982 (8,601 seals). Small et al. (2008) compared counts from the same islands during a 1999 aerial survey (2,859 seals). Counts decreased at a majority of the islands. Islands with greater than 100 seals decreased by 70%. The overall estimates showed a 67% decline during the approximate 20-year period (Small et al. 2008). The current (2007-2011) estimate of the population trend in the Aleutian Islands is +75 seals per year, with a probability that the stock is decreasing of 0.36 (Table 1).

Pribilof Islands: Counts of harbor seals in the Pribilof Islands ranged from 250 to 1,224 in the 1970s. Counts in the 1980s and 1990s ranged between 119 and 232 harbor seals. Prior to July 2010, the most recent count was in 1995 when a total of 202 seals were counted. In July 2010, approximately 185 adults and 27 pups were observed on Otter Island plus approximately 20 on all the other islands combined for a total of 232 harbor seals. Maximum seal counts (all ages) are nearly identical to the 1995 counts (212 vs. 202), but 2010 pup numbers were slightly less (27 vs. 42). The current population trend in the Pribilof Islands is unknown.

Bristol Bay: At Nanvak Bay, the largest haulout in northern Bristol Bay, harbor seals declined in abundance from 1975 to 1990 and increased from 1990 to 2000 (Jemison et al. 2006). Land-based harbor seal counts at Nanvak Bay from 1990 to 2000 increased at 9.2% per year during the pupping period and 2.1% per year during the molting period (Jemison et al. 2006). The Iliamna Lake harbor seal population of about 400 seals, that forms a small portion of the Bristol Bay stock, likely increased through the 1990s and is now stable at around 400 animals (Boveng et al. in press b). The current (2007-2011) estimate of the population trend in the Bristol Bay stock is +1,209 seals per year, with a probability that the stock is decreasing of 0.25 (Table 1).

North Kodiak: The current (2007-2011) estimate of the North Kodiak population trend is +531 seals per year, with a probability that the stock is decreasing of 0.16 (Table 1).

South Kodiak: A significant portion of the harbor seal population within the South Kodiak stock is located at and around Tugidak Island off the southwest coast of Kodiak Island. Sharp declines in the number of seals present on Tugidak were observed between 1976 and 1998. The highest rate of decline was 21% per year between 1976 and 1979 (Pitcher 1990). While the number of seals on Tugidak has stabilized and shown some evidence of increase since the decline, the population in 2000 remained reduced by 80% compared to the levels in the 1970s (Jemison et al. 2006). The current (2007-2011) estimate of the South Kodiak population trend is -461 seals per year, with a probability that the stock is decreasing of 0.72 (Table 1).

Prince William Sound: The Prince William Sound stock includes harbor seals both within and adjacent to Prince William Sound proper. Within Prince William Sound proper, harbor seals declined in abundance by 63% between 1984 and 1997 (Frost et al. 1999). In Aialik Bay, adjacent to Prince William Sound proper, there has been a decline in pup production by 4.6% annually from 40 down to 32 pups born from 1994 to 2009 (Hoover-Miller et al. 2011). The current (2007–2011) estimate of the Prince William Sound population trend over a 5-year period is +26 seals per year, with a probability that the stock is decreasing of 0.56 (Table 1). As noted earlier, this is an example where the skewed nature of the posterior distribution of the abundance estimate has resulted in a higher than 0.5 probability of decrease while subsequently showing an increasing trend.

Cook Inlet/Shelikof Strait: A multi-year study of seasonal movements and abundance of harbor seals in Cook Inlet was conducted between 2004 and 2007. This study involved multiple aerial surveys throughout the year, and the data indicated a stable population of harbor seals during the August molting period (Boveng et al. 2011). Aerial surveys along the Alaska Peninsula present greater logistical challenges and have therefore been conducted less frequently. The current (2007-2011) estimate of the Cook Inlet/Shelikof Strait population trend is +313 seals per year, with a probability that the stock is decreasing of 0.38 (Table 1).

Glacier Bay/Icy Strait: The Glacier Bay/Icy Strait stock showed a negative population trend estimate for harbor seals from 1992 to 2008 in June and August for glacial (-7.7%/yr; -8.2%/yr) and terrestrial sites (-12.4%/yr, August only) (Womble et al. 2010). Trend estimates by Mathews and Pendleton (2006) were similarly negative for both glacial and terrestrial sites. Long-term monitoring of harbor seals on glacial ice has occurred in Glacier Bay since the 1970s (Mathews and Pendleton 2006) and has shown this area to support one of the largest breeding aggregations in Alaska (Steveler 1979, Calambokidis et al. 1987). After a dramatic retreat of Muir Glacier (more than 7 km), in the East Arm of Glacier Bay, between 1973 and 1986 and the subsequent grounding and cessation of calving in 1993, floating glacial ice was greatly reduced as a haul-out substrate for harbor seals and ultimately resulted in the abandonment of upper Muir Inlet by harbor seals (Calambokidis et al. 1987, Hall et al. 1995, Mathews 1995). Prior to 1993, seal counts were up to 1,347 in the East Arm of Glacier Bay; 2008 counts were fewer than 200 (Streveler 1979, Molnia 2007). The current (2007–2011) estimate of the Glacier Bay/Icy Strait population trend is +179 seals per year, with a probability that the stock is decreasing of 0.40 (Table 1).

Lynn Canal/Stephens Passage: The current (2007-2011) estimate of the Lynn Canal/Stephens Passage population trend is -176 seals per year, with a probability that the stock is decreasing of 0.71 (Table 1).

Sitka/Chatham Strait: The current (2007-2011) estimate of the Sitka/Chatham Strait population trend is +411 seals per year, with a probability that the stock is decreasing of 0.23 (Table 1).

Dixon/Cape Decision: The current (2007-2011) estimate of the Dixon/Cape Decision population trend is +216 seals per year, with a probability that the stock is decreasing of 0.29 (Table 1).

Clarence Strait: The current (2007-2011) estimate of the Clarence Strait population trend is +921 seals per year, with a probability that the stock is decreasing of 0.21 (Table 1).

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Reliable rates of maximum net productivity have not been estimated directly from the 12 stocks of harbor seals identified in Alaska. Based on monitoring in Washington State from 1978 to 1999, Jeffries et al. (2003) estimated R_{MAX} to be 12.6% and 18.5% for harbor seals of the inland and coastal stocks, respectively. Harbor seals have been protected in British Columbia since 1970, and the monitored portion of that population responded with an annual rate of increase of approximately 12.5% through the late 1980s (Olesiuk et al. 1990), though a more recent evaluation suggested that 11.5% may be a more appropriate figure (DFO 2010). These empirical estimates of R_{MAX} indicate that the continued use of the pinniped maximum theoretical net productivity rate of 12% is appropriate for the Alaska stocks (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized MMPA, the potential biological removal (PBR) is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: PBR = $N_{MIN} \times 0.5R_{MAX} \times F_R$. Marine mammal stocks such as the harbor seal stocks in Alaska that are taken by subsistence hunting may be given F_R values up to 1.0, provided they are "known to be increasing" or "not known to be decreasing" and "there have not been recent increases in the levels of takes" (Wade and Angliss 1997). For harbor seals in Alaska, these guidelines were followed by assigning all harbor seal stocks an initial, default recovery factor of 0.5. The default value was adjusted up to 0.7 if the estimated probability of decrease was greater than 0.7. The value was adjusted down to 0.3 if the estimated probability of decrease was less than 0.3. This provides a simple, balanced approach for providing a recovery factor consistent with current guidelines while incorporating results from novel statistical methods. Table 2 summarizes the PBR levels for each stock of harbor seals in Alaska based on N_{MIN} estimates, R_{MAX} = 12%, and F_R values.

Table 2. PBR calculations by stock for harbor seals in Alaska. The N_{MIN} values are determined from the 20th percentile of the posterior distribution for stock-level abundance estimates, except for the Pribilof Islands. A default value of 0.5 was used as the recovery factor. Based on evaluation of the trend estimates and probability of decrease, the recovery factor for some stocks was increased to 0.7. For other stocks, the recovery factor was decreased to 0.3.

Stock	N_{MIN}	R_{MAX}	**Recovery Factor (F_R)** (default value = 0.5)	**PBR**
Aleutian Islands	5,772	0.12	0.5	173
Pribilof Islands	232	0.12	0.5	7
Bristol Bay	28,146	0.12	0.7	1,182
North Kodiak	7,096	0.12	0.7	298
South Kodiak	17,479	0.12	0.3	314
Prince William Sound	27,936	0.12	0.5	838
Cook Inlet/Shelikof Strait	25,651	0.12	0.5	770
Glacier Bay/Icy Strait	5,647	0.12	0.5	169
Lynn Canal/Stephens Passage	8,605	0.12	0.3	155
Sitka/Chatham Strait	13,212	0.12	0.7	555
Dixon/Cape Decision	16,727	0.12	0.7	703
Clarence Strait	29,093	0.12	0.7	1,222

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

New Serious Injury Guidelines

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an "*injury that is more likely than not to result in mortality*." Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

Fisheries Information

Detailed information (including observer programs, observer coverage, and observed incidental takes of marine mammals) for federally-managed and state-managed U.S. commercial fisheries in Alaska waters is presented in Appendices 3-6 of the Alaska Stock Assessment Reports.

Previous stock assessments for harbor seals indicated three observed commercial fisheries operated within the range of the Bering Sea stocks of harbor seals, three within the range of stocks in Southeast Alaska, and five within the range of harbor seal stocks in the Gulf of Alaska. As of 2003, changes in how fisheries are defined in the MMPA List of Fisheries have resulted in separating these fisheries into 14 fisheries in the Bering Sea, 9 fisheries in Southeast Alaska, and 22 fisheries in the Gulf of Alaska based on both gear type and target species (69 FR 70094, 2 December 2004). This change does not represent a change in fishing effort but provides managers with better information on the component of each fishery that is responsible for the incidental mortality or serious injury of marine mammal stocks in Alaska.

Observer programs have documented mortality and serious injury of harbor seals in the Bering Sea/Aleutian Islands (BSAI) flatfish trawl fishery (1 in 2011 and 2 in 2012), Gulf of Alaska (GOA) Pacific cod trawl fishery (1 in 2010), and GOA flatfish trawl fishery (1 in 2011 and 2 in 2013) in 2009-2013 (Breiwick 2013; NMML, unpubl. data) (Table 3).

Although a reliable estimate of the overall mortality and serious injury rate incidental to commercial fisheries is currently unavailable because of the absence of observer placements in salmon gillnet fisheries known to interact with several of these stocks, for the purposes of stock assessment, mean annual mortality and serious injury rates are assigned to the following harbor seal stocks based on the location of takes in observed fisheries in 2009-2013 (Table

3): Bristol Bay stock: 0.6 from the BSAI flatfish trawl fishery; South Kodiak stock: 0.6 from the GOA Pacific cod trawl fishery + 1.3 from the GOA flatfish trawl fishery; Cook Inlet/Shelikof Strait stock: 0.4 from the GOA flatfish trawl fishery mortality in 2011 (this seal could have been from either the South Kodiak or Cook Inlet/Shelikof Strait stock, so the mortality is assigned to both stocks).

Table 3. Summary of incidental mortality and serious injury of harbor seals in Alaska due to U.S. commercial fisheries in 2009-2013 and calculation of the mean annual mortality and serious injury rate (Breiwick 2013; NMML, unpubl. data).

Fishery name	Years	Data type	Percent observer coverage	Observed mortality	Estimated mortality	Mean estimated annual mortality
Bering Sea/Aleutian Is. flatfish trawl	2009 2010 2011 2012 2013	obs data	99 99 99 99 99	0 0 1 2 0	0 0 1 2 0	0.6 (CV = 0.02)
Gulf of Alaska Pacific cod trawl	2009 2010 2011 2012 2013	obs data	29 31 41 25 11	0 1 0 0 0	0 2.8 0 0 0	0.6 (CV = 0.81)
Gulf of Alaska flatfish trawl	2009 2010 2011 2012 2013	obs data	21 26 31 42 46	0 0 1 0 2[a]	0 0 1.9 0 4.7	1.3 (CV = 0.69)[b]
Minimum total estimated annual mortality						2.5 (CV = 0.41)

[a]Two pinnipeds incidentally caught in 2013 were recently genetically identified as harbor seals.
[b]The CV for this fishery does not accommodate the 2013 data.

Observer programs in Alaska State-managed salmon set gillnet and salmon drift gillnet fisheries have documented harbor seal mortality and serious injury (Table 4). The Prince William Sound salmon drift gillnet fishery is known to interact with harbor seals, although the most recent observer data available for this fishery are from 1990 and 1991. The minimum estimated average annual mortality and serious injury rate (24 seals) in this fishery will be applied to the Prince William Sound stock of harbor seals.

Table 4. Summary of incidental mortality and serious injury of harbor seals in Alaska due to U.S. commercial salmon drift and set gillnet fisheries in 1990 and 1991 and calculation of the mean annual mortality and serious injury rate based on the most recent observer program data available.

Fishery name	Years	Data type	Percent observer coverage	Observed mortality	Estimated mortality	Mean estimated annual mortality
Prince William Sound salmon drift gillnet	1990 1991	obs data	4 5	2 1	36 12	24 (CV = 0.50)
Minimum total estimated annual mortality						24 (CV = 0.50)

Reports to the NMFS Alaska Region stranding database of harbor seals entangled in fishing gear or with injuries caused by interactions with gear are another source of mortality and serious injury data (Helker et al. 2015). During 2009-2013, harbor seal mortality and serious injury occurred due to interactions with unknown fisheries (1 Clarence Strait harbor seal was observed with a hook and weight in its mouth in 2010 and 1 Cook Inlet/Shelikof Strait harbor seal entangled in an unknown set net in 2011) and recreational fishing gear (1 Prince William Sound harbor seal was caught in hook and line gear and cut loose with trailing gear in 2009), resulting in mean annual mortality and serious injury rates of 0.2 harbor seals from each of these stocks due to fishery-related strandings.

Alaska Native Subsistence/Harvest Information

The Alaska Native subsistence harvest of harbor seals has been estimated by the Alaska Native Harbor Seal Commission (ANHSC) and the Alaska Department of Fish and Game (ADF&G). Information from the ADF&G indicates the average harvest levels for the 12 stocks of harbor seals identified in Alaska from 2004 to 2008, including struck and lost, as follows (see Table 5; average annual harvest column). In 2011 and 2012, data on community subsistence harvests were collected for Kodiak Island, Prince William Sound, and Southeast Alaska (see Table 5; annual harvest 2011-2012 column). The remaining stocks have no updated community subsistence data, therefore, the most recent 5-years of data (2004-2008) will be retained and used for estimating average annual mortality and serious injury for these stocks.

Table 5. Summary of the subsistence harvest data for all 12 harbor seal stocks in Alaska, 2004-2008 and 2011-2012. Data are from Wolfe et al. (2005, 2006, 2008, 2009a, 2009b, 2012, 2013).

Stock	Minimum annual harvest 2004-2008	Maximum annual harvest 2004-2008	Average annual harvest 2004-2008	Annual harvest 2011 or 2012
Aleutian Islands	50	146	90	N/A
Pribilof Islands	0	0	0	N/A
Bristol Bay	82	188	141	N/A
North Kodiak	66	260	131	37
South Kodiak	46	126	78	126
Prince William Sound	325	600	439	255
Cook Inlet/Shelikof Strait	177	288	233	N/A
Glacier Bay/Icy Strait	22	108	52	104
Lynn Canal/Stephens Passage	17	60	30	50
Sitka/Chatham Strait	97	314	222	77
Dixon/Cape Decision	100	203	157	69
Clarence Strait	71	208	164	40

Other Mortality

Reports to the NMFS Alaska Region stranding database of harbor seals entangled in marine debris or with injuries caused by other types of human interaction are another source of mortality and serious injury data (Helker et al. 2015). During 2009-2013, one harbor seal (observed towing a buoy in 2011) was determined to be seriously injured due to entanglement in marine debris and one harbor seal mortality due to a ship strike occurred in 2009, 2010, and 2012. The estimated average annual serious injury and mortality rates based on these stranding data are 0.6 Clarence Strait harbor seals (0.2 due to entanglement in marine debris/gear + 0.4 due to ship strikes in 2009 and 2012) and 0.2 Lynn Canal/Stephens Passage harbor seals (due to a ship strike in 2010) for 2009 to 2013. An additional average annual mortality and serious injury rate of 0.2 will be applied to the Prince William Sound stock for a harbor seal entanglement, observed (with a remotely operated vehicle) in the salmon seine net of a sunken fishing vessel in Prince William Sound in 2011, that was reported to the NMFS Alaska Region (Helker et al. 2015). Mortality and serious injury may occasionally occur incidental to marine mammal research activities authorized under MMPA permits issued to a variety of government, academic, and other research organizations. Between 2003 and 2007, there was no mortality or serious injury resulting from research on any stock of harbor seals in Alaska (Division of Permits and Conservation, Office of Protected Resources, NMFS, 1315 East-West Highway, Silver Spring, MD 20910).

STATUS OF STOCK

No harbor seal stocks in Alaska are designated as "depleted" under the MMPA or listed as "threatened" or "endangered" under the Endangered Species Act, and human-caused mortality does not exceed PBR for any of the stocks; therefore, none of the stocks are strategic. At present, average annual mortality and serious injury levels incidental to U.S. commercial fisheries that are less than 10% of PBR can be considered insignificant and approaching zero mortality and serious injury rate. A reliable estimate of the annual rate of mortality and serious injury incidental to commercial fisheries is unavailable. Therefore, it is unknown whether the mortality and serious injury rate due to commercial fishing is insignificant. The status of all 12 stocks of harbor seals identified in Alaska relative to their Optimum Sustainable Population is unknown.

Aleutian Islands: At present, U.S. commercial fishery-related annual mortality and serious injury levels less than 17 animals (i.e., 10% of PBR) can be considered insignificant and approaching zero mortality and serious injury rate. A reliable estimate of the annual rate of mortality and serious injury incidental to commercial fisheries is unavailable. Therefore, it is unknown whether the mortality and serious injury rate due to commercial fishing is insignificant. Based on the best scientific information available, the estimated level of human-caused mortality and serious injury (0 (commercial fisheries) + 90 (harvest) + 0 (other fisheries + other mortality) = 90) is not known to exceed the PBR (173). The Aleutian Islands stock of harbor seals is not classified as a strategic stock.

Pribilof Islands: At present, U.S. commercial fishery-related annual mortality and serious injury levels less than 0.7 animals (i.e., 10% of PBR) can be considered insignificant and approaching zero mortality and serious injury rate. A reliable estimate of the annual rate of mortality and serious injury incidental to commercial fisheries is unavailable. Therefore, it is unknown whether the mortality and serious injury rate due to commercial fishing is insignificant. Based on the best scientific information available, the estimated level of human-caused mortality and serious injury (0 + 0 + 0 = 0) is not known to exceed the PBR (7). The Pribilof Islands stock of harbor seals is not classified as a strategic stock.

Bristol Bay: At present, U.S. commercial fishery-related annual mortality and serious injury levels less than 118 animals (i.e., 10% of PBR) can be considered insignificant and approaching zero mortality and serious injury rate. A reliable estimate of the annual rate of mortality and serious injury incidental to commercial fisheries is unavailable. Therefore, it is unknown whether the mortality and serious injury rate due to commercial fishing is insignificant. Based on the best scientific information available, the estimated level of human-caused mortality and serious injury (0.6 + 141 + 0 = 142) is not known to exceed the PBR (1,182). The Bristol Bay stock of harbor seals is not classified as a strategic stock.

North Kodiak: At present, U.S. commercial fishery-related annual mortality and serious injury levels less than 30 animals (i.e., 10% of PBR) can be considered insignificant and approaching zero mortality and serious injury rate. A reliable estimate of the annual rate of mortality and serious injury incidental to commercial fisheries is unavailable. Therefore, it is unknown whether the mortality and serious injury rate due to commercial fishing is insignificant. Based on the best scientific information available, the estimated level of human-caused mortality and serious injury (0 + 37 + 0 = 37) is not known to exceed the PBR (298). The North Kodiak stock of harbor seals is not classified as a strategic stock.

South Kodiak: At present, U.S. commercial fishery-related annual mortality and serious injury levels less than 32 animals (i.e., 10% of PBR) can be considered insignificant and approaching zero mortality and serious injury rate. A reliable estimate of the annual rate of mortality and serious injury incidental to commercial fisheries is unavailable. Therefore, it is unknown whether the mortality and serious injury rate due to commercial fishing is insignificant. Based on the best scientific information available, the estimated level of human-caused mortality and serious injury (1.9 + 126 + 0 = 128) is not known to exceed the PBR (315). The South Kodiak stock of harbor seals is not classified as a strategic stock.

Prince William Sound: At present, U.S. commercial fishery-related annual mortality and serious injury levels less than 84 animals (i.e., 10% of PBR) can be considered insignificant and approaching zero mortality and serious injury rate. A reliable estimate of the annual rate of mortality and serious injury incidental to commercial fisheries is unavailable. Therefore, it is unknown whether the mortality and serious injury rate due to commercial fishing is insignificant. Based on the best scientific information available, the estimated level of human-caused mortality and serious injury (24 + 255 + 0.4 = 279) is not known to exceed the PBR (838). The Prince William Sound stock of harbor seals is not classified as a strategic stock.

Cook Inlet/Shelikof Strait: At present, U.S. commercial fishery-related annual mortality and serious injury levels less than 77 animals (i.e., 10% of PBR) can be considered insignificant and approaching zero mortality and serious injury rate. A reliable estimate of the annual rate of mortality and serious injury incidental to commercial fisheries is unavailable. Therefore, it is unknown whether the mortality and serious injury rate due to commercial fishing is insignificant. Based on the best scientific information available, the estimated level of human-caused mortality and serious injury (0.4 + 233 + 0.2 = 234) is not known to exceed the PBR (770). The Bristol Bay stock of harbor seals is not classified as a strategic stock.

Glacier Bay/Icy Strait: At present, U.S. commercial fishery-related annual mortality and serious injury levels less than 17 animals (i.e., 10% of PBR) can be considered insignificant and approaching zero mortality and serious injury rate. A reliable estimate of the annual rate of mortality and serious injury incidental to commercial fisheries is unavailable. Therefore, it is unknown whether the mortality and serious injury rate due to commercial fishing is insignificant. Based on the best scientific information available, the estimated level of human-caused mortality and serious injury (0 + 104 + 0 = 104) is not known to exceed the PBR (169). The Glacier Bay/Icy Strait stock of harbor seals is not classified as a strategic stock.

Lynn Canal/Stephens Passage: At present, U.S. commercial fishery-related annual mortality and serious injury levels less than 16 animals (i.e., 10% of PBR) can be considered insignificant and approaching zero mortality and serious injury rate. A reliable estimate of the annual rate of mortality and serious injury incidental to commercial fisheries is unavailable. Therefore, it is unknown whether the mortality and serious injury rate due to commercial fishing is insignificant. Based on the best scientific information available, the estimated level of human-caused mortality and serious injury (0 + 50 + 0.2 = 50) is not known to exceed the PBR (155). The Lynn Canal/Stephens Passage stock of harbor seals is not classified as a strategic stock.

Sitka/Chatham Strait: At present, U.S. commercial fishery-related annual mortality and serious injury levels less than 56 animals (i.e., 10% of PBR) can be considered insignificant and approaching zero mortality and serious injury rate. A reliable estimate of the annual rate of mortality and serious injury incidental to commercial fisheries is unavailable. Therefore, it is unknown whether the mortality and serious injury rate due to commercial fishing is insignificant. Based on the best scientific information available, the estimated level of human-caused mortality and serious injury (0 + 77 + 0 = 77) is not known to exceed the PBR (555). The Sitka/Chatham Strait stock of harbor seals is not classified as a strategic stock.

Dixon/Cape Decision: At present, U.S. commercial fishery-related annual mortality and serious injury levels less than 70 animals (i.e., 10% of PBR) can be considered insignificant and approaching zero mortality and serious injury rate. A reliable estimate of the annual rate of mortality and serious injury incidental to commercial fisheries is unavailable. Therefore, it is unknown whether the mortality and serious injury rate due to commercial fishing is insignificant. Based on the best scientific information available, the estimated level of human-caused mortality and serious injury (0 + 69 + 0 = 69) is not known to exceed the PBR (703). The Dixon/Cape Decision stock of harbor seals is not classified as a strategic stock.

Clarence Strait: At present, U.S. commercial fishery-related annual mortality and serious injury levels less than 122 animals (i.e., 10% of PBR) can be considered insignificant and approaching zero mortality and serious injury rate. A reliable estimate of the annual rate of mortality and serious injury incidental to commercial fisheries is unavailable. Therefore, it is unknown whether the mortality and serious injury rate due to commercial fishing is insignificant. Based on the best scientific information available, the estimated level of human-caused mortality and serious injury (0 + 40 + 0.8 = 41) is not known to exceed the PBR (1,222). The Clarence Strait stock of harbor seals is not classified as a strategic stock.

HABITAT CONCERNS

Glacial fjords in Alaska are critical for harbor seal whelping, nursing, and molting. Several of these areas have experienced a ten-fold increase in tour ship visitation since the 1980s. This increase in the presence of tour vessels has resulted in additional levels of disturbance to pups and adults (Jansen et al. 2015). The level of serious injury or mortality resulting from increased disturbance is not known.

SPOTTED SEAL (*Phoca largha*): Alaska Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Spotted seals are distributed along the continental shelf of the Bering, Chukchi, and Beaufort seas, and the Sea of Okhotsk south to the western Sea of Japan and northern Yellow Sea (Fig. 1). Eight main areas of spotted seal breeding have been reported (Shaughnessy and Fay 1977). On the basis of small samples and preliminary analyses of genetic composition, potential geographic barriers, and significance of breeding groups Boveng et al. (2009) grouped those breeding areas into three Distinct Population Segments (DPSs): The Bering DPS, which includes breeding areas in the Bering Sea; the Okhotsk DPS; and the Southern DPS, which includes spotted seals breeding in the Yellow Sea and Peter the Great Bay in the Sea of Japan. For the purposes of this stock assessment the Bering DPS is considered the Alaska stock of the spotted seal.

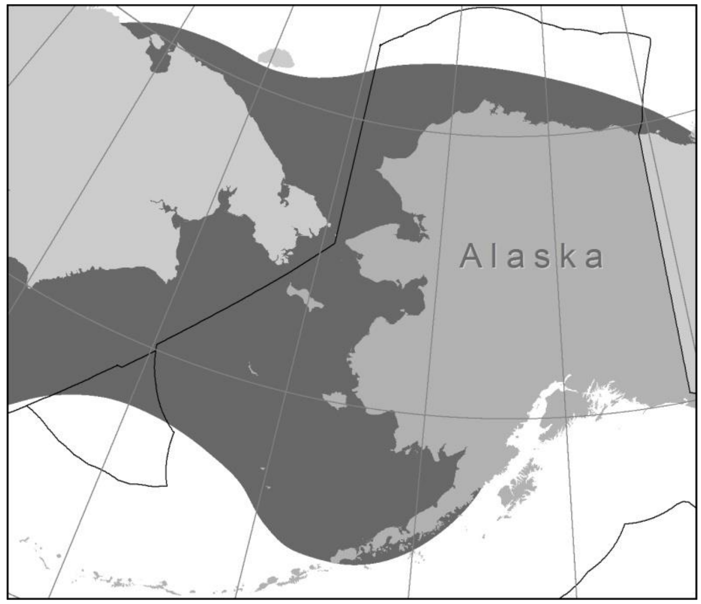

Figure 1. Approximate distribution of spotted seals (shaded area).

The distribution of spotted seals is seasonally related to specific life history events that can be broadly divided into two periods: late-fall through spring when whelping, nursing, breeding, and molting occur in association with the presence of sea ice on which the seals haul out, and summer through fall when seasonal sea ice has melted and most spotted seals use land for hauling out (Boveng et al. 2009). Satellite tagging studies showed that seals tagged in the northeastern Chukchi Sea moved south in October and passed through the Bering Strait in November. Seals overwintered in the Bering Sea along the ice edge and made east-west movements along the edge (Lowry et al. 1998). During spring they tend to prefer small floes (i.e., < 20 m in diameter), and inhabit mainly the southern margin of the ice in areas where water depth does not exceed 200 m, and move to coastal habitats after molting and the retreat of the sea ice (Fay 1974, Shaughnessy and Fay 1977, Lowry et al. 2000, Simpkins et al. 2003). In summer and fall, spotted seals use coastal haul-out sites regularly (Frost et al. 1993, Lowry et al. 1998), and may be found as far north as 69-72°N in the Chukchi and Beaufort Seas (Porsild 1945, Shaughnessy and Fay 1977). To the south, along the west coast of Alaska, spotted seals are known to occur around the Pribilof Islands, Bristol Bay, and the eastern Aleutian Islands. Spotted seals are closely related to and often mistaken for Pacific harbor seals (*Phoca vitulina richardii*). The two species are often seen together and are partially sympatric, as their ranges overlap in the southern part of the Bering Sea (Quakenbush 1988). Yet, spotted seals breed earlier and are less social during the breeding season, and only spotted seals are strongly associated with pack ice (Shaughnessy and Fay 1977). These and other ecological, behavioral, genetic, and morphological differences support their recognition as two separate species (Quakenbush 1988, O'Corry-Crowe and Westlake 1997).

The following information was considered in classifying stock structure based on the Dizon et al. (1992) phylogeographic approach: 1) Distributional data: geographic distribution continuous; 2) Population response data: unknown; 3) Phenotypic data: unknown; 4) Genotypic data: unknown. Based on this limited information, and the absence of any significant fishery interactions, there is currently no strong evidence to suggest splitting Alaska spotted seals into more than one stock. Therefore, only one Alaska stock is recognized in U.S. waters.

POPULATION SIZE

Recent surveys and analyses have substantially improved the documentation of the spotted seal population breeding in the U.S. waters of the Bering Sea. A large segment (280,000 km^2) of the breeding area was surveyed by helicopter from an icebreaker in the spring of 2007; the abundance of spotted seals was estimated using a model that incorporated variation due to detectability, availability (proportion hauled out), and changes in extent and concentration of sea ice during the surveys. The modal estimate of abundance was 233,700 spotted seals with a 95% credible interval of 137,300-793,100 (Ver Hoef et al. 2014). A more extensive fixed-wing aerial survey (767,000 km^2) conducted during April-May of 2012 and 2013 encompassed the vast majority of the spotted seal breeding area. Analysis of a portion of the data, from 10 broadly-distributed survey flights during 20-27 April 2012, resulted in a mean estimate of 460,268 spotted seals, with a 95% CI of 391,000-559,993 (Conn et al. 2014). The method accounted for uncertainty in detection rate and species classification, as well as availability.

Other, previous surveys and estimates for spotted seals in the Bering Sea (e.g., Braham et al. 1984, Fedoseev et al. 1988, Fedoseev 2000, Rugh et al. 1995) are problematic to interpret and to compare with recent estimates because there is insufficient information available to assess detection rates, species mis-classification rates, area surveyed, extrapolation to unsurveyed areas, and other critical factors for estimating abundance and trends (Burkanov et al. 1988, Conn et al. 2013, Ver Hoef et al. 2014).

Minimum Population Estimate

The 2012 survey was used as the basis for the minimum population estimate because it was the most current survey, the survey tracks encompassed more of the spotted seal breeding area than did the 2007 tracks, and it was conducted at a substantially higher altitude (1,000 ft.) than the 2007 survey (400 ft.), reducing the potential for bias from disturbance. Conn et al. (2014) acknowledged potential upward bias resulting from the process of extrapolating to unsurveyed areas; consequently, the lower 95% confidence limit, rather than the lower 80% limit was used for the minimum population estimate, N_{MIN} = 391,000.

Current Population Trend

Frost et al. (1993) report that counts of spotted seals were relatively stable at Kasegaluk Lagoon from the mid-1970s through 1991. Because this represents only a fraction of the stock’s range and the data are outdated, reliable data on trends in population abundance for the Alaska stock of spotted seals are considered unavailable.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

A reliable estimate of the maximum net productivity rate is currently unavailable for the Alaska stock of spotted seals. Hence, until additional data become available, it is recommended that the pinniped maximum theoretical net productivity rate (R_{MAX}) of 12% be employed for this stock (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the potential biological removal (PBR) is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: PBR = $N_{MIN} \times 0.5 R_{MAX} \times F_R$. The recovery factor ($F_R$) for this stock is 0.5, the value for pinniped stocks with unknown population status (Wade and Angliss 1997). Therefore, PBR for this stock is 391,000 × 0.06 × 0.5 = 11,730 individuals.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

New Serious Injury Guidelines

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an “*injury that is more likely than not to result in mortality*”. Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

Fisheries Information

Prior to 2004, there were no reports of incidental serious injuries and mortalities of spotted seals in any of the observed fisheries. Between 2008 and 2012, incidental serious injuries and mortalities of spotted seals were reported in 3 of the 22 federally regulated commercial fisheries in Alaska monitored for incidental mortality by fisheries observers: the Bering Sea/Aleutian Islands flatfish trawl, Bering Sea/Aleutian Islands pollock trawl, and the Bering Sea/Aleutian Islands Pacific cod longline fisheries (Table 1). The total estimated minimum annual mortality rate incidental to commercial fisheries is 1.5 (CV = 0.13) spotted seals per year, based on observer data.

Serious injury and mortality of harbor seals incidental to commercial fisheries has occurred within the past five years and, because it is virtually impossible to distinguish between these two species, some of the reported harbor seal takes may actually have been spotted seals. Further, no observer programs have been done on nearshore Bristol Bay fisheries that are known to interact with this stock, making the total mortality due to fisheries unknown.

Table 1. Summary of incidental mortality of spotted seals (Alaska stock) due to commercial fisheries from 2008 through 2012 and calculation of the mean annual mortality rate (Breiwick 2013). Details of how percent observer coverage is measured are included in Appendix 6.

Fishery name	Years	Data type	Observer coverage	Reported mortality (in given yrs.)	Estimated mortality (in given yrs.)	Mean annual mortality
Bering Sea/Aleutian Islands flatfish trawl	2008 2009 2010 2011 2012	obs data	100 100 100 100 100	2 1 0 0 2	2.0 1.0 0 0 2.0	1.00 (CV = 0.01)
Bering Sea/Aleutian Islands pollock trawl	2008 2009 2010 2011 2012	obs data	85 86 86 98 98	0 0 1 0 0	0 0 1.0 0 0	0.20 (CV = 0.11)
Bering Sea/Aleutian Islands Pacific cod longline	2008 2009 2010 2011 2012	obs data	63 60 64 57 51	0 0 0 1 0	0 0 0 1.6 0	0.32 (CV = 0.61)
Minimum total annual mortality						1.52 (CV = 0.13)

Subsistence/Native Harvest Information

Spotted seals are an important species for Alaskan subsistence hunters, primarily in the Bering Strait and Yukon-Kuskokwim regions.

Few studies give a statewide estimate of subsistence take. The Division of Subsistence, Alaska Department of Fish and Game and the Alaska Native Harbor Seal Commission have reported subsistence harvest levels of harbor seals and sea lions annually (e.g., Wolfe et al. 2009). Harvest data were reported from 63 coastal communities, including 6 communities from northern Bristol Bay. Due to seasonal geographic overlap in spotted and harbor seal distribution in northern Bristol Bay in combination with the difficulty in distinguishing the two species from external morphology, reports of harvests of spotted seals were differentiated from harbor seals based on ecological features of the kill, primarily degree of association with seasonal ice (Wolfe et al. 2008). In 2008, six coastal villages in northern Bristol Bay reported a total of 271 spotted seals taken during for subsistence harvest (213 harvested, 58 struck and lost). As of 2009, data on community subsistence harvests are no longer being collected. Five Alaska Native communities in the Northwest Arctic region of Alaska voluntarily reported a total of 119 spotted seals were harvested during 2012 (Ice Seal Committee 2013). No complete data for the spotted seal harvest and struck and lost animals are available for the 2008-2012 period.

The Division of Subsistence, Alaska Department of Fish and Game, maintains a database that provides additional information on the subsistence harvest of ice seals in different regions of Alaska (ADFG 2000a, b). Information on subsistence harvest of spotted seals has been compiled for 135 villages from reports from the Division of Subsistence (Coffing et al. 1998, Georgette et al. 1998, Wolfe and Hutchinson-Scarbrough 1999) and a report from the Eskimo Walrus Commission (Sherrod 1982). Data were lacking for 22 villages; their harvests were estimated using the annual per capita rates of subsistence harvest from a nearby village. Harvest levels were estimated from data gathered in the 1980s for 16 villages; otherwise, data gathered from 1990-1998 were used. As of August 2000; the subsistence harvest database indicated that the estimated number of spotted seals harvested for subsistence use per year was 5,265.

At this time, there are no efforts to quantify the total statewide level of harvest of spotted seals by all Alaska communities.

A report on ice seal subsistence harvest in three Alaskan communities indicated that the number and species of ice seals harvested in a particular village may vary considerably among years (Coffing et al. 1999). These interannual differences are likely due to differences in ice and wind conditions that change the hunters' access to different ice habitats frequented by different types of seals. Although some of the more recent entries in the ADFG database have associated measures of uncertainty (Coffing et al. 1999, Georgette et al. 1998), the overall total does not. The estimate of 5,265 spotted seals is the best estimate of harvest level currently available.

STATUS OF STOCK

Spotted seals in Alaska are not designated as "depleted" under the MMPA or listed as "threatened" or "endangered" under the Endangered Species Act. Based on currently available data, the minimum estimated U.S. commercial fishery-related mortality and serious injury for this stock (1.52) is less than 10% of the calculated PBR (1,173) and, therefore, can be considered to be insignificant and approaching a zero mortality and serious injury rate. The estimated annual level of total human-caused mortality and serious injury is 1.52 (commercial fisheries) + 5,265 (Alaska Native harvest) = 5,267 does not exceed the PBR (11,730) for this stock. The Alaska stock of spotted seals is not considered a strategic stock.

On 28 March 2008, NMFS initiated a status review of the spotted seal (73 FR 16617). On 28 May 2008, NMFS received a petition to list spotted seals under the ESA, primarily due to concern about threats to this species' habitat from loss of sea ice and climate change in the Arctic. NMFS found that the petition presented sufficient information to consider listing and proceeded with the status review (73 FR 51615, 4 September 2008). After the status review was complete (Boveng et al. 2009), NMFS determined that listing the Bering and Okhotsk DPSs of spotted seals was not warranted at this time. The Southern DPS, however, was proposed for listing as "threatened" under the ESA (74 FR 53683, 20 October 2009). After fully considering comments from peer reviewers and the public, NMFS issued a final rule listing the Southern DPS as "threatened" on 22 October 2010 (75 FR 65239).

Habitat Concerns

The main concern about the conservation status of spotted seals stems from the likelihood that their sea-ice habitat has been modified by the warming climate and, more so, that the scientific consensus projections are for continued and perhaps accelerated warming in the foreseeable future (Boveng et al. 2009). Despite the recent dramatic reductions in Arctic Ocean ice extent during summer, the sea ice in the Bering Sea is expected to continue forming annually in winter for the foreseeable future. There will likely be more frequent years in which ice coverage is reduced, resulting in a decline in the long-term average ice extent, but Bering Sea spotted seals will likely continue to encounter sufficient ice to support adequate vital rates. Even if sea ice were to vanish completely from the Bering Sea, there may be prospects for spotted seals to adjust their breeding grounds to follow the northward shift of the annual ice front into the Chukchi Sea. Laidre et al. (2008) concluded that on a worldwide basis spotted seals were likely to be moderately sensitive to climate change based on an analysis of various life history features that could be affected by climate.

A second major concern, related by the common driver of carbon dioxide (CO_2) emissions, is the modification of habitat by ocean acidification, which may alter prey populations and other important aspects of the marine ecosystem. Ocean acidification, a result of increased CO_2 in the atmosphere, may impact spotted seal survival and recruitment through disruption of trophic regimes that are dependent on calcifying organisms. The nature and timing of such impacts are extremely uncertain. Because of spotted seals' apparent dietary flexibility, this threat should be of less immediate concern than the direct effects of sea-ice degradation (Boveng et al. 2009).

Additional habitat concerns include the potential effects from oil and gas exploration activities, particularly in the outer continental shelf leasing areas, such as disturbance from vessel traffic, seismic exploration noise, or the potential for oil spills.

BEARDED SEAL (*Erignathus barbatus nauticus*): Alaska Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Bearded seals are a boreoarctic species with a circumpolar distribution (Fedoseev 1965; Johnson et al. 1966; Burns 1967, 1981; Burns and Frost 1979; Smith 1981; Kelly 1988). Their normal range extends from the Arctic Ocean (85°N) south to Sakhalin Island (45°N) in the Pacific and south to Hudson Bay (55°N) in the Atlantic (Allen 1880, Ognev 1935, King 1983). Bearded seals inhabit the seasonally ice-covered seas of the Northern Hemisphere, where they whelp and rear their pups and molt their coats on the ice in the spring and early summer. Bearded seals feed primarily on benthic organisms, including epifaunal and infaunal invertebrates, and demersal fishes and so are closely linked to areas where the seafloor is shallow (less than 200 m).

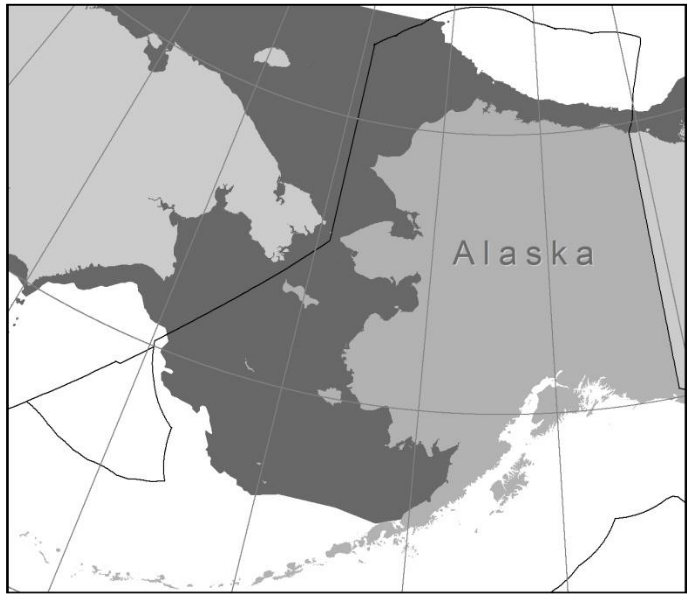

Figure 1. Approximate distribution of bearded seals (dark shaded area) in Alaska. The combined summer and winter distribution are depicted.

Two subspecies have been described: *E. b. barbatus* from the Laptev Sea, Barents Sea, North Atlantic Ocean, and Hudson Bay (Rice 1998); and *E. b. nauticus* from the remaining portions of the Arctic Ocean and the Bering and Okhotsk seas (Ognev 1935, Scheffer 1958, Manning 1974, Heptner et al. 1976). The geographic distributions of these subspecies are not separated by conspicuous gaps, and there are regions of intergrading generally described as somewhere along the northern Russian and central Canadian coasts. As part of a status review of the bearded seal for consideration of listing as threatened or endangered under the Endangered Species Act (ESA), Cameron et al. (2010) defined longitude 145°E as the Eurasian delineation between the two subspecies and 112°W in the Canadian Arctic Archipelago as the North American delineation between the two subspecies. Based on evidence for discreteness and ecological uniqueness of bearded seals in the Sea of Okhotsk, the *E. b. nauticus* subspecies was further divided into an Okhotsk Distinct Population Segment (DPS) and a Beringia DPS, so named because the continental shelf waters of the Bering, Chukchi, Beaufort, and East Siberian seas that are the bearded seals' range in this region overlie much of the land bridge that was exposed during the last glaciation, which has been referred to as Beringia. For the purposes of this stock assessment the Beringia DPS is considered the Alaska stock of the bearded seal (Fig. 1).

Spring surveys conducted in 1999-2000 along the Alaska coast indicate that bearded seals are typically more abundant 20-100 nmi from shore than within 20 nmi from shore, except for high concentrations nearshore to the south of Kivalina (Bengtson et al. 2000, 2005; Simpkins et al. 2003). Many seals that winter in the Bering Sea move north through the Bering Strait from late April through June and spend the summer in the Chukchi Sea (Burns 1967, 1981). Bearded seal sounds (produced by adult males) have been recorded nearly year-round (peak occurrence in December-June, when sea ice concentrations were >50%) at multiple locations in the Bering, Chukchi, and Beaufort seas, and calling behavior is closely related to the presence of sea ice (MacIntyre et al. 2013, 2015). The overall summer distribution is quite broad, with seals rarely hauled out on land, and some seals, mostly juveniles, may not follow the ice northward but remain near the coasts of the Bering and Chukchi seas (Burns 1967, 1981; Heptner et al. 1976; Nelson 1981). As the ice forms again in the fall and winter, most seals move south with the advancing ice edge through the Bering Strait into the Bering Sea where they spend the winter (Burns and Frost 1979; Frost et al. 2005, 2008; Cameron and Boveng 2007, 2009). This southward migration is less noticeable and predictable than the northward movements in late spring and early summer (Burns and Frost 1979, Burns 1981, Kelly 1988). During winter, the central and northern parts of the Bering Sea shelf have the highest densities of bearded seals (Fay 1974, Heptner et al. 1976, Burns and Frost 1979, Braham et al. 1981, Burns 1981, Nelson et al. 1984). In late winter and early spring, bearded seals are widely but not uniformly distributed in the broken, drifting pack ice ranging from the Chukchi Sea south to the ice front in the Bering Sea. In these areas, they tend to avoid the coasts and areas of fast ice (Burns 1967, Burns and Frost 1979).

POPULATION SIZE

A reliable population estimate for the entire stock is not available, but research programs have recently developed new survey methods and partial, but useful, abundance estimates. In spring of 2012 and 2013, U.S. and Russian researchers conducted aerial abundance and distribution surveys over the entire Bering Sea and Sea of Okhotsk (Moreland et al. 2013). The data from these image-based surveys are still being analyzed, but Conn et al. (2014), using a very limited sub-sample of the data collected from the U.S. portion of the Bering Sea in 2012, calculated an abundance estimate of approximately 299,174 (95% CI: 245,476-360,544) bearded seals in U.S. waters. These data do not include bearded seals that were in the Chukchi and Beaufort seas at the time of the surveys.

Minimum Population Estimate

The minimum population estimate (N_{MIN}) for a stock is calculated using Equation 1 from the potential biological removal (PBR) guidelines (Wade and Angliss 1997): $N_{MIN} = N/\exp(0.842\times[\ln(1+[CV(N)]^2)]^{½})$. An N_{MIN} for the entire stock cannot presently be determined because current reliable estimates of abundance are not available for the Chukchi and Beaufort seas. Using the 2012 Bering Sea abundance estimate by Conn et al. (2014), however, provides an N_{MIN} of 273,676 bearded seals in the U.S. sector of the Bering Sea.

Current Population Trend

At present, reliable data on trends in population abundance for the Alaska stock of bearded seals are unavailable.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

A reliable estimate of the maximum net productivity rate is currently unavailable for the Alaska stock of bearded seals. Hence, until additional data become available, it is recommended that the pinniped maximum theoretical net productivity rate (R_{MAX}) of 12% be employed for this stock (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the PBR is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: $PBR = N_{MIN} \times 0.5R_{MAX} \times F_R$. The recovery factor ($F_R$) for this stock is 0.5, the value for pinniped stocks with unknown population status (Wade and Angliss 1997). Using the N_{MIN} calculated for bearded seals in the Bering Sea, a PBR for bearded seals that overwinter and breed in the U.S. portion of the Bering Sea = 8,210 seals (273,676 × 0.06 × 0.5). However, this is not an estimate of PBR for the entire stock because a reliable estimate of N_{MIN} is currently not available for the entire stock; i.e., N_{MIN} is not available for the Chukchi and Beaufort seas.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Detailed information (including observer programs, observer coverage, and observed incidental takes of marine mammals) for federally-managed and state-managed U.S. commercial fisheries in Alaska waters is presented in Appendices 3-6 of the Alaska Stock Assessment Reports.

Of the 22 federally-regulated U.S. commercial fisheries in Alaska monitored for incidental mortality and serious injury by fisheries observers, 12 fisheries could potentially interact with bearded seals. During 2010-2014, incidental mortality and serious injury of bearded seals occurred in three fisheries: the Bering Sea/Aleutian Islands pollock trawl, Bering Sea/Aleutian Islands flatfish trawl, and Bering Sea/Aleutian Islands Pacific cod trawl fisheries (Table 1; Breiwick 2013; MML, unpubl. data). The estimated minimum mean annual mortality and serious injury rate incidental to U.S. commercial fisheries is 1.4 bearded seals, based exclusively on observer data.

Table 1. Summary of incidental mortality and serious injury of Alaska bearded seals due to U.S. commercial fisheries in 2010-2014 and calculation of the mean annual mortality and serious injury rate (Breiwick 2013; MML, unpubl. data). Methods for calculating percent observer coverage are described in Appendix 6 of the Alaska Stock Assessment Reports.

Fishery name	Years	Data type	Percent observer coverage	Observed mortality	Estimated mortality	Mean estimated annual mortality
Bering Sea/Aleutian Is. pollock trawl	2010 2011 2012 2013 2014	obs data	86 98 98 97 98	0 (+1)[a] 0 1 0 1	0 (+1)[b] 0 1.0 0 1.0	0.4 (+0.2)[c] (CV = 0.11)
Bering Sea/Aleutian Is. flatfish trawl	2010 2011 2012 2013 2014	obs data	99 100 99 99 99	0 1 1 0 1	0 1 1.0 0 1	0.6 (CV = 0.03)
Bering Sea/Aleutian Is. Pacific cod trawl	2010 2011 2012 2013 2014	obs data	66 60 68 80 80	0 0 0 1 0	0 0 0 1 0	0.2 (CV = 0)
Minimum total estimated annual mortality						1.4 (CV = 0.04)

[a]Total mortality and serious injury observed in 2010: 0 seals in sampled hauls + 1 seal in an unsampled haul.
[b]Total estimate of mortality and serious injury in 2010: 0 seals (extrapolated estimate from 0 seals observed in sampled hauls) + 1 seal (1 seal observed in an unsampled haul).
[c]Mean annual mortality and serious injury for fishery: 0.4 seals (mean of extrapolated estimates from sampled hauls) + 0.2 seals (mean of number observed in unsampled hauls).

Alaska Native Subsistence/Harvest Information

Bearded seals are an important resource for Alaska Native subsistence hunters. Approximately 64 Alaska Native communities in western and northern Alaska, from Bristol Bay to the Beaufort Sea, regularly harvest ice seals (Ice Seal Committee 2016). The Ice Seal Committee, as co-managers with NMFS, recognizes the importance of harvest information and has collected it since 2008, when funding and personnel have allowed. Annual household survey results compiled in a statewide harvest report include historical ice seal harvest information back to 1960 (Quakenbush et al. 2011). This report is used to determine where and how often harvest information was collected and where to focus in the future (Ice Seal Committee 2016). Information for 2009-2013 is available for 12 communities (Point Lay, Kivalina, Noatak, Buckland, Deering, Emmonak, Scammon Bay, Hooper Bay, Tununak, Quinhagak, Togiak, and Twin Hills) (Table 2); but more than 50 other communities harvest bearded seals and have not been surveyed in this time period or have never been surveyed. Harvest surveys are designed to estimate harvest within the surveyed community, but because of differences in seal availability, cultural hunting practices, and environmental conditions, extrapolating harvest numbers beyond that community is not appropriate. For example, during 2009-2013, only 12 of 64 coastal communities were surveyed for bearded seals; and, of those communities, only 6 were surveyed for two or more consecutive years (Ice Seal Committee 2016). Based on the harvest data from these 12 communities (Table 2), a minimum estimate of the average annual harvest of bearded seals in 2009-2013 is 390 seals. The Ice Seal Committee is working toward a better understanding of ice seal harvest by conducting more consecutive surveys in more communities with a goal to report a statewide ice seal harvest estimate.

Table 2. Alaska bearded seal harvest estimates in 2009-2013 (Ice Seal Committee 2016).

Community	**Estimated bearded seal harvest**				
	2009	**2010**	**2011**	**2012**	**2013**
Point Lay				55	
Kivalina			123		
Noatak			65		
Buckland			47		
Deering			49		
Emmonak			106		
Scammon Bay			82	51	
Hooper Bay	332	148	210	212	171
Tununak	21	40	42	44	
Quinhagak		29	26	44	49
Togiak	0	0	2		
Twin Hills	0	0			
Total	353	217	752	406	220

Other Mortality

Mortality and serious injury may occasionally occur incidental to marine mammal research activities authorized under MMPA permits issued to a variety of government, academic, and other research organizations. During 2010-2014, no research-related mortality or serious injury was reported for the Alaska stock of bearded seals (Division of Permits and Conservation, Office of Protected Resources, NMFS, 1315 East-West Highway, Silver Spring, MD 20910).

Beginning in mid-July 2011, elevated numbers of sick or dead seals, primarily ringed seals, with skin lesions were discovered in the Arctic and Bering Strait regions. By December 2011, there were more than 100 cases of affected pinnipeds, including bearded seals, ringed seals, spotted seals, and walruses in northern and western Alaska. Due to the unusual number of marine mammals discovered with similar symptoms across a wide geographic area, NMFS and USFWS declared a Northern Pinniped Unusual Mortality Event (UME) on December 20, 2011. Disease surveillance efforts in 2012-2013 detected few new cases similar to those observed in 2011, but the UME investigation remains open for bearded seals based on continuing reports in 2013-2014 of ice seals in the Bering Strait region with patchy hair loss (alopecia). To date, no specific cause for the disease has been identified.

STATUS OF STOCK

On December 28, 2012, NMFS listed the Beringia DPS bearded seal (*E. b. nauticus*): and, thus, the Alaska stock of bearded seals, as threatened under the ESA (77 FR 76740). The primary concern for this population is the ongoing and projected loss of sea-ice cover stemming from climate change, which is expected to pose a significant threat to the persistence of these seals in the foreseeable future (based on projections through the end of the 21st century; Cameron et al. 2010). On July 25, 2014, the U.S. District Court for the District of Alaska issued a memorandum decision in a lawsuit that challenged listing bearded seals under the ESA (Alaska Oil and Gas Association v. Pritzker, Case No. 4:13-cv-00018-RPB). The decision vacated NMFS' listing of the Beringia DPS of bearded seals as a threatened species. Consequently, it is also no longer designated as depleted or classified as a strategic stock. Because the PBR for the entire stock is unknown, the mean annual U.S. commercial fishery-related mortality and serious injury rate that can be considered insignificant and approaching zero mortality and serious injury rate is unknown. A PBR for only those bearded seals that overwinter and breed in the U.S. portion of the Bering Sea is 8,210 bearded seals. The total estimated annual level of human-caused mortality and serious injury is 391 bearded seals. Population trends and status of this stock relative to its Optimum Sustainable Population are currently unknown.

HABITAT CONCERNS

The main concern about the conservation status of bearded seals stems from the likelihood that their preferred sea-ice habitats are being modified by the warming climate. Future scientific projections are for continued and perhaps accelerated warming (Cameron et al. 2010). For bearded seals, the presence of sea ice is considered a requirement for whelping and nursing young. Similarly, the molt is believed to be promoted by elevated skin temperatures that, in polar regions, can only be achieved when seals haul out of the water. Thus, if suitable ice cover is absent from shallow feeding areas during times of peak whelping and nursing (April/May), or molting (May/June and sometimes through August), bearded seals would be forced to seek either sea-ice habitat over deeper waters (perhaps with poor access to food) or onshore haul-out sites (perhaps with increased risks of disturbance, predation, and competition). Both scenarios would require bearded seals to adapt to novel (i.e., potentially suboptimal) conditions, and to exploit habitats to which they may not be well adapted, likely compromising their reproduction and survival rates. A reliable assessment for the future conservation status of each bearded seal DPS requires a focus on projections of specific regional conditions, especially sea ice. End of century projections for the Bering Sea in April-May suggest that there will be sufficient ice only in small zones in the Gulf of Anadyr and in the area between St. Lawrence Island and the Bering Strait. Suitable ice in June in the Bering Sea is predicted to disappear as early as mid-century. To adapt to this regime, bearded seals would likely have to shift their nursing, rearing, and molting areas to the ice-covered seas north of the Bering Strait. Laidre et al. (2008) also concluded that on a worldwide basis bearded seals were likely to be highly sensitive to climate change based on an analysis of various life history features that could be affected by climate.

A second major concern, driven primarily by the production of carbon dioxide (CO_2) emissions, is the modification of habitat by ocean acidification, which may alter prey populations and other important aspects of the marine ecosystem. Ocean acidification, a result of increased CO_2 in the atmosphere, may affect bearded seal survival and recruitment through disruption of trophic regimes that are dependent on calcifying organisms. The nature and timing of such impacts are extremely uncertain. Changes in bearded seal prey, anticipated in response to ocean warming and loss of sea ice, have the potential for negative impacts, but the possibilities are complex. Ecosystem responses may have very long lags as they propagate through trophic webs. Because of bearded seals' apparent dietary flexibility, this threat may be of less immediate concern than the threats from sea-ice degradation.

Additional habitat concerns include the potential effects from increased shipping (particularly in the Bering Strait), and oil and gas exploration activities (particularly in the outer continental shelf leasing areas), such as disturbance from vessel traffic, seismic exploration noise, or the potential for oil spills.

RINGED SEAL (*Pusa hispida hispida*): Alaska Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Ringed seals (*Pusa hispida*) have a circumpolar distribution and are found in all seasonally ice-covered seas of the Northern Hemisphere as well as in certain freshwater lakes (King 1983). Most taxonomists currently recognize five subspecies of ringed seals: *P. h. hispida* in the Arctic Ocean and Bering Sea; *P. h. ochotensis* in the Sea of Okhotsk and northern Sea of Japan; *P. h. botnica* in the northern Baltic Sea; *P. h. lagodensis* in Lake Ladoga, Russia; and *P. h. saimensis* in Lake Saimaa, Finland. Morphologically, the Baltic and Okhotsk subspecies are fairly well differentiated from the Arctic subspecies (Ognev 1935, Müller-Wille 1969, Rice 1998) and the Ladoga and Saimaa subspecies differ significantly from each other and from the Baltic subspecies (Müller-Wille 1969, Hyvärinen and Nieminen 1990, Amano et al. 2002). Genetic analyses support isolation of the lake-inhabiting populations (Palo 2003, Palo et al. 2003, Valtonen et al. 2012). Lack of differentiation between the Baltic and the Arctic subspecies may reflect recurrent gene flow (Martinez-Bakker et al. 2013) but is more likely due to retention of high diversity within the relatively large effective population size of the Baltic subspecies since separation from the Arctic subspecies (Nyman et al. 2014). Widespread mixing within the Arctic subspecies is the likely explanation for its high diversity and apparent lack of population structure (Palo et al. 2001, Davis et al. 2008, Kelly et al. 2009, Martinez-Bakker et al. 2013). Differences in body size, morphology, growth rates, and/or diet between Arctic ringed seals in shorefast versus pack ice have been taken as evidence of separate breeding populations in some locations (McLaren 1958, Fedoseev 1975, Finley et al. 1983). This has not been thoroughly examined, however, and the taxonomic status of the Arctic subspecies remains unresolved (Berta and Churchill 2012). For the purposes of this stock assessment, the Alaska stock of ringed seals is considered the portion of the Arctic subspecies (*P. h. hispida*) that occurs within the U.S. Exclusive Economic Zone of the Beaufort, Chukchi, and Bering seas (Fig. 1).

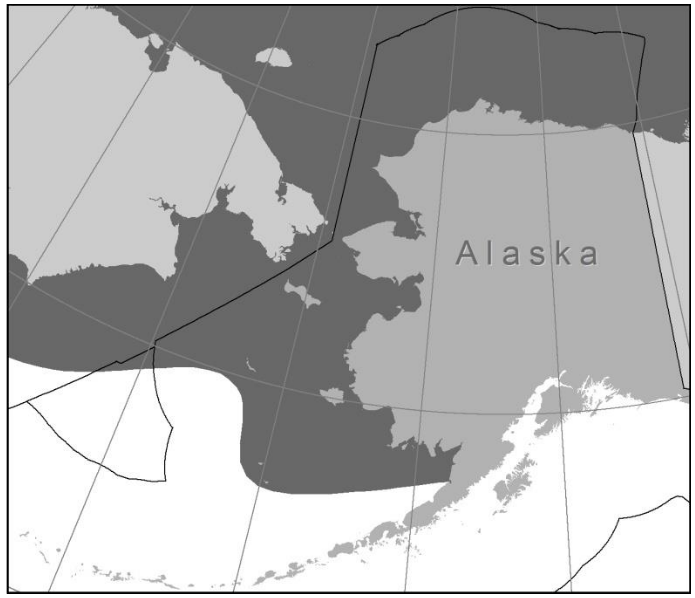

Figure 1. Approximate winter distribution of ringed seals (dark shaded area).

Throughout their range, ringed seals have an affinity for ice-covered waters and are well adapted to occupying both shorefast and pack ice (Kelly 1988a). They remain with the ice most of the year and use it as a platform for pupping and nursing in late winter to early spring, for molting in late spring to early summer, and for resting at other times of the year. This species rarely comes ashore in the Arctic; however, in more southerly portions of its range where sea or lake ice is absent during summer and fall, ringed seals are known to use isolated haul-out sites on land for molting and resting (Härkönen et al. 1998, Trukhin 2000, Kunnasranta 2001, Lukin et al. 2006). In Alaska waters, during winter and early spring when sea ice is at its maximal extent, ringed seals are abundant in the northern Bering Sea, Norton and Kotzebue Sounds, and throughout the Chukchi and Beaufort seas. They occur as far south as Bristol Bay in years of extensive ice coverage but generally are not abundant south of Norton Sound except in nearshore areas (Frost 1985). Although details of their seasonal movements have not been adequately documented, most ringed seals that winter in the Bering and Chukchi seas are thought to migrate north in spring as the seasonal ice melts and retreats (Burns 1970) and spend summers in the pack ice of the northern Chukchi and Beaufort seas, as well as in nearshore ice remnants in the Beaufort Sea (Frost 1985). During summer, ringed seals range hundreds to thousands of kilometers to forage along ice edges or in highly productive open-water areas (Harwood and Stirling 1992, Freitas et al. 2008, Kelly et al. 2010b, Harwood et al. 2015). With the onset of freeze-up in the fall, ringed seal movements become increasingly restricted. Seals that have summered in the Beaufort Sea are thought to move west and south with the advancing ice pack, with many seals dispersing throughout the Chukchi and Bering seas while some remain in the Beaufort Sea (Frost and Lowry 1984, Crawford et al. 2012, Harwood et al. 2012). Some adult ringed seals return to the same small home ranges they occupied during the previous winter (Kelly et al. 2010b).

POPULATION SIZE

Ringed seal population surveys in Alaska have used various methods and assumptions, incompletely covered their habitats and range, and were conducted more than a decade ago; therefore, current, comprehensive, and reliable abundance estimates or trends for the Alaska stock are not available. Frost et al. (2004) conducted aerial surveys within 40 km of shore in the Alaska Beaufort Sea during May-June 1996-1999 and observed ringed seal densities ranging from 0.81 seals/km^2 in 1996 to 1.17 seals/km^2 in 1999. Moulton et al. (2002) conducted similar, concurrent surveys in the Alaska Beaufort Sea during 1997-1999 but reported substantially lower ringed seal densities than Frost et al. (2004). The reason for this disparity was unclear (Frost et al. 2004). Bengtson et al. (2005) conducted aerial surveys in the Alaska Chukchi Sea during May-June 1999-2000. While the surveys were focused on the coastal zone within 37 km of shore, additional survey lines were flown up to 185 km offshore. Population estimates were derived from observed densities corrected for availability bias using a haul-out model from six tagged seals. Ringed seal abundance estimates for the entire survey area were 252,488 (SE = 47,204) in 1999 and 208,857 (SE = 25,502) in 2000. Using the most recent survey estimates from surveys by Bengtson et al. (2005) and Frost et al. (2004) in the late 1990s and 2000, for the purposes of an Endangered Species Act (ESA) status review, Kelly et al. (2010a) estimated the total population in the Alaska Chukchi and Beaufort seas to be at least 300,000 ringed seals. This estimate is likely an underestimate since the Beaufort Sea surveys were limited to within 40 km from shore.

Though a reliable population estimate for the entire Alaska stock is not available, research programs have recently developed new survey methods and partial, but useful, abundance estimates. In spring of 2012 and 2013, U.S. and Russian researchers conducted aerial abundance and distribution surveys of the entire Bering Sea and Sea of Okhotsk (Moreland et al. 2013). The data from these image-based surveys are still being analyzed, but Conn et al. (2014), using a very limited sub-sample of the data collected from the U.S. portion of the Bering Sea in 2012, calculated an abundance estimate of about 170,000 ringed seals. This estimate did not account for availability bias and did not include ringed seals in the shorefast ice zone, which were surveyed using a different method. Thus, the actual number of ringed seals in the U.S. sector of the Bering Sea is likely much higher, perhaps by a factor of two or more.

Minimum Population Estimate

A minimum population estimate (N_{MIN}) for the entire stock of ringed seals cannot presently be determined because current reliable estimates of abundance are not available for the Chukchi and Beaufort seas. The 2012 Bering Sea abundance estimate by Conn et al. (2014) of 170,000, however, can be considered an N_{MIN} for only those ringed seals in the U.S. sector of the Bering Sea.

Current Population Trend

Frost et al. (2002) reported that a trend analysis based on an ANOVA comparison of observed seal densities in the central Beaufort Sea suggested marginally significant but substantial declines of 50% on shorefast ice and 31% on all ice types combined from 1985-1987 to 1996-1999. A Poisson regression model indicated highly significant density declines of 72% on shorefast ice and 43% on pack ice during the 15-year period. However, the apparent decline between the mid-1980s and the late-1990s may have been due to a difference in the timing of surveys rather than an actual decline in abundance (Frost et al. 2002, Kelly et al. 2006). As these surveys represent only a fraction of the stock's range and occurred more than a decade ago, current and reliable data on trends in population abundance for the Alaska stock of ringed seals are considered unavailable.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

A reliable estimate of the maximum net productivity rate is currently unavailable for the Alaska stock of ringed seals. Hence, until additional data become available, it is recommended that the pinniped maximum theoretical net productivity rate (R_{MAX}) of 12% be employed for this stock (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the potential biological removal (PBR) is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: PBR = $N_{MIN} \times 0.5R_{MAX} \times F_R$. The recovery factor ($F_R$) for this stock is 0.5, the value for pinniped stocks with unknown population status (Wade and Angliss 1997). Using the N_{MIN} for ringed seals in the U.S. sector of the Bering Sea, a PBR for ringed seals in this area is 5,100 (170,000 × 0.06 × 0.5) seals. However, this is not an estimate of PBR for the entire stock because a reliable estimate of N_{MIN} is currently not available for the entire stock; i.e., N_{MIN} is not available for the Chukchi and Beaufort seas.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Detailed information (including observer programs, observer coverage, and observed incidental takes of marine mammals) for federally-managed and state-managed U.S. commercial fisheries in Alaska waters is presented in Appendices 3-6 of the Alaska Stock Assessment Reports.

During 2010-2014, incidental mortality and serious injury of ringed seals was reported in 4 of the 22 federally-regulated commercial fisheries in Alaska monitored for incidental mortality and serious injury by fisheries observers: the Bering Sea/Aleutian Islands flatfish trawl, Bering Sea/Aleutian Islands pollock trawl, Bering Sea/Aleutian Islands Pacific cod trawl, and Bering Sea/Aleutian Islands Pacific cod longline fisheries (Table 1; Breiwick 2013; MML, unpubl. data). An additional ringed seal mortality due to U.S. commercial fisheries was reported to the NMFS Alaska Region stranding network in 2011; however, because the seal was discovered during the offloading process, the resulting mean annual mortality and serious injury rate of 0.2 could not be assigned to a specific fishery (Table 2; Helker et al. 2016). Based on data from 2010 to 2014, the average annual rate of mortality and serious injury incidental to U.S. commercial fishing operations is 3.9 ringed seals (3.7 from observer data + 0.2 from stranding data).

In 2010, a ringed seal that was initially considered seriously injured due to entanglement in a subsistence salmon set gillnet in Nome, Alaska, was disentangled and released with non-serious injuries (Helker et al. 2016), so it was not included in the mean annual mortality and serious injury rate in this report.

Table 1. Summary of incidental mortality and serious injury of Alaska ringed seals due to U.S. commercial fisheries in 2010-2014 and calculation of the mean annual mortality and serious injury rate (Breiwick 2013; MML, unpubl. data). Methods for calculating percent observer coverage are described in Appendix 6 of the Alaska Stock Assessment Reports.

Fishery name	Years	Data type	Percent observer coverage	Observed mortality	Estimated mortality	Mean estimated annual mortality
Bering Sea/Aleutian Is. flatfish trawl	2010 2011 2012 2013 2014	obs data	99 100 99 99 99	0 6 (+1)[a] 3 3 0	0 6.0 (+1)[b] 3.0 3 0	2.4 (+0.2)[c] (CV = 0.02)
Bering Sea/Aleutian Is. pollock trawl	2010 2011 2012 2013 2014	obs data	86 98 98 97 98	0 3 0 0 0	0 3.0 0 0 0	0.6 (CV = 0.03)
Bering Sea/Aleutian Is. Pacific cod trawl	2010 2011 2012 2013 2014	obs data	66 60 68 80 80	0 1 0 0 0	0 1 0 0 0	0.2 (CV = 0)
Bering Sea/Aleutian Is. Pacific cod longline	2010 2011 2012 2013 2014	obs data	64 57 51 66 64	0 1 0 0 0	0 1.6 0 0 0	0.3 (CV = 0.61)

Fishery name	Years	Data type	Percent observer coverage	Observed mortality	Estimated mortality	Mean estimated annual mortality
Minimum total estimated annual mortality						3.7 (CV = 0.06)

[a]Total mortality and serious injury observed in 2011: 6 seals in sampled hauls + 1 seal in an unsampled haul.
[b]Total estimate of mortality and serious injury in 2011: 6 seals (extrapolated estimate from 6 seals observed in sampled hauls) + 1 seal (1 seal observed in an unsampled haul).
[c]Mean annual mortality and serious injury for fishery: 2.4 seals (mean of extrapolated estimates from sampled hauls) + 0.2 seals (mean of number observed in unsampled hauls).

Table 2. Summary of mortality and serious injury of Alaska ringed seals, by year and type, reported to the NMFS Alaska Region in 2010-2014 (Helker et al. 2016). Only cases of serious injuries are reported in this table; animals that were disentangled and released with non-serious injuries have been excluded.

Cause of injury	2010	2011	2012	2013	2014	Mean annual mortality
Unidentified commercial fishery	0	1	0	0	0	0.2
Total in commercial fisheries						0.2

Alaska Native Subsistence/Harvest Information

Ringed seals are an important resource for Alaska Native subsistence hunters. Approximately 64 Alaska Native communities in western and northern Alaska, from Bristol Bay to the Beaufort Sea, regularly harvest ice seals (Ice Seal Committee 2016). The Ice Seal Committee, as co-managers with NMFS, recognizes the importance of harvest information and has collected it since 2008, when funding and personnel have allowed. Annual household survey results compiled in a statewide harvest report include historical ice seal harvest information back to 1960 (Quakenbush et al. 2011). This report is used to determine where and how often harvest information was collected and where to focus in the future (Ice Seal Committee 2016). Information for 2009-2013 is available for 12 communities (Point Lay, Kivalina, Noatak, Buckland, Deering, Emmonak, Scammon Bay, Hooper Bay, Tununak, Quinhagak, Togiak, and Twin Hills) (Table 3), but more than 50 other communities harvest ringed seals and have not been surveyed in this time period or have never been surveyed. Harvest surveys are designed to estimate harvest within the surveyed community, but because of differences in seal availability, cultural hunting practices, and environmental conditions, extrapolating harvest numbers beyond that community is not appropriate. For example, during 2009-2013, only 12 of 64 coastal communities were surveyed for ringed seals; and, of those communities, only 6 were surveyed for two or more consecutive years (Ice Seal Committee 2016). Based on the harvest data from these 12 communities (Table 3), a minimum estimate of the average annual harvest of ringed seals in 2009-2013 is 1,050 seals. The Ice Seal Committee is working toward a better understanding of ice seal harvest by conducting more consecutive surveys in more communities with a goal to report a statewide ice seal harvest estimate.

Table 3. Alaska ringed seal harvest estimates in 2009-2013 (Ice Seal Committee 2016).

Community	Estimated ringed seal harvest				
	2009	2010	2011	2012	2013
Point Lay				51	
Kivalina			16		
Noatak			3		
Buckland			26		
Deering			0		
Emmonak			56		
Scammon Bay			137	169	
Hooper Bay	889	458	674	651	667
Tununak	232	162	257	219	

Community	Estimated ringed seal harvest				
	2009	2010	2011	2012	2013
Quinhagak		163	117	140	160
Togiak	1	1	0		
Twin Hills	0	0			
Total	1,122	784	1,286	1,230	827

Other Mortality

Beginning in mid-July 2011, elevated numbers of sick or dead seals, primarily ringed seals, with skin lesions were discovered in the Arctic and Bering Strait regions. By December 2011, there were more than 100 cases of affected pinnipeds, including ringed seals, bearded seals, spotted seals, and walruses, in northern and western Alaska. Due to the unusual number of marine mammals discovered with similar symptoms across a wide geographic area, NMFS and USFWS declared a Northern Pinniped Unusual Mortality Event (UME) on December 20, 2011. Disease surveillance efforts in 2012-2013 detected few new cases similar to those observed in 2011, but the UME investigation remains open for ringed seals based on continuing reports in 2013-2014 of ice seals in the Bering Strait region with patchy hair loss (alopecia). To date, no specific cause for the disease has been identified.

In 2011, a ringed seal mortality, due to a gunshot wound to the head, was reported to the NMFS Alaska Region stranding network (Helker et al. 2016). This seal was presumed to be a struck and lost animal from the Alaska Native subsistence hunt.

Mortality and serious injury may occasionally occur incidental to marine mammal research activities authorized under MMPA permits issued to a variety of government, academic, and other research organizations. In 2013, there was one report of a mortality incidental to research on the Alaska stock of ringed seals, resulting in a mean annual mortality and serious injury rate of 0.2 ringed seals from this stock in 2010-2014 (Division of Permits and Conservation, Office of Protected Resources, NMFS, 1315 East-West Highway, Silver Spring, MD 20910).

STATUS OF STOCK

On December 28, 2012, NMFS listed Arctic ringed seals (*P. h. hispida*) and, thus, the Alaska stock of ringed seals, as threatened under the ESA (77 FR 76706). The primary concern for this population is the ongoing and anticipated loss of sea ice and snow cover stemming from climate change, which is expected to pose a significant threat to the persistence of these seals in the foreseeable future (based on projections through the end of the 21st century; Kelly et al. 2010a). Because of its threatened status under the ESA, this stock was designated as depleted under the MMPA. As a result, the stock was classified as a strategic stock. On March 11, 2016, the U.S. District Court for the District of Alaska issued a memorandum decision in a lawsuit challenging the listing of ringed seals under the ESA (Alaska Oil and Gas Association et al. v. Pritzker, Case No. 4:14-cv-00029-RPB). The decision vacated NMFS' listing of Arctic ringed seals as a threatened species. Consequently, it is also no longer designated as depleted or classified as a strategic stock. Because the PBR for the entire stock is unknown, the mean annual U.S. commercial fishery-related mortality and serious injury rate that can be considered insignificant and approaching zero mortality and serious injury rate is unknown. A PBR for only those ringed seals in the U.S. portion of the Bering Sea is 5,100 ringed seals. The total estimated annual level of human-caused mortality and serious injury is 1,054 ringed seals. Population trends and status of this stock relative to its Optimum Sustainable Population are currently unknown.

HABITAT CONCERNS

The main concern about the conservation status of ringed seals stems from the likelihood that their preferred sea-ice and snow habitats are being modified by the warming climate. Future scientific projections are for continued and perhaps accelerated warming (Kelly et al. 2010a). Climate models consistently project overall diminishing ice and snow cover through the 21st century with regional variation in the timing and severity of those loses. Increasing atmospheric concentrations of greenhouse gases are driving climate warming and increasing acidification of the ringed seal's habitat. Changes in ocean temperature, acidification, and ice cover threaten prey communities on which ringed seals depend. Laidre et al. (2008) concluded that on a worldwide basis ringed seals were likely to be highly sensitive to climate change based on an analysis of various life history features that could be affected by climate.

The greatest impacts to ringed seals from diminished ice cover will be mediated through diminished snow accumulation. While winter precipitation is forecasted to increase in a warming Arctic (Walsh et al. 2005), the duration of ice cover will be substantially reduced, and the net effect will be lower snow accumulation on the ice (Hezel et al. 2012). Ringed seals excavate subnivean lairs (snow caves) in drifts over their breathing holes in the ice, in which they rest, give birth, and nurse their pups for 5-9 weeks during late winter and spring (Chapskii 1940, McLaren 1958, Smith and Stirling 1975). Snow depths of at least 50-65 cm are required for functional birth lairs (Smith and Stirling 1975, Lydersen and Gjertz 1986, Kelly 1988b, Lydersen 1998, Lukin et al. 2006). Such depths typically are found only where 20-30 cm or more of snow has accumulated on flat ice and then drifted along pressure ridges or ice hummocks (Lydersen et al. 1990, Hammill and Smith 1991, Lydersen and Ryg 1991, Smith and Lydersen 1991). According to climate model projections, snow cover is forecasted to be inadequate for the formation and occupation of birth lairs within this century over the Alaska stock's entire range (Kelly et al. 2010a). Without the protection of these lairs, ringed seals—especially newborns—are vulnerable to freezing and predation (Kumlien 1879, McLaren 1958, Lukin and Potelov 1978, Smith and Hammill 1980, Lydersen and Smith 1989, Stirling and Smith 2004). Changes in the ringed seal's habitat will be rapid relative to their generation time and, thereby, will limit adaptive responses. As ringed seal populations decline, the significance of currently lower-level threats—such as ocean acidification, increases in human activities, and changes in populations of predators, prey, competitors, and parasites—may increase.

A second major concern, driven primarily by the production of carbon dioxide (CO_2) emissions, is the modification of habitat by ocean acidification, which may alter prey populations and other important aspects of the marine ecosystem. Ocean acidification, a result of increased CO_2 in the atmosphere, may affect ringed seal survival and recruitment through disruption of trophic regimes that are dependent on calcifying organisms. The nature and timing of such impacts are extremely uncertain. Changes in ringed seal prey, anticipated in response to ocean warming and loss of sea ice, have the potential for negative impacts, but the possibilities are complex. Ecosystem responses may have very long lags as they propagate through trophic webs. Because of ringed seals' apparent dietary flexibility, this threat may be of less immediate concern than the threats from sea ice degradation

Additional habitat concerns include the potential effects from increased shipping (particularly in the Bering Strait) and oil and gas exploration activities (particularly in the outer continental shelf leasing areas), such as disturbance from vessel traffic, seismic exploration noise, or the potential for oil spills.

RIBBON SEAL (*Histriophoca fasciata*): Alaska Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

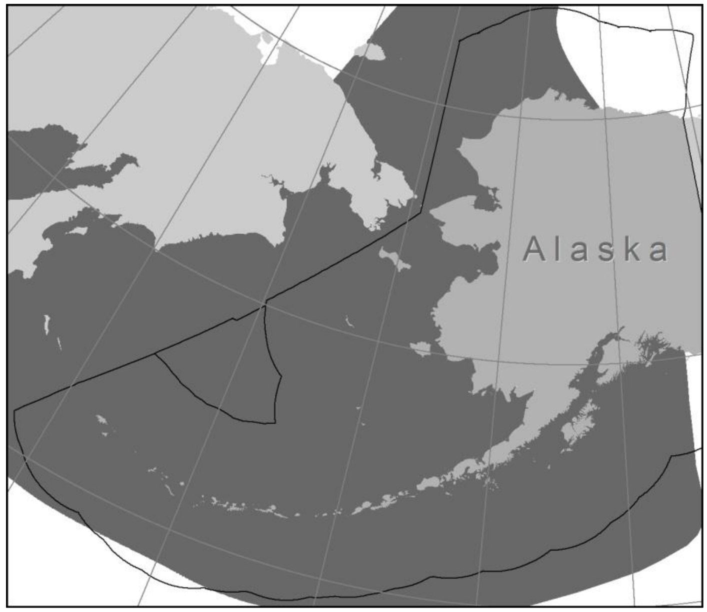

Figure 1. Approximate distribution of ribbon seals (dark shaded area) in Alaska waters. The combined summer and winter distribution is depicted.

Ribbon seals inhabit the North Pacific Ocean and adjacent parts of the Arctic Ocean. In Alaska waters, ribbon seals range from the North Pacific Ocean and Bering Sea into the Chukchi and western Beaufort seas (Fig. 1). From late March to early May, ribbon seals inhabit the Bering Sea ice front (Burns 1970, 1981; Braham et al. 1984). Ribbon seals are very rarely seen on shorefast ice or land. They are most abundant in the northern part of the ice front in the central and western parts of the Bering Sea (Burns 1970, Burns et al. 1981). As the ice recedes in May to mid-July, the seals move farther to the north in the Bering Sea, where they haul out on the receding ice edge and remnant ice (Burns 1970, 1981; Burns et al. 1981). As the ice melts, seals become more concentrated, with at least part of the Bering Sea population moving towards the Bering Strait and the southern part of the Chukchi Sea. By the time the Bering Sea ice recedes through the Bering Strait, there is usually only a small number of ribbon seals hauled out on the ice. Ten ribbon seals tagged in the spring of 2005 near the eastern coast of Kamchatka spent the summer and fall throughout the Bering Sea and Aleutian Islands. However, of 72 ribbon seals satellite tagged in the central Bering Sea during 2007-2010, only 21 (29%) moved to the Bering Strait, Chukchi Sea, or Arctic Basin as the ice retreated northward. About 9.5% of ribbon seals' time budget during July through October was in those areas. The majority of the seals tagged in the central Bering Sea did not pass north of the Bering Strait. These seals, and the 10 seals tagged in 2005 near Kamchatka, dispersed widely, occupying coastal areas as well as the interior of the Bering Sea, both on and off the continental shelf (Boveng et al. 2013). Year-long passive acoustic sampling on the Chukchi Plateau from autumn 2008-2009 detected ribbon seal calls only in October and November 2008 (Moore et al. 2012).

The following information was considered in classifying stock structure based on the Dizon et al. (1992) phylogeographic approach: 1) Distributional data: geographic distribution continuous; 2) Population response data: unknown; 3) Phenotypic data: unknown; and 4) Genotypic data: unknown. Based on this limited information, and the absence of any significant fishery interactions, there is currently no strong evidence to suggest splitting the distribution of ribbon seals into more than one stock (Boveng et al. 2013). Therefore, only the Alaska stock of ribbon seal is recognized in U.S. waters.

POPULATION SIZE

A reliable population estimate for the entire stock is not available, but research programs have recently developed new survey methods and partial, but useful, abundance estimates. In spring of 2012 and 2013, U.S. and Russian researchers conducted aerial abundance and distribution surveys of the entire Bering Sea and Sea of Okhotsk (Moreland et al. 2013). The data from these image-based surveys are still being analyzed, but Conn et al. (2014), using a very limited sub-sample of the data collected from the U.S. portion of the Bering Sea in 2012, calculated an abundance estimate of approximately 184,000 (95% CI: 145,752-230,134) ribbon seals in those waters. Though this should be considered only a preliminary estimate, it is appropriate to consider this a reasonable estimate for the entire U.S. population of ribbon seals because few ribbon seals are expected to be north of the Bering Strait in the spring when these surveys were conducted. When the final analyses for both the Bering and Okhotsk seas are complete they should provide the first range-wide estimates of ribbon seal abundance.

Minimum Population Estimate

The minimum population estimate (N_{MIN}) for a stock is calculated using Equation 1 from the potential biological removal (PBR) guidelines (Wade and Angliss 1997): $N_{MIN} = N/exp(0.842\times[ln(1+[CV(N)]^2)]^{½})$. Using the 2012 Bering Sea abundance estimate by Conn et al. (2014) provides an N_{MIN} of 163,086 ribbon seals in this stock.

Current Population Trend

At present, reliable data on trends in population abundance for the Alaska stock of ribbon seals are unavailable. This stock is thought to occupy its entire historically-observed range (Boveng et al. 2013).

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

A reliable estimate of the maximum net productivity rate is currently unavailable for the Alaska stock of ribbon seals. Hence, until additional data become available, it is recommended that the pinniped maximum theoretical net productivity rate (R_{MAX}) of 12% be employed for this stock (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the PBR is defined as the product of the minimum population estimate (N_{MIN}), one-half the maximum theoretical net productivity rate, and a recovery factor: $PBR = N_{MIN} \times 0.5R_{MAX} \times F_R$. The recovery factor ($F_R$) for this stock is 1.0, the value for stocks thought to be stable (Wade and Angliss 1997). Thus, the PBR for the Alaska stock of ribbon seals = 9,785 (163,086 × 0.06 × 1.0).

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Detailed information (including observer programs, observer coverage, and observed incidental takes of marine mammals) for federally-managed and state-managed U.S. commercial fisheries in Alaska waters is presented in Appendices 3-6 of the Alaska Stock Assessment Reports.

Until 2003, there were three different federally regulated commercial fisheries in Alaska that could have interacted with ribbon seals and were monitored for incidental mortality and serious injury by fishery observers. As of 2003, changes in fishery definitions in the MMPA List of Fisheries have resulted in separating these 3 fisheries into 13 fisheries (69 FR 70094, 2 December 2004). This change does not represent a change in fishing effort but provides managers with better information on the component of each fishery that is responsible for the incidental serious injury or mortality of marine mammal stocks in Alaska. Between 2009 and 2013, incidental mortality and serious injury of ribbon seals occurred in the Bering Sea/Aleutian Islands flatfish trawl, Bering Sea/Aleutian Islands Atka mackerel trawl, and Bering Sea/Aleutian Islands pollock trawl fisheries (Table 1). The minimum estimated average annual mortality and serious injury rate incidental to U.S. commercial fisheries is 0.6 ribbon seals, based exclusively on observer data.

Table 1. Summary of incidental mortality and serious injury of the Alaska stock of ribbon seals due to U.S. commercial fisheries from 2009 to 2013 and calculation of the mean annual mortality and serious injury rate (Breiwick 2013; NMML, unpubl. data). Methods for calculating percent observer coverage are described in Appendix 6 of the Alaska Stock Assessment Reports.

Fishery name	Years	Data type	Percent observer coverage	Observed mortality	Estimated mortality	Mean estimated annual mortality
Bering Sea/Aleutian Is. flatfish trawl	2009 2010 2011 2012 2013	obs data	99 99 99 99 99	0 0 0 1 0	0 0 0 1 0	0.2 (CV = 0.01)
Bering Sea/Aleutian Is. Atka mackerel trawl	2009 2010 2011 2012 2013	obs data	99 99 99 99 99	1 0 0 0 0	1 0 0 0 0	0.2 (CV = 0.01)

Fishery name	Years	Data type	Percent observer coverage	Observed mortality	Estimated mortality	Mean estimated annual mortality
Bering Sea/Aleutian Is. pollock trawl	2009 2010 2011 2012 2013	obs data	86 86 98 98 97	1 0 0 0 0	1 0 0 0 0	0.2 (CV = 0.11)
Minimum total estimated annual mortality						0.6 (CV = 0.04)

Alaska Native Subsistence/Harvest Information

Ribbon seals are an important resource for Alaska Native subsistence hunters. Approximately 64 Alaska Native communities in western and northern Alaska, from Bristol Bay to Kaktovik, regularly harvest ice seals (Ice Seal Committee 2014). The Ice Seal Committee, as co-managers with NMFS, recognizes the importance of harvest information and has been collecting it since 2008 as funding and available personnel have allowed. Annual household survey results are compiled in a statewide harvest report that includes historical ice seal harvest information back to 1960. This report is used to determine where and how often harvest information has been collected and where efforts need to be focused in the future (Ice Seal Committee 2014). Current information, within the last 5 years, is available for 11 communities (Kivalina, Noatak, Buckland, Deering, Emmonak, Scammon Bay, Hooper Bay, Tununak, Quinhagak, Togiak, and Twin Hills) (Table 2), but more than 50 other communities harvest ribbon seals and have not been surveyed in the last 5 years or have never been surveyed. Harvest surveys are designed to confidently estimate harvest within the surveyed community, but because of differences in seal availability, cultural hunting practices, and environmental conditions, extrapolating harvest numbers beyond that community is misleading. For example, during the past 5 years (2009-2013), only 11 of the 64 coastal communities have been surveyed for ribbon seals and of those only 6 have been surveyed for two or more consecutive years (Ice Seal Committee 2015). Based on the harvest data from these 11 communities (Table 2), a minimum estimate of the average annual harvest of ribbon seals in 2009-2013 is 3.2 seals. The Ice Seal Committee is working toward a better understanding of ice seal harvest by conducting more consecutive surveys with the goal of being able to report a statewide ice seal harvest estimate in the future.

Table 2. Ribbon seal harvest estimates from 2009 to 2013 and the Alaska Native population for each community (Ice Seal Committee 2015).

Community	Alaska Native population (2013)	Estimated ribbon seal harvest				
		2009	2010	2011	2012	2013
Kivalina	352			0		
Noatak	514			1		
Buckland	519			0		
Deering	176			0		
Emmonak	782			0		
Scammon Bay	498			4	2	
Hooper Bay	1144	0	0	0	4	0
Tununak	342	0	0	0	0	
Quinhagak	694		2	3	0	0
Togiak	842	0	0	0		
Twin Hills	66	0	0			
Total		0	2	8	6	0

Other Mortality

Beginning in mid-July 2011, elevated numbers of sick or dead seals, primarily ringed seals, with skin lesions were discovered in the Arctic and Bering Strait regions of Alaska. By December 2011, there were more than 100 cases of affected pinnipeds, including ringed seals, spotted seals, bearded seals, and walrus, in northern and western Alaska. Due to the unusual number of marine mammals discovered with similar symptoms across a wide geographic area, NOAA and USFWS declared a Northern Pinniped Unusual Mortality Event (UME) on December 20, 2011. Disease surveillance efforts in 2012-2013 did not detect any new cases similar to those observed in 2011, but the UME investigation remains open for ice seals based on continuing reports in 2013 and 2014 of ice seals in the Bering Strait region with patchy hair loss. To date, no specific cause for the disease has been identified. No ribbon seal cases were reported but they are not a coastal species and are seldom observed.

STATUS OF STOCK

Ribbon seals are not designated as "depleted" under the MMPA or listed as "threatened" or "endangered" under the Endangered Species Act (ESA). The minimum population estimate of ribbon seals in U.S. waters is 163,086, with a PBR of 9,785. Because the estimated average annual level of U.S. commercial fishery-related mortality and serious injury (0.6) is less than 10% of PBR (979), it can be considered insignificant and approaching zero mortality and serious injury rate. The total estimated annual level of human-caused mortality and serious injury based on commercial fisheries observer data (0.6) and a minimum estimate of the Alaska Native harvest (3.2) is 3.8 ribbon seals. The Alaska stock of ribbon seals is not considered a strategic stock.

HABITAT CONCERNS

Evidence indicates that the Arctic climate is changing significantly and that one result of the change is a reduction in the extent of sea ice in at least some regions of the Arctic (ACIA 2004, Johannessen et al. 2004). Ribbon seals, along with other seals that are dependent on sea ice for at least part of their life history, will be vulnerable to reductions in sea ice. The main concern about the conservation status of ribbon seals stems from the likelihood that their sea-ice habitat has been modified by the warming climate and, more so, that the scientific consensus projections are for continued and perhaps accelerated warming in the foreseeable future (Boveng et al. 2013). A second major concern, related by the common driver of carbon dioxide (CO_2) emissions, is the modification of habitat by ocean acidification, which may alter prey populations and other important aspects of the marine ecosystem. Ocean acidification, a result of increased CO_2 in the atmosphere, may impact ribbon seal survival and recruitment through disruption of trophic regimes that are dependent on calcifying organisms. The nature and timing of such impacts are extremely uncertain. Laidre et al. (2008) concluded that on a worldwide basis ribbon seals were likely to be moderately sensitive to climate change based on an analysis of various life history features that could be affected by climate. Additional habitat concerns include the potential effects from increased shipping (particularly in the Bering Strait) and oil and gas exploration activities (particularly in the outer continental shelf leasing areas), such as disturbance from vessel traffic, seismic exploration noise, and the potential for oil spills.

BELUGA WHALE (*Delphinapterus leucas*): Beaufort Sea Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Beluga whales are distributed throughout seasonally ice-covered arctic and subarctic waters of the Northern Hemisphere (Gurevich 1980), and are closely associated with open leads and polynyas in ice-covered regions (Hazard 1988). Depending on season and region, beluga whales may occur in both offshore and coastal waters, with summer concentrations in upper Cook Inlet, Bristol Bay, the eastern Bering Sea (i.e., Yukon Delta, Norton Sound), eastern Chukchi Sea, and the Mackenzie Delta (Hazard 1988). Satellite transmitters on a few whales from the Beaufort Sea, Chukchi Sea and Eastern Bering Sea stocks have lasted through the winter demonstrating that beluga whales from these summering areas overwinter in the Bering Sea and the stocks may use separate wintering locations (Suydam 2009; ABWC, unpublished data). Belugas found in Bristol Bay and the northern Gulf of Alaska/Cook Inlet remain in those areas throughout the year (Shelden 1994, Quakenbush 2003, NMFS and ADF&G unpublished data). Seasonal distribution is affected by ice cover, tidal conditions, access to prey, temperature, and human interaction (Lowry 1985).

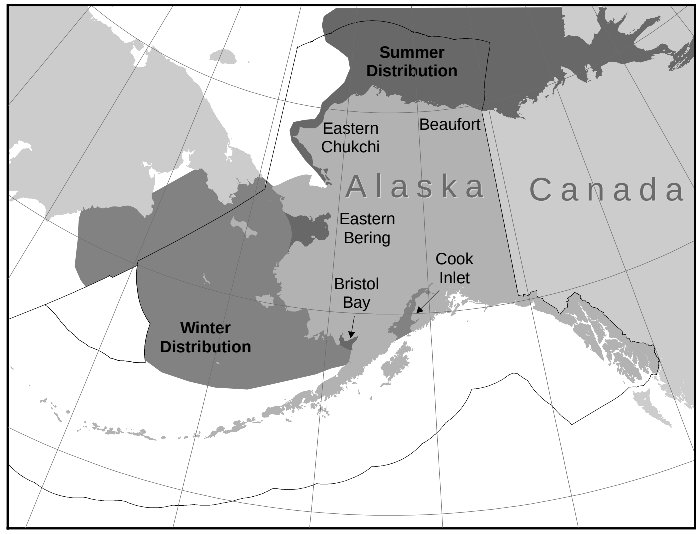

Figure 1. Approximate distribution of beluga whales in Alaska waters. The dark shading displays the summer distribution of the five stocks. Winter distributions are depicted with lighter shading.

The general distribution pattern for beluga whales shows major seasonal changes. During the winter, they occur in offshore waters associated with pack ice. In the spring, they migrate to warmer coastal estuaries, bays, and rivers where they may molt (Finley 1982, Suydam 2009) and give birth to and care for their calves (Sergeant and Brodie 1969). Annual migrations can be more than thousands of kilometers (Richard et al. 2001).

The following information was considered in classifying beluga whale stock structure based on the Dizon et al. (1992) phylogeographic approach: 1) Distributional data: geographic distribution discontinuous in summer (Frost and Lowry 1990); 2) Population response data: distinct population trends between regions occupied in summer; 3) Phenotypic data: unknown; and 4) Genotypic data: mitochondrial DNA analyses indicate distinct differences among the five summering areas (O'Corry-Crowe et al. 1997). Based on this information, 5 beluga whale stocks are recognized within U.S. waters: 1) Cook Inlet, 2) Bristol Bay, 3) eastern Bering Sea, 4) eastern Chukchi Sea, and 5) Beaufort Sea (Fig. 1).

POPULATION SIZE

The sources of information to estimate abundance for belugas in the waters of northern Alaska and western Canada have included both opportunistic and systematic observations. Duval (1993) reported an estimate of 21,000 belugas for the Beaufort Sea stock, similar to that reported by Seaman et al. (1985). The most recent aerial survey was conducted in July 1992, and resulted in an estimate of 19,629 (CV = 0.229) beluga whales in the eastern Beaufort Sea (Harwood et al. 1996). To account for availability bias a correction factor (CF), which was not data-based, has been recommended for the Beaufort Sea beluga whale stock (Duval 1993), resulting in a population estimate of 39,258 (19,629 × 2) animals. A coefficient of variation (CV) for the CF is not available; however, this CF was considered negatively biased by the Alaska SRG considering that aerial survey CFs for this species have been estimated to be between 2.5 and 3.27 (Frost and Lowry 1995). Additionally, the 1992 surveys did not encompass the entire summer range of Beaufort Sea belugas (Richard et al. 2001), thus are negatively biased.

Minimum Population Estimate

For the Beaufort Sea beluga whale stock, the minimum population estimate (N_{MIN}) is calculated according to Equation 1 from the PBR Guidelines (Wade and Angliss 1997). Thus, $N_{MIN} = N/\exp(0.842\times[\ln(1+[CV(N)]^2)]^{½})$. Using the population estimate (N) of 39,258 whales and an associated CV(N) of 0.229, N_{MIN} for this stock is 32,453 whales. Because the survey data are more than 8 years old, it would not be considered a reliable minimum population estimate for calculating a PBR and N_{MIN} would be considered unknown. However, trend data from Harwood and Kingsley (2013) indicate the stock is at least stable or increasing; therefore, the Alaska SRG recommended at the 2014 meeting that NMFS retain the N_{MIN} estimate of 32,453 whales.

Current Population Trend

The current population trend of the Beaufort Sea stock of beluga whales is stable or increasing. Recent and historical aerial surveys off the Mackenzie River Delta indicate that the stock is at least stable or increasing (Harwood and Kingsley 2013). There are no data to suggest the stock is declining.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

A reliable estimate of the maximum net productivity rate is currently unavailable for the Beaufort Sea beluga whale stock. Hence, until additional data become available, it is recommended that the default maximum theoretical net productivity rate (R_{MAX}) for cetaceans of 4% be employed for this stock (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the potential biological removal (PBR) is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: $PBR = N_{MIN} \times 0.5R_{MAX} \times F_R$. As the stock trend is at least stable, the recovery factor (F_R) for this stock is 1 (Wade and Angliss 1997). Thus, using the abundance estimate calculated from 1992 surveys, the PBR for the Beaufort Sea beluga whale stock would be calculated to be 649 animals (32,453 × 0.02 × 1.0). The 2005 revisions to the SAR guidelines (Wade and Angliss 1997) state that abundance estimates older than 8 years should not be used to calculate PBR due to a decline in confidence in the reliability of an aged abundance estimate. However, the recent trend data suggest that the stock is at least as large as it was during the last estimate of N_{MIN}; thus the 1992 estimate of N_{MIN} = 32,452 whales is sufficient to use for a PBR calculation. Therefore, the PBR for this stock is 649 (NMFS 2005).

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

New Serious Injury Guidelines

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an "*injury that is more likely than not to result in mortality.*" Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

Fisheries Information

The total fishery mortality and serious injury for this stock is estimated to be zero as there are no reports of mortality incidental to commercial fisheries.

Subsistence/Native Harvest Information

The subsistence take of beluga whales from this stock within U.S. waters is reported by the Alaska Beluga Whale Committee (ABWC). The most recent Alaska Native subsistence harvest estimates for the Beaufort Sea beluga stock are provided in Table 1 (Alaska Beluga Whale Committee, unpubl. data 2012). Given these data, the annual subsistence take by Alaska Native hunters averaged 65.6 belugas during the 5-year period from 2008 to 2012.

Table 1. Summary of beluga whales from the Beaufort Sea beluga whale stock landed by Alaska Native subsistence hunters, 2008-2012. Total taken includes landed and struck and lost in years 2010-2012; struck and lost data for 2008 and 2009 have not been quantified and are minimum counts.

Year	Harvested whales	Struck and lost whales	Reported total number taken
2008	48	N/A	48
2009	16	N/A	16
2010	71	1+	72
2011	42	6	48
2012	92	42+	144
Mean annual number of animals landed (2008-2012)			65.6+

The subsistence take of beluga whales within the Canadian waters of the Beaufort Sea is reported by the Fisheries Joint Management Committee (FJMC). The data are collected by on-site harvest monitors conducted by the FJMC at Inuvialuit communities in the Mackenzie Delta, Northwest Territories. The Canadian Inuvialuit subsistence harvest estimates for the Beaufort Sea beluga stock are provided in Table 2 (data for 2005 to 2009 from FJMC Beluga Monitor Program, Fisheries Joint Management Committee, Inuvik, NT, Canada). Given these data, the annual subsistence take in Canada averaged 100 belugas during the 5-year period from 2005 to 2009. Thus, the mean estimated subsistence take in Canadian (2005-2009) and U.S. (2008-2012) waters from the Beaufort Sea beluga stock is 166 (100 + 65.6) whales.

Table 2. Summary of the Canadian subsistence harvest from the Beaufort Sea stock of beluga whales, 2005-2009. N/A indicates the data are not available.

Year	Reported total number taken
2005	108
2006	126
2007	82
2008	81
2009	102
Mean annual landed (2005-2009)	100

STATUS OF STOCK

Beaufort Sea beluga whales are not designated as “depleted” under the MMPA or listed as “threatened” or “endangered” under the Endangered Species Act. There are no reported fisheries mortalities, thus the estimated annual U.S. commercial fishery-related mortality is zero (0). The total mean annual human-caused mortality estimate is 166 based on the known subsistence harvest in the United States (65.6) and Canada (100). Because the PBR is less than 10% of PBR (65), the level of annual U.S. commercial fishery-related mortality is considered insignificant and approaching zero mortality and serious injury rate. Although the abundance estimates are more than 8 years old, since there are no records of incidental mortality in commercial fisheries, the level of incidental mortality and serious injury is considered to be insignificant. The Beaufort Sea beluga stock is classified as a non-strategic stock. At this time it is not possible to assess the status of this stock relative to its Optimum Sustainable Population size.

HABITAT CONCERNS

Evidence indicates that the Arctic climate is changing rapidly and significantly, and one result of this change is a reduction in the extent of sea ice in at least some regions (ACIA 2004, Johannessen et al. 2004). These changes are likely to affect marine mammal species in the Arctic. Ice-associated animals, such as the beluga whale, may be sensitive to changes in Arctic weather, sea-surface temperatures, or ice extent, and the concomitant effect on prey availability. Currently, there are insufficient data to make reliable predictions of the effects from Arctic climate change on beluga whales, but Laidre et al. (2008) and Heide-Jørgensen (2010) concluded that on a worldwide basis belugas were likely to be less sensitive to climate change than other Arctic cetaceans because of their wide distribution and flexible behavior. Increased human activity in the Arctic, including increasing oil and gas exploration and development, and increased nearshore development, have the potential to impact beluga whale habitat (Moore et al. 2000, Lowry et al. 2006). However, predicting the type and magnitude of the impacts is difficult at this time.

BELUGA WHALE (*Delphinapterus leucas*): Eastern Chukchi Sea Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Beluga whales are distributed throughout seasonally ice-covered arctic and subarctic waters of the Northern Hemisphere (Gurevich 1980), and are closely associated with open leads and polynyas in ice-covered regions (Hazard 1988). Depending on season and region, beluga whales may occur in both offshore and coastal waters, with summer concentrations in upper Cook Inlet, Bristol Bay, the eastern Bering Sea (i.e., Yukon Delta, Norton Sound), eastern Chukchi Sea, and the Mackenzie Delta (Hazard 1988). Satellite transmitters on a few whales from the Beaufort Sea, Chukchi Sea and eastern Bering Sea stocks have lasted through the winter demonstrating that beluga whales from these summering areas overwinter in the Bering Sea and the stocks may use separate wintering locations (Suydam 2009; Alaska Beluga Whale Committee, unpublished data). Belugas found in Bristol Bay and the northern Gulf of Alaska/Cook Inlet remain in those areas throughout the year (Shelden 1994; Quakenbush 2003; NMFS and ADF&G, unpublished data). Seasonal distribution is affected by ice cover, tidal conditions, access to prey, temperature, and human interaction (Lowry 1985).

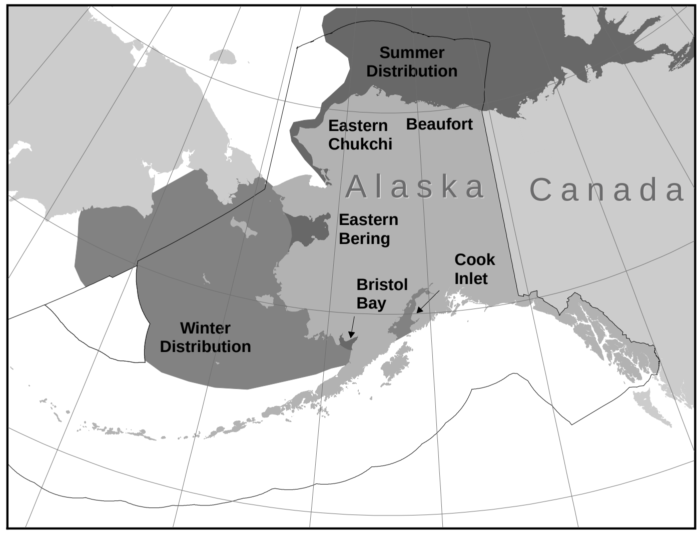

Figure 1. Approximate distribution of beluga whales in Alaska waters. The dark shading displays the summer distribution of the five stocks. Winter distributions are depicted with lighter shading.

The general distribution pattern for beluga whales shows major seasonal changes. During the winter, the Beaufort Sea, eastern Chukchi Sea, and Bering Sea stocks occur in offshore waters associated with pack ice. In the spring, they migrate to warmer coastal estuaries, bays, and rivers where they may molt (Finley 1982, Suydam 2009) and give birth to and care for their calves (Sergeant and Brodie 1969). Annual migrations can be more than thousands of kilometers (Richard et al. 2001).

Eastern Chukchi Sea belugas move into coastal areas, including Kasegaluk Lagoon, in late June and animals are sighted in the area until about mid-July (Frost and Lowry 1990, Frost et al. 1993). Satellite tags attached to eastern Chukchi belugas captured in Kasegaluk Lagoon during the summer showed these whales traveled 1,100 km north of the Alaska coastline, into the Canadian Beaufort Sea within 3 months (Suydam et al. 2001). This movement indicated some overlap in distribution with the Beaufort Sea beluga whale stock during late summer. Satellite telemetry data from 23 whales tagged during 1998-2007 suggest variation in movement patterns for different age and/or sex classes during July-September (Suydam et al. 2005). Adult males used deeper waters and remained there for the duration of the summer; all belugas that moved into the Arctic Ocean (north of 75°N) were males, and males traveled through 90% pack ice cover to reach deeper waters in the Beaufort Sea and Arctic Ocean (79-80°N) by late July/early August. Adult and immature female belugas remained at or near the shelf break in the Chukchi Sea. After October, only three tags continued to transmit, and those whales migrated south through the eastern Bering Strait into the northern Bering Sea, remaining north of Saint Lawrence Island over the winter. A whale tagged in the eastern Chukchi Sea in 2007 overwintered in the waters north of Saint Lawrence Island during 2007/2008 and moved to near King Island in April and May before moving north through the Bering Strait in late May and early June (Suydam 2009).

The following information was considered in classifying beluga whale stock structure based on the Dizon et al. (1992) phylogeographic approach: 1) Distributional data: geographic distribution discontinuous in summer (Frost and Lowry 1990); 2) Population response data: distinct population trends between regions occupied in summer; 3) Phenotypic data: unknown; and 4) Genotypic data: mitochondrial DNA analyses indicate distinct differences among the five summering areas (O'Corry-Crowe et al. 1997). Based on this information, 5 beluga whale stocks are recognized within U.S. waters: 1) Cook Inlet, 2) Bristol Bay, 3) eastern Bering Sea, 4) eastern Chukchi Sea, and 5) Beaufort Sea (Fig. 1).

POPULATION SIZE

Frost et al. (1993) estimated the minimum size of the eastern Chukchi beluga stock at 1,200 whales, based on counts of animals from aerial surveys conducted during 1989-1991. Survey effort was concentrated along the sea side of the 170 km long Kasegaluk Lagoon, an area known to be regularly used by belugas during the open-water season. Other areas that these belugas are known to frequent (e.g., offshore) were not surveyed. Therefore, these surveys provided only a minimum raw count. If this count is corrected using radio telemetry data, for the proportion of animals that were diving and thus not visible at the surface (2.62; Frost and Lowry 1995), and for the proportion of newborns and yearlings not observed due to small size and dark coloration (1.18; Brodie 1971), the total corrected abundance estimate for the eastern Chukchi stock is 3,710 ($1,200 \times 2.62 \times 1.18$) whales.

During 25 June to 6 July 1998, aerial surveys were conducted in the eastern Chukchi Sea (DeMaster et al. 1998). The maximum single day count (1,172 whales) was derived from a photographic count of a large aggregation near Icy Cape (1,018), plus animals (154) counted along an ice edge transect. This count is an underestimate because it was clear to the observers that many more whales were present along and in the ice than they were able to count and only a small portion of the ice edge habitat was surveyed. Furthermore, only one of five belugas equipped with satellite tags a few days earlier remained within the survey area on the day the peak count occurred (DeMaster et al. 1998).

In July 2002, aerial surveys were conducted again in the eastern Chukchi Sea (Lowry and Frost 2002). Those surveys resulted in a peak count of 582 whales. A correction factor for animals that were not available for the count is not available. Offshore sightings during this survey combined with satellite tag data collected in 2001 (Lowry and Frost 2001, Lowry and Frost 2002) indicate that nearshore surveys for belugas will only result in partial counts of this stock.

It is not possible to estimate the abundance for this stock from the 1998 survey. Not only were a large number of whales unavailable for counting, but the large Icy Cape aggregation was in shallow, clear water (DeMaster et al. 1998). Currently, a correction factor (to account for missed whales) does not exist for belugas encountered in such conditions. As a result, the abundance estimate from the 1989-91 surveys (3,710 whales) is still considered to be the most reliable for the eastern Chukchi Sea beluga whale stock.

Aerial surveys were conducted in the summer of 2012 in the northeastern Chukchi and Alaskan Beaufort seas in late June through August (Clarke et al. 2013). Those data are currently being analyzed by the Alaska Beluga Whale Committee and an updated estimate should be available by 2015.

Minimum Population Estimate

The survey technique used for estimating beluga whale abundance is a direct count that incorporates correction factors. Although coefficients of variation (CVs) of the correction factors are not available, the Alaska Scientific Review Group concluded that the population estimate of 3,710 belugas can serve as the estimated minimum population size because the survey did not include all areas where beluga are known to occur (Small and DeMaster 1995). That is, if the beluga distribution in the eastern Chukchi Sea is similar to beluga distribution in the Beaufort Sea, which is likely based on satellite tag results (Suydam et al. 2001, Lowry and Frost 2002), then a substantial fraction of the population was likely to have been in offshore waters during the survey period (DeMaster 1997). However, because the survey data are more than 8 years old, it is not considered a reliable minimum population estimate for calculating a PBR, and N_{MIN} is considered unknown.

Current Population Trend

The current population trend for the eastern Chukchi Sea beluga stock is unknown.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

A reliable estimate of the maximum net productivity rate is currently unavailable for this beluga whale stock. Hence, until additional data become available, it is recommended that the default maximum theoretical net productivity rate (R_{MAX}) for cetaceans of 4% be employed for this stock (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the potential biological removal (PBR) is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: $PBR = N_{MIN} \times 0.5R_{MAX} \times F_R$. This stock is considered relatively stable and not declining in the presence of known take, thus the recovery factor (F_R) for this stock is 1.0 (DeMaster 1995, Wade and Angliss 1997). However, the 2005 revisions to the SAR guidelines (Wade and Angliss 1997) state that abundance estimates older than 8 years should not be used to calculate PBR due to a decline in confidence in the reliability of an aged abundance estimate. Therefore, the PBR for this stock is considered undetermined (NMFS 2005).

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

New Serious Injury Guidelines

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an "*injury that is more likely than not to result in mortality.*" Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

Fisheries Information

Three different commercial fisheries that could have interacted with beluga whales from this stock were monitored for incidental take by fishery observers during 1990-1997: Bering Sea (and Aleutian Islands) groundfish trawl, longline, and pot fisheries. Observers did not report any mortality or serious injury to beluga whales incidental to these groundfish fisheries. In the nearshore waters of the southeastern Chukchi Sea, substantial efforts occur in gillnet (mostly set nets) and personal-use fisheries. Although a potential source of mortality, there have been no reported beluga whale takes as a result of these fisheries.

Based on a lack of reported mortalities, the inferred minimum mortality rate incidental to commercial fisheries is zero belugas per year from this stock.

Subsistence/Native Harvest Information

The subsistence take of beluga whales from the eastern Chukchi Sea stock is provided by the Alaska Beluga Whale Committee (ABWC). The most recent subsistence harvest estimates for the stock are provided in Table 1. Given these data, the annual subsistence take by Alaska Native hunters averaged 57.4 belugas landed during the 5-year period 2008-2012 based on reports from ABWC representatives and on-site harvest monitoring.

Table 1. Summary of the number of beluga whales landed by the Alaska Native subsistence harvest of eastern Chukchi Sea beluga whales, 2008-2012. It should be noted that the 2010 and 2011 statistics include takes at Kivalina (2 in 2010 and 2 in 2011) and Kotzebue/Noatak (0 in 2010 and 30 in 2011) which may be from a population that is genetically distinct from the main population comprising the eastern Chukchi Sea beluga whale stock. Totals include landed and struck and lost.

Year	**Reported total number landed**
2008	74
2009	53
2010	36
2011	66
2012	58
Mean annual number of animals landed (2008-2012)	57.4

STATUS OF STOCK

Eastern Chukchi Sea beluga whales are not designated as "depleted" under the MMPA or listed as "threatened" or "endangered" under the Endangered Species Act. Therefore, the eastern Chukchi Sea stock of beluga whales is not classified as a strategic stock. The population trend is unknown; however, at this time it is not possible to assess the status of this stock relative to its Optimum Sustainable Population size.

HABITAT CONCERNS

Evidence indicates that the Arctic climate is changing rapidly and significantly, and one result of this change is a reduction in the extent of sea ice in at least some regions (ACIA 2004, Johannessen et al. 2004). These changes are likely to affect marine mammal species in the Arctic. Ice-associated animals, such as the beluga whale, may be sensitive to changes in Arctic weather, sea-surface temperatures, or ice extent, and the concomitant effect on prey availability. Currently, there are insufficient data to make reliable predictions of the effects from Arctic climate change on beluga whales, but Laidre et al. (2008) and Heide-Jørgensen (2010) concluded that on a worldwide basis belugas were likely to be less sensitive to climate change than other Arctic cetaceans because of their wide distribution and flexible behavior. Increased human activity in the Arctic, including increasing oil and gas exploration and development, and increased nearshore development, have the potential to impact beluga whale habitat (Moore et al. 2000, Lowry et al. 2006). However, predicting the type and magnitude of the impacts is difficult at this time.

BELUGA WHALE (*Delphinapterus leucas*): Eastern Bering Sea Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Beluga whales are distributed throughout seasonally ice-covered arctic and subarctic waters of the Northern Hemisphere (Gurevich 1980), and are closely associated with open leads and polynyas in ice-covered regions (Hazard 1988). Depending on season and region, beluga whales may occur in both offshore and coastal waters, with summer concentrations in upper Cook Inlet, Bristol Bay, the eastern Bering Sea (i.e., Yukon Delta, Norton Sound), eastern Chukchi Sea, and the Mackenzie Delta (Hazard 1988). Satellite transmitters attached to whales from the Beaufort Sea, Chukchi Sea and eastern Bering Sea stocks have provided detailed information on distribution and movements. The few transmitters that lasted through the winter showed that beluga whales from these summering areas overwinter in the Bering Sea and the stocks may use separate wintering locations (Suydam 2009; Alaska Beluga Whale Committee, unpublished data). Belugas found in Bristol Bay and the northern Gulf of Alaska/Cook Inlet remain in those areas throughout the year, showing only small seasonal shifts in distribution (Shelden 1994; Quakenbush 2003; NMFS and ADF&G, unpublished data). Seasonal distribution is affected by ice cover, tidal conditions, access to prey, temperature, and human activities (Lowry 1985).

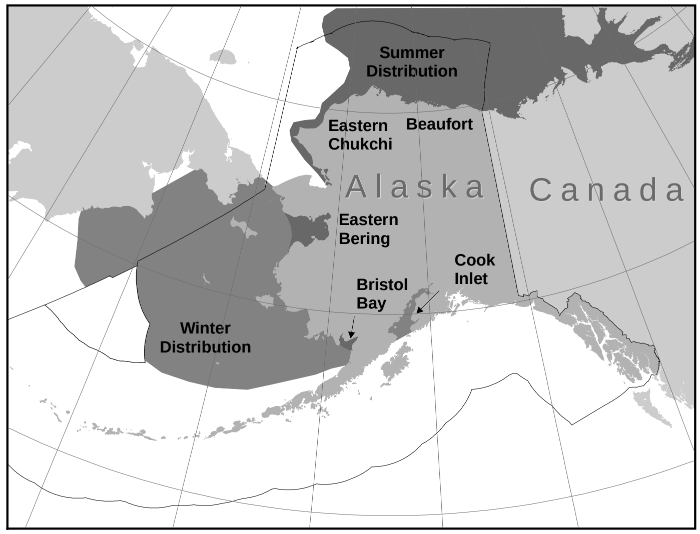

Figure 1. Approximate distribution of beluga whales in Alaska waters. The dark shading displays the summer distribution of the five stocks. Winter distributions are depicted with lighter shading.

The general distribution pattern for beluga whales shows major seasonal changes. During the winter, they occur in offshore waters associated with pack ice. In the spring, they migrate to warmer coastal estuaries, bays, and rivers where they may molt (Finley 1982, Suydam 2009) and give birth to and care for their calves (Sergeant and Brodie 1969). Annual migrations may cover thousands of kilometers (Richard et al. 2001).

Two belugas from the eastern Bering Sea stock were tagged with satellite transmitters in 2012. The belugas were tagged near Nome and moved south from there in ice covered shelf waters during the winter, as far as the vicinity of Hagemeister Island and the Walrus Islands in Bristol Bay, before returning north to Norton Sound in the spring (Alaska Beluga Whale Committee, unpublished data).

The following information was considered in classifying beluga whale stock structure based on the Dizon et al. (1992) phylogeographic approach: 1) Distributional data: geographic distribution discontinuous in summer (Frost and Lowry 1990); 2) Population response data: distinct population trends between regions occupied in summer; 3) Phenotypic data: unknown; and 4) Genotypic data: mitochondrial DNA analyses indicate distinct differences among the five summering areas (O'Corry-Crowe et al. 1997). Based on this information, five beluga whale stocks are recognized within U.S. waters: 1) Cook Inlet, 2) Bristol Bay, 3) eastern Bering Sea, 4) eastern Chukchi Sea, and 5) Beaufort Sea (Fig. 1).

POPULATION SIZE

The Alaska Beluga Whale Committee has been working to develop a population estimate for the eastern Bering Sea stock beginning with the first systematic aerial surveys of beluga whales in the Norton Sound/Yukon Delta region flown during May, June, and September 1992, and June 1993-1995 (Lowry et al. 1999). Beluga density estimates were calculated for June 1992 surveys using strip transect methods, and for June 1993-1995 using line transect methods. Correction factors were applied to account for animals that were missed during the surveys (those below the surface and not visible, and dark colored neonates). Lowry et al. (1999) concluded that the best estimate of abundance for the eastern Bering Sea beluga stock was 17,675 (95% confidence interval 9,056-34,515 not accounting for variance in correction factors) based on counts made in early June 1995. Additional aerial surveys of the Norton Sound/Yukon Delta region were conducted in June 1999 and 2000 (L. Lowry, pers. comm., 29 January 2011). Unlike previous survey years, in 1999 sea ice persisted in western Norton Sound resulting in a much different distribution of belugas, and the data were not used for population estimation. In 2000, systematic transect lines were flown covering the entire study region, and the data were analyzed using a covariate line transect model. Preliminary results indicate 9,593 belugas (CV = 0.32) seen at the surface in the study area (R. Hobbs, AFSC-NMML, pers. comm., 05 March 2014). If this estimate were doubled to correct for the proportion of animals that were diving and thus not visible at the surface, the total abundance for the eastern Bering Sea stock would be 19,186 whales. However, while these results confirm that the eastern Bering Sea beluga stock is quite large they are preliminary and are not ready to use for calculation of N_{MIN} or PBR at this time.

Minimum Population Estimate

For the eastern Bering Sea stock of beluga whales, the minimum population estimate (N_{MIN}) is calculated according to Equation 1 from the PBR Guidelines (Wade and Angliss 1997). Therefore, $N_{MIN} = N/\exp(0.842 \times [\ln(1+[CV(N)]^2)]^{½})$. Using the population estimate (N) of 19,186 and an associated CV(N) of 0.32, N_{MIN} for this stock is 14,751 beluga whales. However, because the survey data are more than 8 years old, it is not considered a reliable minimum population estimate for calculating a PBR, and N_{MIN} is considered unknown. More recent data are considered preliminary and are not ready to be used for calculation of $N_{MIN,}$ but will be available soon (R. Hobbs, AFSC-NMML, pers. comm., 05 March 2014).

Current Population Trend

Surveys to estimate population abundance in Norton Sound were not conducted prior to 1992. Annual estimates of population size from surveys flown in 1992-1995 and 1999-2000 have varied widely, due partly to differences in survey coverage and conditions between years. Data currently available do not allow an evaluation of population trend for the eastern Bering Sea stock.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

A reliable estimate of the maximum net productivity rate is currently unavailable for the eastern Bering Sea stock of beluga whales. Lowry et al. (2008) estimated the rate of increase of the Bristol Bay beluga stock was 4.8% per year (95% CI = 2.1%-7.5%) over a 12-year period. However, until additional data become available specific to the eastern Bering Sea stock, it is recommended that the cetacean maximum theoretical net productivity rate (R_{MAX}) of 4% be employed for this stock (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the potential biological removal (PBR) is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: $PBR = N_{MIN} \times 0.5R_{MAX} \times F_R$. The recovery factor ($F_R$) for this stock is 1.0, the value for cetacean stocks that are thought to be stable in the presence of a subsistence harvest (Wade and Angliss 1997). However, the 2005 revisions to the SAR guidelines state that abundance estimates older than 8 years should not be used to calculate PBR due to a decline in confidence in the reliability of an aged abundance estimate. Therefore, the PBR for the eastern Bering Sea stock of beluga whales is considered undetermined (NMFS 2005).

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

New Serious Injury Guidelines

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an "*injury that is more likely than not to result in mortality.*" Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

Fisheries Information

In previous assessments, there were three different federally observed commercial fisheries in Alaska that could have had incidental serious injuries or mortalities of eastern Bering Sea beluga whales. In 2004, the definitions of these commercial fisheries were changed to reflect target species; this new definition has resulted in the identification of several observed fisheries in the Bering Sea that use trawl, longline, or pot gear. There have been no observed serious injuries or mortalities in any of these commercial fisheries.

In the nearshore waters of the eastern Bering Sea, substantial effort occurs in commercial and subsistence fisheries, mostly for salmon and herring. The salmon fishery uses gillnet gear similar to that used in Bristol Bay where it is known that belugas have been incidentally taken (Frost et al. 1984). However there are no useful data on beluga incidental takes from this stock because there have never been observer programs in the commercial fisheries and there is no reporting requirement for takes in personal use fisheries. In 2010, one beluga was reported entangled in a subsistence salmon gillnet in the eastern Bering Sea (Table 1). NMFS assumes that all beluga whales killed are used for subsistence, regardless of the method of harvest, are reported to the ABWC, and included in the following section on Subsistence/Native Harvest Information.

A reliable estimate of the mortality rate incidental to commercial fisheries is currently unavailable.

Table 1. Summary of eastern Bering Sea stock of beluga whale mortalities and serious injuries by year and type reported to the Alaska Regional Office, marine mammal stranding database, for the 2008-2012 period (Allen et al. 2014, Helker et al. 2015). Only cases of serious injury were recorded in this table; animals with non-serious injuries have been excluded.

Cause of Injury	2008	2009	2010	2011	2012	Mean Annual Mortality
Entangled in subsistence salmon gillnet	0	0	1	0	0	0.2
Minimum total annual mortality						0.20

Because there has never been an observer program for nearshore commercial fisheries in the eastern Bering Sea region, a reliable estimate of the number of deaths incidental to commercial fisheries is currently unavailable.

Subsistence/Native Harvest Information

The subsistence take of beluga whales from the eastern Bering Sea stock is provided by the ABWC. The most recent subsistence harvest estimates for the stock are provided in Table 2 (Alaska Beluga Whale Committee, pers. comm., 13 June 2013). Belugas harvested in Kuskokwim villages are included in the total harvest for the eastern Bering Sea beluga stock. The annual subsistence take by Alaska Natives averaged 181 belugas landed from the eastern Bering Sea stock during the 5-year period 2008-2012.

Table 2. Summary of the number of belugas landed by the Alaska Native subsistence harvest from the eastern Bering Sea stock of beluga whales, 2008-2012.

Year	Reported total number landed
2008	119
2009	181
2010	194
2011	224
2012	186
Mean annual number of animals landed (2008-2012):	180.8

STATUS OF STOCK

The estimated minimum annual mortality incidental to U.S. commercial fisheries is 0. Because the PBR is undetermined, the level of annual U.S. commercial fishery-related mortality that can be considered insignificant and approaching zero mortality and serious injury rate is unknown. The total estimated annual human-caused mortality rate is 181 based on subsistence harvest (180.8) and entanglement in a subsistence salmon gillnet (0.2). Eastern Bering Sea beluga whales are not designated as "depleted" under the MMPA or listed as "threatened" or "endangered" under the Endangered Species Act. The level of incidental mortality in commercial fisheries is unknown, although it is considered to be insignificant. Therefore the eastern Bering Sea stock of beluga whales is classified as a non-strategic stock.

HABITAT CONCERNS

Evidence indicates that the Arctic climate is changing significantly and that one result of the change is a reduction in the extent of sea ice in most regions of the Arctic (ACIA 2004, Johannessen et al. 2004). These changes are likely to affect marine mammal species in the Arctic. Ice-associated animals, such as the beluga whale, may be sensitive to changes in Arctic weather, sea-surface temperatures, or ice extent, and the concomitant effect on prey availability. Currently, there are insufficient data to make reliable predictions of the effects of Arctic climate change on beluga whales, but Laidre et al. (2008) and Heide-Jørgensen (2010) concluded that on a worldwide basis belugas were likely to be less sensitive to climate change than other arctic cetaceans because of their wide distribution and flexible behavior. Increased human activity in the Arctic, including increasing oil and gas exploration and development, and increased nearshore development, have the potential to impact habitat for beluga whales (Moore et al. 2000, Lowry et al. 2006), but predicting the type and magnitude of the impacts is difficult at this time.

BELUGA WHALE (*Delphinapterus leucas*): Bristol Bay Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Beluga whales are distributed throughout seasonally ice-covered arctic and subarctic waters of the Northern Hemisphere (Gurevich 1980), and are closely associated with open leads and polynyas in ice-covered regions (Hazard 1988). Depending on season and region, beluga whales may occur in both offshore and coastal waters, with summer concentrations in upper Cook Inlet, Bristol Bay, the eastern Bering Sea (i.e., Yukon Delta, Norton Sound), eastern Chukchi Sea, and the Mackenzie Delta (Hazard 1988). Satellite transmitters attached to whales from the Beaufort Sea, Chukchi Sea and eastern Bering Sea stocks have provided detailed information on distribution and movements. The few transmitters that lasted through the winter showed that beluga whales from these summering areas overwinter in the Bering Sea and the stocks may use separate wintering locations (Suydam 2009; Alaska Beluga Whale Committee, unpubl. data). Belugas found in Bristol Bay and the northern Gulf of Alaska/Cook Inlet remain in those areas throughout the year, showing only small seasonal shifts in distribution (Shelden 1994; Quakenbush 2003; NMFS and ADF&G, unpubl. data). Seasonal distribution is affected by ice cover, tidal conditions, access to prey, temperature, and human activities (Lowry 1985).

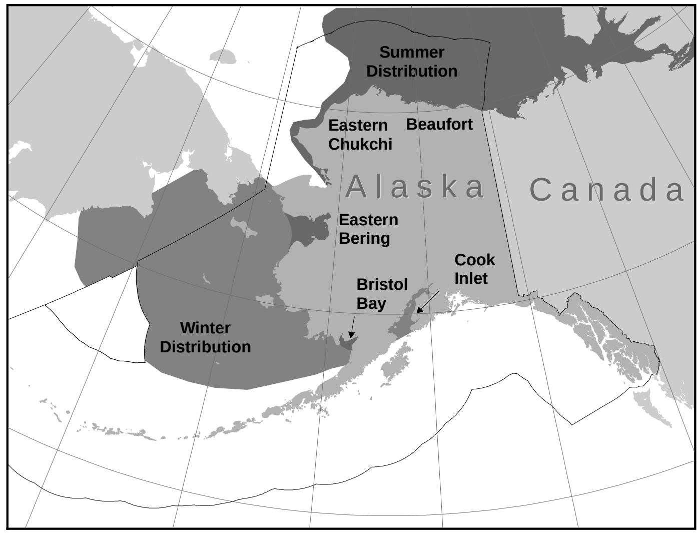

Figure 1. Approximate distribution of beluga whales in Alaska waters. The dark shading displays the summer distribution of the five stocks. Winter distributions are depicted with lighter shading.

The general distribution pattern for beluga whales shows major seasonal changes. During the winter, they occur in offshore waters associated with pack ice. In the spring, they migrate to warmer coastal estuaries, bays, and rivers where they may molt (Finley 1982, Suydam 2009) and give birth to and care for their calves (Sergeant and Brodie 1969). Annual migrations may cover thousands of kilometers (Richard et al. 2001).

Summer movement patterns of Bristol Bay belugas were determined from satellite-linked tags deployed on 10 animals in the Kvichak River during 2002 and 2003, and 5 in the Nushagak River in 2006, 10 in 2008, 5 in 2010, 10 in 2012, and 12 in 2013 (NMFS, BBMMC, ADF&G, unpubl. data). Those whales used the shallow upper portions of Kvichak and Nushagak bays between May and August (Quakenbush, 2003) and remained in the nearshore waters of Bristol Bay through the months of September and October (Quakenbush and Citta 2006). Data from two belugas whose tags lasted into December and January showed that they were in Nushagak and Kvichak bays, suggesting that some belugas do not leave the nearshore waters of Bristol Bay during the winter (L. Quakenbush, Alaska Department of Fish and Game, Fairbanks, AK, pers. comm., 31 March 2008). Tags attached to whales in 2012 and 2013 have confirmed these observations (NMFS, unpubl. data).

The following information was considered in classifying beluga whale stock structure based on the Dizon et al. (1992) phylogeographic approach: 1) Distributional data: geographic distribution discontinuous in summer (Frost and Lowry 1990); 2) Population response data: distinct population trends between regions occupied in summer; 3) Phenotypic data: unknown; and 4) Genotypic data: mitochondrial DNA analyses indicate distinct differences among the five summering areas (O'Corry-Crowe et al. 1997). Based on this information, five beluga whale stocks are recognized within U.S. waters: 1) Cook Inlet, 2) Bristol Bay, 3) eastern Bering Sea, 4) eastern Chukchi Sea, and 5) Beaufort Sea (Fig. 1).

POPULATION SIZE

The sources of information to estimate abundance for belugas in the waters of western and northern Alaska have included both opportunistic and systematic observations. Frost and Lowry (1990) compiled data collected from aerial surveys conducted between 1978 and 1987 that were specifically designed to estimate the number of beluga whales. Surveys did not cover the entire habitat of belugas, but were directed to specific areas at the times of year when belugas are known to concentrate during summer. Frost and Lowry (1990) reported an estimate of 1,000-1,500 whales for Bristol Bay, similar to that reported by Seaman et al. (1985). In 1994, the number was estimated at 1,555 belugas (Lowry and Frost 1998). That estimate was based on a maximum count of 503 animals, which was corrected using radio-telemetry data for the proportion of animals that were diving and thus not visible at the surface (2.62; Frost and Lowry 1995), and for the proportion of newborns and yearlings not observed due to their small size and dark coloration (1.18; Brodie 1971). The Alaska Department of Fish and Game and the Alaska Beluga Whale Committee conducted beluga surveys in Bristol Bay in 1999, 2000, 2004 and 2005, with maximum counts of 690, 531, 794, and 1,067 whales (Lowry et al. 2008). Using the correction factors described above and the maximum counts for 2004 and 2005 gives population estimates of 2,455 and 3,299 whales, with an average annual estimate of 2,877 (L. Lowry, University of Alaska Fairbanks, pers. comm., March 2011).

Minimum Population Estimate

The survey technique used for estimating the abundance of beluga whales in this stock is a direct count which incorporates correction factors. Given this survey method, estimates of the variance of abundance are unavailable. The abundance estimate is thought to be conservative because no correction has been made for whales that were at the surface but were missed by the observers, and the dive correction factor is probably negatively biased (Lowry and Frost 1998). Consistent with the recommendations of the Alaska Scientific Review Group (DeMaster 1997), a default CV(N) of 0.2 was used in the calculation of the minimum population estimate (N_{MIN}). N_{MIN} for this beluga whale stock is calculated using Equation 1 from the PBR Guidelines (Wade and Angliss 1997): $N_{MIN} = N/\exp(0.842\times[\ln(1+[CV(N)]^2)]^{½})$. Using the average estimate for 2004 and 2005 (N) of 2,877 and the default CV (0.2), N_{MIN} for the Bristol Bay stock of beluga whales is 2,435.

Current Population Trend

A survey program involving replicate aerial counts using standardized methods was conducted during 1993-2005. Data from 28 complete counts of Kvichak and Nushagak bays made in good or excellent survey conditions were analyzed, and results showed that the population had increased by 65% over the 12-year period (Lowry et al. 2008).

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

The estimated rate of increase in abundance of belugas in Bristol Bay during 1993-2005 was 4.8% per year (95% CI = 2.1%-7.5%; Lowry et al. 2008). This estimate exceeds the default cetacean maximum net productivity rate (R_{MAX}) of 4% (Wade and Angliss 1997). It is currently not clear why this stock should be increasing at such a high rate, but possibilities include recovery from research kills in the 1960s, a reduction in subsistence harvests, and a delayed response to increases in salmon stocks (Lowry et al. 2008).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the potential biological removal (PBR) is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: $PBR = N_{MIN} \times 0.5R_{MAX} \times F_R$. As this stock is known to be increasing (Lowry et al. 2008), the recovery factor (F_R) is 1.0 (Wade and Angliss 1997, DeMaster 1997; see discussion under PBR for the eastern Bering Sea stock). Thus, for the Bristol Bay stock of beluga whales, PBR = 58 animals (2,435 × 0.024 × 1.0).

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

New Serious Injury Guidelines

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an "*injury that is more likely than not to result in mortality.*" Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

Fisheries Information

Three different commercial fisheries that could have interacted with beluga whales in Bristol Bay were monitored for incidental take by fishery observers during 1990-1997: Bering Sea (and Aleutian Islands) groundfish trawl, longline, and pot fisheries. Observers did not report any mortality or serious injury of beluga whales incidental to these groundfish fisheries.

Observers have never monitored the Bristol Bay commercial salmon set gillnet and drift gillnet fisheries which combined had 2,845 active permits in 2010. These fisheries are known to have caused mortality of beluga whales from this stock in the past (Frost et al. 1984). However, they have never been monitored by an observer program so there is no reliable information on the number of animals that have been or are being taken.

There is substantial effort in a subsistence gillnet fishery for salmon in Bristol Bay. Belugas are occasionally entangled and killed in this fishery, but there is no established protocol for non-commercial takes to be reported to NMFS. During 2008-2012, one mortality of a beluga in a subsistence salmon net was reported to the stranding network (Table 1). Based on this stranding report, the minimum annual mortality estimate due to fishery interactions over the 5-year period from 2008 to 2012 was 0.2 per year. However, this figure is clearly an underestimate because subsistence fishers are not required to report marine mammal takes, and the commercial fishery has not been observed. Also, it should be noted that in this region of western Alaska, belugas taken incidental to the personal-use or commercial salmon fisheries may be used by Alaska Natives for subsistence and may be included in the subsistence harvest data reported below.

A reliable estimate of the mortality rate incidental to commercial fisheries is currently unavailable.

Table 1. Summary of the Bristol Bay stock of beluga whale mortalities and serious injuries by year and type reported to the Alaska Regional Office, marine mammal stranding database, for the 2008-2012 period (Allen et al. 2014, Helker et al. 2015). Only cases of serious injury were recorded in this table; animals with non-serious injuries have been excluded.

Cause of Injury	2008	2009	2010	2011	2012	Mean Annual Mortality
Entangled in Bristol Bay subsistence king salmon set gillnet	0	1	0	0	0	0.2
Minimum total annual mortality						0.20

Subsistence/Native Harvest Information

Data on the subsistence take of beluga whales from the Bristol Bay stock is provided by the ABWC. The most recent subsistence harvest estimates for the stock are provided in Table 2 (Alaska Beluga Whale Committee, 18 February 2010). These data show that the annual subsistence take by Alaska Natives averaged 24 belugas from the Bristol Bay stock during the 5-year period 2008-2012.

Table 2. Summary of the Alaska Native subsistence harvest from the Bristol Bay stock of beluga whales, 2008-2012. N/A indicates the data are not available.

Year	Reported total number landed
2008	19
2009	20
2010	27
2011	22
2012	32
Mean annual number of animals landed (2008-2012)	24.0

STATUS OF STOCK

It is unknown whether the U.S. commercial fishery-related mortality level is insignificant and approaching zero mortality and serious injury rate (i.e., 10% of PBR; less than 5.8 per year) because a reliable estimate of the mortality rate incidental to commercial fisheries is currently unavailable. Bristol Bay beluga whales are not designated as "depleted" under the MMPA or listed as "threatened" or "endangered" under the Endangered Species Act. Based on currently available data, the estimated annual rate of human-caused mortality and serious injury (24 + 0.2 = 24.2) is not known to exceed the PBR (58). Because the population size has been increasing at a rate near R_{MAX}, the sum of human impacts on the population are not a problem at this point (Lowry et al. 2008). Therefore, the Bristol Bay stock of beluga whales is not classified as a strategic stock. However, as noted previously, the estimate of fisheries-related mortality is unreliable and likely to be underestimated.

HABITAT CONCERNS

Evidence indicates that the Arctic climate is changing significantly and that one result of the change is a reduction in the extent of sea ice in most regions of the Arctic (ACIA 2004, Johannessen et al. 2004). These changes are likely to affect marine mammal species in the Arctic. Ice-associated animals, such as the beluga whale, may be sensitive to changes in arctic weather, sea-surface temperatures, or ice extent, and the concomitant effect on prey availability. Currently, there are insufficient data to make reliable predictions of the effects of arctic climate change on beluga whales, but Laidre et al. (2008) and Heide-Jørgensen (2010) concluded that on a worldwide basis belugas were likely to be less sensitive to climate change than other arctic cetaceans because of their wide distribution and flexible behavior. Increased human activity in the Arctic, including increasing oil and gas exploration and development, and increased nearshore development, have the potential to impact habitat for beluga whales (Moore et al. 2000, Lowry et al. 2006), but predicting the type and magnitude of the impacts is difficult at this time. Because the population size has been increasing (Lowry et al. 2008), habitat impacts most likely have been minimal during recent years.

BELUGA WHALE (*Delphinapterus leucas*): Cook Inlet Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Beluga whales are distributed throughout seasonally ice-covered arctic and subarctic waters of the Northern Hemisphere (Gurevich 1980) and are closely associated with open leads and polynyas in ice-covered regions (Hazard 1988). In Alaska, depending on season and region, beluga whales may occur in both offshore and coastal waters, with summer concentrations in upper Cook Inlet (north of the East and West Forelands), Bristol Bay, the eastern Bering Sea (i.e., Yukon Delta and Norton Sound), eastern Chukchi Sea (including Kotzebue Sound), and Beaufort Sea (Mackenzie River Delta) (Hazard 1988). Seasonal distribution is affected by ice cover, tidal conditions, access to prey, temperature, and human interaction (Lowry 1985). Satellite transmitters on whales from the Beaufort Sea, Eastern Chukchi Sea, and Eastern Bering Sea stocks show monthly home ranges that are relatively distinct among these populations' summering areas and autumn migratory routes (e.g., Hauser et al. 2014). Beluga whales satellite-tagged in Bristol Bay (Quakenbush 2003) and Cook Inlet (Hobbs et al. 2005, Goetz et al. 2012a, Shelden et al. 2015a) remained in those respective areas throughout the year, i.e., they are non-migratory.

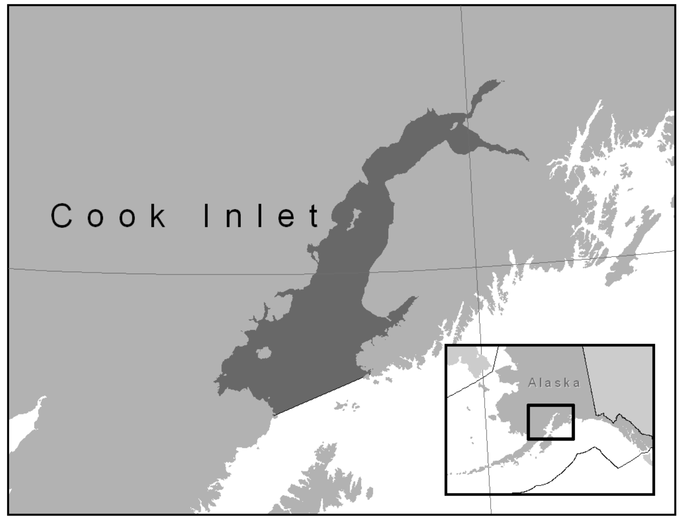

Figure 1. Approximate distribution of beluga whales in Cook Inlet.

Beluga whale stock structure was based on the Dizon et al. (1992) phylogeographic approach: 1) Distributional data: geographic distribution discontinuous (Frost and Lowry 1990); 2) Population response data: possible extirpation of local populations, distinct population trends among regions occupied in summer; 3) Phenotypic data: unknown; and 4) Genotypic data: mitochondrial DNA analyses indicate distinct differences among populations in summering areas (O'Corry-Crowe et al. 2002). Based on this information, five beluga whale stocks are recognized within U.S. waters: 1) Cook Inlet (Fig. 1), 2) Bristol Bay, 3) Eastern Bering Sea, 4) Eastern Chukchi Sea, and 5) Beaufort Sea.

During ice-free months, Cook Inlet beluga whales are typically concentrated near river mouths (Rugh et al. 2010). The fall-winter-spring distribution of this stock is not fully determined; however, there is evidence that most whales in this population inhabit upper Cook Inlet year-round (Hansen and Hubbard 1999, Rugh et al. 2004, Lammers et al. 2013, Shelden et al. 2015a, Castellote et al. 2015). During summers from 1999 to 2002, satellite tags were attached to a total of 18 beluga whales to determine their distribution through the fall and winter months (Hobbs et al. 2005, Goetz et al. 2012a, Shelden et al. 2015a). Tags on four of these whales transmitted for only a few days and transmissions stopped in September for another whale (Shelden et al. 2015a). Ten tags transmitted whale locations from September through November and, of those, three transmitted into January, three into March, and one into late May (Hobbs et al. 2005, Goetz et al. 2012a, Shelden et al. 2015a). All tagged beluga whales remained in Cook Inlet, primarily in upper inlet waters (Shelden et al. 2015a).

A review of all marine mammal surveys and anecdotal sightings in the northern Gulf of Alaska between 1936 and 2000 found only 28 beluga whale sightings, indicating that very few beluga whales occurred in the Gulf of Alaska outside Cook Inlet (Laidre et al. 2000). A small number of beluga whales (fewer than 20 animals: Laidre et al. 2000, Lucey et al. 2015, O'Corry-Crowe et al. 2015) are regularly observed in Yakutat Bay. Based on genetic analyses, traditional ecological knowledge (TEK), and observations by fishers and others reported year-round, the Yakutat beluga whales likely represent a small, resident group that is reproductively separated from Cook Inlet (Lucey et al. 2015, O'Corry-Crowe et al. 2015). Furthermore, this group in Yakutat appears to be showing signs of inbreeding and low diversity due to their isolation and small numbers (O'Corry-Crowe et al. 2015). Although the beluga whales in Yakutat Bay are not included in the Cook Inlet Distinct Population Segment (DPS) of beluga whales under the Endangered Species Act (ESA), they are considered part of the depleted Cook Inlet stock under the Marine Mammal Protection Act (MMPA) (50 CFR 216.15; 75 FR 12498, 16 March 2010). Notice-and-comment rulemaking procedures would be required to change the NMFS regulatory definition under the MMPA. Thus, Yakutat Bay beluga whales remain designated as depleted and part of the Cook Inlet stock.

POPULATION SIZE

Aerial surveys during June documenting the early summer distribution and abundance of beluga whales in Cook Inlet were conducted by NMFS each year from 1993 to 2012 (Rugh et al. 2000, 2005; Shelden et al. 2013), after which NMFS began biennial surveys in 2014 (Shelden et al. 2015b) (Fig. 2). NMFS changed to a biennial survey schedule after detailed analysis showed that there would be little reduction in assessment quality (Hobbs 2013).

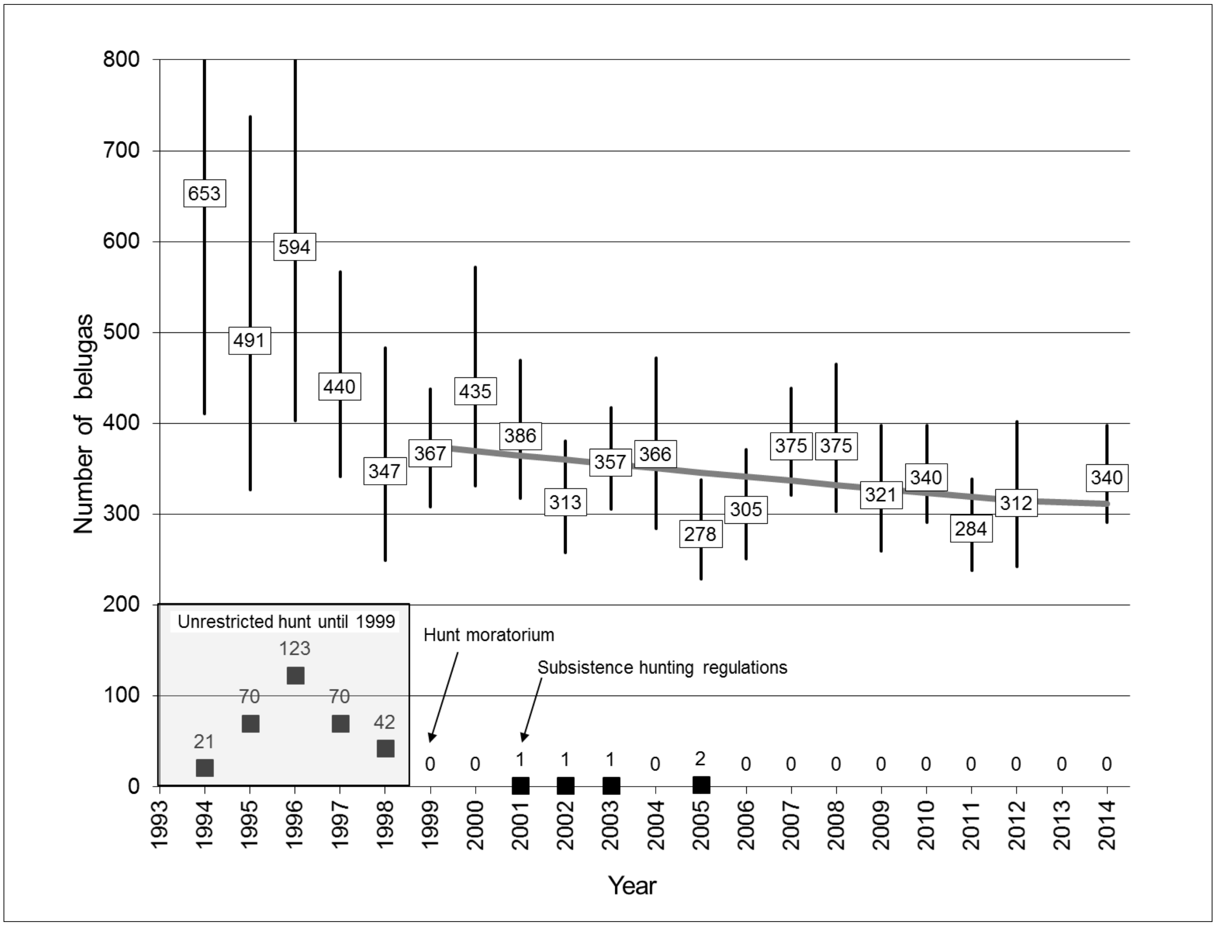

Figure 2. Annual abundance estimates of beluga whales in Cook Inlet, Alaska, 1994-2014 (Hobbs et al. 2015a, Shelden et al. 2015b). Black squares show reported removals (landed plus struck and lost) during the Alaska Native subsistence hunt. A struck and lost average was calculated by the Cook Inlet Marine Mammal Council (CIMMC) and hunters for 1996, 1997, and 1998. Black vertical bars depict plus and minus one standard error for each abundance estimate (box label). From 1999 to 2014, the rate of decline (gray trend line) is 1.3% per year (with a 97% probability that the growth rate is declining), while the 10-year trend (2004-2014) is -0.4% per year (with a 76% probability of declining).

The abundance estimate for beluga whales in Cook Inlet is based on counts by aerial observers and video analysis of whale groups. Paired, independent observers count each whale group while video is collected during each counting pass. Each count is corrected for subsurface animals (availability correction) and animals at the surface that were missed (sightability correction) based on an analysis of the video tapes (Hobbs et al. 2000). When video counts are not available, observers' counts are corrected for availability and sightability using a regression of counts and an interaction term with an encounter rate against the video count estimates (Hobbs et al. 2000). The estimate of the abundance equation variance was revised using the squared standard error of the average for the abundance estimates in place of the abundance estimate variance and the measurement error (Hobbs et al. 2015a). This reduced the coefficients of variation (CVs) by almost half. The June 2014 survey resulted in an estimate of 340 whales (CV = 0.08) (Shelden et al. 2015b). This estimate is more than the estimate of 312 beluga whales for 2012; however, it falls within the statistical variation around the recent trend line and probably represents variability of the estimation process rather than an increase in the population from 2012 to 2014. Annual abundance estimates based on aerial surveys of Cook Inlet beluga whales during the most recent 3-survey period were 284 (2011), 312 (2012), and 340 (2014), resulting in an average abundance estimate for this stock of 312 (CV = 0.10) beluga whales. Data from an abundance estimate survey in June 2016 will be included in a future Stock Assessment Report.

Minimum Population Estimate

The minimum population estimate (N_{MIN}) is calculated according to Equation 1 from the potential biological removal (PBR) guidelines (Wade and Angliss 1997). Thus, $N_{MIN} = N/\exp(0.842\times[\ln(1+[CV(N)]^2)]^{½})$. Using the 3-survey average population estimate (N) of 312 whales and an associated CV(N) of 0.10, N_{MIN} for the Cook Inlet beluga whale stock is 287 beluga whales.

Current Population Trend

The corrected annual abundance estimates for the period 1994-2014 are shown in Figure 2. From 1999 to 2014, the rate of decline was 1.3% (SE = 0.7%) per year, with a 97% probability that the growth rate is declining (i.e., less than zero), while the 10-year trend (2004-2014) is -0.4% per year (with a 76% probability of declining) (Shelden et al. 2015b).

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

A reliable estimate of the maximum net productivity rate is currently not available for the Cook Inlet beluga whale stock. Hence, until additional data become available, the cetacean maximum theoretical net productivity rate (R_{MAX}) of 4% is recommended to be employed for this stock (Wade and Angliss 1997). This figure is similar to the 4.8% annual increase that has been documented for the Bristol Bay beluga whale stock (Lowry et al. 2008).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized MMPA, the PBR was defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: $PBR = N_{MIN} \times 0.5R_{MAX} \times F_R$. In past Stock Assessment Reports for this stock, from 1998 through 2005, NMFS calculated a value for PBR. Given the low abundance relative to historical estimates and low known levels of human-caused mortality since 1999, this stock should have begun to grow at or near its maximum productivity rate (2-6%), but for unknown reasons the Cook Inlet beluga whale stock is not increasing. Because this stock does not meet the assumptions inherent to the use of the PBR, NMFS has decided it would not be appropriate to calculate a maximum number that may be removed while allowing the population to achieve its Optimum Sustainable Population. Thus, the PBR for this stock is undetermined.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Detailed information (including observer programs, observer coverage, and observed incidental takes of marine mammals) for federally-managed and state-managed U.S. commercial fisheries in Alaska waters is presented in Appendices 3-6 of the Alaska Stock Assessment Reports.

The estimated minimum average annual mortality and serious injury rate incidental to U.S. commercial fisheries is unknown, although probably low, because only one known beluga whale mortality due to fishery interaction has been reported in the past 10 years.

One entanglement in a subsistence fishery was reported to the NMFS Alaska Region on 7 May 2012 by a fisherman who reported a juvenile beluga whale entangled in his salmon fishing net near Kenai, Alaska. The beluga whale was dead and necropsy findings indicated that it was in poor health prior to entanglement and the cause of death was drowning. However, it was not determined whether the beluga whale died before or after the net entanglement.

Alaska Native Subsistence/Harvest Information

Subsistence harvest of beluga whales in Cook Inlet is important to one local village (Tyonek) and the Alaska Native subsistence hunter community in Anchorage. Between 1993 and 1998, the annual subsistence take ranged from 17 to more than 123 animals (Fig. 2), including beluga whales struck and lost (NMFS 2015).

Following a significant decline in Cook Inlet beluga whale abundance estimates between 1994 and 1998, the Federal government took actions to conserve, protect, and prevent further declines in the abundance of these whales. In 1999 and 2000, Public Laws 106-31 and 106-553 established a moratorium on Cook Inlet beluga whale harvests except for subsistence hunts conducted under cooperative agreements between NMFS and affected Alaska Native organizations. A cooperative agreement, also referred to as a co-management agreement, was not signed in 1999, so harvest was not authorized in 1999 and 2000. Harvests from 2001 through 2004 were conducted under harvest regulations (69 FR 17973, 6 April 2004) following an interim harvest management plan developed through an administrative hearing. Three beluga whales were harvested in Cook Inlet under this interim harvest plan. In August 2004, an administrative hearing was held to create a long-term harvest plan. An interim plan would have allowed up to eight whales to be harvested between 2005 and 2009 (https://alaskafisheries.noaa.gov/pr/interim-harvest-plan, accessed December 2016). Two whales were taken in 2005 and no takes were authorized in 2006 and later under this agreement. A long-term harvest plan (https://alaskafisheries.noaa.gov/pr/cib-long-term-harvest-management, accessed December 2016) established allowable harvest levels for a 5-year period, based on the average abundance in the previous 5-year period and the growth rate during the previous 10-year period. A harvest is not allowed if the previous 5-year average abundance is less than 350 beluga whales. Under the long-term harvest plan, the 5-year average abundance during the first review period 2003-2007 was 336 whales and a harvest would not have been allowed during the subsequent 5-year period 2008-2012 (73 FR 60976, 15 October 2008), so the cooperative agreement was not signed and no hunt occurred. The average abundance of Cook Inlet beluga whales remained below 350 whales during the second review period 2008-2012; therefore, a harvest is not allowed for the current 5-year period 2013-2017.

Other Mortality

Mortality related to live stranding events, where a group of beluga whales becomes stranded as the tide recedes has been reported in Cook Inlet (Table 1). Improved record-keeping was initiated in 1994, and reports have since included the number of beachcast carcasses and live stranded beluga whales (NMFS 2015). Most whales involved in a live stranding event survive, although some deaths may be missed by observers if whales die later from live stranding-related injuries (Vos and Shelden 2005, Burek-Huntington et al. 2015). Between 2009 and 2014, there were approximately 145-150 whales involved in nine known live stranding events, with two deaths reported (Table 1). In 2014, necropsy results from two dead whales found in Turnagain Arm suggested the whales had recently live stranded and that the live stranding may have contributed to their deaths. No live stranding events were reported to NMFS in the period prior to the discovery of these whales, suggesting that not all strandings are observed (Table 1). Most live strandings occur in Knik Arm or Turnagain Arm, both of which are shallow and dangerous waterways. Turnagain Arm has the largest tidal range in the U.S., with a mean of 9.2 m (30 ft).

Table 1. Cook Inlet beluga whale strandings investigated by NMFS during 2009-2014 (NMFS 2015).

Year	Beachcast carcasses	Number of beluga whales per live stranding event (number of associated known or suspected resulting deaths)
2009	4	16-21 (0)
2010	5	11(0), 2(0)
2011	3	2(0)
2012	3	12(0), 23(0), 3(0)
2013	5	0
2014	10	76+ (0), unknown (2)
Total	30	145-150 (2)

Another source of beluga whale mortality in Cook Inlet is predation by mammal-eating killer whales. Killer whale sightings were not well documented and were likely rare in the upper inlet prior to the mid-1980s. From 1982 through 2014, 29 killer whale sightings in upper Cook Inlet (north of the East and West Forelands) were reported to NMFS. It is not known which of these were mammal-eating killer whales (i.e., transient killer whales) that might prey on beluga whales and which were fish-eating killer whales (i.e., resident killer whales) that would not prey on beluga whales. Between 9 and 12 beluga whale deaths during this time were suspected to be a direct result of killer whale predation (NMFS 2015). The last confirmed killer whale predation of a beluga whale in Cook Inlet occurred in 2008 in Turnagain Arm. In June 2010, a beluga whale carcass found near Point Possession was speculated to have injuries associated with killer whale predation; however, the poor condition of the beluga whale carcass prevented a positive determination of cause of death. From 2011 through 2014, NMFS received no reports of killer whale sightings in upper Cook Inlet or possible predation attempts.

A photo-identification study (Kaplan et al. 2009) did not find any instances where Cook Inlet beluga whales appeared to have been entangled in, or to have otherwise interacted with, fishing gear. However, in 2010, a beluga whale with a rope entangled around its girth was observed and photo-documented during May through August. The same whale was photographed in July and August 2011, August 2012, and July 2013, still entangled in the rope line (McGuire et al. 2014). This whale is currently considered to have a non-serious injury (Helker et al. 2016).

Between 1998 and 2013, 38 necropsies were performed on beluga whale carcasses (23% of the known stranded carcasses during this time period) (Burek-Huntington et al. 2015). The sample included adults (n = 25), juveniles (n = 6), calves (n = 3), and aborted fetuses (n = 4). When possible, a primary cause of death was noted along with contributing factors. Cause of death was unknown for 29% of the necropsied carcasses. Cause of death in the others was attributed to various types of trauma (18%), perinatal mortality (13%), mass stranding (13%), single stranding (11%), malnutrition (8%), or disease (8%). Several animals had mild to moderate pneumonia, kidney disease, and/or stomach ulcers that likely contributed to their cause of death.

STATUS OF STOCK

The Cook Inlet beluga whale stock was designated as depleted under the MMPA (65 FR 34590, 21 May 2000), and on 22 October 2008, NMFS listed Cook Inlet beluga whales as endangered under the ESA (73 FR 62919, 22 October 2008). Therefore, the Cook Inlet beluga whale stock is considered a strategic stock. There are no observers on fisheries in Cook Inlet and there have been no voluntary reports of beluga whale mortality or serious injury in U.S. commercial fisheries. The mean annual mortality and serious injury rate for commercial fisheries is likely low, although the incompleteness of the data for commercial fisheries operating within the range of Cook Inlet beluga whales is a concern for this small population. NMFS convened a Recovery Team to aid in the development of a Recovery Plan for Cook Inlet beluga whales; the Recovery Team's plan was finalized in December 2016 (NMFS 2016).

HABITAT CONCERNS

Beluga whale critical habitat includes two geographic areas of marine habitat in Cook Inlet that comprise 7,800 km^2 (3,013 mi^2), excluding waters by the Port of Anchorage (76 FR 20180, 11 April 2011). Based on available information from aerial surveys, tagged whales, and opportunistic sightings, beluga whales remain within the inlet year-round. Since 2000, most whales have been found in the upper inlet north of the East and West Forelands during the summer months (Rugh et al. 2010) and in the fall as well (Rugh et al. 2004), with tagged whales travelling between the lower and upper inlet and offshore waters >10 m deep during the winter (Hobbs et al. 2005, Goetz et al. 2012a, Shelden et al. 2015a, Castellote et al. 2015). Whether this contracted distribution is a result of changing habitat (Moore et al. 2000), prey concentration, or predator avoidance (Shelden et al. 2003) or can simply be explained as the contraction of a reduced population into a small number of preferred habitat areas (Goetz et al. 2007, 2012b) is unknown. With the limited range of this stock, Cook Inlet beluga whales are vulnerable to human-induced or natural perturbations within their preferred habitat. Goetz et al. (2012b) modeled habitat preferences using NMFS' 1994-2008 abundance survey data. In large areas, such as the Susitna Delta and Knik Arm, they found a high probability of beluga whale presence in larger group sizes. Beluga whale presence also increased closer to rivers with Chinook salmon (*Oncorhynchus tshawytscha*) runs, such as the Susitna River. The Susitna Delta also supports two major spawning migrations of a small, schooling smelt (eulachon, *Thaleichthys pacificus*) in May and July. Threats that have the potential to impact this stock and its habitat include the following: changes in prey availability due to natural environmental variability, ocean acidification, and commercial fisheries; climatic changes affecting habitat; predation by killer whales; contaminants; noise; ship strikes; waste management; urban runoff; construction projects; and physical habitat modifications that may occur as Cook Inlet becomes increasingly urbanized (Moore et al. 2000, Lowry et al. 2006, Hobbs et al. 2015b). Planned projects that may alter the physical habitat of Cook Inlet include highway improvements; mine construction and operation; oil and gas exploration and development; and expansion and improvements to ports.

NARWHAL (*Monodon monoceros*): Unidentified Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Narwhals are found year-round north of 60°N, primarily in the waters of the Canadian Arctic, Hudson Bay, Baffin Bay, Davis Strait, West Greenland, East Greenland, and the waters around Svalbard, Franz Josef Land, and Novaya Zemyla (Gjertz 1991, Jefferson et al. 2012, Higdon and Ferguson 2014) While large aggregations are found in eastern Arctic waters, they rarely occur in the western Arctic, namely the East Siberian, Bering, Chukchi, and Beaufort seas (COSEWIC 2004) (Fig. 1). The three recognized narwhal populations are based on geographic separation: Baffin Bay, Hudson Bay, and East Greenland (DFO 1998a, 1998b; COSEWIC 2004). The Baffin Bay population summers in the waters along West Greenland and the Canadian High Arctic and overwinters in Baffin Bay and Davis Strait (Koski and Davis 1994, Dietz et al. 2001, Heide-Jørgensen et al. 2003). Narwhals from the northwest Hudson Bay population are thought to overwinter in eastern Hudson Strait (Richard 1991). The East Greenland population is believed to winter in the pack ice between eastern Greenland and Svalbard (Dietz et al. 1994). A poorly described population inhabits the waters around Svalbard, Franz Josef Land, and Novaya Zemyla (Gjertz 1991, Lydersen et al. 2007). The amount of interchange between these populations is unknown. Populations are defined for management purposes, and these designated populations may actually consist of several populations (COSEWIC 2004). Population definition based on molecular genetic studies of narwhals remains unresolved at this time due to extremely low genetic variability within and among management stocks (Palsbøll et al. 1997; de March et al. 2001, 2003).

Figure 1. Potential distribution of narwhals in arctic waters based on extralimital sightings and strandings (George and Suydam, unpubl. ms.; Reeves and Tracey 1980; COSEWIC 2004).

Local observations and traditional ecological knowledge are the primary source for any data on narwhals in Alaska waters, dating back to the 1800s (Bee and Hall 1956; Geist et al. 1960; Noongwook et al. 2007; George and Suydam, unpubl. ms.). The earliest record dates back to 1874, with most occasional sightings occurring around the area east of Point Barrow (Scammon 1874, Ray and Murdoch 1885, Turner 1886, Nelson and True 1887, Murdoch 1898, MacFarlane 1905, Dufresne 1946, Anderson 1947, Bee and Hall 1956, Geist et al. 1960). Narwhal occurrences are reported in Bee and Hall (1956) from Point Barrow to the Colville River Delta. Ljungblad et al. (1983) reported a sighting of two male narwhals northwest of King Island in the Bering Sea, during a systematic scientific survey. Sightings have occurred in Russian waters of the northern Chukchi Sea (Yablokov and Bel'kovich 1968, Reeves and Tracey 1980). George and Suydam (unpubl. ms.) summarized observations from Alaska Native hunters during eight sightings of narwhals in the Chukchi and Beaufort seas between 1989 and 2008. Of these records, seven sightings were live animals totaling 11-12 individuals; one record was of a beachcast narwhal tusk at Cape Sabine. Four of the seven live narwhal sightings consisted of mixed groups of belugas and narwhals (George and Suydam, unpubl. ms.).

Several narwhal specimens collected in Alaska have been documented. Murie (1936) reported a single tusk that was found on a sandbar at Cape Chibukak, St. Lawrence Island. Huey (1952) reported on a specimen collected near Cape Halkett, Harrison Bay, at the mouth of the Colville River, in the Beaufort Sea. Three additional specimen records from various locations were documented in Geist et al. (1960): one specimen was found on the beach of Kiwalik Bay (Kotzebue Sound), another was initially sighted alive at the mouth of the Caribou River in Nelson Lagoon (Alaska Peninsula) but later died, and a third specimen was a tusk found on a beach near Wainwright, on the Chukchi Sea.

It is believed that these incidental narwhal records that occurred in the Beaufort, Chukchi, and Bering seas and Bristol Bay are whales from the Baffin Bay population, which are known to move into the Canadian Arctic Archipelago and as far north and west as ice conditions will permit (COSEWIC 2004). However, there is no evidence or method to confirm this. There are insufficient data to apply the phylogeographic approach to stock structure (Dizon et al. 1992) for narwhals.

POPULATION SIZE

Reliable estimates of abundance for narwhals in Alaska are currently unavailable.

Minimum Population Estimate

At this time, it is not possible to produce a reliable minimum population estimate (N_{MIN}) for this stock, as current estimates of abundance are unavailable.

Current Population Trend

At present, reliable data on trends in population abundance are unavailable.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

A reliable estimate of the maximum net productivity rate is currently unavailable for narwhals in Alaska. Hence, until additional data become available, it is recommended that the cetacean maximum theoretical net productivity rate (R_{MAX}) of 4% be employed (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the potential biological removal (PBR) is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: $PBR = N_{MIN} \times 0.5R_{MAX} \times F_R$. The recovery factor ($F_R$) for these stocks is 0.5, the value for cetacean stocks with unknown population status (Wade and Angliss 1997). However, in the absence of a reliable estimate of a minimum abundance, the PBR for this stock is unknown.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

There are no U.S. commercial fisheries operating within the normal range of narwhals in Alaska. There are no observer program records of narwhal mortality or serious injury incidental to commercial fisheries in Alaska. The estimated mean annual mortality and serious injury rate incidental to U.S. commercial fisheries is zero.

Subsistence/Native Harvest Information

There is no known subsistence harvest of narwhals by Alaska Natives.

STATUS OF STOCK

Narwhals are not designated as depleted under the MMPA or listed as threatened or endangered under the Endangered Species Act. Reliable estimates of the minimum population, population trend, PBR, and status of the stock relative to its Optimum Sustainable Population are currently not available. There are no federal or state commercial fisheries operating in the marine waters of the Arctic, and there are no reports of mortality or serious injury of narwhals in Alaska, therefore, the mean annual mortality and serious injury rate is considered insignificant and approaching zero. The estimated annual rate of human-caused mortality and serious injury is believed to be zero for this stock. Thus, the Unidentified stock of narwhals in Alaska is not classified as strategic.

HABITAT CONCERNS

Narwhals tend to prefer heavy ice cover in the winter and animals studied in Baffin Bay chose areas associated with high concentrations of Greenland halibut, which correspond to the coldest bottom temperatures (Laidre et al. 2004b; Laidre and Heide-Jørgensen 2005b, 2011). Narwhals wintering in Hudson Strait are also found in ice-covered areas of deep water, but the maximum depths are much shallower than the areas used by narwhals in Baffin Bay (Laidre et al. 2003, 2004a). As the Arctic warms through climate change, ice cover will be thinner, form later, melt earlier, and be less predictable. A warming Arctic will also see changes in ocean currents which create conditions that support concentrations of winter narwhal prey species, such as Greenland halibut. This may result in a shift in distribution of narwhals and their prey, requiring changes in migration timing, as well as destinations

(Kovaks and Lydersen 2008; Laidre et al. 2008, 2010, 2015). An increased risk of ice entrapment is associated with the changes in sea-ice formation, because seasonal cues for the timing of freeze up have changed and because later freezing may result in large expanses of open water freezing at one time (Heide-Jørgensen et al. 2002, Heide-Jørgensen and Laidre 2004, Laidre and Heide-Jørgensen 2005a, Laidre et al. 2012).

In addition to changing sea ice, narwhals are threatened by a number of changes associated with warming of the Arctic, including increased shipping and development, which adds noise; risk of pollution and ship strikes; risk of predation by killer whales (*Orcinus orca*) (Laidre et al. 2006); shifts in prey abundance and distribution; and exposure to novel diseases (Laidre et al. 2015).

KILLER WHALE (*Orcinus orca*): Eastern North Pacific Alaska Resident Stock

NOTE – NMFS has preliminary genetic information on killer whales in Alaska which indicates that the current stock structure of killer whales in Alaska needs to be reassessed. NMFS is evaluating the new genetic information. In the interim, new information on killer whale mortality levels is provided within this report. A complete revision of the killer whale stock assessments will be postponed until the stock structure evaluation is completed and any new stocks are identified.

STOCK DEFINITION AND GEOGRAPHIC RANGE

Killer whales have been observed in all oceans and seas of the world (Leatherwood and Dahlheim 1978). Although reported from tropical and offshore waters, killer whales occur at higher densities in colder and more productive waters of both hemispheres, with the greatest densities found at high latitudes (Mitchell 1975, Leatherwood and Dahlheim 1978, Forney and Wade, 2006). Killer whales are found throughout the North Pacific. Along the west coast of North America, killer whales occur along the entire Alaska coast (Braham and Dahlheim 1982), in British Columbia and Washington inland waterways (Bigg et al. 1990), and along the outer coasts of Washington, Oregon, and California (Green et al. 1992; Barlow 1995, 1997; Forney et al. 1995). Seasonal and year-round occurrence has been noted for killer whales throughout Alaska (Braham and Dahlheim 1982) and in the intracoastal waterways of British Columbia and Washington State, where whales have been labeled as "resident," "transient," and "offshore" type killer whales (Bigg et al. 1990, Ford et al. 2000, Dahlheim et al. 2008) based on aspects of morphology, ecology, genetics, and behavior (Ford and Fisher 1982; Baird and Stacey 1988; Baird et al. 1992; Hoelzel et al. 1998, 2002; Barrett-Lennard 2000; Dahlheim et al. 2008). Through examination of photographs of recognizable individuals and pods, movements of whales between geographical areas have been documented. For example, whales identified in Prince William Sound have been observed near Kodiak Island (Matkin et al. 1999) and whales identified in Southeast Alaska have been observed in Prince William Sound, British Columbia, and Puget Sound (Leatherwood et al. 1990, Dahlheim et al. 1997). Movements of killer whales between the waters of Southeast Alaska and central California have also been documented (Goley and Straley 1994, Black et al. 1997, Dahlheim and White 2010).

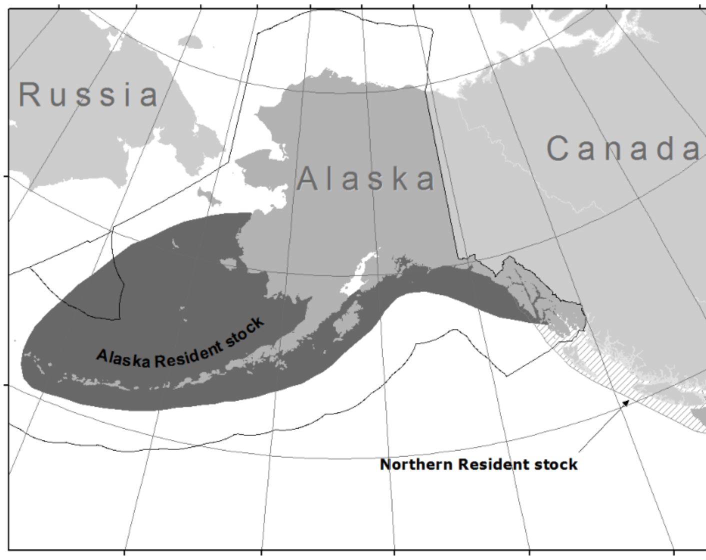

Figure 1. Approximate distribution of resident killer whales in the eastern North Pacific (shaded areas). The distribution of resident and transient killer whale stocks in the eastern North Pacific largely overlap (see text).

Several studies provide evidence that the resident, offshore, and transient ecotypes are genetically distinct in both mtDNA and nuclear DNA (Hoelzel and Dover 1991; Hoelzel et al. 1998, 2002; Barrett-Lennard 2000). A recent global genetic study of killer whales using the entire mitochondrial genome found that some killer whale ecotypes represent deeply divergent evolutionary lineages and warrant elevation to species or subspecies status (Morin et al. 2010). In particular, estimates from mitogenome sequence data indicate that transient killer whales diverged from all other killer whale lineages ~700,000 years ago. In light of these differences, the Society for Marine Mammalogy's Committee on Taxonomy currently recognizes the resident and transient North Pacific ecotypes as un-named *Orcinus orca* subspecies (Committee on Taxonomy 2012). In recognition of its status as an un-named subspecies or species, some researchers now refer to transient-type killer whales as Bigg's killer whales (e.g., Ford 2011, Riesch et al. 2012), in tribute to the late Dr. Michael Bigg.

Genetic differences have also been found between populations within the transient and resident ecotypes (Hoelzel et al. 1998, 2002; Barrett-Lennard 2000). Within the resident ecotype, association data were used to describe three separate populations in the North Pacific: Southern Residents, Northern Residents, and Alaska Residents (Bigg et al. 1990; Ford et al. 1994, 2000; Dahlheim et al. 1997; Matkin et al. 1999). In previous stock assessment reports, the Alaska and Northern Resident populations were considered one stock. Acoustic data (Ford 1989, 1991; Yurk et al. 2002) and genetic data (Hoelzel et al. 1998, 2002; Barrett-Lennard 2000) have now confirmed that these three units represent discrete populations. The Southern Resident population is found in summer primarily in waters of Washington state and southern British Columbia and has never been seen to associate with other resident stocks. The Northern Resident population is found in summer primarily in central and northern British Columbia. Members of the Northern Resident population have been documented in southeastern Alaska; however, they have not been seen to intermix with Alaska Residents (Fig. 1). Alaska Resident whales are found from southeastern Alaska to the Aleutian Islands and Bering Sea. Intermixing of Alaska Residents have been documented among the three areas, at least as far west as the eastern Aleutian Islands.

Based on data regarding association patterns, acoustics, movements, and genetic differences, eight killer whale stocks are now recognized within the Pacific U.S. EEZ: 1) the Alaska Resident stock - occurring from southeastern Alaska to the Aleutian Islands and Bering Sea, 2) the Northern Resident stock - occurring from Washington State through part of southeastern Alaska, 3) the Southern Resident stock - occurring mainly within the inland waters of Washington State and southern British Columbia, but also in coastal waters from southeastern Alaska through California, 4) the Gulf of Alaska, Aleutian Islands, and Bering Sea Transient stock - occurring mainly from Prince William Sound through the Aleutian Islands and Bering Sea, 5) the AT1 Transient stock - occurring in Alaska from Prince William Sound through the Kenai Fjords, 6) the West Coast transient stock - occurring from California through southeastern Alaska, 7) the Offshore stock - occurring from California through Alaska, and 8) the Hawaiian stock. Transient whales in Canadian waters are considered part of the West Coast Transient stock. The Stock Assessment Reports for the Alaska Region contain information concerning all the killer whale stocks except the Hawaiian and Offshore stocks.

Resident killer whales ranging from Southeastern Alaska to Kodiak Island have been observed in regular association during multipod encounters since 1984 (Matkin et al. 2010). Tagging data also indicates the range of killer whales seen in these aggregations extends from Southeastern Alaska to south of Kodiak Island (Matkin et al. 2010). Although recent studies have documented movements of Alaska Resident killer whales from the Bering Sea into the Gulf of Alaska as far north as southern Kodiak Island, none of these whales have been photographed further north and east in the Gulf of Alaska where regular photoidentification studies have been conducted since 1984 (P. Wade, pers. comm., MML-AFSC, Seattle, WA, 10 December 2012; unpublished data; Matkin et al. 2010). The resident-type killer whales encountered in western Alaska possibly belong to groups that are distinct from the groups of resident killer whales in the Gulf of Alaska because no call syllables or call patterns (sequence of syllables) between groups were found to match (Matkin et al. 2007).

POPULATION SIZE

The Alaska Resident stock includes killer whales from southeastern Alaska to the Aleutian Islands and Bering Sea. Preliminary analysis of photographic data resulted in the following minimum counts for resident killer whales belonging to the Alaska Resident stock (Note: individual whales have been matched between geographical regions and missing animals likely to be dead have been subtracted). In southeastern Alaska, 109 resident whales have been identified as of 2009 (MML and North Gulf Oceanic Society (NGOS), 3430 Main Street, Suite B1, Homer, Alaska; unpublished data). In Prince William Sound and Kenai Fjords, another 675 resident whales have been identified as of 2009 (Matkin et al. 2003; C. Matkin, North Gulf Oceanic Society, pers. comm.).

Beginning in 2001, dedicated killer whale studies were initiated by the NMFS Marine Mammal Laboratory (MML) in Alaska waters west of Kodiak Island, including the Aleutian Islands and Bering Sea. Between 2001 and 2009, using field assessments based on morphology, association data, and genetic analyses, additional resident whales were added to the Alaska Resident stock. Internal matches within the MML data set have been subtracted, resulting in a final count of western Alaska residents for 2001-2012 as 1,475 whales. Studies conducted in western Alaska by the NGOS have resulted in the collection of photographs of approximately 600 resident killer whales; however, the NGOS and MML data sets have not yet been matched so it is unknown how many of these 600 animals are included in the MML collection. Another 41 whales were identified off Kodiak between 2000 and 2003 by the NGOS. These whales are added to the total of western Alaska residents although they have not been matched to MML photographs.

MML conducted killer whale line-transect surveys for 3 years in July and August in 2001-2003. These surveys covered an area from approximately Resurrection Bay in the Kenai Fjords to the central Aleutians. The surveys covered an area from shore to 30-45 nautical miles offshore, with randomly located transects in a zigzag pattern. A total of 9,053 km of tracklines were surveyed between the Kenai Peninsula (~150°W) and Amchitka Pass

(~179ºW). A total of 41 on-effort sightings of killer whales were recorded, with an additional 16 sightings off-effort. Estimated abundance of resident killer whale from these surveys was 991 (CV = 0.52), with a 95% confidence interval of 380-2,585 (Zerbini et al. 2007).

The line transect surveys provide an "instantaneous" (across ~40 days) estimate of the number of resident killer whales in the survey area. It should be noted that the photographic catalogue encompasses a larger area, including some data from areas such as Prince William Sound and the Bering Sea that were outside the line-transect survey area. Additionally, the number of whales in the photographic catalogue is a documentation of all whales seen in the area over the time period of the catalogue; movements of some individual whales have been documented between the line-transect survey area and locations outside the survey area. Accordingly, a larger number of resident killer whales may use the line-transect survey area at some point over the 3 years than would necessarily be found at one time in the survey area in July and August in a particular year.

Combining the counts of known resident whales gives a minimum number of 2,347 (Southeast Alaska + Prince William Sound + Western Alaska; 121 + 751 + 1,475) killer whales belonging to the Alaska Resident stock (Table 1).

Table 1. Numbers of animals in each pod of killer whales belonging to the Alaska Resident stock of killer whales. A number followed by a "+" indicates a minimum count for that pod.

[1]Although there is strong evidence (Matkin et al. 2003, 2010) the resident killer whale numbers have been increasing in the Gulf of Alaska, the bulk of the increase from the 2001-2004 counts to the 2005-2009 counts is believed to be due to the discovery of new animals, not recruitment. Animals reported here have been photographed in the 2001-2012 period. [2]Available from M. Dahlheim, Marine Mammal Laboratory, Alaska Fisheries Science Center, 7600 Sand Point Way NE, Seattle, WA 98115.

Minimum Population Estimate

The survey technique utilized for obtaining the abundance estimate of killer whales is a direct count of individually identifiable animals. Thus the minimum population estimate (N_{MIN}) for the Alaska Resident stock of killer whales based on photo-identification studies conducted between 2005-2009 is 2,084 animals (Table 1). Other estimates of the overall population size (i.e., N_{BEST}) and associated CV(N) are not currently available. Given that researchers continue to identify new whales, the estimate of abundance based on the number of uniquely identified individuals known to be alive is likely conservative. However, the rate of discovering new resident whales within southeastern Alaska and Prince William Sound is relatively low (MML, unpublished data). Conversely, the rate of discovery of new whales in western Alaska was initially high (i.e., 2001 and 2002 field seasons). However, recent photographic data collected during 2003 and 2004 indicates that the rate of discovering new individual whales has decreased.

Using the line-transect estimate of 991 (CV = 0.52) results in an estimate of N_{MIN} (20th percentile) of 656. This is lower than the minimum number of individuals identified from photographs in recent years, so the photographic catalogue number is used for PBR calculations.

Some overlap of Northern Resident whales occur with the Alaska Resident stock in southeastern Alaska. However, information on the percentage of time that the Northern Resident stock spends in Alaska waters is unknown. However, as noted above, this minimum population estimate is considered conservative. This approach is consistent with the recommendations of the Alaska Scientific Review Group (DeMaster 1996).

Current Population Trend

Data from Matkin et al. (2003) indicate that the component of the Alaska Resident stock that summers in the Prince William Sound and Kenai Fjords area is increasing. With the exception of AB pod, which declined drastically after the *Exxon Valdez* oil spill and has not yet recovered, the component of the Alaska Resident stock in the Prince William Sound and Kenai Fjords area increased 3.2% (95% CI = 1.94 to 4.36%) per year from 1990 to 2005 (Matkin et al. 2008). Although the current minimum population count of 2,084 is higher than the last population count of 1,123, examination of only count data does not provide a direct indication of the net recruitment into the population. At present, reliable data on trends in population abundance for the entire Alaska Resident stock of killer whales are unavailable.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

A reliable estimate of the maximum net productivity rate is currently unavailable for this stock of killer whales. Studies of resident killer whale pods in the Pacific Northwest resulted in estimated population growth rates of 2.92% and 2.54% over the period from 1973 to 1987 (Olesiuk et al. 1990, Brault and Caswell 1993), and 3.3% over the period 1984-2002 (Matkin et al. 2003). Until additional stock-specific data become available, it is recommended that the cetacean maximum theoretical net productivity rate (R_{MAX}) of 4% be employed for this stock (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the potential biological removal (PBR) is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: PBR = $N_{MIN} \times 0.5R_{MAX} \times F_R$. The recovery factor ($F_R$) for this stock is 0.5, the value for cetacean stocks with unknown population status (Wade and Angliss 1997). Thus, for the Eastern North Pacific Alaska Resident killer whale stock, PBR = 24 animals (2,347 × 0.02 × 0.5).

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Detailed information on U.S. commercial fisheries in Alaska waters (including observer programs, observer coverage, and observed incidental takes of marine mammals) is presented in Appendices 3-6 of the Alaska Stock Assessment Reports.

Three of the federally-regulated U.S. commercial fisheries, monitored for incidental mortality and serious injury of marine mammals by fishery observers, incurred mortality and serious injury of killer whales (unknown stock) between 2010 and 2014: the Bering Sea/Aleutian Islands flatfish trawl, Bering Sea/Aleutian Islands rockfish trawl, and Bering Sea/Aleutian Islands Pacific cod longline fisheries (Table 1; Breiwick 2013; MML, unpubl. data).

Fishery observers have collected tissue samples from many of the killer whales that were killed incidental to U.S. commercial fisheries. Genetic analyses of samples from seven killer whales collected between 1999 and 2004 have confirmed that Alaska Resident killer whale mortality occurred incidental to the Bering Sea/Aleutian Islands flatfish trawl (n = 3) and Bering Sea/Aleutian Islands Pacific cod longline fisheries (n = 1) and that Gulf of Alaska, Aleutian Islands, and Bering Sea Transient killer whale mortality occurred incidental to the Bering Sea/Aleutian Islands pollock trawl fishery (n = 3) (M. Dahlheim, NMFS-AFSC-MML, pers. comm., 20 February 2013). Given the overlap in the range of transient and resident stocks in Alaska waters, unless genetic samples can be collected from animals injured or killed by gear or the ship's propeller, these events are assigned to both the transient and resident stock occurring in that area. Thus, the estimated mean annual mortality and serious injury rate of one killer whale in 2010-2014 will be assigned to both the Alaska Resident and Gulf of Alaska, Aleutian Islands, and Bering Sea Transient stocks of killer whales (Table 2; Breiwick 2013; MML, unpubl. data).

Typically, if mortality or serious injury occurs incidental to U.S. commercial fishing, it is due to interactions with the fishing gear. However, reports indicate that observed killer whale mortality incidental to the Bering Sea/Aleutian Islands trawl fisheries often occurs due to contact with the ship's propeller (e.g., the 2010 mortality in the Bering Sea/Aleutian Islands rockfish trawl fishery).

Table 2. Summary of incidental mortality and serious injury of Alaska Resident killer whales due to U.S. commercial fisheries in 2010-2014 and calculation of the mean annual mortality and serious injury rate (Breiwick 2013; MML, unpubl. data). Methods for calculating percent observer coverage are described in Appendix 6 of the Alaska Stock Assessment Reports. N/A indicates that data are not available.

Fishery name	Years	Data type	Percent observer coverage	Observed mortality	Estimated mortality	Mean estimated annual mortality
Bering Sea/Aleutian Is. flatfish trawl	2010 2011 2012 2013 2014	obs data	99 100 99 99 99	0 0 0 (+1)[a] 2 0	0 0 0 (+1)[b] 2 0	0.4 (+0.2)[c] (CV = 0)
Bering Sea/Aleutian Is. rockfish trawl	2010 2011 2012 2013 2014	obs data	99 99 100 99 99	1 0 0 0 0	1 0 0 0 0	0.2 (CV = 0)

Fishery name	Years	Data type	Percent observer coverage	Observed mortality	Estimated mortality	Mean estimated annual mortality
Bering Sea/Aleutian Is. Pacific cod longline	2010 2011 2012 2013 2014	obs data	64 57 51 66 64	0 0 0 (+1)[d] 0 0	0 0 0 (+1)[e] 0 0	0 (+0.2)[f] (CV = N/A)
Minimum total estimated annual mortality						1 (CV = 0)

[a]Total mortality and serious injury observed in 2012: 0 whales in sampled hauls + 1 whale in an unsampled haul.
[b]Total estimate of mortality and serious injury in 2012: 0 whales (extrapolated estimate from 0 whales observed in sampled hauls) + 1 whale (1 whale observed in an unsampled haul).
[c]Mean annual mortality and serious injury for fishery: 0.4 whales (mean of extrapolated estimates from sampled hauls) + 0.2 whales (mean of number observed in unsampled hauls).
[d]Total mortality and serious injury observed in 2012: 0 whales in sampled hauls + 1 whale in an unsampled haul.
[e]Total estimate of mortality and serious injury in 2012: 0 whales (extrapolated estimate from 0 whales observed in sampled hauls) + 1 whale (1 whale observed in an unsampled haul).
[f]Mean annual mortality and serious injury for fishery: 0 whales (mean of extrapolated estimates from sampled hauls) + 0.2 whales (mean of number observed in unsampled hauls).

A minimum estimate of the mean annual mortality and serious injury rate incidental to U.S. commercial fisheries in 2010-2014 is one Alaska Resident killer whale, based on observer data (Table 2).

Subsistence/Native Harvest Information

There are no reports of a subsistence harvest of killer whales in Alaska.

Other Mortality

During the 1992 killer whale surveys conducted in the Bering Sea and western Gulf of Alaska, 9 of 182 (4.9%) individual whales in 7 of the 12 (58%) pods encountered had evidence of bullet wounds (Dahlheim and Waite 1993). The relationship between wounding due to shooting and survival is unknown. In Prince William Sound, the pod responsible for most of the fishery interactions experienced a high level of mortality: between 1986 and 1991, 22 whales out of a pod of 37 (59%) disappeared (Matkin et al. 1994). The cause of death for these whales is unknown, but it may be related to gunshot wounds or effects of the *Exxon Valdez* oil spill (Dahlheim and Matkin 1994). It is unknown who was responsible for shooting at killer whales.

There have been no obvious bullet wounds observed on killer whales during surveys in the Bering Sea and western Gulf of Alaska (J. Durban, NMFS-SWFSC, pers. comm.). However, researchers have reported that killer whale pods in certain areas exhibit vessel avoidance behavior, which may indicate that shootings occur in some places.

Other Issues

Killer whales are known to depredate longline catches in the Bering Sea (Dahlheim 1988; Yano and Dahlheim 1995; Perez 2003, 2006; Sigler et al. 2003) and in the Gulf of Alaska (Sigler et al. 2003, Perez 2006). In addition, there have been many reports of killer whales consuming the processing waste of Bering Sea groundfish trawl fishing vessels (Perez 2006). Resident killer whales are most likely to be involved in such fishery interactions since these whales are known to be fish eaters.

Fisheries observers report that large groups of killer whales in the Bering Sea follow vessels for days at a time, actively consuming the processing waste (NMFS-AFSC, Fishery Observer Program, unpubl. data). On some vessels, the waste is discharged in the vicinity of the vessel's propeller (NMFS, unpubl. data); consumption of the processing waste in the vicinity of the propeller may be the cause of the propeller-caused mortalities of killer whales in the trawl fisheries.

STATUS OF STOCK

The Eastern North Pacific Alaska Resident stock of killer whales is not designated as depleted under the MMPA or listed as threatened or endangered under the Endangered Species Act. The minimum abundance estimate for the Alaska Resident stock is likely underestimated because researchers continue to encounter new whales in the

Gulf of Alaska and western Alaska waters. Because the population estimate is likely to be conservative, the PBR is also conservative.

Based on currently available data, a minimum estimate of the mean annual mortality and serious injury rate due to U.S. commercial fisheries (1 whale) is less than 10% of the PBR (10% of PBR = 2.4) and, therefore, is considered to be insignificant and approaching zero mortality and serious injury rate. A minimum estimate of the total annual level of human-caused mortality and serious injury (1 whale) is not known to exceed the PBR (24). Therefore, the Eastern North Pacific Alaska Resident stock of killer whales is not classified as a strategic stock. Population trends and status of this stock relative to its Optimum Sustainable Population are currently unknown.

KILLER WHALE (*Orcinus orca*): Eastern North Pacific Northern Resident Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Killer whales have been observed in all oceans and seas of the world (Leatherwood and Dahlheim 1978). Although reported from tropical and offshore waters, killer whales occur at higher densities in colder and more productive waters of both hemispheres, with the greatest densities found at high latitudes (Mitchell 1975, Leatherwood and Dahlheim 1978, Forney and Wade, 2006). Killer whales are found throughout the North Pacific. Along the west coast of North America, killer whales occur along the entire Alaskan coast (Braham and Dahlheim 1982), in British Columbia and Washington inland waterways (Bigg et al. 1990), and along the outer coasts of Washington, Oregon, and California (Green et al. 1992; Barlow 1995, 1997; Forney et al. 1995). Seasonal and year-round occurrence has been noted for killer whales throughout Alaska (Braham and Dahlheim 1982) and in the intracoastal waterways of British Columbia and Washington State, where whales have been labeled as 'resident,' 'transient,' and 'offshore' type killer whales (Bigg et al. 1990, Ford et al. 2000; Dahlheim et al. 2008) based on aspects of morphology, ecology, genetics, and behavior (Ford and Fisher 1982; Baird and Stacey 1988; Baird et al. 1992; Hoelzel et al. 1998, 2002; Barrett-Lennard 2000; Dahlheim et al. 2008). Through examination of photographs of recognizable individuals and pods, movements of whales between geographical areas have been documented. For example, resident type whales identified in Prince William Sound have been observed in southeastern Alaska and lower Cook Inlet. (Matkin et al. 2010) Movements of transient type killer whales between the waters of Southeast Alaska and central California have also been documented (Goley and Straley 1994; Black et al. 1997; Dahlheim and White 2010).

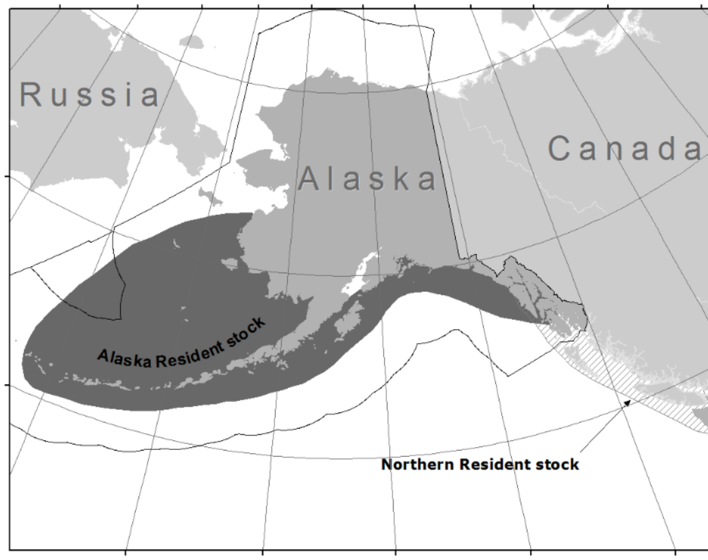

Figure 1. Approximate distribution of killer whales in the eastern North Pacific (shaded area). The distribution of the eastern North Pacific Resident and Transient stocks are largely overlapping (see text).

Several studies provide evidence that the 'resident', 'offshore', and 'transient' ecotypes are genetically distinct in both mtDNA and nuclear DNA (Hoelzel and Dover 1991; Hoelzel et al. 1998, 2002; Barrett-Lennard 2000). A recent global genetic study of killer whales using the entire mitochondrial genome found that some killer whale ecotypes represent deeply divergent evolutionary lineages and warrant elevation to species or subspecies status (Morin et al. 2010). In particular, estimates from mitogenome sequence data indicate that transient killer whales diverged from all other killer whale lineages ~700,000 years ago. In light of these differences, the Society for Marine Mammalogy's Committee on Taxonomy currently recognizes the resident and transient North Pacific ecotypes as un-named *Orcinus orca* subspecies (Committee on Taxonomy 2012). In recognition of its status as an un-named subspecies or species, some researchers now refer to transient-type killer whales as Bigg's killer whales (e.g., Ford 2011; Riesch et al. 2012), in tribute to the late Dr. Michael Bigg.

Genetic differences have also been found between populations within the 'transient' and 'resident' ecotypes (Hoelzel et al. 1998, 2002; Barrett-Lennard 2000). Within the resident ecotype, association data were initially used to describe three separate communities in the North Pacific (Bigg et al. 1990; Ford et al. 1994, 2000; Matkin et al. 1999). The Southern Resident population is found in summer primarily in waters of Washington state and southern British Columbia. The Northern Resident population is found in summer primarily in central and northern British Columbia. Alaska resident whales are found in marine waters of southern and southwestern Alaska. Acoustic data (Ford 1989, 1991; Yurk et al. 2002) and genetic data (Hoelzel et al. 1998, 2002; Barrett-Lennard 2000) have confirmed that these three units represent discrete populations.

Based on data regarding association patterns, acoustics, movements, and genetic differences, eight killer whale stocks are now recognized within the Pacific U.S. EEZ: 1) the Alaska Resident stock - occurring from southeastern Alaska to the Aleutian Islands and Bering Sea, 2) the Northern Resident stock - occurring from Washington State through part of southeastern Alaska, 3) the Southern Resident stock - occurring mainly within the inland waters of Washington State and southern British Columbia, but also in coastal waters from southeastern Alaska through California, 4) the Gulf of Alaska, Aleutian Islands, and Bering Sea Transient stock - occurring mainly from Prince William Sound through the Aleutian Islands and Bering Sea, 5) the AT1 transient stock - occurring in Alaska from Prince William Sound through the Kenai Fjords, 6) the West Coast transient stock - occurring from California through southeastern Alaska, 7) the Offshore stock - occurring from California through Alaska, and 8) the Hawaiian stock. 'Transient' whales in Canadian waters are considered part of the West Coast Transient stock. The Stock Assessment Reports for the Alaska Region contain information concerning all the killer whale stocks except the Hawaiian and Offshore stocks.

The Eastern North Pacific Northern Resident stock is a transboundary stock, and includes killer whales that frequent British Columbia, Canada and southeastern Alaska (Dahlheim et al. 1997; Ford et al. 2000). They have been seen infrequently in Washington state waters.

POPULATION SIZE

Photo-identification studies since 1970 (Ford et al. 2000) have catalogued every individual belonging to the Eastern North Pacific Northern Resident stock (note that individual whales that have been matched between geographical regions and missing animals likely to be dead have been subtracted). In 1998, the photo catalog included 216 whales (Ford et al. 2000). The photo-identification catalogue was updated in 2011 summarizing individual identifications made between 1974 and 2010. At the conclusion of the 2010 field season, the population was composed of three clans representing a total of 261 whales (plus four missing and possibly dead). The population is twice the size it was in 1974, representing an average annual increase of 2.1% (Ellis et al. 2011).

Table 1. Numbers of animals in each pod of killer whales belonging to the Eastern North Pacific Northern Resident stock of killer whales.

British Columbia	Ford et al. 1994	Ford et al. 2000	Ellis et al. 2011
A1	15	16	22

R1	23	29	38
W1	3	3	1
Total	**204**	**216**	**261**

Note: * indicates that one whale may be missing/ dead

Minimum Population Estimate

The technique used for estimating abundance of killer whales is a direct count of individually identifiable animals. Other estimates of the overall population size (i.e., N_{BEST}) and associated CV(N) are not currently available. Because this population has been studied for such a long time, each individual is well documented, and except for births, no new individuals are expected to be discovered. Therefore, the estimated population size of 261 animals can also serve as a minimum count of the population.

Thus, the minimum population estimate (N_{MIN}) for the Northern Resident stock of killer whales is 261 animals, which includes animals found in Canadian waters (see PBR Guidelines (Wade and Angliss 1997) regarding the status of migratory transboundary stocks). This approach is consistent with the recommendations of the Alaska Scientific Review Group (DeMaster 1996). Information on the percentage of time animals typically encountered in Canadian waters spend in U. S. waters is unknown.

Current Population Trend

From the mid 1970s to the mid 1990s, the northern resident killer whale population grew steadily at an annual rate of 2.6% (i.e., from 122 whales in 1974 to 218 in 1997). A decline was reported during the 1998 -2001 period at a rate of 7%. That period coincided with a significant reduction in Chinook salmon (Ford et al. 2010). Then after 2001, the growth was positive with the population increasing at an average rate of 3.1% per year (2001 – 2010). At the end of the 2010 field season, 261 whales were catalogued. This represents an average annual increase of 2.1% over the 36-year time series (Ellis et al. 2011).

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Studies of northern 'resident' killer whale pods in British Columbia and Washington waters resulted in estimated population growth rates of 2.92% and 2.54% over the period from 1973 to 1987 (Olesiuk et al. 1990, Brault and Caswell 1993). Analyses of photographic data collected from 1974 through 2010 indicated a population growth from 122 individuals to 261 whales. This represents an average annual increase of 2.1% over the 36-year period (Ellis et al. 2011). The period from 2001 to 2010 was a period of maximum growth for this population when it grew at an average rate of 3.1% per year. Therefore, the maximum net productivity rate (R_{MAX}) is estimated to be 3.1% (Ellis et al. 2011, Olesiuk et al. 2005).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the potential biological removal (PBR) is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: $PBR = N_{MIN} \times 0.5R_{MAX} \times F_R$. The recovery factor ($F_R$) for this stock is 0.5, the value for cetacean stocks with unknown population status (Wade and Angliss 1997). Thus, for the Eastern North Pacific Northern Resident killer whale stock, PBR = 1.96 animals ($261 \times 0.015 \times 0.5$).

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

New Serious Injury Guidelines

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an "*injury that is more likely than not to result in mortality*." Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

Fisheries Information

All Canadian trawl and longline fisheries are monitored by observers or video; salmon net fisheries are not observed (J. Ford, pers. comm., Department of Fisheries and Oceans, British Columbia, Canada, 30 January 2013). The interaction of resident killer whales with the sablefish longline fishery accounts for a large proportion of the commercial fishing/killer whale interactions in Alaska waters. Such interactions have not been reported in Canadian waters where sablefish are taken via a pot fishery. Interactions have been reported between northern resident killer whales in the British Columbia halibut longline and salmon troll fisheries (J. Ford, pers. comm., Department of Fisheries and Oceans, British Columbia, Canada, 30 January 2013). Since 1990, there have been no reported fishery-related strandings or bycatch of killer whales in Canadian waters. However, in 1994, one killer whale was reported to have contacted a salmon gillnet but did not entangle (Guenther et al. 1995).

Subsistence/Native Harvest Information

Killer whales are not harvested for subsistence in Alaska or Canada.

Other Mortality

Collisions of killer whales with vessels occur occasionally. One mortality of a northern resident killer whale (C21) in Prince Rupert, BC was reported in 2006 (Williams and O'Hara 2010). The shooting of killer whales in Canadian waters has been a concern in the past. However, in recent years the Canadian portion of the stock has been researched so extensively that evidence of bullet wounds would have been noticed if shooting was prevalent (G. Ellis, Pacific Biological Station, Canada, pers. comm.).

Other Issues

In U.S. waters, there is considerable interaction between killer whales and fisheries aside from incidental take. Interactions between killer whales and longline vessels, specifically predation by killer whales on sablefish catch, have been well documented (Dahlheim 1988, Yano and Dahlheim 1995, Sigler et al. 2002). In Canada, northern resident killer whales have been reported to depredate fish from both commercial salmon trollers and recreational sportfishers, as well as halibut longliners. Most reports occur in the northern half of the coast, especially Dixon Entrance, and early in the season (April to June), although some are scattered throughout the summer (J. Ford, pers. comm., Department of Fisheries and Oceans, British Columbia, Canada, 3 December 2012).

STATUS OF STOCK

The Northern Resident killer whale stock is not designated as "depleted" under the MMPA or listed as "threatened" or "endangered" under the Endangered Species Act. In 2001, the Committee on the Status of Endangered Wildlife in Canada designated northern resident killer whales in British Columbia as "threatened" and listed in Schedule 1 of the Species at Risk Act (SARA) for Canada. Resident killer whales in British Columbia are considered to be at risk based on their small population size, low reproductive rate, and the existence of a variety of anthropogenic threats that have the potential to prevent recovery or to cause further declines (DFO, 2008). Monitoring of fisheries in BC over the past decade has been quite extensive and likely at the same level as in U.S. waters. No incidental killer whale mortalities from fishery interactions have been reported or observed (J. Ford, pers. comm., Department of Fisheries and Oceans, British Columbia, Canada, 30 January 2013).

Based on currently available data, the estimated annual U. S. commercial fishery-related mortality level is zero, which does not exceed 10% of the PBR (0.20) and therefore is considered to be insignificant and approaching zero mortality and serious injury rate. The estimated annual level of human-caused mortality and serious injury (0) is not known to exceed the PBR (2.0). Therefore, the eastern North Pacific Northern Resident stock of killer whales is not classified as a strategic stock. Population trends and status of this stock relative to its Optimum Sustainable Population size are currently unknown.

HABITAT CONCERNS

Ford et al. (2005) showed that a sharp drop in coast-wide Chinook salmon abundance during the late 1990s was correlated with a significant decline in resident whale survival. They noted that the whales' preference for chinook salmon is likely due to this species' relatively large size, high lipid content and, unlike other salmonids, its year-round presence in the whales' range. They further note that resident killer whales may be especially dependent on chinook during winter, when this species is the primary salmonid available in coastal waters, and the whales may be subject to nutritional stress leading to increased mortality if the quantity and/or quality of this prey resource declines.

Vessel traffic, particularly increased whale-watching activity, is another potential concern for this stock.

Revised 12/30/2016

KILLER WHALE (*Orcinus orca*): Eastern North Pacific Gulf of Alaska, Aleutian Islands, and Bering Sea Transient Stock

NOTE – NMFS has preliminary genetic information on killer whales in Alaska which indicates that the current stock structure of killer whales in Alaska needs to be reassessed. NMFS is evaluating the new genetic information. In the interim, new information on killer whale mortality levels is provided within this report. A complete revision of the killer whale stock assessments will be postponed until the stock structure evaluation is completed and any new stocks are identified.

STOCK DEFINITION AND GEOGRAPHIC RANGE

Killer whales have been observed in all oceans and seas of the world (Leatherwood and Dahlheim 1978). Although reported from tropical and offshore waters, killer whales occur at higher densities in colder and more productive waters of both hemispheres, with the greatest densities found at high latitudes (Mitchell 1975, Leatherwood and Dahlheim 1978, Forney and Wade 2006). Killer whales are found throughout the North Pacific. Along the west coast of North America, killer whales occur along the entire Alaska coast (Braham and Dahlheim 1982), in British Columbia and Washington inland waterways (Bigg et al. 1990), and along the outer coasts of Washington, Oregon, and California (Green et al. 1992; Barlow 1995, 1997; Forney et al. 1995). Seasonal and year-round occurrence has been noted for killer whales throughout Alaska (Braham and Dahlheim 1982) and in the intracoastal waterways of British Columbia and Washington State, where whales have been labeled as "resident," "transient," and "offshore" type killer whales (Bigg et al. 1990, Ford et al. 2000, Dahlheim et al. 2008) based on aspects of morphology, ecology, genetics, and behavior (Ford and Fisher 1982; Baird and Stacey 1988; Baird et al. 1992; Hoelzel et al. 1998, 2002; Barrett-Lennard 2000; Dahlheim et al. 2008). Through examination of photographs of recognizable individuals, movements of whales between geographical areas have been documented. For example, whales identified in Prince William Sound have been observed near Kodiak Island (Matkin et al. 1999) and whales identified in Southeast Alaska have been observed in Prince William Sound, British Columbia, and Puget Sound (Leatherwood et al. 1990, Dahlheim et al. 1997). Movements of killer whales between the waters of Southeast Alaska and central California have also been documented (Goley and Straley 1994, Black et al. 1997, Dahlheim and White 2010).

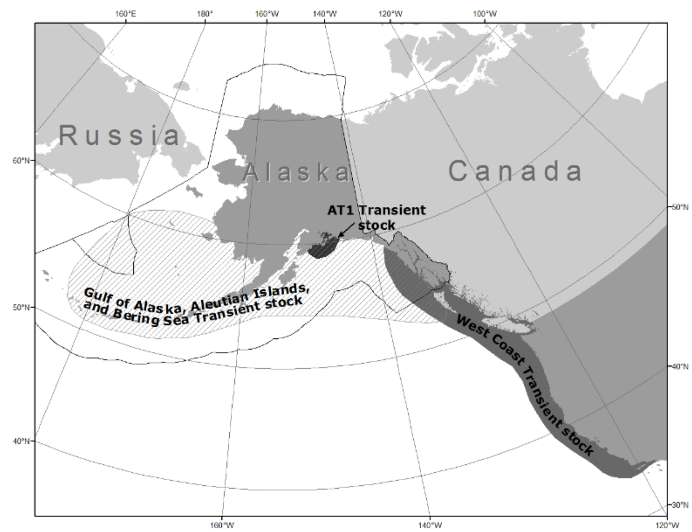

Figure 1. Approximate distribution of transient killer whales in the eastern North Pacific (shaded areas). The distribution of resident and transient killer whale stocks in the eastern North Pacific largely overlap (see text).

Several studies provide evidence that the resident, offshore, and transient ecotypes are genetically distinct in both mtDNA and nuclear DNA (Hoelzel and Dover 1991; Hoelzel et al. 1998, 2002; Barrett-Lennard 2000). Genetic differences have also been found between populations within the transient and resident ecotypes (Hoelzel et al. 1998, 2002; Barrett-Lennard 2000). A recent global genetic study of killer whales using the entire mitochondrial genome found that some killer whale ecotypes represent deeply divergent evolutionary lineages and warrant elevation to species or subspecies status (Morin et al. 2010). In particular, estimates from mitogenome sequence data indicate that transient killer whales diverged from all other killer whale lineages ~700,000 years ago. In light of these differences, the Society for Marine Mammalogy's Committee on Taxonomy currently recognizes the resident and transient North Pacific ecotypes as un-named *Orcinus orca* subspecies (Committee on Taxonomy 2012). In recognition of its status as an un-named subspecies or species, some researchers now refer to transient-type killer whales as Bigg's killer whales (e.g., Ford 2011, Riesch et al. 2012), in tribute to the late Dr. Michael Bigg.

Until recently, transient killer whales in Alaska had only been studied intensively in Southeast Alaska and in the Gulf of Alaska (from Prince William Sound, through the Kenai Fjords, and around Kodiak Island). In the Gulf of Alaska, Matkin et al. (1999) described two populations of transients which were never found in association with one another, the so-called "Gulf of Alaska" transients and "AT1" transients. Gulf of Alaska transients are documented throughout the Gulf of Alaska, including occasional sightings in Prince William Sound. AT1 transients are primarily seen in Prince William Sound and in the Kenai Fjords region, and are therefore partially sympatric with Gulf of Alaska transients. Recently, on one occasion, members of the Gulf of Alaska transient population were seen in association with the transient killer whales that range from California to southeastern Alaska, the West Coast Transients, which are identified by a unique mtDNA haplotype (Matkin et al. 2012). Photographs have identified 14 out of 217 whales considered "outer coast" transients in British Columbia that were also photographed in Alaska waters and considered Gulf of Alaska transients (Matkin et al. 2012, Ford et al. 2013). Transients that are within the Gulf of Alaska population have been found to have two mtDNA haplotypes, neither of which is found in the West Coast or AT1 populations. Members of the AT1 population share a single mtDNA haplotype. Transient killer whales from the West Coast stock have been found to share a single mtDNA haplotype that is not found in the other stocks. Additionally, all three populations have been found to have significant differences in nuclear (microsatellite) DNA (Barrett-Lennard 2000). Acoustic differences have been found between these stocks by Saulitis (1993) and Saulitis et al. (2005). For these reasons, the Gulf of Alaska transients are considered part of a population that is discrete from the AT1 population, and both of these communities are considered discrete from the West Coast Transients.

Biopsy samples from the eastern Aleutians and south side of the end of the Alaska Peninsula have produced the same haplotypes as killer whales in the northern Gulf of Alaska; however, nuclear DNA analysis strongly suggest they belong to a separate population (Parsons et al. 2013). Samples from the central Aleutian Islands and Bering Sea have identified mtDNA haplotypes not found in Gulf of Alaska transients, suggesting additional population structure in western Alaska. At this time transient-type killer whales from the Aleutian Islands and Bering Sea are considered to be part of a single population that includes Gulf of Alaska transients. Killer whales are observed in the northern Bering Sea and Beaufort Sea that have the physical characteristics of transient type whales, but little is known about these whales.

In summary, within the transient ecotype, association data (Ford et al. 1994, Ford and Ellis 1999, Matkin et al. 1999), acoustic data (Saulitis 1993, Ford and Ellis 1999) and genetic data (Hoelzel et al. 1998, 2002; Barrett-Lennard 2000) confirm that at least three communities of transient whales exist and represent three discrete populations: 1) Gulf of Alaska, Aleutian Islands, and Bering Sea Transients, 2) AT1 Transients, and 3) West Coast Transients (Fig. 1).

Based on data regarding association patterns, acoustics, movements, and genetic differences, eight killer whale stocks are now recognized within the Pacific U.S. EEZ: 1) the Alaska Resident stock - occurring from southeastern Alaska to the Aleutian Islands and Bering Sea, 2) the Northern Resident stock - occurring from Washington State through part of southeastern Alaska, 3) the Southern Resident stock - occurring mainly within the inland waters of Washington State and southern British Columbia, but also in coastal waters from southeastern Alaska through California, 4) the Gulf of Alaska, Aleutian Islands, and Bering Sea Transient stock - occurring mainly from Prince William Sound through the Aleutian Islands and Bering Sea, 5) the AT1 Transient stock - occurring in Alaska from Prince William Sound through the Kenai Fjords, 6) the West Coast Transient stock - occurring from California through southeastern Alaska, 7) the Offshore stock - occurring from California through Alaska, and 8) the Hawaiian stock. Transient whales in Canadian waters are considered part of the West Coast Transient stock. The Stock Assessment Reports for the Alaska Region contain information concerning all the killer whale stocks except the Hawaiian and Offshore stocks.

In recent years, a small number of the Gulf of Alaska transients (identified by genetics and association) have been seen in southeastern Alaska; previously only West Coast Transients had been seen in southeastern Alaska. Therefore, the Gulf of Alaska, Aleutian Islands, and Bering Sea Transient stock occupies a range that includes all of the U.S. EEZ in Alaska, though few individuals from this population have been seen in southeastern Alaska.

POPULATION SIZE

In January 2004 the North Gulf Oceanic Society (NGOS) and the Marine Mammal Laboratory (MML) held a joint workshop to match identification photographs of transient killer whales from this population. That analysis of photographic data resulted in the following minimum counts for transient killer whales belonging to the Gulf of Alaska, Aleutian Islands, and Bering Sea Transient stock. In the Gulf of Alaska (east of the Shumagin Islands), 82 whales were identified by NGOS, including whales from Matkin et al. (1999) as well as whales identified in subsequent years (but not including whales identified as part of the AT1 population). MML identified 43 whales and 11 matches were found between the NGOS and MML catalogues. Since that time an additional 22 whales have been added to the NGOS catalogue (Matkin et al. in prep.). Therefore, a total of 136 transients (104 + 43 - 11) have been identified in the Gulf of Alaska. In the Aleutian Islands (west of and including the Shumagin Islands) and Bering Sea, the combined NGOS/MML catalogue (NGOS/MML 2012) now contains 451 individually identifiable whales (not counting unmarked calves and not counting two Gulf of Alaska transient whales that have been photographed in that region). All have been photographed in the past ten years. Combining the Aleutian Islands and Bering Sea count (451) with the Gulf of Alaska count (136), a total count of 587 individual whales have been identified in catalogues of this stock.

MML conducted killer whale line-transect surveys for 3 years in July and August in 2001-2003. These surveys covered an area from approximately Resurrection Bay in the Kenai Fjords to the central Aleutians. The surveys covered an area from shore to 30-45 nautical miles offshore, with randomly located transects in a zigzag pattern. Estimated transient killer whale abundance from these surveys, using post-encounter estimates of group size, was 249 (CV = 0.50), with a 95% confidence interval of 99-628 (Zerbini et al. 2007).

Mark-recapture methods were used to estimate the number of mammal-eating transient killer whales using the coastal waters from the central Gulf of Alaska to the central Aleutian Islands, using photographs collected during the three line-transect surveys (Zerbini et al. 2007), along with photographs collected from a variety of additional surveys during the same time period (Durban et al. 2010). A total of 154 individuals were identified from 6,489 photographs collected between July 2001 and August 2003. A Bayesian mixture model estimated seven distinct clusters (95% Probability Interval = 7-10) of individuals that were differentially covered by 14 boat-based surveys exhibiting varying degrees of association in space and time, leading to a total estimate of 345 whales (95% Probability Interval = 255-487). This estimate is higher than the line-transect estimate for at least two reasons. First, the line-transect estimate provides an "instantaneous" (across ~40 days) estimate of the average number of transient killer whales in the survey area, whereas the mark-recapture methods provide an estimate of the total number of whales to use the survey area over the three years, which is known to be greater due to the long distance movements documented by satellite tags (J. Durban, Southwest Fisheries Science Center, pers. comm.). Second, the mark-recapture estimate included photographic data from a broader seasonal time period, and therefore includes transient killer whales documented in the False Pass/Unimak Island area in spring where they aggregate to prey on gray whales on migration (Matkin et al. 2007). Many of these whales have not been seen in that region in the summer. However, mark recapture estimates do not include most of the Bering Sea and Pribilof Islands.

It should be noted that the photographic catalogue encompasses a larger area, including some data from areas such as the Bering Sea and Pribilof Islands that were outside the line-transect survey area. The photo catalogue also encompasses a much longer time period (through 2012). Additionally, the number of whales in the photographic catalogue is a documentation of all whales seen in the area over the time period of the catalogue; movements of some individual whales have been documented between the line-transect survey area and locations outside the survey area. Accordingly, a larger number of transient killer whales may use the line-transect survey area at some point over the 3 years than would necessarily be found at one time in the survey area in July and August in a particular year.

Minimum Population Estimate

The 20^{th} percentile of the line transect survey estimate is 167. The 20^{th} percentile of the mark-recapture estimates of 345 is ~303. A total count of 587 individual whales have been identified in the photograph catalogues from the Gulf of Alaska (Matkin et al. in prep.) and from western Alaska (NGOS/MML 2012). The photograph catalogue estimate of transient killer whales is a direct count of individually identifiable animals. However, the number of catalogued whales does not necessarily represent the number of live animals. Some animals may have died, but whales cannot be presumed dead if not resighted because long periods of time between sightings are common for some transient animals. The catalogue for the western area used data only from 2001-2012, decreasing the potential bias from using whales that may have died prior to the end of the time period. However, given that researchers continue to identify new whales and the entire range has not been surveyed, the estimate of abundance based on the number of uniquely identified individuals catalogued is likely conservative. The catalogue count is slightly higher than the 20^{th} percentile of the mark-recapture estimates, in part because it included data from areas such as Prince William Sound and the Bering Sea that were outside the survey area.

Thus, the minimum population estimate (N_{MIN}) for the Gulf of Alaska, Aleutian Islands, and Bering Sea Transient stock of killer whales is 587 animals based on the count of individuals using photo-identification.

Current Population Trend

Recently Matkin et al. (2012) analyzed photographic data collected since 1984 and determined Gulf of Alaska transients in the northern Gulf of Alaska have had stable numbers. At present, reliable data on trends in population abundance for the Aleutian Islands and Bering Sea portion of this stock of killer whales are unavailable.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

A reliable estimate of the maximum net productivity rate is currently unavailable for this stock of killer whales. Studies of resident killer whale pods in the Pacific Northwest resulted in estimated population growth rates of 2.92% and 2.54% over the period from 1973 to 1987 (Olesiuk et al. 1990, Brault and Caswell 1993). Until stock-specific data become available, it is recommended that the cetacean maximum theoretical net productivity rate (R_{MAX}) of 4% be employed for this stock (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the potential biological removal (PBR) is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: PBR = $N_{MIN} \times 0.5R_{Max} \times F_R$. The recovery factor ($F_R$) for this stock is 0.5, the value for cetacean stocks with unknown population status with a mortality rate CV ≥ 0.80 (Wade and Angliss 1997). Thus, for the Gulf of Alaska, Aleutian Islands, and Bering Sea Transient killer whale stock, PBR = 5.87 animals (587 × 0.02 × 0.5). Although only a few individuals have been observed in Canadian waters, the proportion of time that this trans-boundary stock spends in Canadian waters cannot be determined (G. Ellis, Pacific Biological Station, Canada, pers. comm.).

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Detailed information on U.S. commercial fisheries in Alaska waters (including observer programs, observer coverage, and observed incidental takes of marine mammals) is presented in Appendices 3-6 of the Alaska Stock Assessment Reports.

Three of the federally-regulated U.S. commercial fisheries, monitored for incidental mortality and serious injury of marine mammals by fishery observers, incurred serious injury and mortality of killer whales (unknown stock) in 2010-2014: the Bering Sea/Aleutian Islands flatfish trawl, Bering Sea/Aleutian Islands rockfish trawl, and Bering Sea/Aleutian Islands Pacific cod longline fisheries (Table 1; Breiwick 2013; MML, unpubl. data).

Fishery observers have collected tissue samples from many of the killer whales that were killed incidental to U.S. commercial fisheries. Genetic analyses of samples from seven killer whales collected between 1999 and 2004 have confirmed that Alaska Resident killer whale mortality occurred incidental to the Bering Sea/Aleutian Islands flatfish trawl (n = 3) and Bering Sea/Aleutian Islands Pacific cod longline fisheries (n = 1) and that Gulf of Alaska, Aleutian Islands, and Bering Sea Transient killer whale mortality occurred incidental to the Bering Sea/Aleutian Islands pollock trawl fishery (n = 3) (M. Dahlheim, NMFS-AFSC-MML, pers. comm., 20 February 2013). Given the overlap in the range of transient and resident stocks in Alaska waters, unless genetic samples can be collected from animals injured or killed by gear or the ship's propeller, these events are assigned to both the transient and resident stock occurring in that area. Thus, the estimated mean annual mortality and serious injury rate of one killer whale in 2010-2014 will be assigned to both the Gulf of Alaska, Aleutian Islands, and Bering Sea Transient and the Alaska Resident stocks of killer whales (Table 1).

Typically, if mortality or serious injury occurs incidental to U.S. commercial fishing, it is due to interactions with the fishing gear. However, reports indicate that observed killer whale mortality incidental to Bering Sea/Aleutian Islands trawl fisheries often occurs due to contact with the ship's propeller (e.g., the 2010 mortality in the Bering Sea/Aleutian Islands rockfish trawl fishery).

Table 1. Summary of incidental mortality and serious injury of Gulf of Alaska, Aleutian Islands, and Bering Sea Transient killer whales due to U.S. commercial fisheries in 2010-2014 and calculation of the mean annual mortality and serious injury rate (Breiwick 2013; MML, unpubl. data). Methods for calculating percent observer coverage are described in Appendix 6 of the Alaska Stock Assessment Reports. N/A indicates that data are not available.

Fishery name	Years	Data type	Percent observer coverage	Observed mortality	Estimated mortality	Mean estimated annual mortality
Bering Sea/Aleutian Is. flatfish trawl	2010 2011 2012 2013 2014	obs data	99 100 99 99 99	0 0 0 (+1)[a] 2 0	0 0 0 (+1)[b] 2 0	0.4 (+0.2)[c] (CV = 0)
Bering Sea/Aleutian Is. rockfish trawl	2010 2011 2012 2013 2014	obs data	99 99 100 99 99	1 0 0 0 0	1 0 0 0 0	0.2 (CV = 0)
Bering Sea/Aleutian Is. Pacific cod longline	2010 2011 2012 2013 2014	obs data	64 57 51 66 64	0 0 0 (+1)[d] 0 0	0 0 0 (+1)[e] 0 0	0 (+0.2)[f] (CV = N/A)
Minimum total estimated annual mortality						1 (CV = 0)

[a]Total mortality and serious injury observed in 2012: 0 whales in sampled hauls + 1 whale in an unsampled haul.
[b]Total estimate of mortality and serious injury in 2012: 0 whales (extrapolated estimate from 0 whales observed in sampled hauls) + 1 whale (1 whale observed in an unsampled haul).
[c]Mean annual mortality and serious injury for fishery: 0.4 whales (mean of extrapolated estimates from sampled hauls) + 0.2 whales (mean of number observed in unsampled hauls).
[d]Total mortality and serious injury observed in 2012: 0 whales in sampled hauls + 1 whale in an unsampled haul.
[e]Total estimate of mortality and serious injury in 2012: 0 whales (extrapolated estimate from 0 whales observed in sampled hauls) + 1 whale (1 whale observed in an unsampled haul).
[f]Mean annual mortality and serious injury for fishery: 0 whales (mean of extrapolated estimates from sampled hauls) + 0.2 whales (mean of number observed in unsampled hauls).

A minimum estimate of the mean annual mortality and serious injury rate incidental to U.S. commercial fisheries in 2010-2014 is one Gulf of Alaska, Aleutian Islands, and Bering Sea Transient killer whale, based on observer data (Table 1).

Subsistence/Native Harvest Information

There are no reports of a subsistence harvest of killer whales in Alaska or Canada.

Other Mortality

Collisions with boats may be an occasional source of mortality or serious injury of killer whales. For example, a killer whale struck the propeller of a vessel in the Bering Sea/Aleutian Islands rockfish trawl fishery in 2010 (Table 1).

Other Issues

Killer whales are known to depredate longline catches in the Bering Sea (Dahlheim 1988; Yano and Dahlheim 1995; Perez 2003, 2006; Sigler et al. 2003) and in the Gulf of Alaska (Sigler et al. 2003, Perez 2006). In addition, there have been many reports of killer whales consuming the processing waste of Bering Sea groundfish trawl fishing vessels (Perez 2006). However, resident killer whales are most likely to be involved in such fishery interactions since these whales are known to be fish eaters.

STATUS OF STOCK

The Eastern North Pacific Gulf of Alaska, Aleutian Islands, and Bering Sea Transient stock of killer whales is not designated as depleted under the MMPA or listed as threatened or endangered under the Endangered Species Act. Based on currently available data, a minimum estimate of the mean annual mortality and serious injury rate due to U.S. commercial fisheries (1 whale) is greater than 10% of the PBR (10% of PBR = 0.6) and, therefore, cannot be considered to be insignificant and approaching zero mortality and serious injury rate. A minimum estimate of the total annual level of human-caused mortality and serious injury (1 whale) is less than the PBR (5.9). Therefore, the Gulf of Alaska, Aleutian Islands, and Bering Sea Transient stock of killer whales is not classified as a strategic stock. Population trends and status of this stock relative to its Optimum Sustainable Population are currently unknown.

KILLER WHALE (*Orcinus orca*): AT1 Transient Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Killer whales have been observed in all oceans and seas of the world (Leatherwood and Dahlheim 1978). Although reported from tropical and offshore waters, killer whales occur at higher densities in colder and more productive waters of both hemispheres, with the greatest densities found at high latitudes (Mitchell 1975, Leatherwood and Dahlheim 1978, Forney and Wade 2006). Killer whales are found throughout the North Pacific. Along the west coast of North America, seasonal and year-round occurrence of killer whales has been noted along the entire Alaska coast (Braham and Dahlheim 1982), in British Columbia and Washington inland waterways (Bigg et al. 1990), and along the outer coasts of Washington, Oregon, and California (Green et al. 1992; Barlow 1995, 1997; Forney et al. 1995). Killer whales from these areas have been labeled as "resident," "transient," and "offshore" type killer whales (Bigg et al. 1990, Ford et al. 2000, Dahlheim et al. 2008) based on aspects of morphology, ecology, genetics, and behavior (Ford and Fisher 1982; Baird and Stacey 1988; Baird et al. 1992; Hoelzel et al. 1998, 2002; Barrett-Lennard 2000; Dahlheim et al. 2008). Through examination of photographs of recognizable individuals and pods, movements of whales between geographical areas have been documented. For example, whales identified in Prince William Sound have been observed near Kodiak Island (Matkin et al. 1999) and whales identified in Southeast Alaska have been observed in Prince William Sound, British Columbia, and Puget Sound (Leatherwood et al. 1990, Dahlheim et al. 1997). Movements of killer whales between the waters of Southeast Alaska and central California have also been documented (Goley and Straley 1994, Black et al. 1997, Dahlheim and White 2010).

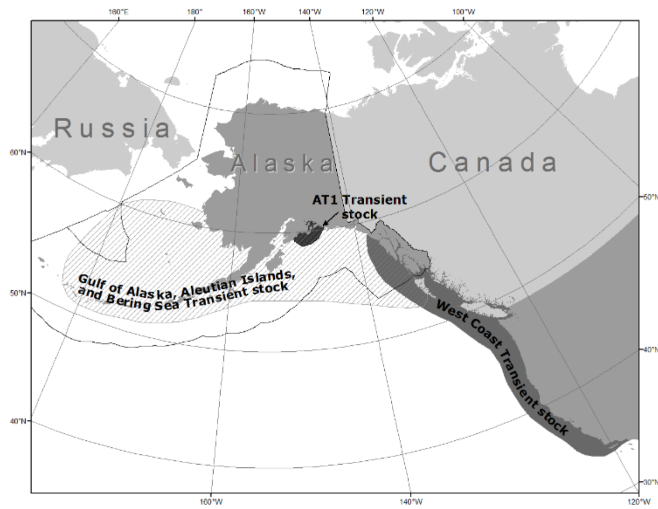

Figure 1. Approximate distribution of transient killer whales in the eastern North Pacific (shaded areas). The distribution of resident and transient killer whale stocks in the eastern North Pacific largely overlap (see text).

Several studies provide evidence that the resident, offshore, and transient ecotypes are genetically distinct in both mtDNA and nuclear DNA (Hoelzel and Dover 1991; Hoelzel et al. 1998, 2002; Barrett-Lennard 2000). Genetic differences have also been found between populations within the transient and resident ecotypes (Hoelzel et al. 1998, 2002; Barrett-Lennard 2000). A recent global genetic study of killer whales using the entire mitochondrial genome found that some killer whale ecotypes represent deeply divergent evolutionary lineages and warrant elevation to species or subspecies status (Morin et al. 2010). In particular, estimates from mitogenome sequence data indicate that transient killer whales diverged from all other killer whale lineages ~700,000 years ago. In light of these differences, the Society for Marine Mammalogy's Committee on Taxonomy currently recognizes the resident and transient North Pacific ecotypes as un-named *Orcinus orca* subspecies (Committee on Taxonomy 2016). In recognition of its status as an un-named subspecies or species, some researchers now refer to transient-type killer whales as Bigg's killer whales (e.g., Ford 2011, Riesch et al. 2012), in tribute to the late Dr. Michael Bigg.

The first studies of transient killer whales in Alaska were conducted in Southeast Alaska and in the Gulf of Alaska (from Prince William Sound, through the Kenai Fjords, and around Kodiak Island). In the Gulf of Alaska, Matkin et al. (1999) described two genetically distinct populations of transients which were never found in association with one another, the so-called "Gulf of Alaska" transients and "AT1" transients. In the past, neither of these populations were known to associate with the population of transient killer whales that ranged from California to Southeast Alaska, which are described as the West Coast Transient stock. Gulf of Alaska transients are documented throughout the Gulf of Alaska, including occasional sightings in Prince William Sound. AT1 transients have been seen only in Prince William Sound and in the Kenai Fjords region, and are therefore partially sympatric with Gulf of Alaska transients. In addition, recent data have identified 14 out of 217 transients on the outer coast of Southeast Alaska and British Columbia as Gulf of Alaska transients and in one encounter they were observed mixing with West Coast Transients (Matkin et al. 2012, Ford et al. 2013). Transients within the Gulf of Alaska population have been found to have two mtDNA haplotypes, neither of which is found in the West Coast or AT1 populations. Members of the AT1 population share a single mtDNA haplotype. Transient killer whales from the West Coast population have been found to share a single mtDNA haplotype that is not found in the other populations. Additionally, all three populations have been found to have significant differences in nuclear (microsatellite) DNA (Barrett-Lennard 2000). Acoustic differences have been found as well; Saulitis et al. (2005) described acoustic differences between Gulf of Alaska transients and AT1 transients. For these reasons, the Gulf of Alaska transients are considered part of a population that is discrete from the AT1 population, and both of these populations are considered discrete from the West Coast Transients.

Biopsy samples from the eastern Aleutians and the south side of the west end of the Alaska Peninsula have produced the same haplotypes as killer whales in the northern Gulf of Alaska, however, nuclear DNA analysis strongly suggests they belong to a separate population (Parsons et al. 2013). The geographic distribution of mtDNA haplotypes revealed samples from the central Aleutian Islands and Bering Sea with haplotypes not found in Gulf of Alaska transients, suggesting additional population structure in western Alaska. At this time, transient-type killer whales from the Aleutian Islands and Bering Sea are considered to be part of a single population that includes Gulf of Alaska transients. Killer whales observed in the northern Bering Sea and Beaufort Sea have physical characteristics of transient-type whales, but little is known about these whales. AT1 haplotype whales are also present west of the Aleutian Islands and into the Bering Sea; however, nuclear DNA analysis indicates these animals are not part of the AT1 transient population in the Gulf of Alaska (L. Barrett-Lennard, Vancouver Aquarium, pers. comm., 21 March 2014).

In summary, within the transient ecotype, association data (Ford et al. 1994, Ford and Ellis 1999, Matkin et al. 1999), acoustic data (Ford and Ellis 1999, Saulitis et al. 2005), and genetic data (Hoelzel et al. 1998, 2002; Barrett-Lennard 2000) confirm that at least three communities of transient whales exist and represent three discrete populations: 1) Gulf of Alaska, Aleutian Islands, and Bering Sea transients, 2) AT1 transients, and 3) West Coast transients.

Based on data regarding association patterns, acoustics, movements, and genetic differences, eight killer whale stocks are now recognized within the Pacific U.S. Exclusive Economic Zone: 1) the Alaska Resident stock - occurring from Southeast Alaska to the Aleutian Islands and Bering Sea, 2) the Northern Resident stock - occurring from Washington State through part of Southeast Alaska, 3) the Southern Resident stock - occurring mainly within the inland waters of Washington State and southern British Columbia, but also in coastal waters from Southeast Alaska through California, 4) the Gulf of Alaska, Aleutian Islands, and Bering Sea Transient stock - occurring mainly from Prince William Sound through the Aleutian Islands and Bering Sea, 5) the AT1 Transient stock - occurring in Alaska from Prince William Sound through the Kenai Fjords (Fig. 1), 6) the West Coast Transient stock - occurring from California through Southeast Alaska, 7) the Offshore stock - occurring from California through Alaska, and 8) the Hawaiian stock. Transient whales in Canadian waters are considered part of the West Coast Transient stock. The Hawaiian and Offshore stocks are reported separately in the Stock Assessment Reports for the U.S. Pacific Region.

AT1 killer whales were first identified as a separate, cohesive group in 1984, when 22 transient-type whales were documented in Prince William Sound (Leatherwood et al. 1984, Heise et al. 1991), though individual whales from the group had been photographed as early as 1978 (von Ziegesar et al. 1986). Once the North Gulf Oceanic Society began consistent annual research effort in Prince William Sound, AT1 killer whales were resighted frequently. In fact, AT1 killer whales were found to be some of the most frequently sighted killer whales in Prince William Sound (Matkin et al. 1993, 1994, 1999). Gulf of Alaska transients are seen less frequently in Prince William Sound, with periods of several years or more between resightings.

AT1 killer whales have never been seen in association with sympatric resident killer whale pods or with Gulf of Alaska transients (Matkin et al. 1999, 2012), are genetically and acoustically distinct from other transient killer whales in the North Pacific (Barrett-Lennard 2000, Saulitis et al. 2005), and appear to have a more limited range than other transients. Their approximately 200-mile known range includes only Prince William Sound and Kenai Fjords and adjacent offshore waters (Matkin et al. 1999, 2012).

POPULATION SIZE

Using photographic-identification methods, all 22 individuals in the AT1 Transient population were censused for the first time in 1984 (Leatherwood et al. 1984). All 22 AT1s were seen annually or biannually from 1984 to 1988 (Matkin et al. 1999, 2003). The *Exxon Valdez* oil spill occurred in spring of 1989. Nine individuals from the AT1 group have been missing since 1990 (last seen in 1989), and two have been missing since 1992 (last seen in 1990 and 1991). Three of the missing AT1s (AT5, AT7, and AT8) were seen near the leaking *Exxon Valdez* shortly after the spill (Matkin et al. 1993, 1994, 2008). Two whales were found dead, stranded in 1989-1990, both genetically assigned to the AT1 population and one visually recognized as AT19, one of the missing nine (Matkin et al. 1994, 2008; Heise et al. 2003). The second unidentified whale was most likely one of the other missing AT1 whales. Additional mortalities of four older males include whales AT1 found stranded in 2000, AT13 and AT17 missing in 2002 (one of which was thought to be the carcass from the AT1 population that was found in 2002), and AT14 missing in 2003. A genetically assigned AT1 stranded whale found in 2003 was probably AT14 but could also have been AT13 (Matkin et al. 2008). No births have occurred in this population since 1984 and none of the missing whales have been seen since 2003 and are presumed dead. There is an extremely small probability (0.4%) that AT1 killer whales that are missing for 3 years or more are still alive (Matkin et al. 2008). No AT1 whale missing for at least 4 years has ever been resighted and all 15 missing whales are presumed dead (Matkin et al. 2008). In 2015, all seven whales (AT2, AT3, AT4, AT6, AT9, AT10, and AT18) were observed by researchers from the North Gulf Oceanic Society. Therefore, the population estimate as of the summer of 2015 remains at seven whales (C. Matkin, North Gulf Oceanic Society, pers. comm., 20 October 2015). There has been no recruitment in this population since 1984 (Matkin et al. 2012).

Minimum Population Estimate

The abundance estimate of killer whales is a direct count of individually identifiable animals. Only 11 whales were seen between 1990 and 1999. Since then, four of those whales have not been seen for four or more consecutive years, so the minimum population estimate is seven whales (Matkin et al. 2008). Fourteen years of annual effort have failed to discover any whales that had not been seen previously, so there is no reason to believe there are additional whales in the population. Therefore, this minimum population estimate is the total population size.

Current Population Trend

The population counts have declined from a level of 22 whales in 1989 to 7 whales in 2015, a decline of 68%. Most of the mortality apparently occurred in 1989-1990.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

A reliable estimate of the maximum net productivity rate is currently unavailable for this stock of killer whales. Studies of resident killer whale pods in the Pacific Northwest resulted in estimated population growth rates of 2.9% and 2.5% over the period from 1973 to 1987 (Olesiuk et al. 1990, Brault and Caswell 1993). Until additional stock-specific data become available, it is recommended that the cetacean maximum theoretical net productivity rate (R_{MAX}) of 4% be employed for this stock (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the potential biological removal (PBR) is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: $PBR = N_{MIN} \times 0.5R_{MAX} \times F_R$. The recovery factor ($F_R$) for this stock is 0.1, as the stock is considered depleted under the MMPA and there has been no recruitment into the stock since 1984. Thus, for the AT1 killer whale stock, PBR = 0 whales ($7 \times 0.02 \times 0.1$).

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Detailed information on U.S. commercial fisheries in Alaska waters (including observer programs, observer coverage, and observed incidental takes of marine mammals) is presented in Appendices 3-6 of the Alaska Stock Assessment Reports.

The known range of the AT1 stock is limited to waters of Prince William Sound and Kenai Fjords. There are no federally-managed commercial fisheries in this area. State-managed commercial fisheries prosecuted within the range of this stock, such as the Prince William Sound salmon set and drift gillnet fisheries, and various herring fisheries, are not known to incur incidental mortality or serious injury of AT1 killer whales. Several subsistence fisheries (salmon, halibut, non-salmon finfish, and shellfish) also occur within this area, and no incidental mortality or serious injury has been reported for these fisheries.

Alaska Native Subsistence/Harvest Information

There are no reports of a subsistence harvest of killer whales in Alaska or Canada.

Other Mortality

Collisions with boats may be an occasional source of mortality or serious injury of killer whales. For example, a killer whale struck the propeller of a vessel in the Bering Sea/Aleutian Islands rockfish trawl fishery in 2010; however, this mortality did not involve a whale from the AT1 stock. There has been no known mortality or serious injury of AT1 killer whales due to ship strikes. Most of the mortality occurred from 1989 to 1990 following the *Exxon Valdez* oil spill.

STATUS OF STOCK

The AT1 Transient stock of killer whales is below its Optimum Sustainable Population and designated as depleted under the MMPA; therefore, it is classified as a strategic stock. The AT1 Transient stock is not listed as threatened or endangered under the Endangered Species Act. Based on currently available data, the estimated mean annual mortality and serious injury rate due to U.S. commercial fisheries (0) does not exceed 10% of the PBR (0) and, therefore, can be considered insignificant and approaching zero mortality and serious injury rate. At least 11 animals were alive in 1998, but it appears that only 7 individuals remain alive. The AT1 group has been reduced to 32% (7/22) of its 1984 level. Since no births have occurred in the past 30 years, it is unlikely that this stock will recover.

KILLER WHALE (*Orcinus orca*):
West Coast Transient Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Killer whales have been observed in all oceans and seas of the world (Leatherwood and Dahlheim 1978). Although reported from tropical and offshore waters, killer whales occur at higher densities in colder and more productive waters of both hemispheres, with the greatest densities found at high latitudes (Mitchell 1975, Leatherwood and Dahlheim 1978, Forney and Wade, 2006). Killer whales are found throughout the North Pacific. Along the west coast of North America, killer whales occur along the entire Alaskan coast (Braham and Dahlheim 1982), in British Columbia and Washington inland waterways (Bigg et al. 1990), and along the outer coasts of Washington, Oregon, and California (Green et al. 1992; Barlow 1995, 1997; Forney et al. 1995). Seasonal and year-round occurrence has been noted for killer whales throughout Alaska (Braham and Dahlheim 1982) and in the intracoastal waterways of British Columbia and Washington State, where whales have been labeled as 'resident,' 'transient,' and 'offshore' type killer whales (Bigg et al. 1990, Ford et al. 2000; Dahlheim et al. 2008) based on aspects of morphology, ecology, genetics, and behavior (Ford and Fisher 1982; Baird and Stacey 1988; Baird et al. 1992; Hoelzel et al. 1998, 2002; Barrett-Lennard 2000; Dahlheim et al. 2008). Through examination of photographs of recognizable individuals and pods, movements of whales between geographical areas have been documented. For example, whales identified in Prince William Sound have been observed near Kodiak Island (Matkin et al. 1999) and whales identified in Southeast Alaska have been observed in Prince William Sound, British Columbia, and Puget Sound (Leatherwood et al. 1990, Dahlheim et al. 1997). Movements of killer whales between the waters of Southeast Alaska and central California have also been documented (Goley and Straley 1994; Black et al. 1997; Dahlheim and White 2010).

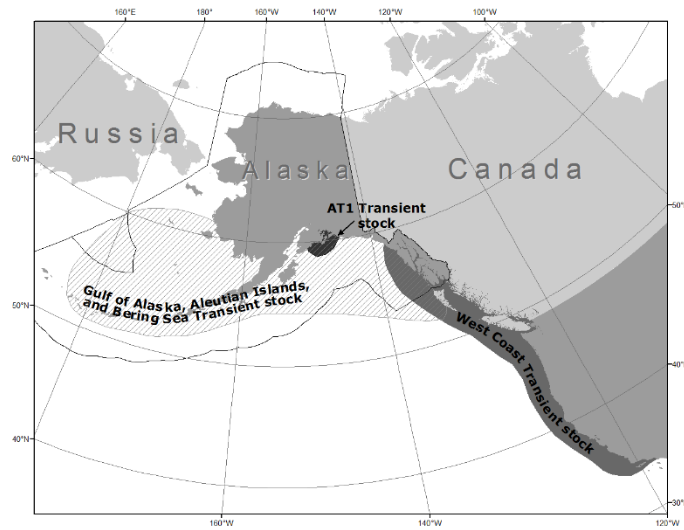

Figure 1. Approximate distribution of killer whales in the eastern North Pacific (shaded area). The distribution of the eastern North Pacific Resident and Transient stocks are largely overlapping (see text).

Several studies provide evidence that the 'resident', 'offshore', and 'transient' ecotypes are genetically distinct in both mtDNA and nuclear DNA (Hoelzel and Dover 1991; Hoelzel et al. 1998, 2002; Barrett-Lennard 2000). Genetic differences have also been found between populations within the 'transient' and 'resident' ecotypes (Hoelzel et al. 1998, 2002; Barrett-Lennard 2000). A recent global genetic study of killer whales using the entire mitochondrial genome found that some killer whale ecotypes represent deeply divergent evolutionary lineages and warrant elevation to species or subspecies status (Morin et al. 2010). In particular, estimates from mitogenome sequence data indicate that transient killer whales diverged from all other killer whale lineages ~700,000 years ago. In light of these differences, the Society for Marine Mammalogy's Committee on Taxonomy currently recognizes the resident and transient North Pacific ecotypes as un-named *Orcinus orca* subspecies (Committee on Taxonomy 2012). In recognition of its status as an un-named subspecies or species, some researchers now refer to transient-type killer whales as Bigg's killer whales (e.g., Ford 2011, Riesch et al. 2012), in tribute to the late Dr. Michael Bigg.

Based on data regarding association patterns, acoustics, movements, and genetic differences, eight killer whale stocks are now recognized within the Pacific U.S. EEZ: 1) the Alaska Resident stock - occurring from southeastern Alaska to the Aleutian Islands and Bering Sea, 2) the Northern Resident stock - occurring from Washington State through part of southeastern Alaska, 3) the Southern Resident stock - occurring mainly within the inland waters of Washington State and southern British Columbia, but also in coastal waters from southeastern Alaska through California, 4) the Gulf of Alaska, Aleutian Islands, and Bering Sea Transient stock - occurring mainly from Prince William Sound through the Aleutian Islands and Bering Sea, 5) the AT1 transient stock - occurring in Alaska from Prince William Sound through the Kenai Fjords, 6) the West Coast transient stock - occurring from California through southeastern Alaska, 7) the Offshore stock - occurring from California through Alaska, and 8) the Hawaiian stock. 'Transient' whales in Canadian waters are considered part of the West Coast Transient stock. The Stock Assessment Reports for the Alaska Region contain information concerning all the killer whale stocks except the Hawaiian and Offshore stocks.

Until recently, transient killer whales in Alaska had only been studied intensively in Southeast Alaska and in the Gulf of Alaska (from Prince William Sound, through the Kenai Fjords, and around Kodiak Island). In the Gulf of Alaska, Matkin et al. (1999) described two populations of transients which were never found in association with one another, the so-called 'Gulf of Alaska' transients and 'AT1' transients. Gulf of Alaska' transients are documented throughout the Gulf of Alaska, including occasional sightings in Prince William Sound. AT1 transients are primarily seen in Prince William Sound and in the Kenai Fjords region, and are therefore partially sympatric with 'Gulf of Alaska' transients. Recently members of the Gulf of Alaska transient population have been seen in association with the transient killer whales that range from California to southeastern Alaska, the west coast transients, which are identified by a unique mtDNA haplotype. Recent data have identified 14 out of 217 whales considered "outer coast" transients in British Columbia as photographed in Alaskan waters and considered Gulf of Alaska transients (Ford et al. 2013). Transients within the 'Gulf of Alaska' population have been found to have two mtDNA haplotypes, neither of which is found in the west coast or AT1 populations. Members of the AT1 population share a single mtDNA haplotype. Transient killer whales from the 'west coast' stock have been found to share a single mtDNA haplotype that is not found in the other communities. Additionally, all three populations have been found to have significant differences in nuclear (microsatellite) DNA (Barrett-Lennard 2000). Acoustic differences have been found, as well, as Saulitis (1993) and Saulitis et al. 2005 described acoustic differences between 'Gulf of Alaska' transients and AT1 transients. For these reasons, the 'Gulf of Alaska' transients are considered part of a population that is discrete from the AT1 population, and both of these communities are considered discrete from the 'west coast' transients.

Biopsy samples from the eastern Aleutians and south side of the end of the Alaska Peninsula have produced the same haplotypes as killer whales in the northern Gulf of Alaska, however nuclear DNA analysis strongly suggest they belong to a separate population (Parsons et al. 2013). Samples from the central Aleutian Islands and Bering Sea have identified mtDNA haplotypes not found in Gulf of Alaska transients, suggesting additional population structure in western Alaska. At this time, transient-type killer whales from the Aleutian Islands and Bering Sea are considered to be part of a single population that includes 'Gulf of Alaska' transients. Killer whales are observed in the northern Bering Sea and Beaufort Sea that have the physical characteristics of transient type whales, but little is known about these whales.

In summary, within the transient ecotype, association data (Ford et al. 1994, Ford and Ellis 1999, Matkin et al. 1999), acoustic data (Saulitis 1993, Ford and Ellis 1999) and genetic data (Hoelzel et al. 1998, 2002; Barrett-Lennard 2000, Parsons et al. 2013) confirm that at least three communities of transient whales exist and represent three discrete populations: 1) Gulf of Alaska, Aleutian Islands, and Bering Sea transients, 2) AT1 transients, and 3) West Coast transients.

Most of the transient whales photographed in the inland waters of Southeast Alaska share the west coast transient haplotype and have been seen in association with British Columbia/Washington State transients. Transients most often seen off California have also share the West Coast Transient (WCT) haplotype and have been observed in association with transients in Washington and British Columbia. The West Coast Transient Stock is therefore considered to include transient killer whales from California through southeastern Alaska. However, it should be noted that Fisheries and Oceans Canada recently decided to exclude whales from California from their assessment of the "West Coast Transient (WCT) Population" (DFO 2007). They noted that 100 or so transient killer whales identified off the central coast of California (Black et al. 1997) were in the past considered to be an extension of this population because of acoustical similarities and occasional mixing with WCT individuals in BC waters (Ford and Ellis 1999), but that a recent reassessment indicated that the available evidence was insufficient to warrant inclusion of those whales in the WCT population (DFO 2010). Canadian researchers have now identified 46 individual whales in British Columbia that are known from California (J. Ford, pers. comm., Department of Fisheries and Oceans, British Columbia, Canada, 30 January 2013). They also noted that the Gulf of Alaska transients are seen occasionally within the range of WCTs (in southeastern Alaska and off British Columbia) but have only been observed to travel in association with WCTs on one occasion (DFO 2007, Matkin et al. 2012). For the purposes of this stock assessment report, the West Coast Transient Stock continues to include animals that occur in California, Oregon, Washington, British Columbia and southeastern Alaska.

POPULATION SIZE

The west coast transient stock is a trans-boundary stock, including killer whales from British Columbia. Preliminary analysis of photographic data resulted in the following minimum counts for 'transient' killer whales belonging to the west coast transient stock. Over the time series from 1975 to 2012, 521 individual transient killer whales have been identified. Of these, 217 are considered part of the poorly known "outer coast" subpopulation and 304 belong to the well-known "inner coast" population. However of the 304, the number of whales currently alive is not certain (see Ford et al. 2013). A recent mark-recapture estimate that does not include the "outer coast" subpopulation or whales from California for the west coast transient population resulted in an estimate of 243 (95% probability interval = 180-339) in 2006 (DFO 2009). This estimate applies to the population of west coast transient whales that occur in the inside waters of southeastern Alaska, British Columbia, and northern Washington. Given that the California transient numbers have not been updated since the publication of the catalogue in 1997 (Black et al. 1997), the total number of transient killer whales reported above should be considered as a minimum count for the west coast transient stock.

Minimum Population Estimate

The abundance estimate of killer whales is a direct count of individually identifiable animals. However, the number of cataloged whales does not necessarily represent the number of live animals. Some animals may have died, but whales can not be presumed dead if not resighted because long periods of time between sightings are common for some 'transient' animals. The connection of the outer coast whales with the west coast transient population of inshore waters is not well established, and the photographic catalogue from California has not been updated in 15 years. Estimates of the overall population size (i.e., N_{BEST}) and associated CV(N) that include the "outer coast" whales are not currently available. Thus, the minimum population estimate (N_{MIN}) for the West Coast Transient stock of killer whales is derived from the recent mark-recapture analysis for West Coast transient population whales from the inside waters of Alaska and British Columbia of 243 whales (95% probability interval = 180-339) in 2006 (DFO 2009), which includes animals found in Canadian waters (see PBR Guidelines regarding the status of migratory trans-boundary stocks, Wade and Angliss 1997). Information on the percentage of time animals typically encountered in Canadian waters spend in U.S. waters is unknown. However, as noted above, this minimum population estimate is considered conservative. This approach is consistent with previous recommendations of the Alaska Scientific Review Group (DeMaster 1996).

Current Population Trend

Recent analyses of the inshore west coast transient population indicate that this segment grew rapidly from the mid-1970s to mid-1990s as a result of a combination of high birth rate, survival, as well as greater immigration of animals into the nearshore study area (DFO 2009). The rapid growth of the west coast transient population in the mid-1970s to mid-1990s coincided with a dramatic increase in the abundance of the whales' primary prey, harbor seals, in nearshore waters. Population growth began slowing in the mid-1990s and has continued to slow in recent years (DFO 2009). Given population estimates are based on photo identification of individuals and considered minimum estimates, no reliable estimate of trend is available.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

A reliable estimate of the maximum net productivity rate is currently unavailable for this stock of killer whales. Analyses in DFO (2009) estimated a rate of increase of about 6% per year in this population from 1975 to 2006, but this included recruitment of non-calf whales into the population, at least in the first half of the time period, interpreted as either a movement of some whales into nearshore waters from elsewhere, or from better spatial sampling coverage. The population increased at a rate of approximately 2% for the second half of the time period, when recruitment of new individuals was nearly exclusively from new-born individuals (DFO 2009). Studies of 'resident' killer whale pods in the Pacific Northwest resulted in estimated population growth rates of 2.92% and 2.54% over the period from 1973 to 1987 (Olesiuk et al. 1990, Brault and Caswell 1993) and an observed growth rate of 3.1% was observed in northern resident killer whales and used in calculations of R_{MAX} for that stock. However, until additional data become available for this stock of transient type killer whales, it is recommended that the cetacean maximum theoretical net productivity rate (R_{MAX}) of 4% be employed for this stock (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the potential biological removal (PBR) is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: PBR = $N_{MIN} \times 0.5R_{MAX} \times F_R$. The recovery factor ($F_R$) for this stock is 0.5, the value for cetacean stocks with unknown population status with a mortality rate CV = 0.80 (Wade and Angliss 1997). Thus, for the West Coast Transient killer whale stock, PBR = 2.4 animals (243 × 0.02 × 0.5). The proportion of time that this trans-boundary stock spends in Canadian waters cannot be determined (G. Ellis, Pacific Biological Station, Canada, pers. comm.)

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

New Serious Injury Guidelines

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an "*injury that is more likely than not to result in mortality*." Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

Fisheries Information

NMFS observers monitored the California/Oregon thresher shark/swordfish drift gillnet fishery from 1994 to 2003 (Julian 1997, Julian and Beeson 1998, Cameron and Forney 1999, Carretta 2002, Carretta and Chivers 2003, Carretta and Chivers 2004). The observed mortality in this fishery, in 1995, was a transient whale as determined by genetic testing (S. Chivers, NMFS-SWFSC, pers. comm.). Overall entanglement rates in the California/Oregon thresher shark/swordfish drift gillnet fishery dropped considerably after the 1997 implementation of a Take Reduction Plan, which included skipper education workshops and required the use of pingers and minimum 6-fathom extenders (Barlow and Cameron 1999). Because the California/Oregon thresher shark/swordfish drift gillnet fishery is observed and has not incurred incidental serious injuries or mortalities of killer whales between 1999-2003, the estimate of fishery-related take for this fishery is zero. Thus, the mean annual mortality rate for this stock is zero. Additional fisheries that could interact with the Eastern North Pacific Transient stock of killer whales are listed in Appendix 3.

The estimated minimum mortality rate incidental to recently monitored U.S. commercial fisheries is zero animals per year.

All Canadian trawl and longline fisheries are monitored by observers or video; salmon net fisheries are not observed (J. Ford, pers. comm., Department of Fisheries and Oceans, British Columbia, Canada, 30 January 2013). The sablefish longline fishery accounts for a large proportion of the commercial fishing/killer whale interactions in Alaska waters. However, transient killer whales typically are not involved in these interactions. Resident killer whales are well documented to interact with the longline fishery. Such interactions have not been reported in Canadian waters where sablefish are taken via a pot fishery. Canada has a Marine Mammal Response Network to track human interaction incidents such as entanglements (J. Ford, pers. comm., Department of Fisheries and Oceans, British Columbia, Canada, 30 January 2013). Since 1990, there have been no reported fishery-related strandings of killer whales in Canadian waters. In 1994, one killer whale was reported to have contacted a salmon gillnet, but it did not entangle (Guenther et al. 1995).

Subsistence/Native Harvest Information

There are no reports of a subsistence harvest of killer whales in Alaska or Canada.

Other Mortality

The shooting of killer whales in Canadian waters has been a concern in the past. However, in recent years there have been no reports of shooting incidents in Canadian waters. In fact, the likelihood of shooting incidents involving 'transient' killer whales is thought to be minimal since commercial fishermen are most likely to observe 'transients' feeding on seals or sea lions instead of interacting with their fishing gear (G. Ellis, Pacific Biological Station, Canada, pers. comm.).

Collisions with boats are another source of mortality. Killer whales interacting with trawl vessels are occasionally struck by the propeller; there were 4 incidents of mortality and serious injury in the Bering Sea/Aleutian Islands flatfish trawl and Bering Sea/ Aleutian Islands rockfish trawl fisheries between 2007-2011. Stock identification for these occurrences is unknown; however, this area is outside of the known range for this stock. There have been no reported mortalities of killer whales from this stock due to vessel collisions.

STATUS OF STOCK

The West Coast transient killer whale stock is not designated as "depleted" under the MMPA or listed as "threatened" or "endangered" under the Endangered Species Act. In 2001, the Committee on the Status of Endangered Wildlife in Canada designated west coast transient killer whales in British Columbia as "threatened" under the Species at Risk Act (SARA) for Canada. Human-caused mortality may have been underestimated, primarily due to a lack of information on Canadian fisheries, and that the minimum abundance estimate is considered conservative (because researchers continue to encounter new whales and provisionally classified whales from Southeast Alaska and off the coast of California were not included), resulting in a conservative PBR estimate. Based on currently available data, the estimated annual U. S. commercial fishery-related mortality level (0) does not exceed 10% of the PBR (0.2) and, therefore, can be considered to be insignificant and approaching zero mortality and serious injury rate. The estimated annual level of human-caused mortality and serious injury (0 animals per year) does not exceed the PBR (2.4). Therefore, the West Coast Transient stock of killer whales is not classified as a strategic stock. Population trends and status of this stock relative to its Optimum Sustainable Population (OSP) level are currently unknown.

PACIFIC WHITE-SIDED DOLPHIN (*Lagenorhynchus obliquidens*): North Pacific Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

The Pacific white-sided dolphin is found throughout the temperate North Pacific Ocean, north of the coasts of Japan and Baja California, Mexico. In the eastern North Pacific the species occurs from the southern Gulf of California, north to the Gulf of Alaska, west to Amchitka in the Aleutian Islands, and is rarely encountered in the southern Bering Sea. The species is common both on the high seas and along the continental margins, and animals are known to enter the inshore passes of Alaska, British Columbia, and Washington (Ferrero and Walker 1996).

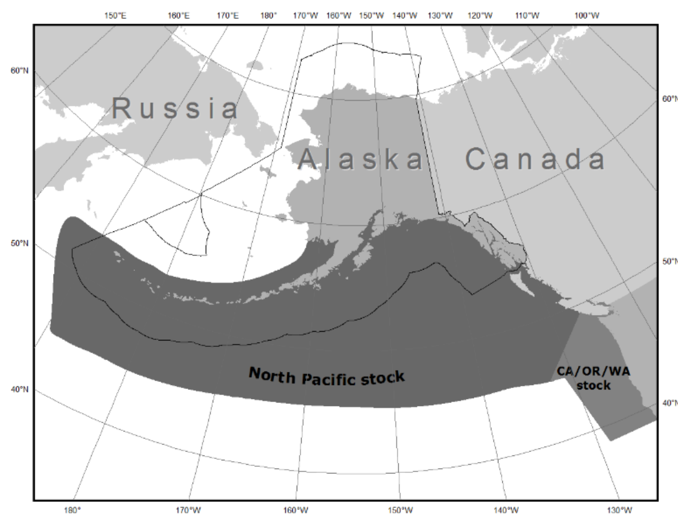

Figure 1. Approximate distribution of Pacific white-sided dolphins in the eastern North Pacific (dark shaded areas).

The following information was considered in classifying Pacific white-sided dolphin stock structure based on the Dizon et al. (1992) phylogeographic approach: 1) Distributional data: geographic distribution is continuous; 2) Population response data: unknown; 3) Phenotypic data: two morphological forms are recognized (Walker et al. 1986, Chivers et al. 1993); and 4) Genotypic data: preliminary genetic analyses on 116 Pacific white-sided dolphins collected in four areas (Baja California, the U.S. west coast, British Columbia/Southeast Alaska, and offshore) do not support phylogeographic partitioning, though they are sufficiently differentiated to be treated as separate management units (Lux et al. 1997). This limited information is not sufficient to define stock structure throughout the North Pacific beyond the generalization that a northern form occurs north of about 33°N from southern California along the coast to Alaska and a southern form ranges from about 36°N southward along the coasts of California and Baja California, while the core of the population ranges across the North Pacific to Japan at latitudes south of 45°N. Data are lacking to determine whether this latter group might include animals from one or both of the coastal forms. Although the genetic data are unclear, management issues support the designation of two stocks; because the California and Oregon thresher shark/swordfish drift gillnet fishery (operating between 33°N and approximately 47°N) and, to a lesser extent, the groundfish and salmon fisheries in Alaska are known to interact with Pacific white-sided dolphins, two management stocks are recognized: 1) the California/Oregon/Washington stock, and 2) the North Pacific stock (Fig. 1). The California/Oregon/Washington stock is reported separately in the Stock Assessment Reports for the U.S. Pacific Region.

POPULATION SIZE

The most complete population abundance estimate for Pacific white-sided dolphins was calculated from line-transect analyses applied to the 1987-1990 central North Pacific marine mammal sighting survey data (Buckland et al. 1993). The Buckland et al. (1993) abundance estimate, 931,000 (CV = 0.90) animals, more closely reflects a range-wide estimate rather than one that can be applied to either of the two management stocks off the west coast of North America. Furthermore, Buckland et al. (1993) suggested that Pacific white-sided dolphins show strong vessel attraction but that a correction factor was not available to apply to the estimate. While the Buckland et al. (1993) abundance estimate is not considered appropriate to apply to the management stock in Alaskan waters, the portion of the estimate derived from sightings north of 45°N in the Gulf of Alaska can be used as the population estimate for this area (26,880). For comparison, Hobbs and Lerczak (1993) estimated 15,200 (95% CI: 868-265,000) Pacific white-sided dolphins in the Gulf of Alaska based on a single sighting of 20 animals. Small cetacean aerial surveys in the Gulf of Alaska during 1997 sighted one group of 164 Pacific white-sided dolphins off Dixon entrance, while similar surveys in Bristol Bay in 1999 made 18 sightings of a school, or parts thereof, off Port Moller (R. Hobbs, NMFS-AFSC-NMML, pers. comm.).

Minimum Population Estimate

Historically, the minimum population estimate (N_{MIN}) for this stock was 26,880, based on the sum of abundance estimates for four separate 5° × 5° blocks north of 45°N (1,970 + 6,427 + 6,101 + 12,382 = 26,880) from surveys conducted during 1987-1990, reported in Buckland et al. (1993). This was considered a minimum estimate because the abundance of animals in a fifth 5° × 5° block (53,885), which straddled the boundary of the two coastal management stocks, was not included in the estimate for the North Pacific stock and because much of the potential habitat for this stock was not surveyed between 1987 and 1990. However, because the abundance estimate is more than 8 years old, the current minimum population estimate for this stock is unknown.

Current Population Trend

At present, there is no reliable information on trends in abundance for this stock of Pacific white-sided dolphins.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

A reliable estimate of the maximum net productivity rate is not currently available for the North Pacific stock of Pacific white-sided dolphins. Life-history analyses by Ferrero and Walker (1996) suggest a reproductive strategy consistent with the delphinid pattern on which the 4% cetacean maximum net productivity rate (R_{MAX}) was based. Thus, it is recommended that the cetacean maximum net productivity rate (R_{MAX}) of 4% be employed for this stock (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the potential biological removal (PBR) is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: PBR = $N_{MIN} \times 0.5R_{MAX} \times F_R$. The recovery factor ($F_R$) for this stock is 0.5, the value for cetacean stocks of unknown status (Wade and Angliss 1997). The estimate of abundance for Pacific white-sided dolphins is more than 8 years old; Wade and Angliss (1997) recommend that abundance estimates older than 8 years no longer be used to calculate a PBR level. In addition, there is no corroborating evidence from recent surveys in Alaska that provide abundance estimates for a portion of the stock's range or any indication of the current status of this stock. Thus, the PBR for this stock is undetermined (NMFS 2005).

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

New Serious Injury Guidelines

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an "*injury that is more likely than not to result in mortality*." Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

Fisheries Information

Between 1978 and 1991, mortality and serious injury of thousands of Pacific white-sided dolphins occurred annually incidental to high-seas fisheries for salmon and squid. However, these fisheries were closed in 1991 and no other large-scale fisheries have operated in the central North Pacific since 1991.

Detailed information (including observer programs, observer coverage, and observed incidental takes of marine mammals) for federally-managed and state-managed U.S. commercial fisheries in Alaska waters is presented in Appendices 3-6 of the Alaska Stock Assessment Reports.

Until 2003, there were six different federally-regulated commercial fisheries in Alaska that could have interacted with Pacific white-sided dolphins. These fisheries were monitored for incidental mortality and serious injury by fishery observers. As of 2003, changes in fishery definitions in the MMPA List of Fisheries have resulted in separating these 6 fisheries into 22 fisheries (69 FR 70094, 2 December 2004). This change does not represent a change in fishing effort but provides managers with better information on the component of each fishery that is responsible for the incidental mortality or serious injury of marine mammal stocks in Alaska. No mortality or serious injury of Pacific white-sided dolphins incidental to observed U.S. commercial fisheries was reported between 2009 and 2013 (Breiwick 2013; NMML, unpubl. data).

Note that no observers have been assigned to several of the gillnet fisheries that are known to interact with this stock, making the estimated mortality and serious injury rate unreliable. However, because the stock size is large, it is unlikely that unreported mortality and serious injury from those fisheries would be significant.

Alaska Native Subsistence/Harvest Information

There are no reports of subsistence takes of Pacific white-sided dolphins in Alaska.

Other Mortality

From 2009 to 2013, no human-caused mortality or serious injury of Pacific white-sided dolphins was reported to the NMFS Alaska Region stranding database (Helker et al. 2015).

STATUS OF STOCK

Pacific white-sided dolphins are not designated as "depleted" under the MMPA or listed as "threatened" or "endangered" under the Endangered Species Act. The North Pacific stock of Pacific white-sided dolphins is not classified as a strategic stock. Because the PBR for Pacific white-sided dolphins is undetermined, the level of human-caused mortality and serious injury relative to PBR is unknown and the level of annual U.S. commercial fishery-related mortality and serious injury that can be considered insignificant and approaching zero mortality and serious injury rate is unknown. Population trends and status of this stock relative to its Optimum Sustainable Population are currently unknown.

HABITAT CONCERNS

While the majority of Pacific white-sided dolphins are found throughout the North Pacific, there are also significant numbers found in shelf break and deeper nearshore areas. Thus, they are subject to a variety of habitat impacts. Of particular concern are nearshore areas, bays, channels, and inlets where some Pacific white-sided dolphins are vulnerable to physical modifications of nearshore habitats, resulting from urban and industrial development (including waste management and nonpoint source runoff), and noise (Linnenschmidt et al. 2013).

HARBOR PORPOISE (*Phocoena phocoena*): Southeast Alaska Stock

NOTE – December 2015: In areas outside of Alaska, studies of harbor porpoise distribution have indicated that stock structure is likely more fine-scaled than is reflected in the Alaska Stock Assessment Reports. At this time, no data are available to define stock structure for harbor porpoise on a finer scale in Alaska. However, based on comparisons with other regions, it is likely that several regional and sub-regional populations exist. Should new information on harbor porpoise stocks become available, the harbor porpoise Stock Assessment Reports will be updated.

STOCK DEFINITION AND GEOGRAPHIC RANGE

In the eastern North Pacific Ocean, harbor porpoise range from Point Barrow and offshore areas of the Chukchi Sea, along the Alaska coast, and down the west coast of North America to Point Conception, California (Gaskin 1984, Christman and Aerts 2015). Harbor porpoise primarily frequent the coastal waters of the Gulf of Alaska and Southeast Alaska (Dahlheim et al. 2000, 2009), typically occurring in waters less than 100 m deep (Hobbs and Waite 2010). Within the inland waters of Southeast Alaska, harbor porpoise distribution is clumped with greatest densities observed in the Glacier Bay/Icy Strait region and near Zarembo and Wrangell Islands and the adjacent waters of Sumner Strait (Dahlheim et al. 2009). The average density of harbor porpoise in Alaska appears to be less than that reported off the west coast of the continental U.S., although areas of high densities do occur in Glacier Bay and the adjacent waters of Icy Strait, Yakutat Bay, the Copper River Delta, Sitkalidak Strait (Dahlheim et al. 2000, 2009, 2015; Hobbs and Waite 2010), and lower Cook Inlet (Shelden et al. 2014).

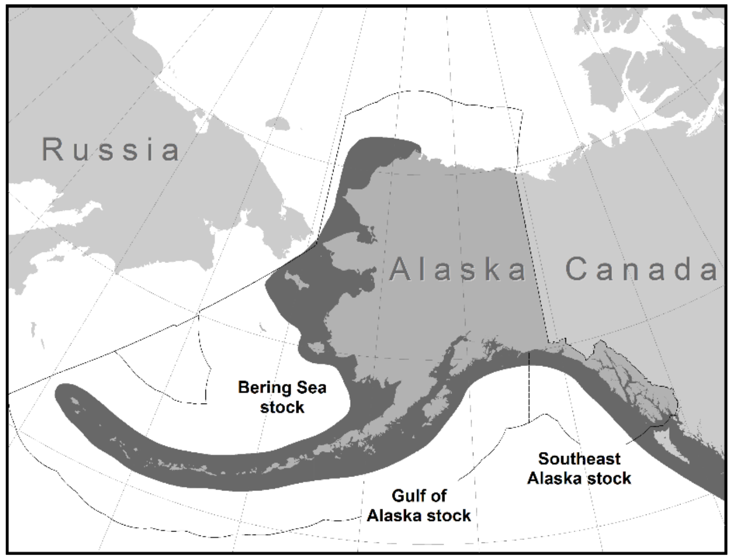

Figure 1. Approximate distribution of harbor porpoise in Alaska waters (dark shaded area).

Stock discreteness in the eastern North Pacific was analyzed using mitochondrial DNA from samples collected along the west coast (Rosel 1992), including one sample from Alaska. Two distinct mitochondrial DNA groupings or clades were found. One clade is present in California, Washington, British Columbia, and the single sample from Alaska (no samples were available from Oregon), while the other is found only in California and Washington. Although these two clades are not geographically distinct by latitude, the results may indicate a low mixing rate for harbor porpoise along the west coast of North America. Investigation of pollutant loads in harbor porpoise ranging from California to the Canadian border also suggests restricted harbor porpoise movements (Calambokidis and Barlow 1991); these results are reinforced by a similar study in the northwest Atlantic (Westgate and Tolley 1999). Further genetic testing of the same samples mentioned above, along with a few additional samples including eight more from Alaska, found differences between some of the four areas investigated, California, Washington, British Columbia, and Alaska, but inference was limited by small sample size (Rosel et al. 1995). Those results demonstrate that harbor porpoise along the west coast of North America are not panmictic and that movement is sufficiently restricted to result in genetic differences. This is consistent with low movement suggested by genetic analysis of harbor porpoise specimens from the North Atlantic (Rosel et al. 1999). Numerous stocks have been delineated with clinal differences over areas as small as the waters surrounding the British Isles (Walton 1997). In a molecular genetic analysis of small-scale population structure of eastern North Pacific harbor porpoise, Chivers et al. (2002) included 30 samples from Alaska, 16 of which were from the Copper River Delta, 5 from Barrow, 5 from Southeast Alaska, and 1 sample each from St. Paul, Adak, Kodiak, and Kenai. Unfortunately, no conclusions could be drawn about the genetic structure of harbor porpoise within Alaska because of the insufficient number of samples from each region. Accordingly, harbor porpoise stock structure in Alaska is defined by geographic areas at this time.

Although it is difficult to determine the true stock structure of harbor porpoise populations in the northeast Pacific, from a management standpoint it would be prudent to assume that regional populations exist and that they should be managed independently (Rosel et al. 1995, Taylor et al. 1996). For example, the porpoise concentrations found in Glacier Bay/Icy Strait and around Zarembo/Wrangell Islands may represent different subpopulations (Dahlheim et al. 2015) based on analogy with other west coast harbor porpoise populations, differences in trends in abundance of the two concentrations, and a hiatus in distribution between the northern and southern harbor porpoise concentrations. NMFS will consider whether these concentrations should be considered "prospective stocks" in a future Stock Assessment Report. Incidental takes from commercial fisheries within a small region (e.g., Wrangell and Zarembo Islands area) are of concern because of the potential impact on undefined localized stocks of harbor porpoise.

Accordingly, from the above information, three harbor porpoise stocks in Alaska were specified, recognizing that the boundaries of these three stocks were identified primarily based upon geography or perceived areas of porpoise low density: 1) the Southeast Alaska stock - occurring from Dixon Entrance to Cape Suckling, Alaska, 2) the Gulf of Alaska stock - occurring from Cape Suckling to Unimak Pass, and 3) the Bering Sea stock - occurring throughout the Aleutian Islands and all waters north of Unimak Pass (Fig. 1). To date, there have been no analyses to assess the validity of these stock designations or to assess possible substructure within these stocks.

POPULATION SIZE

Information on harbor porpoise abundance and relative abundance has been collected for coastal and inside waters of Southeast Alaska by the Alaska Fisheries Science Center's Marine Mammal Laboratory (MML) using both aerial and shipboard surveys. Aerial surveys of this stock were conducted in June and July 1997 and resulted in an observed abundance estimate of 3,766 (CV = 0.162) porpoise (Hobbs and Waite 2010); the surveys included a subset of smaller bays and inlets. Correction factors for observer perception bias and porpoise availability at the surface were used to develop an estimated corrected abundance of 11,146 (3,766 × 2.96; CV = 0.242) harbor porpoise in the coastal and inside waters of Southeast Alaska (Hobbs and Waite 2010).

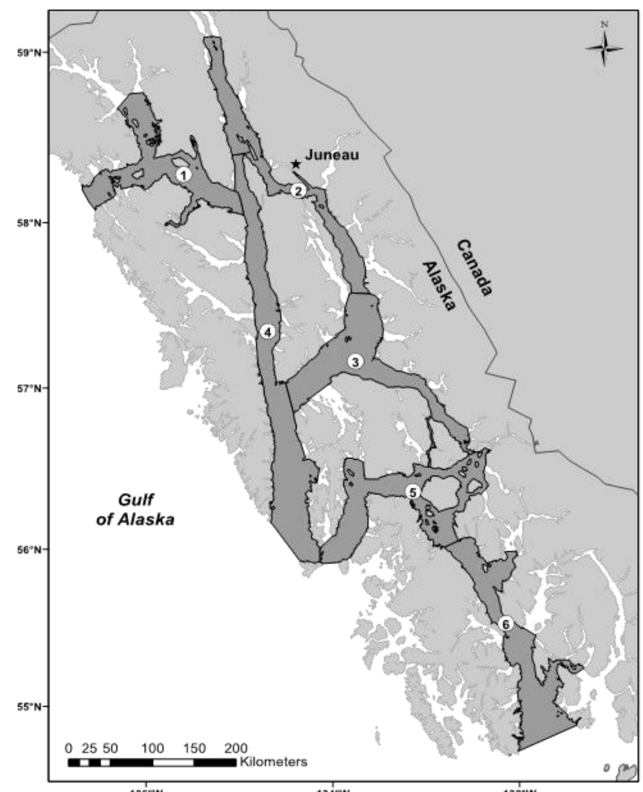

Figure 2. Survey strata defined for line-transect survey effort allocation in Southeast Alaska (as illustrated in Fig. 1 of Dahlheim et al. 2015).

In 1991, researchers initiated harbor porpoise studies aboard the NOAA ship *John N. Cobb* with broad survey coverage through the inland waters of Southeast Alaska. Between 1991 and 1993, line-transect methodology was used to 1) obtain population estimates of harbor porpoise, 2) establish a baseline for detecting trends in abundance, and 3) define overall distributional patterns and seasonality of harbor porpoise. The 1991-1993 vessel surveys were carried out each year in the spring, summer, and fall. Annual surveys were continued between 1994 and 2005; however, only two trips per year were conducted, one either in spring or summer and the other in fall. These surveys were not designed to survey harbor porpoise habitat and standard line-transect methodology was not used; however, all cetaceans observed were recorded. During this 12-year period, observers reported fewer overall encounters with harbor porpoise. To fully assess abundance and population trends for harbor porpoise, line-transect methodology was used during the survey cruises in 2006 and 2007 (Dahlheim et al. 2009) and in 2010-2012. Previous studies reported no evidence of seasonality for harbor porpoise occupying the inland waters of Southeast Alaska. Thus, only data collected during the summer season were analyzed, given the broader spatial coverage and the greater number of surveys (i.e., a total of eight line-transect vessel surveys) completed during this season. Methods applied to the 2006-2012 surveys were comparable to those employed during the early 1990s; however, because these surveys only covered a portion of inland waters and not the entire range of this stock, they are not used to compute a stock-specific estimate of abundance. Each year, greater densities of harbor porpoise were observed in the Glacier Bay/Icy Strait region and near Zarembo and Wrangell Islands and adjacent waters of Sumner Strait. The relative abundance of harbor porpoise in inland waters of Southeast Alaska was found to vary across survey periods spanning the 22-year study (1991-2012). Abundance estimated in 1991-1993 (N = 1,076; 95% CI = 910-1,272) was higher than the estimate obtained for 2006-2007 (N = 604; 95% CI = 468-780) but comparable to the estimate for 2010-2012 (N = 975; 95% CI = 857-1,109; Dahlheim et al. 2015). These estimates assume the probability of detection directly on the trackline to be unity (g(0) = 1) because estimates of g(0) have not been computed for these surveys. Therefore, these estimates may be biased low to an unknown degree. A range of possible g(0) values for harbor porpoise vessel surveys in other regions is 0.5-0.8 (Barlow 1988, Palka 1995), suggesting that as much as 50% of the porpoise can be missed, even by experienced observers.

Using the 2010-2012 survey data for the inland waters of Southeast Alaska, Dahlheim et al. (2015) calculated abundance estimates for the concentrations of harbor porpoise in the northern (Areas 1, 2, and 4) and southern (Areas 3, 5, and 6) regions of the inland waters (Fig. 2). The resulting abundance estimates are 398 (CV = 0.12) harbor porpoise in the northern inland waters (including Cross Sound, Icy Strait, Glacier Bay, Lynn Canal, Stephens Passage, and Chatham Strait) and 577 (CV = 0.14) harbor porpoise in the southern inland waters (including Frederick Sound, Sumner Strait, Wrangell and Zarembo Islands, and Clarence Strait as far south as Ketchikan). Because these abundance estimates have not been corrected for g(0), these estimates are likely conservative.

Minimum Population Estimate

For the Southeast Alaska stock of harbor porpoise, the minimum population estimate (N_{MIN}) for the 1997 aerial surveys is 1,996 calculated using Equation 1 from the potential biological removal (PBR) guidelines (Wade and Angliss 1997): $N_{MIN} = N/\exp(0.842 \times [\ln(1+[CV(N)]^2)]^{½})$. However, these survey data are now more than 8 years old. Using the 2010-2012 abundance estimate for harbor porpoise occupying the inland waters of Southeast Alaska of 975 (CV = 0.10), N_{MIN} is 896 harbor porpoise. Since the abundance estimate represents some portion of the total number of animals in the stock, using this estimate to calculate N_{MIN} results in a negatively-biased N_{MIN} for the stock. Although harbor porpoise in the northern and southern regions of the inland waters of Southeast Alaska have not been determined to be subpopulations or stocks, PBR calculations for these areas may provide a frame of reference for comparison to harbor porpoise takes in the portion of the Southeast Alaska salmon drift gillnet fishery that was monitored in 2012-2013. We used pooled 2010-2012 abundance estimates of 398 (CV = 0.12; assumes g(0) = 1) for the northern region and 577 (CV = 0.14; assumes g(0) = 1) for the southern region (Dahlheim et al. 2015) to calculate N_{MINs} of 359 and 513, respectively, for the concentrations of harbor porpoise in the northern and southern regions of the inland waters of Southeast Alaska. ADF&G Districts 6, 7, and 8, where the Southeast Alaska salmon drift gillnet fishery was observed in 2012-2013 (Manly 2015), partially overlap porpoise survey areas (Areas 5 and 6: Dahlheim et al. 2015) in the southern region of the inland waters.

Current Population Trend

The abundance of harbor porpoise in the Southeast Alaska stock was estimated in 1993 and 1997. In 1993, abundance estimates were determined from a coastal aerial survey from Prince William Sound to Dixon Entrance and a vessel survey in the inside waters of Southeast Alaska (Dahlheim et al. 2000). These surveys produced abundance estimates of 3,982 and 1,586 for the two areas, respectively, giving a combined estimate for the range of the Southeast Alaska harbor porpoise stock of 5,568. The 1997 abundance estimate was determined with an aerial survey for both the coastal region from Prince William Sound to Dixon Entrance and the inside waters of Southeast Alaska (Hobbs and Waite 2010). The 1997 estimate of 11,146 is double the 1993 estimate; however these estimates are not directly comparable because of differences in survey methods. The total area surveyed in 1997 was greater than in 1993 and included a correction of perception bias. For this reason, these estimates from aerial surveys are not appropriate to estimate trends.

An analysis of the line-transect vessel survey data collected throughout the inland waters of Southeast Alaska between 1991 and 2010 suggested high probabilities of a population decline ranging from 2 to 4% per year for the whole study area and highlighted a potentially important conservation issue (Zerbini et al. 2011). However, when data from 2011 and 2012 were added to this analysis, the population decline was no longer significant (Dahlheim et al. 2015). It is unclear why a negative trend in harbor porpoise numbers was detected in inland waters of Southeast Alaska in 1991-2010 and reversed thereafter (Dahlheim et al. 2015). Regionally, abundance was relatively constant in the northern region of the inland waters of Southeast Alaska throughout the survey period, while declines were documented in the southern region (Dahlheim et al. 2015).

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

A reliable estimate of the maximum net productivity rate (R_{MAX}) is not currently available for the Southeast Alaska stock of harbor porpoise. Hence, until additional data become available, it is recommended that the cetacean maximum theoretical net productivity rate of 4% be employed (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the PBR is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: PBR = $N_{MIN} \times 0.5R_{MAX} \times F_R$. The recovery factor ($F_R$) for this stock is 0.5, the value for cetacean stocks with unknown population status (Wade and Angliss 1997). Using the N_{MIN} of 896 (based on the 2010-2012 abundance estimate for harbor porpoise in the inland waters of Southeast Alaska), PBR is 8.9 (896 × 0.02 × 0.5). However, based on text above related to prospective stocks, we have also calculated N_{MINs} and PBRs for harbor porpoise in the northern and southern regions of the inland waters of Southeast Alaska. These PBR calculations may provide a frame of reference for the observed takes of harbor porpoise in the portion of the Southeast Alaska salmon drift gillnet fishery that was monitored in 2012-2013. Based on the pooled 2010-2012 abundance estimates and corresponding N_{MINs}, the PBR calculations for the northern and southern regions of the inland waters of Southeast Alaska are 3.6 (N = 398; CV = 0.12; N_{MIN} = 359) and 5.1 (N = 577; CV = 0.14; N_{MIN} = 513) harbor porpoise, respectively.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Detailed information on U.S. commercial fisheries in Alaska waters (including observer programs, observer coverage, and observed incidental takes of marine mammals) is presented in Appendices 3-6 of the Alaska Stock Assessment Reports.

No mortality or serious injury of harbor porpoise from the Southeast Alaska stock has been observed incidental to U.S. federal commercial fisheries in Alaska in 2010-2014 (Breiwick 2013; MML, unpubl. data).

In 2007 and 2008, the Alaska Marine Mammal Observer Program (AMMOP) placed observers in four regions where the state-managed Yakutat salmon set gillnet fishery operates (Manly 2009). These regions included the Alsek River area, the Situk area, the Yakutat Bay area, and the Kaliakh River and Tsiu River areas. Based on four mortalities and serious injuries observed during these 2 years, the estimated mean annual mortality and serious injury rate in the Yakutat salmon set gillnet fishery was 22 harbor porpoise (Table 1).

In 2012 and 2013, the AMMOP placed observers on independent vessels in the state-managed Southeast Alaska salmon drift gillnet fishery in ADF&G Management Districts 6, 7, and 8 to assess mortality and serious injury of marine mammals (Manly 2015). These Management Districts cover areas of Frederick Sound, Sumner Strait, Clarence Strait, and Anita Bay which include, but are not limited to, areas around and adjacent to Petersburg and Wrangell and Zarembo Islands. In 2013, four harbor porpoise were observed entangled and released: two were determined to be seriously injured and two were determined to be not seriously injured. Based on the two observed serious injuries, 23 serious injuries were estimated for Districts 6, 7, and 8 in 2013, resulting in an estimated mean annual mortality and serious injury rate of 12 harbor porpoise in 2012-2013 (Table 1). Since these three districts represent only a portion of the overall fishing effort in this fishery, this is a minimum estimate of mortality for the fishery.

Table 1. Summary of incidental mortality and serious injury of harbor porpoise from the Southeast Alaska stock due to U.S. commercial fisheries in 2010-2014 (or the most recent data available) and calculation of the mean annual mortality and serious injury rate (Manly 2009, 2015). Methods for calculating percent observer coverage are described in Appendix 6 of the Alaska Stock Assessment Reports.

Fishery name	Years	Data type	Percent observer coverage	Observed mortality	Estimated mortality	Mean estimated annual mortality
Yakutat salmon set gillnet	2007 2008	obs data	5.3 7.6	1 3	16.1 27.5	22 (CV = 0.54)
SE Alaska salmon drift gillnet (Districts 6, 7, and 8)	2012 2013	obs data	6.4 6.6	0 2	0 23	12 (CV = 1.0)
Minimum total estimated annual mortality						34 (CV = 0.77)

One harbor porpoise mortality due to entanglement in a Yakutat salmon set gillnet, was reported to the NMFS Alaska Region in 2010 (Helker et al. 2016); however, the AMMOP mean estimated annual mortality for the fishery accounts for this mortality (Table 1).

A complete estimate of the total mortality and serious injury incidental to U.S. commercial fisheries is unavailable for this stock because not all salmon and herring fisheries have been observed. However, the minimum mean annual mortality and serious injury rate incidental to U.S. fisheries is estimated as 34 harbor porpoise.

Alaska Native Subsistence/Harvest Information

Subsistence hunters in Alaska have not been reported to take from this stock of harbor porpoise.

STATUS OF STOCK

Harbor porpoise are not designated as depleted under the MMPA or listed as threatened or endangered under the Endangered Species Act. The total estimated annual level of human-caused mortality and serious injury for Southeast Alaska harbor porpoise (34 porpoise) exceeds the calculated PBR (8.9 porpoise), and the mean annual U.S. commercial fishery-related mortality and serious injury rate (34 porpoise) is more than 10% of the calculated PBR (10% of PBR = 0.9 porpoise). However, the calculated PBR is considered unreliable for the entire stock because it is based on estimates from surveys of only a portion (the inside waters of Southeast Alaska) of the range of this stock as currently designated. Because the abundance estimates are more than 8 years old (with the exception of the 2010-2012 abundance estimates provided for the inland waters of Southeast Alaska) and the frequency of incidental mortality and serious injury in U.S. commercial fisheries throughout Southeast Alaska is not known, the Southeast Alaska stock of harbor porpoise is classified as a strategic stock. Population trends and status of this stock relative to its Optimum Sustainable Population are currently unknown.

HABITAT CONCERNS

Harbor porpoise are mostly found in nearshore areas and inland waters, including bays, tidal areas, and river mouths (Dahlheim et al. 2000, 2009, 2015; Hobbs and Waite 2010). As a result, harbor porpoise are vulnerable to physical modifications of nearshore habitats resulting from urban and industrial development (including waste management and nonpoint source runoff) and activities such as construction of docks and other over-water structures, filling of shallow areas, dredging, and noise (Linnenschmidt et al. 2013).

HARBOR PORPOISE (*Phocoena phocoena*): Gulf of Alaska Stock

NOTE – December 2015: In areas outside of Alaska, studies of harbor porpoise distribution have indicated that stock structure is likely more fine-scaled than is reflected in the Alaska Stock Assessment Reports. At this time, no data are available to define stock structure for harbor porpoise on a finer scale in Alaska. However, based on comparisons with other regions, it is likely that several regional and sub-regional populations exist. Should new information on harbor porpoise stocks become available, the harbor porpoise Stock Assessment Reports will be updated.

STOCK DEFINITION AND GEOGRAPHIC RANGE

In the eastern North Pacific Ocean, the harbor porpoise ranges from Point Barrow and offshore areas of the Chukchi Sea, along the Alaska coast, and down the west coast of North America to Point Conception, California (Gaskin 1984, Christman and Aerts 2015). Harbor porpoise primarily frequent the coastal waters of the Gulf of Alaska and Southeast Alaska (Dahlheim et al. 2000, 2009), typically occurring in waters less than 100 m deep (Hobbs and Waite 2010). The average density of harbor porpoise in Alaska appears to be less than that reported off the west coast of the continental U.S., although areas of high densities do occur in Glacier Bay and the adjacent waters of Icy Strait, Yakutat Bay, the Copper River Delta, Sitkalidak Strait (Dahlheim et al. 2000, 2009, 2015; Hobbs and Waite 2010), and lower Cook Inlet (Shelden et al. 2014).

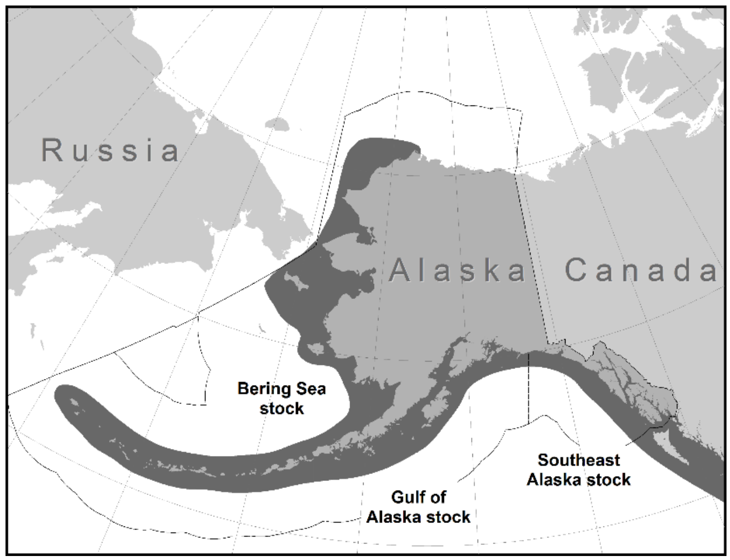

Figure 1. Approximate distribution of harbor porpoise in Alaska waters (dark shaded area).

Stock discreteness in the eastern North Pacific was analyzed using mitochondrial DNA from samples collected along the west coast (Rosel 1992), including one sample from Alaska. Two distinct mitochondrial DNA groupings or clades were found. One clade is present in California, Washington, British Columbia, and the single sample from Alaska (no samples were available from Oregon), while the other is found only in California and Washington. Although these two clades are not geographically distinct by latitude, the results may indicate a low mixing rate for harbor porpoise along the west coast of North America. Investigation of pollutant loads in harbor porpoise ranging from California to the Canadian border also suggests restricted harbor porpoise movements (Calambokidis and Barlow 1991); these results are reinforced by a similar study in the northwest Atlantic (Westgate and Tolley 1999). Further genetic testing of the same samples mentioned above, along with a few additional samples including eight more from Alaska, found differences between some of the four areas investigated, California, Washington, British Columbia, and Alaska, but inference was limited by small sample size (Rosel et al. 1995). Those results demonstrate that harbor porpoise along the west coast of North America are not panmictic and that movement is sufficiently restricted to result in genetic differences. This is consistent with low movement suggested by genetic analysis of harbor porpoise specimens from the North Atlantic (Rosel et al. 1999). Numerous stocks have been delineated with clinal differences over areas as small as the waters surrounding the British Isles (Walton 1997). In a molecular genetic analysis of small-scale population structure of eastern North Pacific harbor porpoise, Chivers et al. (2002) included 30 samples from Alaska, 16 of which were from Copper River Delta, 5 from Barrow, 5 from Southeast Alaska, and 1 sample each from St. Paul, Adak, Kodiak, and Kenai. Unfortunately, no conclusions could be drawn about the genetic structure of harbor porpoise within Alaska because of the insufficient number of samples from each region. Accordingly, harbor porpoise stock structure in Alaska is defined by geographic areas at this time.

Although it is difficult to determine the true stock structure of harbor porpoise populations in the northeast Pacific, from a management standpoint, it would be prudent to assume that regional populations exist and that they should be managed independently (Rosel et al. 1995, Taylor et al. 1996). Accordingly, from the above information, three harbor porpoise stocks in Alaska were specified, recognizing that the boundaries of these three stocks were inferred primarily based upon geography or perceived areas of low porpoise density: 1) the Southeast Alaska stock - occurring from Dixon Entrance to Cape Suckling, Alaska, 2) the Gulf of Alaska stock - occurring from Cape Suckling to Unimak Pass, and 3) the Bering Sea stock - occurring throughout the Aleutian Islands and all waters north of Unimak Pass (Fig. 1). To date, there have been no analyses to assess the validity of these stock designations or to assess possible substructure within these stocks.

POPULATION SIZE

In June and July of 1998 and 1999, an aerial survey covered the waters of the western Gulf of Alaska from Cape Suckling to Unimak Island, offshore to the 1,000 fathom depth contour. Two types of corrections were needed for these aerial surveys: one for observer perception bias and one to correct for porpoise availability/visibility at the surface. The 1998 survey resulted in an abundance estimate for the Gulf of Alaska harbor porpoise stock of 10,489 (CV = 0.115) animals (Hobbs and Waite 2010), which includes a correction factor (1.372; CV = 0.066) for perception bias to correct for animals that were present but not counted because they were not detected by observers. Laake et al. (1997) estimated the availability bias for aerial surveys of harbor porpoise in Puget Sound to be 2.96 (CV = 0.180); the use of this correction factor is preferred to other published correction factors (e.g., Barlow et al. 1988, Calambokidis et al. 1993) because it is an empirical estimate of availability bias. The estimated corrected abundance estimate from the 1998 survey is 31,046 (10,489 × 2.96 = 31,046; CV = 0.214) (Hobbs and Waite 2010).

This latest estimate of abundance (31,046) is considerably higher than the estimate reported in the 1999 stock assessment (8,271; CV = 0.309), which was based on surveys in 1991-1993. This disparity largely stems from changes in the area covered by the two surveys and differences in harbor porpoise density encountered in areas added to, or dropped from, the 1998 survey relative to the 1991-1993 surveys. The survey area in 1998 (119,183 km^2) was greater than the area covered in the combined portions of the 1991, 1992, and 1993 surveys (106,600 km^2). The 1998 survey included selected bays, channels, and inlets in Prince William Sound, the outer Kenai Peninsula, the south side of the Alaska Peninsula, and the Kodiak Archipelago, whereas, the earlier survey included only open water areas. Several of the bays and inlets covered by the 1998 survey had higher harbor porpoise densities than observed in the open waters. In addition, the 1998 estimate provided by Hobbs and Waite (2010) empirically estimates the perception bias and uses this in addition to the correction factor for availability bias. Finally, the 1998 estimate extrapolates available densities to estimate the number of porpoise which would likely be found in unsurveyed inlets within the study area. For these reasons, the 1998 survey result is probably more representative of the size of the Gulf of Alaska harbor porpoise stock.

Minimum Population Estimate

The minimum population estimate (N_{MIN}) for this stock is calculated using Equation 1 from the potential biological removal (PBR) guidelines (Wade and Angliss 1997): $N_{MIN} = N/\exp(0.842\times[\ln(1+[CV(N)]^2)]^{½})$. Using the population estimate (N) of 31,046 and its associated coefficient of variation (CV) of 0.214, N_{MIN} for the Gulf of Alaska stock of harbor porpoise is 25,987 (Hobbs and Waite 2010). However, because the survey data are now more than 8 years old, N_{MIN} is considered unknown.

Current Population Trend

At present, there is no reliable information on trends in abundance for the Gulf of Alaska stock of harbor porpoise since survey methods and results are not comparable.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

A reliable estimate of the maximum net productivity rate (R_{MAX}) is not currently available for the Gulf of Alaska stock of harbor porpoise. Hence, until additional data become available, it is recommended that the cetacean maximum theoretical net productivity rate of 4% be employed (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the PBR is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: $PBR = N_{MIN} \times 0.5R_{MAX} \times F_R$. The recovery factor ($F_R$) for this stock is 0.5, the value for cetacean stocks with unknown population status (Wade and Angliss 1997). However, the 2005 revisions to the Stock Assessment Report guidelines (Wade and Angliss 1997) state that abundance estimates older than 8 years should not be used to calculate PBR due to a decline in confidence in the reliability of an aged abundance estimate (NMFS 2005). Therefore, the PBR for this stock is considered undetermined.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Detailed information on U.S. commercial fisheries in Alaska waters (including observer programs, observer coverage, and observed incidental takes of marine mammals) is presented in Appendices 3-6 of the Alaska Stock Assessment Reports.

No incidental mortality or serious injury of the Gulf of Alaska stock of harbor porpoise was observed in U.S. commercial fisheries in 2010-2014 (Breiwick 2013; MML, unpubl. data). Observers monitoring the State of Alaska-managed Prince William Sound salmon drift gillnet fishery in 1990 and 1991 recorded 1 mortality in 1990 and 3 in 1991, which extrapolated to 8 (95% CI: 1-23) and 32 (95% CI: 3-103) for the entire fishery, resulting in a mean annual mortality and serious injury rate of 20 (CV = 0.60) porpoise when averaged over 1990 and 1991 (Table 1; Wynne et al. 1991, 1992). The Prince William Sound salmon drift gillnet fishery has not been observed since 1991 and no additional data are available for that fishery.

In 1999 and 2000, observers were placed on the state-managed Cook Inlet salmon set and drift gillnet vessels. One harbor porpoise mortality was observed in 2000 in the Cook Inlet salmon drift gillnet fishery (Manly 2006). This single mortality extrapolates to an estimated mortality and serious injury rate of 31 porpoise for that year and an average of 16 porpoise per year when averaged over the 2 years of observer data (Table 1).

In 2002 and 2005, observers were placed on state-managed Kodiak Island set gillnet vessels. Harbor porpoise mortality observed in this fishery (2 each in both 2002 and 2005) (Manly 2007) extrapolates to an estimated mean annual mortality and serious injury rate of 36 harbor porpoise (Table 1).

Table 1. Summary of incidental mortality and serious injury of Gulf of Alaska harbor porpoise due to state-managed fisheries from 1990 through 2005 and calculation of the mean annual mortality and serious injury rate (Wynne et al. 1991, 1992; Manly 2006, 2007). Methods for calculating percent observer coverage are described in Appendix 6 of the Alaska Stock Assessment Reports.

Fishery name	Years	Data type	Percent observer coverage	Observed mortality	Estimated mortality	Mean estimated annual mortality
Prince William Sound salmon drift gillnet	1990 1991	obs data	4 5	1 3	8 32	20 (CV = 0.60)
Cook Inlet salmon drift gillnet	1999 2000	obs data	1.6 3.6	0 1	0 31	16 (CV = 1.0)
Cook Inlet salmon set gillnet	1999 2000	obs data	0.16-1.1 0.34-2.7	0 0	0 0	0
Kodiak Island set gillnet	2002 2005	obs data	6.0 4.9	2 2	32 39	36 (CV = 0.68)
Minimum total estimated annual mortality						72 (CV = 0.44)

Strandings of marine mammals with fishing gear attached or with injuries caused by interactions with fishing gear are another source of mortality data. In 2013, one Gulf of Alaska harbor porpoise mortality, due to entanglement in a commercial salmon drift gillnet near Kenai, Alaska, was reported to the NMFS Alaska Region stranding network (Helker et al. 2016). However, this event is accounted for in the extrapolated estimate (derived from Alaska Marine Mammal Observer Program (AMMOP) observer data) of annual mortality and serious injury occurring in the commercial Cook Inlet salmon drift gillnet fishery (Table 1). An additional harbor porpoise mortality from this stock, due to entanglement in unidentified fishing net near Homer, Alaska, was reported to the NMFS Alaska Region in 2014, resulting in a minimum mean annual mortality and serious injury rate of 0.2 harbor porpoise in unknown (commercial, recreational, or subsistence) fisheries in 2010-2014 (Table 2; Helker et al. 2016).

Table 2. Summary of incidental mortality and serious injury of Gulf of Alaska harbor porpoise, by year and type, reported to the NMFS Alaska Region marine mammal stranding network in 2010-2014 (Helker et al. 2016). Only cases of serious injury were recorded in this table; animals with non-serious injuries have been excluded.

Cause of Injury	2010	2011	2012	2013	2014	Mean annual mortality
Entangled in unidentified net*	0	0	0	0	1	0.2
*Total in unknown (commercial, recreational, or subsistence) fisheries						0.2

A complete estimate of the total mortality and serious injury incidental to U.S. commercial fisheries is unavailable because of the absence of observer placements in all salmon and herring fisheries. However, the minimum estimated mean annual mortality and serious injury rate incidental to all fisheries is 72 harbor porpoise from this stock (72 in U.S. commercial fisheries + 0.2 in unknown fisheries).

Alaska Native Subsistence/Harvest Information

Porpoise in the Gulf of Alaska were hunted by prehistoric societies in Kodiak, Cook Inlet, and Prince William Sound (Shelden et al. 2014). Subsistence hunters have not been reported to harvest from this stock of harbor porpoise since the early 1900s (Shelden et al. 2014).

STATUS OF STOCK

Harbor porpoise are not designated as depleted under the MMPA or listed as threatened or endangered under the Endangered Species Act. Because the PBR is undetermined, it is unknown if the minimum estimate of the mean annual U.S. commercial fishery-related mortality and serious injury rate (72 porpoise) can be considered insignificant and approaching zero mortality and serious injury rate. The total estimated annual level of human-caused mortality and serious injury is 72 harbor porpoise. Because the most recent abundance estimate is more than 8 years old and information on incidental harbor porpoise mortality and serious injury in commercial fisheries is not complete, the Gulf of Alaska stock of harbor porpoise is classified as a strategic stock. Population trends and status of this stock relative to its Optimum Sustainable Population are currently unknown.

HABITAT CONCERNS

Harbor porpoise are mostly found in nearshore areas, bays, tidal areas, and river mouths (Dahlheim et al. 2000, Hobbs and Waite 2010). As a result, harbor porpoise are vulnerable to physical modifications of nearshore habitats resulting from urban and industrial development (including waste management and nonpoint source runoff) and activities such as construction of docks and other over-water structures, filling of shallow areas, dredging, and noise (Linnenschmidt et al. 2013).

HARBOR PORPOISE (*Phocoena phocoena*): Bering Sea Stock

NOTE – December 2015: In areas outside of Alaska, studies of harbor porpoise distribution have indicated that stock structure is likely more fine-scaled than is reflected in the Alaska Stock Assessment Reports. At this time, no data are available to define stock structure for harbor porpoise on a finer scale in Alaska. However, based on comparisons with other regions, it is likely that several regional and sub-regional populations exist. Should new information on harbor porpoise stocks become available, the harbor porpoise Stock Assessment Reports will be updated.

STOCK DEFINITION AND GEOGRAPHIC RANGE

In the eastern North Pacific Ocean, the harbor porpoise ranges from Point Barrow and offshore areas of the Chukchi Sea, along the Alaska coast, and down the west coast of North America to Point Conception, California (Gaskin 1984, Christman and Aerts 2015). Harbor porpoise primarily frequent the coastal waters of the Gulf of Alaska and Southeast Alaska (Dahlheim et al. 2000, 2009), typically occurring in waters less than 100 m deep (Hobbs and Waite 2010). The average density of harbor porpoise in Alaska appears to be less than that reported off the west coast of the continental U.S., although areas of high densities do occur in Glacier Bay and the adjacent waters of Icy Strait, Yakutat Bay, the Copper River Delta, Sitkalidak Strait (Dahlheim et al. 2000, 2009, 2015; Hobbs and Waite 2010), and lower Cook Inlet (Shelden et al. 2014).

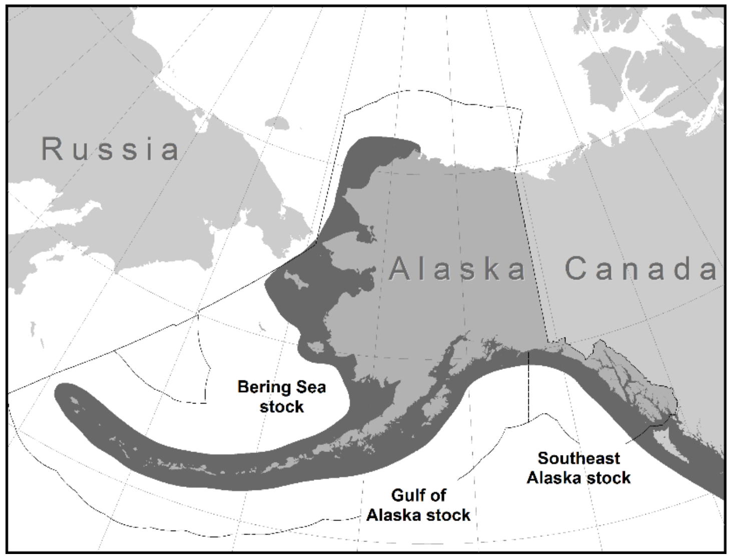

Figure 1. Approximate distribution of harbor porpoise in Alaska waters (dark shaded area).

Stock discreteness in the eastern North Pacific was analyzed using mitochondrial DNA from samples collected along the west coast (Rosel 1992), including one sample from Alaska. Two distinct mitochondrial DNA groupings or clades were found. One clade is present in California, Washington, British Columbia, and the single sample from Alaska (no samples were available from Oregon), while the other is found only in California and Washington. Although these two clades are not geographically distinct by latitude, the results may indicate a low mixing rate for harbor porpoise along the west coast of North America. Investigation of pollutant loads in harbor porpoise ranging from California to the Canadian border also suggests restricted harbor porpoise movements (Calambokidis and Barlow 1991); these results are reinforced by a similar study in the northwest Atlantic (Westgate and Tolley 1999). Further genetic testing of the same samples mentioned above, along with a few additional samples including eight more from Alaska, found differences between some of the four areas investigated, California, Washington, British Columbia, and Alaska, but inference was limited by small sample size (Rosel et al. 1995). Those results demonstrate that harbor porpoise along the west coast of North America are not panmictic and that movement is sufficiently restricted to result in genetic differences. This is consistent with low movement suggested by genetic analysis of harbor porpoise specimens from the North Atlantic (Rosel et al. 1999). Numerous stocks have been delineated with clinal differences over areas as small as the waters surrounding the British Isles (Walton 1997). In a molecular genetic analysis of small-scale population structure of eastern North Pacific harbor porpoise, Chivers et al. (2002) included 30 samples from Alaska, 16 of which were from Copper River Delta, 5 from Barrow, 5 from Southeast Alaska, and 1 sample each from St. Paul, Adak, Kodiak, and Kenai. Unfortunately, no conclusions could be drawn about the genetic structure of harbor porpoise within Alaska because of the insufficient number of samples from each region. Accordingly, harbor porpoise stock structure in Alaska is defined by geographic areas at this time.

Although it is difficult to determine the true stock structure of harbor porpoise populations in the northeast Pacific, from a management standpoint it would be prudent to assume that regional populations exist and that they should be managed independently (Rosel et al. 1995, Taylor et al. 1996). Accordingly, from the above information, three harbor porpoise stocks in Alaska were specified, recognizing that the boundaries of these three stocks were inferred primarily based upon geography or perceived areas of low porpoise density: 1) the Southeast Alaska stock - occurring from Dixon Entrance to Cape Suckling, Alaska, 2) the Gulf of Alaska stock - occurring from Cape Suckling to Unimak Pass, and 3) the Bering Sea stock - occurring throughout the Aleutian Islands and all waters north of Unimak Pass (Fig. 1). To date, there have been no analyses to assess the validity of these stock designations or to assess possible substructure within these stocks.

Harbor porpoise have been sighted during seismic surveys of the Chukchi Sea conducted in the nearshore and offshore waters by the oil and gas industry between July and November from 2006 to 2010 (Funk et al. 2010, 2011; Aerts et al. 2011; Reiser et al. 2011). Harbor porpoise were the third most frequently sighted cetacean species in the Chukchi Sea, after gray and bowhead whales, with most sightings occurring during the September-October monitoring period (Funk et al. 2011, Reiser et al. 2011). Over the 2006-2010 industry-sponsored monitoring period, six sightings of 11 harbor porpoise were reported in the Beaufort Sea, suggesting harbor porpoise regularly occur in both the Chukchi and Beaufort seas (Funk et al. 2011).

POPULATION SIZE

In June and July of 1999, an aerial survey covered the waters of Bristol Bay. Two types of corrections were needed for these aerial surveys: one for observer perception bias to correct for animals not counted because they were not observed and one to correct for porpoise availability/visibility at the surface. The 1999 survey resulted in an observed abundance estimate for the Bering Sea harbor porpoise stock of 16,289 (CV = 0.132; Hobbs and Waite 2010), which includes the perception bias correction factor (1.337; CV = 0.062) obtained during the survey using an independent belly window observer. Laake et al. (1997) estimated the availability bias for aerial surveys of harbor porpoise in Puget Sound to be 2.96 (CV = 0.180); the use of this correction factor is preferred to other published correction factors (e.g., Barlow et al. 1988, Calambokidis et al. 1993) because it is an empirical estimate of availability bias. However the Laake et al. (1997) correction results from a different area and should be replaced with a correction derived from data collected in Alaska. Applying this second correction factor, the corrected abundance estimate is 48,215 (16,289 × 2.96 = 48,215; CV = 0.223). The estimate for 1999 can be considered conservative for that time period, as the surveyed areas did not include known harbor porpoise range along the Aleutian Island chain, near the Pribilof Islands, or in the waters north of Cape Newenham (approximately 59°N).

Shipboard visual line-transect surveys for cetaceans were conducted on the eastern Bering Sea shelf in association with pollock stock assessment surveys in June and July of 1999, 2000, 2002, 2004, 2008, and 2010 (Moore et al. 2002; Friday et al. 2012, 2013). The entire range of the survey was completed in three of those years (2002, 2008, and 2010) and harbor porpoise abundance estimates were calculated for each of these surveys (Friday et al. 2013); however, correction factors were not applied for perception bias, availability bias, or responsive movement to the ship. The abundance estimate was 1,971 (CV = 0.46) for 2002, 4,056 (CV = 0.40) for 2008, and 833 (CV = 0.66) for 2010. Although the 2010 estimate is the lowest of the three years, it is not significantly different from the 2002 and 2008 estimates (Friday et al. 2013). These surveys are useful for showing distribution throughout the southeastern Bering Sea and the relationship to hydrographic domains; however, because the surveys were not designed for harbor porpoise and no correction factors are available, the abundance estimates are not used to calculate a population estimate.

Minimum Population Estimate

The minimum population estimate (N_{MIN}) for this stock is calculated using Equation 1 from the potential biological removal (PBR) guidelines (Wade and Angliss 1997): $N_{MIN} = N/\exp(0.842\times[\ln(1+[CV(N)]^2)]^{½})$. Using the 1999 partial population estimate (N) of 48,215 and its associated coefficient of variation (CV) of 0.223, N_{MIN} for the Bering Sea stock of harbor porpoise is 40,039 (Hobbs and Waite 2010). However, because the survey data are more than 8 years old, N_{MIN} is considered unknown.

Current Population Trend

There is no reliable information on current trends in abundance for the Bering Sea stock of harbor porpoise.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

A reliable estimate of the maximum net productivity rate (R_{MAX}) is not available for this stock of harbor porpoise. Hence, until additional data become available, it is recommended that the cetacean maximum theoretical net productivity rate of 4% be employed (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the PBR is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: PBR = $N_{MIN} \times 0.5R_{MAX} \times F_R$. The recovery factor ($F_R$) for this stock is 0.5, the value for cetacean stocks with unknown population status (Wade and Angliss 1997). However, the 2005 revisions to the Stock Assessment Report guidelines (Wade and Angliss 1997) state that abundance estimates older than 8 years should not be used to calculate PBR due to a decline in confidence in the reliability of an aged abundance estimate (NMFS 2005). Therefore, the PBR for this stock is considered undetermined.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Detailed information on U.S. commercial fisheries in Alaska waters (including observer programs, observer coverage, and observed incidental takes of marine mammals) is presented in Appendices 3-6 of the Alaska Stock Assessment Reports.

No mortality or serious injury of Bering Sea harbor porpoise was observed incidental to U.S. commercial fisheries during 2010-2014 (Breiwick 2013; MML, unpubl. data).

One harbor porpoise mortality due to entanglement in a commercial salmon gillnet in Kotzebue, Alaska, was reported to the NMFS Alaska Region stranding network in 2013 (Table 1; Helker et al. 2016), resulting in a minimum average annual mortality and serious injury rate of 0.2 Bering Sea harbor porpoise in U.S. commercial fisheries in 2010-2014 (Table 1). A complete estimate of the total mortality and serious injury rate incidental to U.S. commercial fisheries is currently unavailable because of the absence of observer placements in all of the salmon and herring fisheries.

In 2012, one harbor porpoise entangled in a subsistence salmon gillnet in Nome, Alaska (Helker et al. 2016), resulting in a minimum average annual mortality and serious injury rate of 0.2 harbor porpoise due to subsistence fishery interactions in 2010-2014 (Table 1).

Table 1. Summary of incidental mortality and serious injury of Bering Sea harbor porpoise, by year and type, reported to the NMFS Alaska Region marine mammal stranding network in 2010-2014 (Helker et al. 2016). Only cases of serious injury were recorded in this table; animals with non-serious injuries have been excluded.

Cause of injury	2010	2011	2012	2013	2014	Mean annual mortality
Entangled in Kotzebue commercial salmon set gillnet	0	0	0	1	0	0.2
Entangled in Nome subsistence salmon gillnet	0	0	1	0	0	0.2
Total in commercial fisheries						0.2
Total in subsistence fisheries						0.2

Alaska Native Subsistence/Harvest Information

Subsistence hunters in Alaska have not been reported to hunt from this stock of harbor porpoise; however, when porpoise are caught incidental to subsistence or commercial fisheries, subsistence hunters may claim the carcass for subsistence use (R. Suydam, North Slope Borough, pers. comm.).

STATUS OF STOCK

Harbor porpoise are not designated as depleted under the MMPA or listed as threatened or endangered under the Endangered Species Act. Because the PBR is undetermined, the mean annual U.S. commercial fishery-related mortality and serious injury rate that can be considered insignificant and approaching zero mortality and serious injury rate is unknown; a minimum estimate of the current rate (from stranding data) is 0.2 harbor porpoise; however, most of the fisheries likely to interact with this stock of harbor porpoise have never been monitored. A minimum estimate of the total annual level of human-caused mortality and serious injury is 0.4 harbor porpoise; however, the estimated annual level of human-caused mortality and serious injury relative to PBR is unknown. Because the abundance estimates are more than 8 years old and information on incidental mortality and serious injury in commercial fisheries is sparse, the Bering Sea stock of harbor porpoise is classified as a strategic stock. Population trends and status of this stock relative to its Optimum Sustainable Population are currently unknown.

HABITAT CONCERNS

Harbor porpoise are found over the shelf waters of the southeastern Bering Sea (Dahlheim et al. 2000, Hobbs and Waite 2010). In the nearshore waters of this region, harbor porpoise are vulnerable to physical modifications of nearshore habitats resulting from urban and industrial development (including waste management and nonpoint source runoff) and activities such as construction of docks and other over-water structures, filling of shallow areas, dredging, and noise (Linnenschmidt et al. 2013). Climate change and changes to sea-ice coverage may be opening up new habitats, or resulting in shifts in habitat, as evident by an increase in the number of reported sightings of harbor porpoise in the Chukchi Sea (Funk et al. 2010, 2011). Shipping and noise from oil and gas activities may also be a habitat concern for harbor porpoise, particularly in the Chukchi Sea.

DALL'S PORPOISE (*Phocoenoides dalli*): Alaska Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Dall's porpoise are widely distributed across the entire North Pacific Ocean (Fig. 1). They are found over the continental shelf adjacent to the slope and over deep (2,500+ m) oceanic waters (Hall 1979). They have been sighted throughout the North Pacific as far north as 65°N (Buckland et al. 1993) and as far south as 28°N in the eastern North Pacific (Leatherwood and Fielding 1974). The only apparent distribution gaps in Alaska waters are upper Cook Inlet and the shallow eastern flats of the Bering Sea. Throughout most of the eastern North Pacific they are present during all months of the year, although there may be seasonal onshore-offshore movements along the west coast of the continental U.S. (Loeb 1972, Leatherwood and Fielding 1974) and winter movements of populations out of areas with ice such as Prince William Sound (Hall 1979).

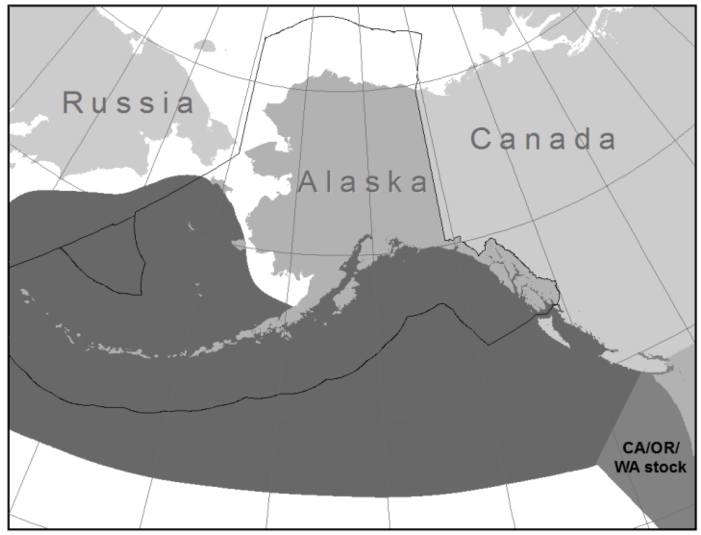

Figure 1. Approximate distribution of Dall's porpoise in Alaska waters (dark shaded area).

Surveys on the eastern Bering Sea shelf and slope to the 1,000 m isobath in 1999, 2000, 2002, 2004, 2008, and 2010 provided information about the distribution and relative abundance of Dall's porpoise in this area (Moore et al. 2002; Friday et al. 2012, 2013). Dall's porpoise were sighted on the shelf and slope in waters deeper than 100 m in 2002, 2008, and 2010 with greater densities at the shelf break than in shallower waters (Friday et al. 2013).

The following information was considered in classifying stock structure based on the Dizon et al. (1992) phylogeographic approach: 1) Distributional data: geographic distribution continuous; 2) Population response data: differential timing of reproduction between the Bering Sea and western North Pacific; 3) Phenotypic data: unknown; and 4) Genotypic data: unknown. The stock structure of eastern North Pacific Dall's porpoise is not adequately understood at this time, but based on patterns of stock differentiation in the western North Pacific, where they have been more intensively studied, it is expected that separate stocks will emerge when data become available (Perrin and Brownell 1994). Based primarily on the population response data (Jones et al. 1986) and preliminary genetics analyses (Winans and Jones 1988), a delineation between Bering Sea and western North Pacific stocks has been recognized. However, similar data are not available for the eastern North Pacific; thus, one stock of Dall's porpoise is recognized in Alaskan waters. Dall's porpoise along the west coast of the continental U.S. from California to Washington comprise a separate stock and are reported separately in the Stock Assessment Reports for the U.S. Pacific Region.

POPULATION SIZE

Data collected from vessel surveys, performed by both U.S. fishery observers and U.S. researchers from 1987 to 1991, were analyzed to provide population estimates of Dall's porpoise throughout the North Pacific and the Bering Sea (Hobbs and Lerczak 1993). The quality of data used in analyses was determined by the procedures recommended by Boucher and Boaz (1989). Survey effort was not well distributed throughout the U.S. Exclusive Economic Zone (EEZ) in Alaska and, as a result, Bristol Bay and the northern Bering Sea received little survey effort. Only three sightings were reported between 1987 and 1991 in this area by Hobbs and Lerczak (1993), resulting in an estimate of 9,000 (CV = 0.91). In the U.S. EEZ north and south of the Aleutian Islands, Hobbs and Lerczak (1993) reported an estimated abundance of 302,000 (CV = 0.11), whereas, for the Gulf of Alaska EEZ, they reported 106,000 (CV = 0.20). Combining these three estimates (9,000 + 302,000 + 106,000) results in a total abundance estimate of 417,000 (CV = 0.097) for the Alaska stock of Dall's porpoise. Turnock and Quinn (1991) estimate that abundance estimates of Dall's porpoise are inflated by as much as five times because of vessel attraction behavior. Therefore, a corrected population estimate from 1987-1991 is 83,400 (417,000 × 0.2) for this stock. Surveys for this stock are more than 8 years old, consequently there are no reliable abundance data for the Alaska stock of Dall's porpoise. No reliable abundance estimates for British Columbia are currently available.

Sighting surveys for cetaceans were conducted during NMFS pollock stock assessment surveys in 1999, 2000, 2002, 2004, 2008, and 2010 on the eastern Bering Sea shelf (Moore et al. 2002; Friday et al. 2012, 2013). The entire range of the survey was completed in three of those years (2002, 2008, and 2010) and Dall's porpoise estimates were calculated for each of these surveys (Friday et al. 2013). The abundance estimate was 35,303 (CV = 0.53) in 2002, 14,543 (CV = 0.32) in 2008, and 11,143 (CV = 0.32) in 2010. Although the 2010 estimate is the lowest of the three years, it is not significantly different from the 2002 and 2008 estimates (Friday et al. 2013). These estimates have not been corrected for animals missed on the trackline (perception bias) or animals submerged when the ship passed (availability bias). They are also uncorrected for potential biases from responsive movements (ship attraction) and are, therefore, not used as minimum population estimates.

Minimum Population Estimate

The minimum population estimate (N_{MIN}) for this stock is calculated using Equation 1 from the potential biological removal (PBR) guidelines (Wade and Angliss 1997): $N_{MIN} = N/\exp(0.842\times[\ln(1+[CV(N)]^2)]^{½})$. However, since the abundance estimate is based on data older than 8 years, the N_{MIN} is considered unknown.

Current Population Trend

At present, there is no reliable information on trends in abundance for the Alaska stock of Dall's porpoise.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

A reliable estimate of the maximum net productivity rate is not currently available for the Alaska stock of Dall's porpoise. Hence, until additional data become available, it is recommended that the cetacean maximum theoretical net productivity rate (R_{MAX}) of 4% be employed for the Alaska stock of Dall's porpoise (Wade and Angliss 1997). However, based on life-history analyses in Ferrero and Walker (1999), Dall's porpoise reproductive strategy is not consistent with the delphinid pattern on which the default R_{MAX} for cetaceans is based. In contrast to the delphinids, Dall's porpoise mature earlier and reproduce annually which suggest that a higher R_{MAX} may be warranted.

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the PBR is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: $PBR = N_{MIN} \times 0.5R_{MAX} \times F_R$. Wade and Angliss (1997) recommend that abundance estimates older than 8 years no longer be used to calculate a PBR level; thus, because the abundance estimate for this stock is more than 8 years old, the N_{MIN} is unknown and therefore the PBR level is undetermined.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

New Serious Injury Guidelines

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an "*injury that is more likely than not to result in mortality*." Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

Fisheries Information

Detailed information (including observer programs, observer coverage, and observed incidental takes of marine mammals) for federally-managed and state-managed U.S. commercial fisheries in Alaska waters is presented in Appendices 3-6 of the Alaska Stock Assessment Reports.

Until 2003, there were six different federally-regulated commercial fisheries in Alaska that could have interacted with Dall's porpoise and were monitored for incidental mortality and serious injury by fishery observers. As of 2003, changes in fishery definitions in the MMPA List of Fisheries have resulted in separating these 6 fisheries into 22 fisheries (69 FR 70094, 2 December 2004). This change does not represent a change in fishing effort but provides managers with better information on the component of each fishery that is responsible for the incidental serious injury or mortality of marine mammal stocks in Alaska. For the fisheries with observed takes, the range of observer coverage in 2009-2013, as well as the annual observed and estimated mortality and serious injury, are presented in Table 1.

The Alaska Peninsula/Aleutian Islands salmon drift gillnet fishery was monitored in 1990 (Wynne et al. 1991). One Dall's porpoise mortality was observed, which extrapolated to an annual (total) incidental mortality and serious injury rate of 28 Dall's porpoise (Table 1).

In 2012 and 2013, the Alaska Marine Mammal Observer Program (AMMOP) placed observers on independent vessels in the state-managed Southeast Alaska salmon drift gillnet fishery to assess mortality and serious injury of marine mammals. Areas around and adjacent to Wrangell and Zarembo Islands (ADF&G Districts 6, 7, and 8) were observed during the 2012-2013 program (Manly 2015). In 2012, one Dall's porpoise was seriously injured. Based on the one observed serious injury, 18 serious injuries were estimated for Districts 6, 7, and 8 in 2012, resulting in an estimated mean annual mortality and serious injury rate of 9 Dall's porpoise in 2012-2013 (Table 1). Since these three districts represent only a portion of the overall fishing effort in this fishery, we expect this to be a minimum estimate of mortality for the fishery. Note that the AMMOP has not observed the Southeast Alaska salmon drift gillnet fishery in the other districts; additionally, NMFS has not observed several other gillnet fisheries that are known to interact with this stock, therefore, the total estimated mortality and serious injury is unavailable. However, due to the large stock size, it is unlikely that unreported mortality and serious injury from those fisheries are a significant source of mortality. Combining the estimates from the Bering Sea and Gulf of Alaska fisheries (0.5) with the estimate from the Alaska Peninsula/Aleutian Islands salmon drift gillnet fishery (28) and the Southeast Alaska salmon drift gillnet fishery (9) results in an estimated average annual mortality and serious injury rate in observed fisheries of 38 Dall's porpoise from this stock.

Table 1. Summary of incidental mortality and serious injury of the Alaska stock of Dall's porpoise due to U.S. commercial fisheries from 2009 to 2013 (or the most recent data available) and calculation of the mean annual mortality and serious injury rate (Wynne et al. 1991; Breiwick 2013; Manly 2015; NMML, unpubl. data). Methods for calculating percent observer coverage are described in Appendix 6 of the Alaska Stock Assessment Reports.

Fishery name	Years	Data type	Percent observer coverage	Observed mortality	Estimated mortality	Mean estimated annual mortality
Bering Sea/Aleutian Is. pollock trawl	2009 2010 2011 2012 2013	obs data	86 86 98 98 97	1 0 0 0 0	1.04 0 0 0 0	0.2 (CV = 0.19)
Bering Sea/Aleutian Is. Pacific cod longline	2009 2010 2011 2012 2013	obs data	60 64 57 51 67	1 0 0 0 0	1.5 0 0 0 0	0.3 (CV = 0.77)
SE Alaska salmon drift gillnet (Districts 6, 7, 8)	2012 2013	obs data	6.4 6.6	1 0	18 0	9 (CV = 1.0)
AK Peninsula/Aleutian Is. salmon drift gillnet	1990	obs data	4	1	28	28 (CV = 0.585)
Minimum total estimated annual mortality						38 (CV = 0.498)

From 2009 to 2013, no mortality or serious injury of Dall's porpoise was reported to the NMFS Alaska Region stranding database (Helker et al. 2015).

Alaska Native Subsistence/Harvest Information

There are no reports of subsistence take of Dall's porpoise in Alaska.

STATUS OF STOCK

Dall's porpoise are not designated as "depleted" under the MMPA or listed as "threatened" or "endangered" under the Endangered Species Act. The level of human-caused mortality and serious injury (38) is not known to exceed the PBR, which is undetermined as the most recent abundance estimate is more than 8 years old. Because the PBR is undetermined, the annual level of U.S. commercial fishery-related mortality and serious injury that can be considered insignificant and approaching zero mortality and serious injury rate is unknown. The Alaska stock of Dall's porpoise is not classified as a strategic stock. Population trends and status of this stock relative to its Optimum Sustainable Population are currently unknown.

HABITAT CONCERNS

While the majority of Dall's porpoise are found throughout the North Pacific, there are also significant numbers found in shelf break and deeper nearshore areas. Thus, they are subject to a variety of habitat impacts. Of particular concern are nearshore areas, bays, channels, and inlets where some Dall's porpoise are vulnerable to physical modifications of nearshore habitats (resulting from urban and industrial development, including waste management and nonpoint source runoff) and noise (Linnenschmidt et al. 2013). Climate change and changes to sea-ice coverage may be opening up new habitats, or resulting in shifts in habitat, as evident by an increase in the number of reported sightings of Dall's porpoise in the Chukchi Sea (Funk et al. 2010, 2011). Shipping and noise from oil and gas activities may also be a habitat concern for Dall's porpoise, particularly in the Chukchi Sea.

SPERM WHALE (*Physeter macrocephalus*): North Pacific Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

The sperm whale is one of the most widely distributed marine mammal species, perhaps exceeded in its global range only by the killer whale (Rice 1989). In the North Pacific Ocean, sperm whales were depleted by extensive commercial whaling over a period of more than a hundred years, and the species was the primary target of illegal Soviet whaling in the second half of the 20th century (Ivashchenko et al. 2013, 2014). Systematic illegal catches were also made on a large scale by Japan in at least the late 1960s (Ivashchenko and Clapham 2015).

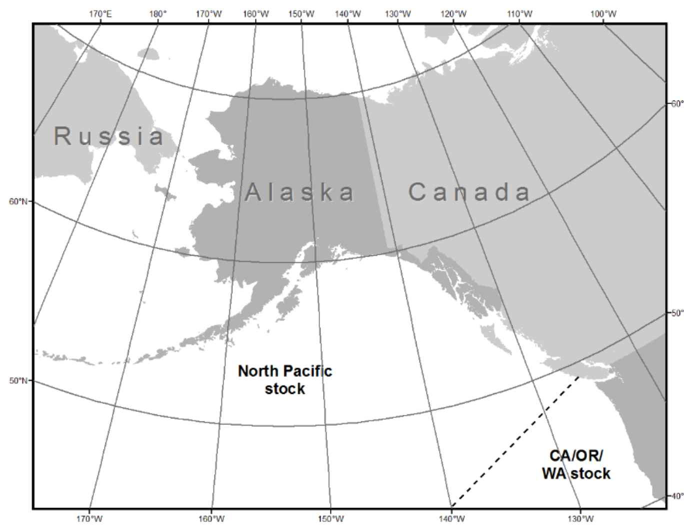

Figure 1. The approximate distribution of sperm whales in the North Pacific includes deep waters south of 62°N to the equator.

Sperm whales feed primarily on medium-sized to large-sized squids but also take substantial quantities of large demersal and mesopelagic sharks, skates, and fishes (Rice 1989). In the North Pacific, sperm whales are distributed widely (Fig. 1), with the northernmost boundary extending from Cape Navarin (62°N) to the Pribilof Islands (Omura 1955). Although females and young sperm whales were thought to remain in tropical and temperate waters year-round, Mizroch and Rice (2006) and Ivashchenko et al. (2014) showed that there were extensive catches of female sperm whales above 50°N, in the western Bering Sea and in the western Aleutian Islands. Mizroch and Rice (2013) also showed female movements into the Gulf of Alaska and western Aleutians. Males are found in the summer in the Gulf of Alaska, Bering Sea, and waters around the Aleutian Islands (Kasuya and Miyashita 1988, Mizroch and Rice 2013, Ivashchenko et al. 2014). Sighting surveys conducted by the Alaska Fisheries Science Center's Marine Mammal Laboratory (MML) in the summer months between 2001 and 2010 have found sperm whales to be the most frequently sighted large cetacean in the coastal waters around the central and western Aleutian Islands (MML, unpubl. data). Acoustic surveys detected the presence of sperm whales year-round in the Gulf of Alaska, although they appear to be more common in summer than in winter (Mellinger et al. 2004). These seasonal detections are consistent with the hypothesis that sperm whales move to higher latitudes in summer and to lower latitudes in winter (Whitehead and Arnbom 1987).

Mizroch and Rice (2013) examined 261 Discovery mark recoveries from the days of commercial whaling and found extensive movements from U.S. and Canadian coastal waters into the Gulf of Alaska and Bering Sea. The U.S. marked 176 sperm whales from 1962 to 1969 off southern California and northern Baja California (Mizroch and Rice 2013). Seven of those marked whales were recovered in locations ranging from offshore California, Oregon, and British Columbia waters to the western Gulf of Alaska. A male whale marked by Canadian researchers moved from near Vancouver Island, British Columbia, to the Aleutian Islands near Adak. A whale marked by Soviet researchers moved from coastal Michoacán, mainland Mexico, to a location about 1,300 km offshore of Washington State. Similar extensive movements have also been demonstrated by recent satellite-tagging studies (Straley et al. 2014). Three adult males satellite-tagged off southeastern Alaska moved far south, one to coastal Baja California, one into the north-central Gulf of California, and the third to a location near the Mexico-Guatemala border (Straley et al. 2014). Marking data show extensive movements throughout the North Pacific and along the U.S. west coast into the Gulf of Alaska and Bering Sea/Aleutian Islands region.

Mizroch and Rice (2013) also analyzed whaling data and found that males and females concentrated seasonally along oceanic frontal zones, for example, in the subtropical frontal zone (ca. 28-34°N) and the subarctic frontal zones (ca. 40-43°N). Males also concentrated seasonally near the Aleutian Islands and along the Bering Sea shelf edge. Their analyses of marking and whaling data indicate that there are no apparent divisions between separate demes or stocks within the North Pacific. Analysis of Soviet catch data by Ivashchenko et al. (2014) showed broad agreement with these results, although a sharp division was evident at Amchitka Pass in the Aleutians, with mature males to the east and males and family groups to the west, including in the Commander Islands. There were four main areas of concentration in the Soviet catches: a large pelagic area (30-50°N) in the eastern North Pacific, including the Gulf of Alaska and western coast of North America; the northeastern and southwestern central North Pacific; and the southern Kuril Islands. Some of the catch distribution was similar to that of 19th-century Yankee whaling catches plotted by Townsend (1935), notably in the "Japan Ground" (in the pelagic western Pacific) and the "Coast of Japan Ground." Many females were caught in Olyutorsky Bay (western Bering Sea) and around the Commander Islands.

The following information was considered in classifying stock structure based on the Dizon et al. (1992) phylogeographic approach: 1) Distributional data: no apparent discontinuities based on whale marking data; 2) Population response data: unknown; 3) Phenotypic data: unknown; and 4) Genotypic data: genetic studies indicate the possibility of a "somewhat" discrete U.S. coastal stock (Mesnick et al. 2011). For management purposes, the International Whaling Commission (IWC) recognizes two management units of sperm whales in the North Pacific (eastern and western). However, the IWC has not reviewed its sperm whale stock boundaries in recent years (Donovan 1991). For management purposes, three stocks of sperm whales are currently recognized in U.S. waters: 1) Alaska (North Pacific stock), 2) California/Washington/Oregon, and 3) Hawaii. Information from Mizroch and Rice (2013) suggests that this structure should be reviewed and updated to reflect current data. The California/Oregon/Washington and Hawaii sperm whale stocks are reported separately in the Stock Assessment Reports for the U.S. Pacific Region.

POPULATION SIZE

Current and historical estimates of the abundance of sperm whales in the North Pacific are considered unreliable, and caution should be exercised in interpreting published estimates. The abundance of sperm whales in the North Pacific was reported to be 1,260,000 prior to exploitation, which by the late 1970s was estimated to have been reduced to 930,000 whales (Rice 1989). Confidence intervals for these estimates were not provided. These estimates include whales from the California/Oregon/Washington stock, for which a separate abundance estimate is currently available (see the Stock Assessment Reports for the U.S. Pacific Region). Estimates for a large area of the eastern temperate North Pacific were produced from line-transect and acoustic survey data by Barlow and Taylor (2005), but no recent estimate exists for other areas, including for the central or western North Pacific.

Although Kato and Miyashita (1998) believe their estimate to be positively biased, their analysis suggested 102,112 (CV = 0.155) sperm whales in the western North Pacific. The number of sperm whales occurring within Alaska waters is unknown.

As the data used in estimating the abundance of sperm whales in the entire North Pacific are more than 8 years old, and there are no available estimates for numbers of sperm whales in Alaska waters, a reliable estimate of abundance for the North Pacific stock is not available.

Minimum Population Estimate

At this time, it is not possible to produce a reliable estimate of minimum abundance for this stock, as a current estimate of abundance is not available.

Current Population Trend

No current estimate of abundance exists for this stock; therefore, reliable information on trends in abundance for this stock is currently not available (Braham 1992).

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

A reliable estimate of the maximum net productivity rate is not currently available for the North Pacific stock of sperm whales. Hence, until additional data become available, it is recommended that the cetacean maximum net productivity rate (R_{MAX}) of 4% be employed for this stock at this time (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the potential biological removal (PBR) is defined as the product of the minimum population estimate (N_{MIN}), one-half the maximum theoretical net productivity rate, and a recovery factor: PBR = $N_{MIN} \times 0.5R_{MAX} \times F_R$. The recovery factor ($F_R$) for this stock is 0.1, the value for cetacean stocks which are classified as endangered (Wade and Angliss 1997). However, because a reliable estimate of N_{MIN} is currently not available, the PBR for this stock is unknown.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Detailed information (including observer programs, observer coverage, and observed incidental takes of marine mammals) for federally-managed and state-managed U.S. commercial fisheries in Alaska waters is presented in Appendices 3-6 of the Alaska Stock Assessment Reports.

In 2010-2014, there were five serious injuries of sperm whales observed in the Gulf of Alaska sablefish longline fishery (two each in 2012 and 2013 and one in 2014). Each of these injuries was prorated at a value of 0.75, resulting in a minimum average annual estimated mortality and serious injury rate of 2.2 sperm whales in U.S. commercial fisheries in 2010-2014 (Table 1; Breiwick 2013; MML, unpubl. data).

Table 1. Summary of incidental mortality and serious injury of North Pacific sperm whales due to U.S. commercial fisheries in 2010-2014 and calculation of the mean annual mortality and serious injury rate (Breiwick 2013; MML, unpubl. data). Methods for calculating percent observer coverage are described in Appendix 6 of the Alaska Stock Assessment Reports.

Fishery name	Years	Data type	Percent observer coverage	Observed mortality	Estimated mortality	Mean estimated annual mortality
Gulf of Alaska sablefish longline	2010 2011 2012 2013 2014	obs data	15 14 14 14 19	0 0 1.5 0.75 (+0.75)[a] 0 (+0.75)[c]	0 0 3.4 6.2 (+0.75)[b] 0 (+0.75)[d]	1.9 (+0.3)[e] (CV = 0.63)
Minimum total estimated annual mortality						2.2 (CV = 0.63)

[a]Total mortality and serious injury observed in 2013: 0.75 whales in sampled hauls + 0.75 whales in an unsampled haul.
[b]Total estimate of mortality and serious injury in 2013: 6.2 whales (extrapolated estimate from 0.75 whales observed in sampled hauls) + 0.75 whales (0.75 whales observed in an unsampled haul).
[c]Total mortality and serious injury observed in 2014: 0 whales in sampled hauls + 0.75 whales in an unsampled haul.
[d]Total estimate of mortality and serious injury in 2014: 0 whales (extrapolated estimate from 0 whales observed in sampled hauls) + 0.75 whales (0.75 whales observed in an unsampled haul).
[e]Mean annual mortality and serious injury for fishery: 1.9 whales (mean of extrapolated estimates from sampled hauls) + 0.3 whales (mean of number observed in unsampled hauls).

Alaska Native Subsistence/Harvest Information

Sperm whales have never been reported to be taken by subsistence hunters (Rice 1989).

Other Mortality

Sperm whales were the dominant species killed by the commercial whaling industry as it developed in the North Pacific in the years after World War II (Mizroch and Rice 2006, Ivashchenko et al. 2014). Between 1946 and 1967, most of the sperm whales were caught in waters near Japan and in the Bering Sea/Aleutian Islands (BSAI) region. The BSAI catches were dominated by males. After 1967, whalers moved out of the BSAI region and began to catch even larger numbers of sperm whales further south in the North Pacific between 30° and 50°N (Mizroch and Rice 2006: Figs. 7-9). The reported catch of sperm whales taken by commercial whalers operating in the North Pacific between 1912 and 2006 was 261,148 sperm whales, of which, 259,120 were taken between 1946 and 1987 (IWC, Bureau of International Whaling Statistics (BIWS) catch data, February 2008 version, unpubl.). This value underestimates the actual kill in the North Pacific as a result of under-reporting by U.S.S.R. and Japanese pelagic whaling operations. Berzin (2008) described extreme under-reporting and misreporting of Soviet sperm whale catches from the mid-1960s into the early 1970s, including enormous (and under-reported) whaling pressure on female sperm whales in the latter years of whaling. More recently, Ivashchenko et al. (2013, 2014) estimate that 157,680 sperm whales were killed by the U.S.S.R. in the North Pacific between 1948 and 1979, of which 25,175 were unreported; the Soviets also extensively misreported the sex and length of catches. In addition, it is known that Japanese land-based whaling operations also misreported the number and sex of sperm whale catches during the post-World War II era (Kasuya 1999), and other studies indicate that falsifications also occurred on a large scale in the Japanese pelagic fishery (Cooke et al. 1983, Ivashchenko and Clapham 2015). The last year that the U.S.S.R. reported catches of sperm whales was in 1979 and the last year that Japan reported substantial catches was in 1987, but Japanese whalers reported catches of 48 sperm whales between 2000 and 2009 (IWC, BIWS catch data, October 2010 version, unpubl.). Although the Soviet data on catches of this species in the North Pacific have now been largely corrected (Ivashchenko et al. 2013), the North Pacific sperm whale data in the IWC's Catch Database (Allison 2012) are known to be unreliable because of falsified catch information from both the Japanese coastal and pelagic fisheries (Kasuya 1999, Ivashchenko and Clapham 2015).

From 2010 to 2014, one suspected human-related sperm whale mortality was reported to the NMFS Alaska Region stranding network (Helker et al. 2016). A beachcast sperm whale was found in 2012 on a beach near Yakutat with a net from an unknown fishery wrapped around its lower jaw. However, due to the advanced decomposition of this whale, the cause of death could not be determined.

Other Issues

NMFS observers aboard longline vessels targeting both sablefish and halibut have documented sperm whales feeding off longline gear in the Gulf of Alaska (Hill and Mitchell 1998, Hill et al. 1999, Perez 2006, Sigler et al. 2008). Fishery observers recorded several instances during 1995-1997 in which sperm whales were deterred by fishermen (i.e., yelling at the whales or throwing seal bombs in the water).

Annual longline surveys have been recording sperm whale predation on catch since 1998 (Hanselman et al. 2008). Sperm whale depredation in the sablefish longline fishery is widespread in the central and eastern Gulf of Alaska but rarely observed in the Bering Sea; the majority of interactions occur in the West Yakutat and East Yakutat/Southeast Alaska areas (Perez 2006, Hanselman et al. 2008). Sigler et al. (2008) analyzed catch data from 1998 to 2004 and found that catch rates were about 2% less at locations where depredation occurred, but the effect was not significant ($p = 0.34$). Hill et al. (1999) analyzed data collected by fisheries observers in Alaska waters and also found no significant effect on catch. A small, significant effect on catch rates was found in a study using data collected in Southeast Alaska, in which longline fishery catches in sets with sperm whales present were compared to catches in sets with sperm whales absent (3% reduction, t-test, 95% CI of 0.4-5.5%, $p = 0.02$: Straley et al. 2005). Undamaged catches may also occur when sperm whales are present; in these cases, sperm whales apparently feed off the discard.

STATUS OF STOCK

Sperm whales are listed as endangered under the Endangered Species Act of 1973, and therefore designated as depleted under the MMPA. As a result, this stock is classified as a strategic stock. However, on the basis of total abundance, current distribution, and regulatory measures that are currently in place, it is unlikely that this stock is in danger of extinction (Braham 1992). Reliable estimates of the minimum population, population trends, PBR, and status of the stock relative to its Optimum Sustainable Population are currently not available. A minimum estimate of the total annual level of human-caused mortality and serious injury is 2.2 whales. Because the PBR is unknown, it is not known if the minimum estimate of the mean annual U.S. commercial fishery-related mortality and serious injury rate (2.2 whales) can be considered insignificant and approaching zero mortality and serious injury rate.

HABITAT CONCERNS

Potential habitat concerns for this stock include elevated levels of sound from anthropogenic sources (e.g., shipping, military exercises), possible changes in prey distribution and quality with climate change, entanglement in fishing gear, ship strikes due to increased vessel traffic (e.g., from increased shipping in higher latitudes), and oil and gas activities.

BAIRD'S BEAKED WHALE (*Berardius bairdii*): Alaska Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Baird's beaked, or giant bottlenose, whale inhabits the North Pacific Ocean and adjacent seas (Bering Sea, Okhotsk Sea, Sea of Japan, and the Sea of Cortez in the southern Gulf of California, Mexico), with the best-known populations occurring in the coastal waters around Japan (Balcomb 1989) and the Commander Islands (Fedutin et al. 2012). Within the North Pacific Ocean, Baird's beaked whales have been sighted in virtually all areas north of 30°N in deep waters over the continental shelf, particularly in regions with submarine escarpments and seamounts (Ohsumi 1983, Kasuya and Ohsumi 1984, Kasuya 2002). The range of the species extends north from Cape Navarin (62° N) and the central Sea of Okhotsk (57° N) to St. Matthew Island, the Pribilof Islands in the Bering Sea, and the northern Gulf of Alaska (Rice 1986, Rice 1998, Kasuya 2002) (Fig. 1). An apparent break in distribution occurs in the eastern Gulf of Alaska, but from the mid-Gulf to the Aleutian Islands and in the southern Bering Sea there are numerous sighting records (Kasuya and Ohsumi 1984, Forney and Brownell 1996, Moore et al. 2002). In the Sea of Okhotsk and the Bering Sea, Baird's beaked whales arrive in April-May, are numerous during the summer, and decrease in October (Tomilin 1957, Kasuya 2002). Observations during 2007-2011 in the western Bering Sea were made in all months except winter (December to March) around the Commander Islands, with encounters peaking in April-June and to a lesser extent in August-November (Fedutin et al. 2012). During winter months, they are rarely found in offshore waters and their winter distribution is unknown (Kasuya 2002). However, acoustic detections of Baird's beaked whales from November through January (and no detections in July-October) in the northern Gulf of Alaska suggest that this region may be wintering habitat for some Baird's beaked whales (Baumann-Pickering et al. 2012b). There were no detections of this species from early June to late August 2010 off Kiska Island (Baumann-Pickering et al. 2012a). They are the most commonly seen beaked whales within their range, perhaps because they are relatively large and gregarious, traveling in schools of a few to several dozen, making them more noticeable to observers than other beaked whale species. Baird's beaked whales are migratory, arriving in continental slope waters during summer and fall months when surface water temperatures are the highest (Dohl et al. 1983, Kasuya 1986). Photo-identification analysis of animals sighted between 2007-2011 revealed resightings of some individuals around the Commander Islands and confirmed associations of individuals over several years in this species (Fedutin et al. 2012).

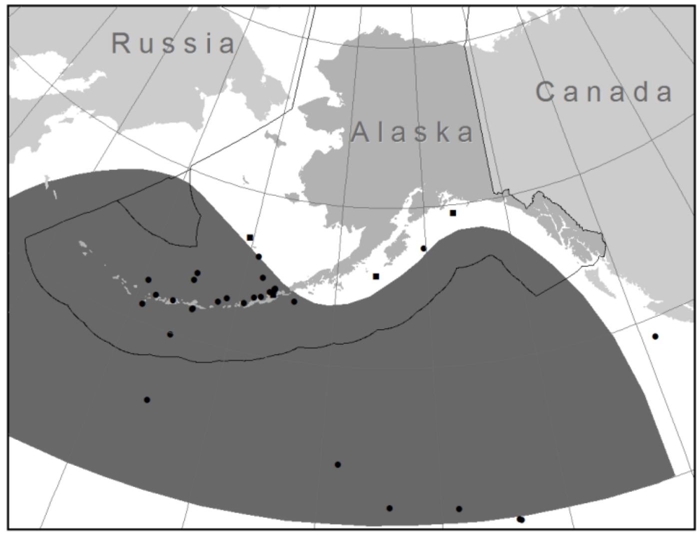

Figure 1. Approximate distribution of Baird's beaked whales in the eastern North Pacific (shaded area). Sightings (circles) and strandings (squares) within the last 10 years are also depicted. (Forney and Brownell 1996, Moore et al. 2002, NMFS unpublished data). Note: Distribution updated based on Kasuya 2002.

There are insufficient data to apply the phylogeographic approach to stock structure (Dizon et al. 1992) for Baird's beaked whale. Therefore, Baird's beaked whale stocks are defined as the two non-contiguous areas within Pacific U. S. waters where they are found: 1) Alaska and 2) California/Oregon/Washington. These two stocks were defined in this manner because of: 1) the large distance between the two areas in conjunction with the lack of any information about whether animals move between the two areas, 2) the somewhat different oceanographic habitats found in the two areas, and 3) the different fisheries that operate within portions of those two areas, with bycatch of Baird's beaked whales only reported from the California/Oregon thresher shark and swordfish drift gillnet fishery. The California/Oregon/Washington Baird's beaked whale stock is reported separately in the Stock Assessment Reports for the Pacific Region.

POPULATION SIZE

Reliable estimates of abundance for this stock are currently unavailable.

Minimum Population Estimate

At this time, it is not possible to produce a reliable minimum population estimate (N_{MIN}) for this stock, as current estimates of abundance are unavailable.

Current Population Trend

No reliable estimates of abundance are available for this stock; therefore, reliable data on trends in population abundance are unavailable.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

A reliable estimate of the maximum net productivity rate is currently unavailable for the Alaska stock of Baird's beaked whale. Hence, until additional data become available, it is recommended that the cetacean maximum theoretical net productivity rate (R_{MAX}) of 4% be employed (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the potential biological removal (PBR) is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: $PBR = N_{MIN} \times 0.5R_{MAX} \times F_R$. The recovery factor ($F_R$) for these stocks is 0.5, the value for cetacean stocks with unknown population status (Wade and Angliss 1997). However, in the absence of a reliable estimate of minimum abundance, the PBR for this stock is unknown.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

New Serious Injury Guidelines

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an "*injury that is more likely than not to result in mortality*." Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

Fisheries Information

Twenty-two different commercial fisheries operating within the potential range of the Alaska stock of Baird's beaked whale were monitored for incidental take by fisheries observers from 2007-2011 (see 76 FR 73912, final List of Fisheries for 2012) . There were no serious injuries or mortalities of Baird's beaked whales incidental to observed commercial fisheries reported between 2007-2011 (Breiwick 2013). The estimated annual mortality rate incidental to commercial fisheries is zero.

Subsistence/Native Harvest Information

There is no known subsistence harvest of Baird's beaked whales by Alaska Natives.

Other Mortality

Between 1925 and 1987, 618 Baird's beaked whales were reported taken throughout the North Pacific (International Whaling Commission, BWIS catch data, February 2003 version, unpublished). The annual quota of Baird's beaked whales for small-type whaling in Japan was 62 from 1999-2004, which increased temporarily to 66 from 2005-2010 and will remain a permanent increase (Kasuya 2011). Due to the unknown stock structure and migratory patterns in the North Pacific, it is unclear whether these animals belong to the Alaska stock of Baird's beaked whales.

STATUS OF STOCK

Baird's beaked whales are not designated as "depleted" under the MMPA or listed as "threatened" or "endangered" under the Endangered Species Act. Reliable estimates of the minimum population, population trends, PBR, and status of the stock relative to its Optimum Sustainable Population size are currently not available. Because the PBR is unknown, the level of annual U.S. commercial fishery-related mortality that can be considered insignificant and approaching zero mortality and serious injury rate is unknown. However, the estimated annual rate of human-caused mortality and serious injury seems minimal for this stock. Thus, the Alaska stock of Baird's beaked whale is not classified as strategic.

Habitat concerns

Disturbance by anthropogenic noise is an increasing habitat concern for most species of beaked whales, particularly in areas of oil and gas activities or where shipping or military activities are high. Shipping noise and the use of military sonars have been found to alter dive behavior and movements, as well as vocal activity in some species of beaked whales (Aguilar de Soto et al. 2006, McCarthy et al. 2011, Tyack et al. 2011). Little is known about the effects of noise on beaked whales in Alaska. Ingestion of marine debris, particularly plastics, is a concern; plastic is occasionally found in the stomach contents of stranded beaked whales, including Baird's beaked whales (Smithsonian Institution, Cetacean Distributional Database, accessed 04 June 2012).

CUVIER'S BEAKED WHALE (*Ziphius cavirostris*): Alaska Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

The distribution of Cuvier's beaked, or goosebeak, whale (Fig. 1) is known primarily from strandings, which indicate that it is the most widespread of the beaked whales and is distributed in all oceans and most seas except in the high polar waters (Moore 1963). In the Pacific, they range north to the northern Gulf of Alaska, the Aleutian Islands, and the Commander Islands (Rice 1986, 1998). In the northeastern Pacific from Alaska to Baja California, no obvious pattern of seasonality to strandings has been identified (Mitchell 1968). Strandings of Cuvier's beaked whales are the most numerous of all beaked whales, indicating that they are probably not as rare as originally thought (Heyning 1989). Observations reveal that the blow is low, diffuse, and directed forward (Backus and Schevill 1961, Norris and Prescott 1961), making sightings more difficult, and there is some evidence that they avoid vessels by diving (Heyning 1989). Relatively few (4 total) acoustic detections of Cuvier's beaked whales were recorded off Kiska Island (1 in summer) and in the offshore Gulf of Alaska (3 total detections, 1 in October and 2 in January; Baumann-Pickering et al. 2012a, 2012b).

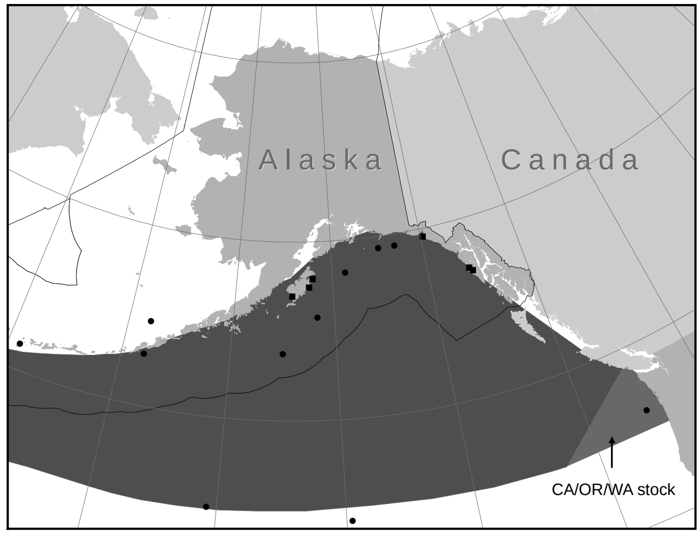

Figure 1. Approximate distribution of Cuvier's beaked whales in the eastern North Pacific (shaded area). Sightings (circles) and strandings (squares) within the last 10 years are also depicted (Forney and Brownell 1996, NMFS unpublished data).

Mitchell (1968) examined skulls of stranded whales for geographical differences and thought that there was probably one panmictic population in the northeastern Pacific. Otherwise, there are insufficient data to apply the phylogeographic approach to stock structure (Dizon et al. 1992) for the Cuvier's beaked whale. Therefore, Cuvier's beaked whale stocks are defined as the three non-contiguous areas within Pacific U. S. waters where they are found: 1) Alaska, 2) California/Oregon/Washington, and 3) Hawaii. These three stocks were defined in this way because of: 1) the large distance between the areas in conjunction with the lack of any information about whether animals move between the three areas, 2) the different oceanographic habitats found in the three areas, and 3) the different fisheries that operate within portions of those three areas, with bycatch of Cuvier's beaked whales only reported from the California/Oregon thresher shark and swordfish drift gillnet fishery. The California/Oregon/Washington and Hawaiian Baird's beaked whale stocks are reported separately in the Stock Assessment Reports for the Pacific Region.

POPULATION SIZE

Reliable estimates of abundance for this stock are currently unavailable.

Minimum Population Estimate

At this time, it is not possible to produce a reliable minimum population estimate (N_{MIN}) for this stock, as current estimates of abundance are unavailable.

Current Population Trend

No reliable estimates of abundance are available for this stock; therefore, reliable data on trends in population abundance are unavailable.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

A reliable estimate of the maximum net productivity rate is currently unavailable for the Alaska stock of Cuvier's beaked whale. Hence, until additional data become available, it is recommended that the cetacean maximum theoretical net productivity rate (R_{MAX}) of 4% be employed (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the potential biological removal (PBR) is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: $PBR = N_{MIN} \times 0.5R_{MAX} \times F_R$. The recovery factor ($F_R$) for this stock is 0.5, the value for cetacean stocks with unknown population status (Wade and Angliss 1997). However, in the absence of a reliable estimate of minimum abundance, the PBR for this stock is unknown.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

New Serious Injury Guidelines

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an "*injury that is more likely than not to result in mortality*". Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

Fisheries Information

Twenty-two different commercial fisheries operating within the potential range of the Alaska stock of Cuvier's beaked whale were monitored for incidental take by fishery observers from 2007-2011 (see 76 FR 73912, final List of Fisheries for 2012) . There were no serious injuries or mortalities of Cuvier's beaked whales incidental to observed commercial fisheries reported between 2007-2011 (Breiwick 2013). The estimated annual mortality rate incidental to commercial fisheries is zero.

Subsistence/Native Harvest Information

There is no known subsistence harvest of Cuvier's beaked whales.

Other Mortality

Unknown levels of injuries and mortality of Cuvier's beaked whales may occur as a result of anthropogenic noise, such as military sonars (U.S. Dept. of Commerce and Secretary of the Navy 2001) or other commercial and scientific activities producing high-energy sound. The use of active sonar from military vessels has been implicated or coincident with mass strandings of beaked whales (Cox et al. 2006, Frantzis 1998, Martel 2002, Jepson et al. 2003, Simmonds and Lopez-Jurado 1991, U.S. Dept. of Commerce and Secretary of the Navy 2001), and all atypical single and mixed-species mass strandings involved Cuvier's beaked whales (D'Amico et al. 2009). There is concern regarding the potential effects of underwater sounds from seismic operations on beaked whales, although investigations of causation of atypical strandings of Cuvier's beaked whales and nearby seismic air gun operations have been inconclusive (Gentry 2002, Gordon et al. 2003/2004, Malakoff 2002). Changes in dive behavior, particularly a quick ascent from deep dives, in response to sound exposure may result in injuries related to bubble growth during decompression (Cox et al. 2006, Tyack et al. 2011, Hooker et al. 2011). Such injuries or mortality would rarely be documented due to the remote nature of many of these activities and the low probability that an injured or dead beaked whale would strand. No estimates of potential mortality or serious injury are available for Cuvier's beaked whales in Alaska waters.

STATUS OF STOCK

Cuvier's beaked whales are not designated as "depleted" under the MMPA or listed as "threatened" or "endangered" under the Endangered Species Act. Reliable estimates of the minimum population, population trends, PBR, and status of the stock relative to its Optimum Sustainable Population size are currently not available. Because the PBR is unknown, the level of annual U.S. commercial fishery-related mortality that can be considered insignificant and approaching zero mortality and serious injury rate is unknown. However, the estimated annual rate of human-caused mortality and serious injury seems minimal for this stock. Thus, the Alaska stock of Cuvier's beaked whale is not classified as strategic.

Habitat concerns

Disturbance by anthropogenic noise is an increasing habitat concern for most species of beaked whales, particularly in areas of oil and gas activities or where shipping or military activities are high. Shipping noise may disrupt the behavior of Cuvier's beaked whales (Aguilar de Soto et al. 2006), and the use of military sonars has been found to alter dive behavior and movements, as well as vocal activity in some species of beaked whales (McCarthy et al. 2011, Tyack et al. 2011). Moore and Barlow (2013) report impacts of anthropogenic sound and ecosystem change as the most plausible hypotheses for declining abundance of *Ziphius* and *Mesoplodon* spp. in the California Current large marine ecosystem. Little is known about the effects of noise or ecosystem change on beaked whales in Alaska, and the lack of abundance estimates hinder the detection of any population trends. Ingestion of marine debris, particularly plastics, is a concern; plastic is occasionally found in the stomach contents of stranded beaked whales, including Cuvier's beaked whales. (Smithsonian Institution, Cetacean Distributional Database, accessed 04 June 2012).

STEJNEGER'S BEAKED WHALE (*Mesoplodon stejnegeri*): Alaska Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Stejneger's, or Bering Sea, beaked whale is rarely seen at sea, and its distribution generally has been inferred from stranded specimens (Loughlin and Perez 1985, Mead 1989, Walker and Hanson 1999). It is endemic to the cold-temperate waters of the North Pacific Ocean, Sea of Japan, and deep waters of the southwest Bering Sea (Fig. 1). The range of Stejneger's beaked whale extends along the coast of North America from Cardiff, California, north through the Gulf of Alaska to the Aleutian Islands, into the Bering Sea to the Pribilof Islands and Commander Islands, and, off Asia, south to Akita Beach on Noto Peninsula, Honshu, in the Sea of Japan (Loughlin and Perez 1985). Near the central Aleutian Islands, groups of 3-15 Stejneger's beaked whales have been sighted on a number of occasions (Rice 1986). The species is not known to enter the Arctic Ocean and is the only species of *Mesoplodon* known to occur in Alaska waters. The distribution of *M. stejnegeri* in the North Pacific corresponds closely, in occupying the same cold-temperate niche and position, to that of *M. bidens* in the North Atlantic. It lies principally between 50°and 60°N and extends only to about 45°N in the eastern Pacific, but to about 40°N in the western Pacific (Moore 1963, 1966). Acoustic signals believed to be produced by Stejneger's beaked whales (based on frequency characteristics, interpulse interval and geographic location, Baumann-Pickering et al. 2012a) were recorded 2-5 times a week in July off Kiska Island and almost weekly from July 2011 to February 2012 in the northern Gulf of Alaska (Baumann-Pickering et al. 2012b).

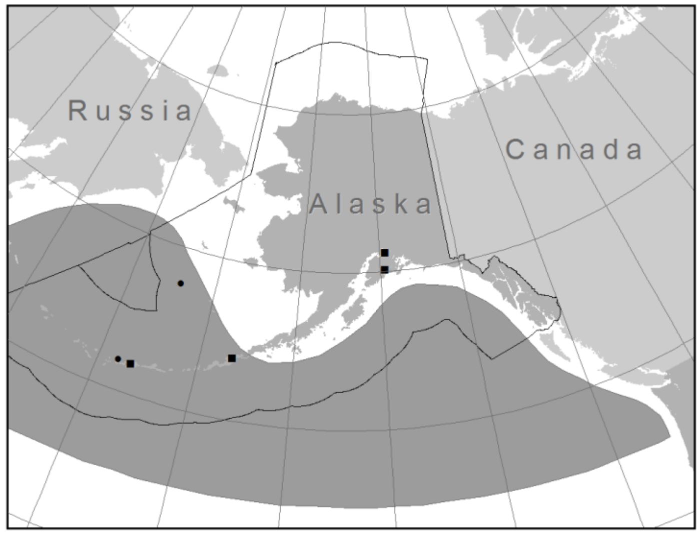

Figure 1. Approximate distribution of Stejneger's beaked whales in the eastern North Pacific (shaded area). Sightings (circles) and strandings (squares) within the last 10 years are also depicted (Walker and Hanson 1999, NMFS unpublished data).

There are insufficient data to apply the phylogeographic approach to stock structure (Dizon et al. 1992) for Stejneger's beaked whale. The Alaska Stejneger's beaked whale stock is recognized separately from *Mesoplodon* spp. off California, Oregon, and Washington because of: 1) the distribution of Stejneger's beaked whale and the different oceanographic habitats found in the two areas, 2) the large distance between the two non-contiguous areas of U.S. waters in conjunction with the lack of any information about whether animals move between the two areas, and 3) the different fisheries that operate within portions of those two areas, with bycatch of *Mesoplodon* spp. only reported from the California/Oregon thresher shark and swordfish drift gillnet fishery. The California/Oregon/Washington stock of all *Mesoplodon* spp. and a *Mesoplodon densirostris* stock in Hawaiian waters are reported separately in the Stock Assessment Reports for the Pacific Region.

POPULATION SIZE

Reliable estimates of abundance for this stock are currently unavailable.

Minimum Population Estimate

At this time, it is not possible to produce a reliable minimum population estimate (N_{MIN}) for this stock, as current estimates of abundance are unavailable.

Current Population Trend

No reliable estimates of abundance are available for this stock; therefore, reliable data on trends in population abundance are unavailable.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

A reliable estimate of the maximum net productivity rate is currently unavailable for the Alaska stock of Stejneger's beaked whale. Hence, until additional data become available, it is recommended that the cetacean maximum theoretical net productivity rate (R_{MAX}) of 4% be employed (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the potential biological removal (PBR) is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: $PBR = N_{MIN} \times 0.5R_{MAX} \times F_R$. The recovery factor ($F_R$) for this stock is 0.5, the value for cetacean stocks with unknown population status (Wade and Angliss 1997). However, in the absence of a reliable estimate of minimum abundance, the PBR for this stock is unknown.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

New Serious Injury Guidelines

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an "*injury that is more likely than not to result in mortality*." Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

Fisheries Information

Twenty-two different commercial fisheries operating within the potential range of the Alaska stock of Cuvier's beaked whale were monitored for incidental take by fishery observers from 2007-2011 (see 76 FR 73912, final List of Fisheries for 2012) . There were no serious injuries or mortalities of Stejneger's beaked whales incidental to observed commercial fisheries reported between 2007-2011 (Breiwick 2013). The estimated annual mortality rate incidental to commercial fisheries is zero.

Subsistence/Native Harvest Information

There is no known subsistence harvest of Stejneger's beaked whales.

STATUS OF STOCK

Stejneger's beaked whales are not designated as "depleted" under the MMPA or listed as "threatened" or "endangered" under the Endangered Species Act. Reliable estimates of the minimum population, population trends, PBR, and status of the stock relative to its Optimum Sustainable Population size are currently not available. Because the PBR is unknown, the level of annual U.S. commercial fishery-related mortality that can be considered insignificant and approaching zero mortality and serious injury rate is unknown. However, the estimated annual rate of human-caused mortality and serious injury seems minimal for this stock. Thus, the Alaska stock of Stejneger's beaked whale is not classified as strategic.

Habitat concerns

Disturbance by anthropogenic noise is an increasing habitat concern for most species of beaked whales, particularly in areas of oil and gas activities or where shipping or military activities are high. Shipping noise and the use of military sonars have been found to alter dive behavior and movements, as well as vocal activity in some species of beaked whales (Aguilar de Soto et al. 2006, McCarthy et al. 2011, Tyack et al. 2011). Moore and Barlow (2013) report impacts of anthropogenic sound and ecosystem change as the most plausible hypotheses for declining abundance of *Ziphius* and *Mesoplodon* spp., including *M. stejnegeri*, in the California Current large marine ecosystem. Little is known about the effects of noise on beaked whales in Alaska. Ingestion of marine debris, particularly plastics, is a concern; plastic is occasionally found in the stomach contents of stranded beaked whales, including Stejneger's beaked whales. (Smithsonian Institution, Cetacean Distributional Database, accessed 04 June 2012).

HUMPBACK WHALE (*Megaptera novaeangliae*): Western North Pacific Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

The humpback whale is distributed worldwide in all ocean basins. In winter, most humpback whales occur in the subtropical and tropical waters of the Northern and Southern Hemispheres. Humpback whales in the high latitudes of the North Pacific Ocean are seasonal migrants that feed on euphausiids and small schooling fishes (Nemoto 1957, 1959; Clapham and Mead 1999). The humpback whale population was considerably reduced as a result of intensive commercial exploitation during the 20th century.

A large-scale study of humpback whales throughout the North Pacific was conducted in 2004-2006 (the Structure of Populations, Levels of Abundance, and Status of Humpbacks (SPLASH) project). Initial results from this project (Calambokidis et al. 2008, Barlow et al. 2011), including abundance estimates and movement information, have been reported in Baker et al. (2008, 2013) and are also summarized in Fleming and Jackson (2011); however, these results are still being considered for stock structure analysis.

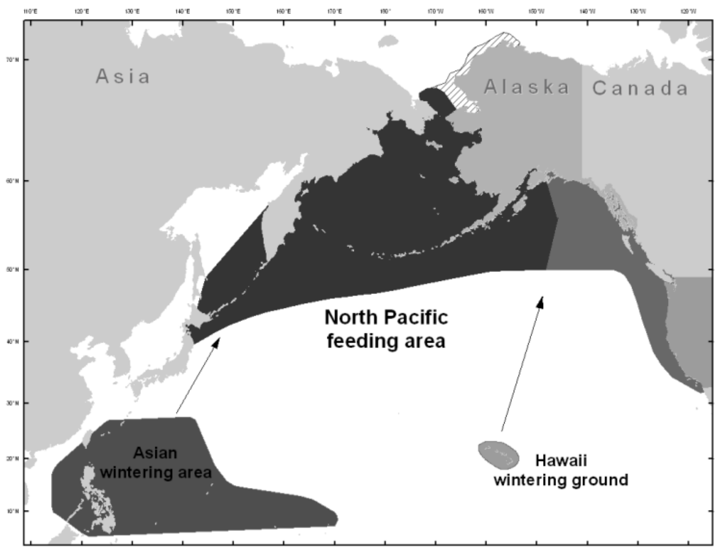

Figure 1. Approximate distribution of humpback whales in the western North Pacific (dark shaded areas). Feeding and wintering grounds are presented above (see text). Area within the hash lines is a probable distribution area based on sightings in the Beaufort Sea (Hashagen et al. 2009). See Figure 1 in the Central North Pacific humpback whale Stock Assessment Report for humpback whale distribution in the eastern North Pacific.

The historical summer feeding range of humpback whales in the North Pacific encompassed coastal and inland waters around the Pacific Rim from Point Conception, California, north to the Gulf of Alaska and the Bering Sea, and west along the Aleutian Islands to the Kamchatka Peninsula and into the Sea of Okhotsk and north of the Bering Strait (Zenkovich 1954, Nemoto 1957, Tomlin 1967, Johnson and Wolman 1984). Historically, the Asian wintering area extended from the South China Sea east through the Philippines, Ryukyu Retto, Ogasawara Gunto, Mariana Islands, and Marshall Islands (Rice 1998). Humpback whales are currently found throughout this historical range (Clarke et al. 2013b), with sightings during summer months occurring as far north as the Beaufort Sea (Hashagen et al. 2009). Most of the current winter range of humpback whales in the North Pacific is relatively well known, with aggregations of whales in Japan, the Philippines, Hawaii, Mexico, and Central America. The winter range includes the main islands of the Hawaiian archipelago, with the greatest concentration along the west side of Maui. In Mexico, the winter breeding range includes waters around the southern part of the Baja California peninsula, the central portions of the Pacific coast of mainland Mexico, and the Revillagigedo Islands off the mainland coast. The winter range also extends from southern Mexico into Central America, including Guatemala, El Salvador, Nicaragua, and Costa Rica (Calambokidis et al. 2008).

Photo-identification data, distribution information, and genetic analyses have indicated that in the North Pacific there are at least three breeding populations (Asia, Hawaii, and Mexico/Central America) that all migrate between their respective winter/spring calving and mating areas and their summer/fall feeding areas (Calambokidis et al. 1997, Baker et al. 1998). Calambokidis et al. (2001) further suggested that there may be as many as six subpopulations on the wintering grounds. From photo-identification and Discovery tag mark information there are known connections between Asia and Russia, between Hawaii and Alaska, and between Mexico/Central America and California (Darling 1991, Darling and Cerchio 1993, Calambokidis et al. 1997, Baker et al. 1998). This information led to the designation of three stocks of humpback whales in the North Pacific: 1) the California/Oregon/Washington and Mexico stock, consisting of winter/spring populations in coastal Central

America and coastal Mexico which migrate to the coast of California and as far north as southern British Columbia in summer/fall (Calambokidis et al. 1989, 1993; Steiger et al. 1991); 2) the Central North Pacific stock, consisting of winter/spring populations of the Hawaiian Islands which migrate primarily to northern British Columbia/Southeast Alaska, the Gulf of Alaska, and the Bering Sea/Aleutian Islands (Baker et al. 1990, Perry et al. 1990, Calambokidis et al. 1997); and 3) the Western North Pacific stock, consisting of winter/spring populations off Asia which migrate primarily to Russia and the Bering Sea/Aleutian Islands (Fig. 1).

Information from the SPLASH project largely confirms this view of humpback whale distribution and movements in the North Pacific. For example, the SPLASH results confirm low rates of interchange between the three principal wintering regions (Asia, Hawaii, and Mexico). However, the full SPLASH results suggest that the current view of population structure is incomplete. The overall pattern of movements is complex but indicates a high degree of population structure. Whales from wintering areas at the extremes of their range on both sides of the Pacific migrate to coastal feeding areas that are on the same side of the Pacific: whales from Asia in the west migrate to Russia and whales from mainland Mexico and Central America in the east migrate to coastal waters off California/Oregon.

The SPLASH data now show the Revillagigedo whales are seen in all sampled feeding areas except northern California/Oregon and the south side of the Aleutians. They are primarily distributed in the Bering Sea, Gulf of Alaska, and Southeast Alaska/northern British Columbia but are also found in Russia and southern British Columbia/Washington. The migratory destinations of humpback whales from Hawaii were found to be quite similar, and a number of matches (14) were seen during SPLASH between Hawaii and the Revillagigedos (Calambokidis et al. 2008).

The winter distribution of humpback whales in the Western stock includes several island chains in the western North Pacific. In the Ogasawara Islands, humpback whale sampling during SPLASH was conducted at the three main island groups of Chichi-jima, Haha-jima, and Muko-jima, separated from each other by ~50-70 km. SPLASH sampling in Okinawa (southwest of Honshu) occurred at the Okinawa mainland and Zamami in the Kerama Islands (40 km from the Okinawa mainland), and in the Philippines SPLASH sampling occurred only at the northern tip of the archipelago around the Babuyan Islands. Humpback whales are reported to also occur in the South China Sea north of the Philippines near Taiwan, and east of Ogasawara in the Marshall and Mariana Islands (Rice 1998), but as yet there are no known areas of high density in these regions that could be efficiently sampled.

The SPLASH project also found that whales from the Aleutian Islands and Bering Sea, and perhaps the Gulf of Anadyr and the Chukotka Peninsula on the west side of the Bering Strait in Russia, have an unusually low resighting rate in winter areas compared to whales from other feeding areas. It is now believed that some of these whales have a winter migratory destination that was not sampled during the SPLASH project. Given the location of these feeding areas, the most parsimonious explanation would be that some of these whales winter somewhere between Hawaii and Asia, which would include the possibility of the Mariana Islands (southwest of the Ogasawara Islands), the Marshall Islands (approximately half-way between the Mariana Islands and the Hawaiian Islands), and the Northwestern Hawaiian Islands. Subsequent to the SPLASH project, a survey in 2007 documented humpback whales from a number of locations in the Northwestern Hawaiian Islands at relatively low densities (Johnston et al. 2007), but no sampling occurred there during the SPLASH project. Some humpback whales, including mother/calf pairs, have also been found in the Mariana Islands (Hill et al. 2016). Both of these locations are plausible migratory destinations for whales from the Aleutian Islands and Bering Sea. Which stock that whales in these locations would belong to is currently unknown.

The migratory destination of Western North Pacific humpback whales is not completely known. Discovery tag recaptures have indicated movement of whales between Ogasawara and Okinawa and feeding areas in the Bering Sea, on the southern side of the Aleutian Islands, and in the Gulf of Alaska (Omura and Ohsumi 1964, Nishiwaki 1966, Ohsumi and Masaki 1975). Research on humpback whales at the Ogasawara Islands has documented recent movements of whales between there and British Columbia (Darling et al. 1996), the Kodiak Archipelago in the central Gulf of Alaska (Calambokidis et al. 2001), and the Shumagin Islands in the western Gulf of Alaska (Witteveen et al. 2004), but no photo-identification studies had previously been conducted in Russia. Individual movement information from the SPLASH study documents that Russia is likely the primary migratory destination for whales in Okinawa and the Philippines but also reconfirms that some Asian whales go to Ogasawara, the Aleutian Islands, Bering Sea, and Gulf of Alaska (Calambokidis et al. 2008). A small amount of inter-yearly interchange was also found between the wintering areas (Philippines, Okinawa, and Ogasawara).

During the SPLASH study in Russia, humpback whales were primarily found along the Pacific east side of the Kamchatka Peninsula, near the Commander Islands between Kamchatka and the Aleutian Islands, and in the Gulf of Anadyr just southwest of the Bering Strait. Analysis of whaling data shows historical catches of humpback whales well into the Bering Sea and catches in the Bering Strait and Chukchi Sea in August-October in the 1930s

(Mizroch and Rice 2007), but no survey effort occurred during SPLASH north of the Bering Strait. Humpback whales are increasingly seen north of the Bering Strait into the northeastern Chukchi Sea (Clarke et al. 2013a, 2013b), with some indication that more humpback whales are seen on the Russian side north of the Bering Strait (Clarke et al. 2013b). Humpback whales are the most commonly recorded cetacean on hydrophones just north of the Bering Strait and occurred from September into early November from 2009 to 2012 (K. Stafford, Applied Physics Laboratory-University of Washington, Seattle, WA, pers. comm.). Other locations in the far western Pacific where humpback whales have been seen in summer include the northern Kuril Islands (V. Burkanov, NMFS-AFSC-MML, pers. comm.), far offshore southeast of the Kamchatka Peninsula and south of the Commander Islands (Miyashita 2006), and along the north coast of the Chukotka Peninsula in the Chukchi Sea (Melnikov 2000).

These results indicate humpback whales from the Western North Pacific (Asian) breeding stock overlap broadly on summer feeding grounds with whales from the Central North Pacific breeding stock, as well as with whales that winter in the Revillagigedos in Mexico. Given the relatively small size of the Asian population, Asian whales probably represent a small fraction of all the whales found in the Aleutian Islands, Bering Sea, and Gulf of Alaska, which are primarily whales from Hawaii and the Revillagigedos. The only feeding area that appears to be primarily (or exclusively) composed of Asian whales is along the Kamchatka Peninsula in Russia. The initial SPLASH abundance estimates for Asia ranged from about 900 to 1,100, and the estimates for Kamchatka in Russia ranged from about 100 to 700, suggesting a large portion of the Asian population migrates to Kamchatka. This also shows that Asian whales that migrate to feeding areas besides Russia would be only a small fraction of the total number of whales in those areas, given the much larger abundance estimates for the Bering Sea and Aleutian Islands (6,000-14,000) and the Gulf of Alaska (3,000-5,000) (Calambokidis et al. 2008). A full description of the distribution and density of humpback whales in the Aleutian Islands, Bering Sea, and Gulf of Alaska is in the Stock Assessment Report for the Central North Pacific stock of humpback whales.

In summary, information from a variety of sources indicates that humpback whales from the Western and Central North Pacific stocks mix to a limited extent on summer feeding grounds ranging from British Columbia through the central Gulf of Alaska and up to the Bering Sea.

NMFS has conducted a global Status Review of humpback whales (Bettridge et al. 2015) and recently revised the ESA listing of the species (81 FR 62259, 8 September 2016). NMFS is evaluating the stock structure of humpback whales under the MMPA, but no changes to current stock structure are presented at this time. However, effects of the ESA-listing final rule on the status of the stock are discussed below.

POPULATION SIZE

In the SPLASH study, fluke photographs were collected by over 400 researchers in all known feeding areas from Russia to California and in all known wintering areas from Okinawa and the Philippines to the coast of Central America and Mexico during 2004-2006. Over 18,000 fluke identification photographs were collected, and these have been used to estimate the abundance of humpback whales in the entire North Pacific Basin. A total of 566 unique individuals were seen in the Asian wintering areas during the 2-year period (3 winter field seasons) of the SPLASH study. Based on a comparison of all winter identifications to all summer identifications, the Chapman-Petersen estimate of abundance is 21,808 (CV=0.04) (Barlow et al. 2011). A simulation study identifies significant biases in this estimate from violations of the closed population assumption (+5.3%), exclusion of calves (-10.3%), failure to achieve random geographic sampling (+1.5%), and missed matches (+9.8%) (Barlow et al. 2011). Sex-biased sampling favoring males in wintering areas does not add significant bias if both sexes are proportionately sampled in the feeding areas. The bias-corrected estimate is 20,800 after accounting for a net positive bias of 4.8%. This estimate is likely to be lower than the true abundance due to two additional sources of bias: individual heterogeneity in the probability of being sampled (unquantified) and the likely existence of an unknown and unsampled wintering area (-7.2%).

During the SPLASH study, surveys were conducted in three winter field seasons (2004-2006). The total numbers of unique individuals found in each area during the study were 77 in the Philippines, 215 in Okinawa, and 294 in the Ogasawara Islands. There was a total of 20 individuals seen in more than one area, leaving a total of 566 unique individuals seen in the Asian wintering areas (Calambokidis et al. 2008). For abundance in winter or summer areas, a multistrata Hilborn mark-recapture model was used, which is a form of a spatially-stratified model that explicitly estimates movement rates between winter and summer areas. Two broad categories of models were used making different assumptions about the movement rates, and four different models were used for capture probability. Point estimates of abundance for Asia (combined across the three areas) were relatively consistent across models, ranging from 938 to 1,107. The model that fit the data the best (as selected by AICc) gave an estimate of 1,107 for the Ogasawara Islands, Okinawa, and the Philippines. Confidence limits or coefficients of variation (CVs) have not yet been calculated for the SPLASH abundance estimates. Although no other high density aggregations of humpback whales are known on the Asian wintering ground, whales have been seen in other locations, indicating this is likely to represent an underestimate of the stock's true abundance to an unknown degree. This estimate is more than 8 years old and is outdated for use in stock assessments; however, because this population is growing (Calambokidis et al. 2008), this is still a valid minimum population estimate.

On the summer feeding grounds, the initial SPLASH abundance estimates for Kamchatka in Russia ranged from about 100 to 700, suggesting a large portion of the Asian population occurs near Kamchatka. No separate estimates are available for the other areas in Russia, the Gulf of Anadyr and the Commander Islands; abundance from those areas is included in the estimate of abundance for the Bering Sea and Aleutian Islands, which ranged from about 6,000 to 14,000. Abundance estimates for the Gulf of Alaska and for Southeast Alaska/northern British Columbia both ranged from 3,000 to 5,000 (Calambokidis et al. 2008).

Minimum Population Estimate

As discussed above, point estimates of abundance for Asia ranged from 938 to 1,107 (for 2004-2006), but no associated CV has yet been calculated. The 1991-1993 abundance estimate for Asia using similar (though likely less) data had a CV of 0.084. Therefore, it is unlikely the CV of the SPLASH estimate, once calculated, would be greater than 0.300. The minimum population estimate (N_{MIN}) for this stock is calculated according to Equation 1 from the potential biological removal (PBR) guidelines (Wade and Angliss 1997): $N_{MIN} = N/\exp(0.842\times[\ln(1+[CV(N)]^2)]^{½})$. Using the SPLASH population estimate (N) of 1,107 from the best fit model and an assumed conservative CV(N) of 0.300 would result in an N_{MIN} for this humpback whale stock of 865.

Current Population Trend

The SPLASH abundance estimate for Asia represents a 6.7% annual rate of increase over the 1991-1993 abundance estimate (Calambokidis et al. 2008). However, the 1991-1993 estimate was for Ogasawara and Okinawa only, whereas the SPLASH estimate includes the Philippines, so the annual rate of increase is biased high to an unknown degree.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Utilizing a birth-interval model, Barlow and Clapham (1997) have estimated a population growth rate of 6.5% (SE = 1.2%) for the well-studied humpback whale population in the Gulf of Maine, although there are indications that this rate has slowed in recent years (Clapham et al. 2003). Mobley et al. (2001) estimated a trend of 7% per year for 1993-2000 using data from aerial surveys that were conducted in a consistent manner for several years across all of the Hawaiian Islands and were developed specifically to estimate a trend for the Central North Pacific stock. Mizroch et al. (2004) estimated survival rates for North Pacific humpback whales using mark-recapture methods, and a Pradel model fit to data from Hawaii for the years 1980-1996 resulted in an estimated rate of increase of 10% per year (95% CI: 3-16%). For shelf waters of the northern Gulf of Alaska, Zerbini et al. (2006) estimated an annual rate of increase for humpback whales from 1987 to 2003 of 6.6% (95% CI: 5.2-8.6%). The SPLASH abundance estimate for the total North Pacific represents an annual increase of 4.9% over the most complete estimate for the North Pacific for 1991-1993. Comparisons of SPLASH abundance estimates for Hawaii to estimates for 1991-1993 gave estimates of annual increase that ranged from 5.5 to 6.0% (Calambokidis et al. 2008). No confidence limits were calculated for these rates of increase from SPLASH data.

Estimates of observed rates of increase can be used to estimate maximum net productivity rates, although in most cases these estimates may be biased low, as maximum net productivity rates are only achieved at very low population sizes. However, if the observed rates of increase are greater than the default value recommended for R_{MAX}, it would be reasonable to use a higher value based on those observations. The rates of increase summarized above include estimates for the North Pacific of 7%, 10%, and 6.6%. Although there is no estimate of the maximum net productivity rate for just the Western stock (i.e., from trends in abundance in the Asia breeding areas), it is reasonable to assume that R_{MAX} for this stock would be at least 7% based on the other observations from the North Pacific. Hence, until additional data become available for the Western North Pacific humpback whale stock, it is recommended that 7% be employed as the maximum net productivity rate (R_{MAX}) for this stock (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized MMPA, the PBR is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: PBR = $N_{MIN} \times 0.5R_{MAX} \times F_R$. The recovery factor ($F_R$) for this stock is 0.1, the value for cetacean stocks listed as endangered under the ESA (Wade and Angliss 1997; see Status of Stock section below regarding ESA listing status). Using the N_{MIN} of 865 calculated from the SPLASH abundance estimate for 2004-2006, of 1,107 with an assumed CV of 0.300, the PBR is calculated to be 3.0 whales (865 × 0.035 × 0.1).

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Detailed information on U.S. commercial fisheries in Alaska waters (including observer programs, observer coverage, and observed incidental takes of marine mammals) is presented in Appendices 3-6 of the Alaska Stock Assessment Reports.

During 2010-2014, mortality and serious injury of humpback whales occurred in the Bering Sea/Aleutian Islands pollock trawl fishery (1 each in 2010 and 2012) and the Bering Sea/Aleutian Islands flatfish trawl fishery (1 in 2010) (Table 1; Breiwick 2013; MML, unpubl. data). Since the stock identification of these whales is unknown, and the events occurred within the area where the Western North Pacific and Central North Pacific stocks are known to overlap, the mortality in these fisheries is assigned to both stocks of humpback whales. The estimated average annual mortality and serious injury rate from observed U.S. commercial fisheries is 0.6 Western North Pacific humpback whales in 2010-2014 (Table 1).

Table 1. Summary of incidental mortality and serious injury of Western North Pacific humpback whales due to observed U.S. commercial fisheries in 2010-2014 and calculation of the mean annual mortality and serious injury rate (Breiwick 2013; MML, unpubl. data). Methods for calculating percent observer coverage are described in Appendix 6 of the Alaska Stock Assessment Reports. N/A indicates that data are not available.

Fishery name	Years	Data type	Percent observer coverage	Observed mortality	Estimated mortality	Mean estimated annual mortality
Bering Sea/Aleutian Is. flatfish trawl[a]	2010 2011 2012 2013 2014	obs data	99 100 99 99 99	0 (+1)[b] 0 0 0 0	0 (+1)[c] 0 0 0 0	0 (+0.2)[d] (CV = N/A)
Bering Sea/Aleutian Is. pollock trawl[a]	2010 2011 2012 2013 2014	obs data	86 98 98 97 98	1 0 1 0 0	1.0 0 1.0 0 0	0.4 (CV = 0.09)
Minimum total estimated annual mortality						0.6 (CV = 0.09)

[a]Mortality and serious injury in this fishery is assigned to both the Western North Pacific and Central North Pacific stocks of humpback whales, since the stock identification is unknown and the two stocks overlap within the area of operation of the fishery.
[b]Total mortality and serious injury observed in 2010: 0 whales in sampled hauls + 1 whale in an unsampled haul.
[c]Total estimate of mortality and serious injury in 2010: 0 whales (extrapolated estimate from 0 whales observed in sampled hauls) + 1 whale (1 whale observed in an unsampled haul).
[d]Mean annual mortality and serious injury for fishery: 0 whales (mean of extrapolated estimates from sampled hauls) + 0.2 whales (mean of number observed in unsampled hauls).

One entanglement in the ground tackle of a commercial Pacific cod jig fishery vessel in Kodiak, Alaska, was reported to the NMFS Alaska Region stranding network in 2013 (Table 2; Helker et al. 2016). Since observer data are not available for this fishery, this mortality results in a minimum mean annual mortality and serious injury rate of 0.2 humpback whales in 2010-2014 (Table 2) and, since the event occurred in the area where the two stocks overlap, the mortality is assigned to both the Western North Pacific and Central North Pacific stocks of humpback whales.

The estimated mean annual mortality and serious injury rate incidental to U.S. commercial fisheries is 0.8 Western North Pacific humpback whales (0.6 based on observed fisheries + 0.2 based on stranding data); however, this estimate is considered a minimum because there are no data concerning fishery-related mortality and serious injury in Japanese, Russian, or international waters.

Reports of swimming, floating, or beachcast humpback whales entangled in fishing gear or with injuries caused by interactions with gear, which may be from commercial, recreational, or subsistence fisheries, are another source of fishery-related mortality and serious injury data. The minimum mean annual mortality and serious injury rate from fishery-related gear entanglements and interactions reported to the NMFS Alaska Region stranding network in 2010-2014, in which the events have not been attributed to a specific fishery listed on the MMPA List of Fisheries (76 FR 73912, 29 November 2011), is 0.6 humpback whales (Table 2; Helker et al. 2016). Since these events occurred in the area where the two stocks overlap, this mortality is assigned to both the Western North Pacific and Central North Pacific stocks of humpback whales. These estimates are considered a minimum because not all entangled animals strand and not all stranded animals are found, reported, or have the cause of death determined.

One additional humpback whale, initially considered seriously injured due to entanglement in Gulf of Alaska/Kodiak Dungeness crab pot gear, was disentangled in Alaska waters in 2012 and released with non-serious injuries (Helker et al. 2016); therefore, it was not included in the mean annual mortality and serious injury rate for 2010-2014. Since this event occurred in the area where the two stocks overlap, this injury was also assigned to the Central North Pacific stock.

The minimum average annual mortality and serious injury rate due to interactions with all fisheries in 2010-2014 is 1.4 Western North Pacific humpback whales (0.8 in commercial fisheries + 0.6 in unknown fisheries).

Table 2. Summary of mortality and serious injury of Western North Pacific humpback whales, by year and type, reported to the NMFS Alaska Region marine mammal stranding network in 2010-2014 (Helker et al. 2016). Injury events lacking detailed injury information are assigned prorated values following injury determination guidelines described in NOAA (2012). All events occurred within the area of known overlap between the Western North Pacific and Central North Pacific humpback whale stocks. Since the stock identification is unknown, the mortality and serious injury is reflected in both Stock Assessment Reports. A summary of information used to determine whether an injury was serious or non-serious, as well as a table of prorate values used for large whale reports with incomplete information, is reported in Helker et al. (2016).

Cause of injury	2010	2011	2012	2013	2014	Mean annual mortality
Entangled in ground tackle of Kodiak commercial Pacific cod jig vessel	0	0	0	1	0	0.2
Entangled in Bering Sea pot gear*	0	0.75	0	0	0	0.2
Entangled in Prince William Sound shrimp pot gear*	0	0	0	0	1	0.2
Entangled in gillnet*	0	0.75	0	0	0	0.2
Entangled in marine debris	0	2.5	0.75	0	0.75	0.8
Ship strike	0	0	1.2	0	1	0.4
Total in commercial fisheries						0.2
*Total in unknown (commercial, recreational, or subsistence) fisheries						0.6
Total in marine debris						0.8
Total due to other sources (ship strike)						0.4

Brownell et al. (2000) compiled records of bycatch in Japanese and Korean commercial fisheries between 1993 and 2000. During the period 1995-1999, there were six humpback whales indicated as "bycatch." In addition, two strandings were reported during this period. Furthermore, analysis of four samples from meat found in markets indicated that humpback whales are being sold. At this time, it is not known whether any or all strandings were caused by incidental interactions with commercial fisheries; similarly, it is not known whether the humpback whales identified in market samples were killed as a result of incidental interactions with commercial fisheries. It is also not known which fishery may be responsible for the bycatch. Regardless, these data indicate a minimum mortality level of 1.1 per year (using bycatch data only) to 2.4 per year (using bycatch, stranding, and market data) in the waters of Japan and Korea. Because many mortalities pass unreported, the actual rate in these areas is likely much higher. An analysis of entanglement rates from photographs collected for SPLASH found a minimum entanglement rate of 31% for humpback whales from the Asia breeding grounds (Cascadia Research NFWF Report #2003-0170-019).

Alaska Native Subsistence/Harvest Information

There were no reported takes of humpback whales from this stock by Native subsistence hunters in Alaska or Russia in 2010-2014.

Other Mortality

In 2015, increased mortality of large whales (including 11 fin whales, 14 humpback whales, 1 gray whale, and 4 unidentified cetaceans from May to mid-August 2015) was observed along the western Gulf of Alaska, including the areas around Kodiak Island, Afognak Island, Chirikof Island, the Semidi Islands, and the southern shoreline of the Alaska Peninsula (http://www.nmfs.noaa.gov/pr/health/mmume/faqs_2015_large_whale.html, accessed December 2016). On 20 August 2015, NMFS declared an Unusual Mortality Event for large whales in the western Gulf of Alaska; however, to date, no specific cause for the increased mortality has been identified.

Other sources of human-caused mortality and serious injury include ship strikes and entanglement in marine debris. The minimum mean annual mortality and serious injury rate of 1.2 Western North Pacific humpback whales in 2010-2014 is based on ship strikes (0.4) and entanglement in marine debris (0.8) reported to the NMFS Alaska Region stranding network (Table 2; Helker et al. 2016). Since these events occurred in the area where the stocks overlap, this mortality is assigned to both the Western North Pacific and Central North Pacific stocks of humpback whales.

HISTORICAL WHALING

Rice (1978) estimated that the number of humpback whales in the North Pacific may have been approximately 15,000 individuals prior to exploitation; however, this was based upon incomplete data and, given the level of known catches (legal and illegal) since World War II, may be an underestimate. Intensive commercial whaling removed more than 28,000 animals from the North Pacific during the 20th century (Rice 1978). A total of 3,277 reported catches occurred in Asia between 1910 and 1964, with 817 catches from Ogasawara between 1924 and 1944 (Nishiwaki 1966, Rice 1978). After World War II, substantial catches occurred in Asia near Okinawa (including 970 between 1958 and 1961), as well as around the main islands of Japan and the Ogasawara Islands. On the feeding grounds, substantial catches occurred around the Commander Islands and western Aleutian Islands, as well as in the Gulf of Anadyr (Springer et al. 2006).

Humpback whales in the North Pacific were theoretically fully protected in 1965, but illegal catches by the U.S.S.R. continued until 1972 (Ivashchenko et al. 2007). From 1961 to 1971, 6,793 humpback whales were killed illegally by the U.S.S.R. Many animals during this period were taken from the Gulf of Alaska and Bering Sea (Doroshenko 2000); however, additional illegal catches were made across the North Pacific, from the Kuril Islands to the Queen Charlotte Islands, and other takes in earlier years may have gone unrecorded.

STATUS OF STOCK

The total estimated annual level of human-caused mortality and serious injury of 2.6 Western North Pacific humpback whales is less than the calculated conservative PBR level for this stock (3.0). The minimum estimate of the mean annual U.S. commercial fishery-related mortality and serious injury rate for this stock (0.8 whales) exceeds 10% of the PBR (10% of PBR = 0.3) and cannot be considered insignificant and approaching a zero mortality and serious injury rate. In addition, there is a lack of information about fisheries bycatch from Russia, Japan, Korea, and international waters, as well as earlier evidence of bycatch in Japan and Korea (Brownell et al. 2000: 1.1 to 2.4 whales per year based on bycatch, stranding, and market data). The humpback whale ESA listing final rule (81 FR 62259, 8 September 2016) established 14 Distinct Population Segments (DPSs) with different listing statuses. The DPSs that occur in waters under the jurisdiction of the United States do not necessarily equate to the existing MMPA stocks. Some of the listed DPSs partially coincide with the currently defined Western North Pacific stock. Because we cannot manage one portion of an MMPA stock as ESA-listed and another portion of a stock as not ESA-listed, until such time as the MMPA stock delineations are reviewed in light of the DPS designations, NMFS considers this stock to be endangered and depleted for MMPA management purposes (e.g., selection of a recovery factor, stock status). As a result, the Western North Pacific stock of humpback whale is classified as a strategic stock.

HABITAT CONCERNS

Elevated levels of sound from anthropogenic sources (e.g., shipping, military sonars) are a potential concern for humpback whales in the North Pacific, but no specific habitat concerns have been identified for this stock. Other potential impacts include possible changes in prey distribution with climate change, entanglement in fishing gear, and ship strikes due to increased vessel traffic (e.g., from increased shipping in higher latitudes and through the Bering Sea with changes in sea-ice coverage).

HUMPBACK WHALE (*Megaptera novaeangliae*): Central North Pacific Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

The humpback whale is distributed worldwide in all ocean basins. In winter, most humpback whales occur in the subtropical and tropical waters of the Northern and Southern Hemispheres. Humpback whales in the high latitudes of the North Pacific Ocean are seasonal migrants that feed on euphausiids and small schooling fishes (Nemoto 1957, 1959; Clapham and Mead 1999). The humpback whale population was considerably reduced as a result of intensive commercial exploitation during the 20th century.

A large-scale study of humpback whales throughout the North Pacific was conducted in 2004-2006 (the Structure of Populations, Levels of Abundance, and Status of Humpbacks (SPLASH) project). Initial results from this project (Calambokidis et al. 2008, Barlow et al. 2011), including abundance estimates and movement information, have been reported in Baker et al. (2008, 2013) and are also summarized in Fleming and Jackson (2011); however, these results are still being considered for stock structure analysis.

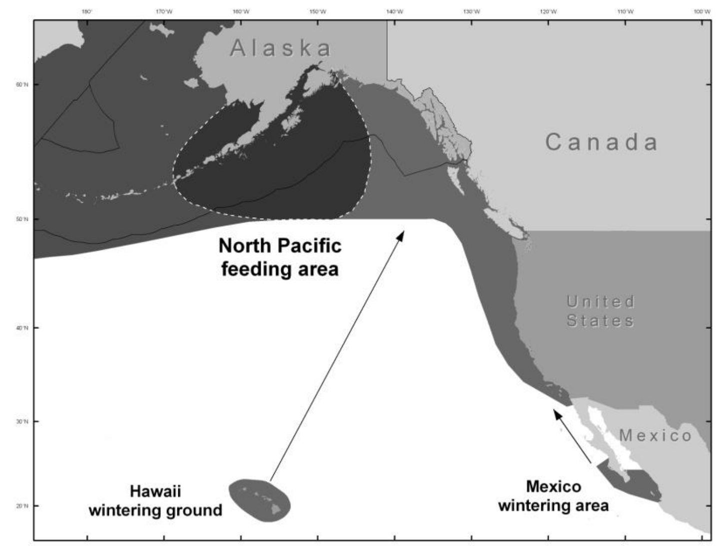

Figure 1. Approximate distribution of humpback whales in the eastern North Pacific (dark shaded areas). Feeding and wintering areas are presented above (see text). Area within the dotted line is known to be an area where the Central North Pacific and Western North Pacific stocks overlap. See Figure 1 in the Western North Pacific humpback whale Stock Assessment Report for distribution of humpback whales in the western North Pacific.

The historical summer feeding range of humpback whales in the North Pacific encompassed coastal and inland waters around the Pacific Rim from Point Conception, California, north to the Gulf of Alaska and the Bering Sea, and west along the Aleutian Islands to the Kamchatka Peninsula and into the Sea of Okhotsk and north of the Bering Strait (Zenkovich 1954, Nemoto 1957, Tomlin 1967, Johnson and Wolman 1984). Historically, the Asian wintering area extended from the South China Sea east through the Philippines, Ryukyu Retto, Ogasawara Gunto, Mariana Islands, and Marshall Islands (Rice 1998). Humpback whales are currently found throughout this historical range. Most of the current winter range of humpback whales in the North Pacific is relatively well known, with aggregations of whales in Japan, the Philippines, Hawaii, Mexico, and Central America. The winter range includes the main islands of the Hawaiian archipelago, with the greatest concentration along the west side of Maui. In Mexico, the winter breeding range includes waters around the southern part of the Baja California peninsula, the central portions of the Pacific coast of mainland Mexico, and the Revillagigedo Islands off the mainland coast. The winter range also extends from southern Mexico into Central America, including Guatemala, El Salvador, Nicaragua, and Costa Rica (Calambokidis et al. 2008).

Photo-identification data, distribution information, and genetic analyses have indicated that in the North Pacific there are at least three breeding populations (Asia, Hawaii, and Mexico/Central America) that all migrate between their respective winter/spring calving and mating areas and their summer/fall feeding areas (Calambokidis et al. 1997, Baker et al. 1998). Calambokidis et al. (2001) further suggested that there may be as many as six subpopulations on the wintering grounds. From photo-identification and Discovery tag mark information there are known connections between Asia and Russia, between Hawaii and Alaska, and between Mexico/Central America and California (Darling 1991, Darling and Cerchio 1993, Calambokidis et al. 1997, Baker et al. 1998). This information led to the designation of three stocks of humpback whales in the North Pacific: 1) the California/Oregon/Washington and Mexico stock, consisting of winter/spring populations in coastal Central America and coastal Mexico which migrate to the coast of California and as far north as southern British Columbia in summer/fall (Calambokidis et al. 1989, 1993; Steiger et al. 1991); 2) the Central North Pacific stock, consisting of winter/spring populations of the Hawaiian Islands which migrate primarily to northern British Columbia/Southeast Alaska, the Gulf of Alaska, and the Bering Sea/Aleutian Islands (Baker et al. 1990, Perry et al. 1990, Calambokidis et al. 1997) (Fig. 1); and 3) the Western North Pacific stock, consisting of winter/spring populations off Asia which migrate primarily to Russia and the Bering Sea/Aleutian Islands.

Information from the SPLASH project largely confirms this view of humpback whale distribution and movements in the North Pacific. For example, the SPLASH results confirm low rates of interchange between the three principal wintering regions (Asia, Hawaii, and Mexico). However, the full SPLASH results suggest that the current view of population structure is incomplete. The overall pattern of movements is complex but indicates a high degree of population structure. Whales from wintering areas at the extremes of their range on both sides of the Pacific migrate to coastal feeding areas that are on the same side of the Pacific: whales from Asia in the west migrate to Russia and whales from mainland Mexico and Central America in the east migrate to coastal waters off California/Oregon.

The SPLASH data now show the Revillagigedo whales are seen in all sampled feeding areas except northern California/Oregon and the south side of the Aleutians. They are primarily distributed in the Bering Sea, Gulf of Alaska, and Southeast Alaska/northern British Columbia but are also found in Russia and southern British Columbia/Washington. The migratory destinations of humpback whales from Hawaii were found to be quite similar, and a significant number of matches (14) were seen during SPLASH between Hawaii and the Revillagigedos (Calambokidis et al. 2008). The SPLASH project also found that whales from the Aleutian Islands and Bering Sea, and perhaps the Gulf of Anadyr and the Chukotka Peninsula on the west side of the Bering Strait in Russia, have an unusually low resighting rate in winter areas compared to whales from other feeding areas. It is now believed that some of these whales have a winter migratory destination that was not sampled during the SPLASH project. Given the location of these feeding areas, the most parsimonious explanation would be that some of these whales winter somewhere between Hawaii and Asia, which would include the possibility of the Mariana Islands (southwest of the Ogasawara Islands), the Marshall Islands (approximately half-way between the Mariana Islands and the Hawaiian Islands), and the Northwestern Hawaiian Islands. Subsequent to the SPLASH project, a survey in 2007 documented humpback whales from a number of locations in the Northwestern Hawaiian Islands at relatively low densities (Johnston et al. 2007), but no sampling occurred there during the SPLASH project. Some humpback whales, including mother/calf pairs, have also been found in the Mariana Islands (Hill et al. 2016). Both of these locations are plausible migratory destinations for whales from the Aleutian Islands and Bering Sea. Which stock that whales in these locations would belong to is currently unknown.

The winter distribution of the Central North Pacific stock is primarily in the Hawaiian archipelago. In the SPLASH study, sampling occurred on Kauai, Oahu, Penguin Bank (off the southwest tip of the island of Molokai), Maui, and the island of Hawaii (the Big Island). Interchange within Hawaii was extensive. Although most of the Hawaii identifications came from the Maui sub-area, identifications from the Big Island and Kauai at the eastern and western end of the region showed a high rate of interchange with Maui.

In summer, the majority of whales from the Central North Pacific stock are found in the Aleutian Islands, Bering Sea, Gulf of Alaska, and Southeast Alaska/northern British Columbia. High densities of humpback whales are found in the eastern Aleutian Islands, particularly along the northern side of Unalaska Island, and along the Bering Sea shelf edge and break to the north towards the Pribilof Islands. Small numbers of humpback whales are known from a few locations not sampled during the SPLASH study, including northern Bristol Bay and the Chukchi and Beaufort seas. In the Gulf of Alaska, high densities of humpback whales are found in the Shumagin Islands, south and east of Kodiak Island, and from the Barren Islands through Prince William Sound. Although densities in any particular location are not high, humpback whales are also found in deep waters south of the continental shelf from the eastern Aleutians through the Gulf of Alaska. Relatively high densities of humpback whales occur throughout much of Southeast Alaska and northern British Columbia.

NMFS has conducted a global Status Review of humpback whales (Bettridge et al. 2015) and recently revised the ESA listing of the species (81 FR 62259, September 8, 2016). NMFS is evaluating the stock structure of humpback whales under the MMPA, but no changes to current stock structure are presented at this time. However, effects of the ESA-listing final rule on the status of the stock are discussed below.

POPULATION SIZE

Prior to the SPLASH study, the most complete estimate of abundance for humpback whales in the North Pacific was from data collected in 1991-1993, with a best mark-recapture estimate of 6,010 (CV = 0.08) for the entire North Pacific, using a winter-to-winter comparison (Calambokidis et al. 1997). Estimates for Hawaii and Mexico were higher, using marks from summer feeding areas with recaptures on the winter grounds, and totaled almost 10,000 summed across all winter areas. In the SPLASH study, fluke photographs were collected by over 400 researchers in all known feeding areas from Russia to California and in all known wintering areas from Okinawa and the Philippines to the coast of Central America and Mexico during 2004-2006. Over 18,000 fluke identification photographs were collected, and these have been used to estimate the abundance of humpback whales in the entire North Pacific Basin. Based on a comparison of all winter identifications to all summer identifications, the Chapman-Petersen estimate of abundance is 21,808 (CV = 0.04) (Barlow et al. 2011). A simulation study identifies significant biases in this estimate from violations of the closed population assumption (+5.3%), exclusion of calves (-10.3%), failure to achieve random geographic sampling (+1.5%), and missed matches (+9.8%) (Barlow et al. 2011). Sex-biased sampling favoring males in wintering areas does not add significant bias if both sexes are proportionately sampled in the feeding areas. The bias-corrected estimate is 20,800 after accounting for a net positive bias of 4.8%. This estimate is likely to be lower than the true abundance due to two additional sources of bias: individual heterogeneity in the probability of being sampled (unquantified) and the likely existence of an unknown and unsampled wintering area (-7.2%).

The Central North Pacific stock of humpback whales winters in Hawaiian waters (Baker et al. 1986). Preliminary mark-recapture abundance estimates from the SPLASH data were calculated in Calambokidis et al. (2008), using a multistrata Hilborn model. The best estimate for Hawaii (as chosen by AICc) was 10,103; no confidence limit or coefficient of variation (CV) was calculated for that estimate. This estimate is more than 8 years old and is outdated for use in stock assessments; however, because this population is growing (Calambokidis et al. 2008), this is still a valid minimum population estimate.

In the SPLASH study, the number of unique identifications in different regions during 2004 and 2005 included 63 in the Aleutian Islands (defined as everything on the south side of the islands), 491 in the Bering Sea, 301 in the western Gulf of Alaska (including the Shumagin Islands), and 1,038 in the northern Gulf of Alaska (including Kodiak and Prince William Sound), with a few whales seen in more than one area (Calambokidis et al. 2008). The SPLASH combined estimates ranged from 6,000 to 19,000 for the Aleutian Islands, Bering Sea, and Gulf of Alaska, a considerable increase from previous estimates that were available (e.g., Waite et al. 1999, Moore et al. 2002, Witteveen et al. 2004, Zerbini et al. 2006). However, the SPLASH surveys covered areas not covered in those previous surveys, such as parts of Russian waters (Gulf of Anadyr and Commander Islands), the western and central Aleutian Islands, offshore waters in the Gulf of Alaska and Aleutian Islands, and Prince William Sound. Additionally, mark-recapture estimates can be higher than line-transect estimates because they estimate the total number of whales that have used the study area during the study period, whereas, line-transect surveys provide a snapshot of average abundance in the survey area at the time of the survey. For the Aleutian Islands and Bering Sea (including the Commander Islands and Gulf of Anadyr in Russia), the SPLASH estimates ranged from 2,889 to 13,594; for the Gulf of Alaska (from Prince William Sound to the Shumagin Islands, including Kodiak Island), the SPLASH estimates ranged from 2,845 to 5,122. Given known overlap in the distribution of the Western and Central North Pacific humpback whale stocks, estimates for these feeding areas may include whales from the Western North Pacific stock.

The SPLASH study showed a relatively high rate of interchange between Southeast Alaska and northern British Columbia, so they are considered together. Humpback whale studies have been conducted since the late 1960s in Southeast Alaska. Baker et al. (1992) estimated an abundance of 547 (95% CI: 504-590) using data collected in 1979-1986. Straley (1994) recalculated the estimate using a different analytical approach (Jolly-Seber open model for capture-recapture data) and obtained a mean population estimate of 393 animals (95% CI: 331-455) using the same 1979-1986 data set. Using 1986-1992 data and the Jolly-Seber approach, Straley et al. (1995) estimated that the annual abundance of humpback whales in Southeast Alaska was 404 animals (95% CI: 350-458). Straley et al. (2009) examined data for the northern portion of Southeast Alaska in 1994-2000 and provided an updated abundance estimate of 961 (CV=0.12). Using 1992-2006 photo-identification data and an SIR Jolly-Seber model, Ford et al. (2009) estimated an abundance of 2,145 humpback whales (95% CI: 1,970-2,331) in British Columbia waters. During the SPLASH study, 1,115 unique identifications were made in Southeast Alaska and 583 in northern British Columbia, for a total of 1,669 individual whales, after subtracting whales seen in both areas (1,115+583-13-16 = 1,669) (Calambokidis et al. 2008). From the SPLASH study, the estimates of abundance for Southeast Alaska/northern British Columbia ranged from 2,883 to 6,414. The estimates from SPLASH are considerably larger than the estimate from Straley et al. (2009). This is because the SPLASH estimates included areas not part of the Straley et al. (2009) estimate, including southern Southeast Alaska, northern British Columbia, and offshore waters of both British Columbia and Southeast Alaska.

Minimum Population Estimate

A total of 2,367 unique individuals were seen in the Hawaiian wintering areas during the 2-year period (3 winter field seasons, 2004-2006) of the SPLASH study. As discussed above, point estimates of abundance for

Hawaii from SPLASH ranged from 7,469 to 10,103: the estimate from the best model was 10,103, but no associated CV has yet been calculated. The 1991-1993 abundance estimate for Hawaii using similar (but less) data had a CV of 0.095. Therefore, it is unlikely the CV of the SPLASH estimate, once calculated, would be greater than 0.300. The minimum population estimate (N_{MIN}) for this stock is calculated according to Equation 1 from the potential biological removal (PBR) guidelines (Wade and Angliss 1997): $N_{MIN} = N/\exp(0.842\times[\ln(1+[CV(N)]^2)]^{½})$. Using the population estimate (N) of 10,103 from the best fit model and an assumed conservative CV(N) of 0.300 results in an N_{MIN} for the Central North Pacific humpback whale stock of 7,890.

Although the Southeast Alaska/northern British Columbia feeding aggregation is not formally considered a stock, the calculation of what a PBR would be for this area is useful for management purposes. The total number of unique individuals seen during the SPLASH study was 1,669 (1,115 in Southeast Alaska). The abundance estimate of Straley et al. (2009) had a CV of 0.12, and the SPLASH abundance estimates are unlikely to have a much higher CV. Using the lowest population estimate (N) of 2,883 and an assumed worst case CV(N) of 0.300, N_{MIN} for this aggregation is 2,251. Similarly, for the Aleutian Islands and Bering Sea, using the lowest SPLASH estimate of 2,889 with an assumed worst-case CV of 0.300 results in an N_{MIN} of 2,256. For the Gulf of Alaska (from Prince William Sound to the Shumagin Islands, including Kodiak Island), using the lowest SPLASH estimate of 2,845 with an assumed worst-case CV of 0.300 results in an N_{MIN} of 2,222. Estimates for these feeding areas may include whales from the Western North Pacific stock and the Mexican breeding population.

Current Population Trend

Comparison of the estimate for the entire stock provided by Calambokidis et al. (1997) with the 1981 estimate of 1,407 (95% CI: 1,113-1,701) from Baker et al. (1987) suggests that abundance increased in Hawaii between the early 1980s and early 1990s. Mobley et al. (2001) estimated a trend of 7% per year for 1993-2000 using data from aerial surveys that were conducted in a consistent manner for several years across all of the Hawaiian Islands and were developed specifically to estimate a trend for the Central North Pacific stock. Mizroch et al. (2004) estimated survival rates for North Pacific humpback whales using mark-recapture methods, and a Pradel model fit to data from Hawaii for the years 1980-1996 resulted in an estimated rate of increase of 10% per year (95% CI: 3-16%). For shelf waters of the northern Gulf of Alaska, Zerbini et al. (2006) estimated an annual rate of increase for humpback whales from 1987 to 2003 of 6.6% (95% CI: 5.2-8.6%). The SPLASH abundance estimate for the total North Pacific represents an annual increase of 4.9% over the most complete estimate for the North Pacific for 1991-1993. Comparisons of SPLASH abundance estimates for Hawaii to estimates for 1991-1993 gave estimates of annual increase that ranged from 5.5 to 6.0% (Calambokidis et al. 2008). No confidence limits were calculated for these rates of increase from SPLASH data. It is also clear that the abundance has increased in Southeast Alaska, though a trend for the Southeast Alaska portion of this stock cannot be estimated from the data because of differences in methods and areas covered.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Using a birth-interval model, Barlow and Clapham (1997) have estimated a population growth rate of 6.5% (SE = 1.2%) for the well-studied humpback whale population in the Gulf of Maine, although there are indications that this rate has slowed over the last decade (Clapham et al. 2003). Estimated rates of increase for the Central North Pacific stock include values for Hawaii of 7.0% (from aerial surveys), 5.5-6.0% (from mark-recapture abundance estimates), and 10% (95% CI: 3-16%) (from a model fit to mark-recapture data) and a value for the northern Gulf of Alaska of 6.6% (95% CI: 5.2-8.6%) from ship surveys (Calambokidis et al. 2008). Although there is no estimate of the maximum net productivity rate for the Central North Pacific stock, it is reasonable to assume that R_{MAX} for this stock would be at least 7%. Hence, until additional data become available for the Central North Pacific humpback whale stock, it is recommended that 7% be employed as the maximum net productivity rate (R_{MAX}) for this stock.

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized MMPA, the PBR is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: $PBR = N_{MIN} \times 0.5R_{MAX} \times F_R$. The default recovery factor (F_R) for this stock is 0.1, the recommended value for cetacean stocks listed as endangered under the ESA (Wade and Angliss 1997; see Status of Stock section below regarding ESA listing status). A recovery factor of 0.3 is used in calculating the PBR based on the suggested guidelines of Taylor et al. (2003). The default value of 0.04 for the maximum net productivity rate is replaced by 0.07, which is the best estimate of the current rate of increase and is considered a conservative estimate of the maximum net productivity rate. For the Central North Pacific stock of humpback whales, using the SPLASH study abundance estimate from the best fit model for 2004-2006 for Hawaii of 10,103 with an assumed CV of 0.300 and its associated N_{MIN} of 7,890, PBR is calculated to be 83 animals (7,890 x 0.035 x 0.3).

At this time, stock structure of humpback whales is under consideration and revisions may be proposed within the next few years. Just for information purposes, PBR calculations are completed here for the feeding area aggregations. For Southeast Alaska and northern British Columbia, the smallest abundance estimates from the SPLASH study were used with an assumed worst-case CV of 0.300 to calculate PBRs for feeding areas. Using the suggested guidelines presented in Taylor et al. (2003), it would be appropriate to use a recovery factor of 0.3 for the Southeast Alaska/northern British Columbia feeding aggregation since this aggregation has an N_{MIN} greater than 1,500 and less than 5,000 and has an increasing population trend. A recovery factor of 0.1 is appropriate for the Aleutian Islands and Bering Sea feeding aggregation and the Gulf of Alaska feeding aggregation because the N_{MIN} is greater than 1,500 and less than 5,000 and has an unknown population trend. If we calculated a PBR for the Southeast Alaska/northern British Columbia feeding aggregation it would be 24 (2,251 x 0.035 x 0.3). If we calculated a PBR for the Aleutian Islands and Bering Sea, it would be 7.9 (2,256 x 0.035 x 0.1). If we calculated a PBR for the Gulf of Alaska, it would be 7.8 (2,222 x 0.035 x 0.1). However, note that the actual PBR for the Central North Pacific stock is 83 based on the breeding population size in Hawaii, as calculated above.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Detailed information (including observer programs, observer coverage, and observed incidental takes of marine mammals) for federally-managed and state-managed U.S. commercial fisheries in Alaska waters is presented in Appendices 3-6 of the Alaska Stock Assessment Reports.

Between 2010 and 2014, mortality and serious injury of humpback whales occurred in the Bering Sea/Aleutian Islands flatfish trawl fishery (1 in 2010) and the Bering Sea/Aleutian Islands pollock trawl fishery (1 each in 2010 and 2012) (Table 1; Breiwick 2013; MML, unpubl. data). Since the stock identification of these whales is unknown, and the events occurred within the area where the Central North Pacific and Western North Pacific stocks are known to overlap, the mortality in these fisheries is assigned to both stocks of humpback whales. Two Central North Pacific humpback whales were injured in Hawaii longline fisheries in 2010-2014: one in the Hawaii shallow-set longline fishery in 2011 (prorated at 0.75 under the injury determination guidelines for large whales, since the severity of its injury is unknown) and one in the Hawaii deep-set longline fishery in 2014 (Table 1; Bradford and Forney 2014; NMFS-PIFSC, unpubl. data).

In 2012 and 2013, the Alaska Marine Mammal Observer Program (AMMOP) placed observers on independent vessels in the state-managed Southeast Alaska salmon drift gillnet fishery to assess mortality and serious injury of marine mammals. Areas around and adjacent to Wrangell and Zarembo Islands (ADF&G Districts 6, 7, and 8) were observed during the 2012-2013 program (Manly 2015). In 2013, one humpback whale was seriously injured. Based on the one observed serious injury, 11 serious injuries were estimated for Districts 6, 7, and 8 in 2013, resulting in an estimated mean annual mortality and serious injury rate of 5.5 Central North Pacific humpback whales in 2012-2013 (Table 1). Since these three districts represent only a portion of the overall fishing effort in this fishery, we expect this to be a minimum estimate of mortality and serious injury for the fishery.

Humpback whale mortality and serious injury due to entanglement in the commercial Southeast Alaska salmon drift gillnet fishery was reported to the NMFS Alaska Region stranding network in 2010-2014. Prorated values for serious injuries resulted in a total of 3 whales in 2010, 0.75 whales in 2011, 1.75 whales in 2012, 0.75 whales in 2013, and 2.5 whales in 2014 (Helker et al. 2016); however, this mortality and serious injury is accounted for by the AMMOP observer data for this fishery (in Table 1). One entanglement in the ground tackle of a commercial Pacific cod jig fishery vessel in Kodiak, Alaska, was also reported to the NMFS Alaska Region in 2013 (Table 2; Helker et al. 2016). Since observer data are not available for this fishery, this mortality results in a minimum mean annual mortality and serious injury rate of 0.2 humpback whales in 2010-2014 (Table 2) and, since the event occurred in the area where the two stocks overlap, the mortality is assigned to both the Central North Pacific and Western North Pacific stocks of humpback whales.

The minimum estimate of the mean annual mortality and serious injury rate incidental to U.S. commercial fisheries for the entire Central North Pacific stock in 2010-2014 is 7.4 humpback whales, based on observer data from Alaska (Table 1: 0.6 in federal fisheries + 5.5 in the state-managed Southeast Alaska salmon drift gillnet fishery) and Hawaii (Table 1: 1.1) and on reports, in which the commercial fishery is confirmed, to the NMFS Alaska Region stranding network (Table 2: 0.2).

Table 1. Summary of incidental mortality and serious injury of Central North Pacific humpback whales due to observed U.S. commercial fisheries in 2010-2014 and calculation of the mean annual mortality and serious injury rate (Breiwick 2013; Bradford and Forney 2014; Manly 2015; NMFS-PIFSC, unpubl. data; MML, unpubl. data). Methods for calculating percent observer coverage are described in Appendix 6 of the Alaska Stock Assessment Reports. N/A indicates that data are not available.

Fishery name	**Years**	**Data type**	**Percent observer coverage**	**Observed mortality**	**Estimated mortality**	**Mean estimated annual mortality**
Bering Sea/Aleutian Is. flatfish trawl[a]	2010 2011 2012 2013 2014	obs data	99 100 99 99 99	0 (+1)[b] 0 0 0 0	0 (+1)[c] 0 0 0 0	0 (+0.2)[d] (CV = N/A)

Minimum total estimated annual mortality					Bering Sea/Aleutian Is.: SE Alaska: Hawaii: Total:	0.6 5.5 1.1 7.2 (CV = 0.86)

[a]Mortality and serious injury in this fishery is assigned to both the Western North Pacific and Central North Pacific stocks of humpback whales, since the stock identification is unknown and the two stocks overlap within the area of operation of the fishery.
[b]Total mortality and serious injury observed in 2010: 0 whales in sampled hauls + 1 whale in an unsampled haul.
[c]Total estimate of mortality and serious injury in 2010: 0 whales (extrapolated estimate from 0 whales observed in sampled hauls) + 1 whale (1 whale observed in an unsampled haul).
[d]Mean annual mortality and serious injury for fishery: 0 whales (mean of extrapolated estimates from sampled hauls) + 0.2 whales (mean of number observed in unsampled hauls).
[e]A humpback whale was entangled and cut free with trailing gear. Due to the unknown configuration of the entanglement, this injury was prorated at a value of 0.75 (Bradford and Forney 2014).

Reports of swimming, floating, or beachcast humpback whales entangled in fishing gear or with injuries caused by interactions with gear, which may be from commercial, recreational, or subsistence fisheries, are another source of information on fishery-related mortality and serious injury. One whale with a serious injury (prorated at 0.75 under the injury determination guidelines for large whales) entangled in subsistence Southeast Alaska halibut longline gear was reported to the NMFS Alaska Region in 2012, resulting in a minimum mean annual mortality and serious injury rate of 0.2 humpback whales in 2010-2014 in this fishery (Table 2; Helker et al. 2016). Two whales (each with a serious injury prorated at 0.75) entangled in recreational troll gear were reported to the NMFS Pacific Islands Region in 2011, resulting in a minimum mean annual mortality and serious injury rate of 0.3 Central North Pacific humpback whales in recreational gear in 2010-2014 (Table 3; Bradford and Lyman 2015; NMFS-PIFSC, unpubl. data). Based on events that have not been attributed to a specific fishery listed on the MMPA List of Fisheries (76 FR 73912, 29 November 2011), the minimum mean annual mortality and serious injury rate from gear entanglements in unknown (commercial, recreational, or subsistence) fisheries is 7.7 humpback whales in 2010-2014: 1.7 reported to the NMFS Alaska Region stranding network (Table 2; Helker et al. 2016) and 6 reported to the NMFS Pacific Islands Region stranding network (Table 3; Bradford and Lyman 2015; NMFS-PIFSC, unpubl. data). These estimates are considered a minimum because not all entangled animals strand and not all stranded animals are found, reported, or have the cause of death determined.

Five humpback whales that were initially considered seriously injured due to entanglement in Southeast Alaska commercial Dungeness crab pot gear (1 in 2010), Southeast Alaska crab pot gear (1 in 2011 and 1 in 2012), Southeast Alaska shrimp pot gear (1 in 2011), and Gulf of Alaska/Kodiak Island Dungeness crab pot gear (1 in 2012) were disentangled in Alaska waters and released with non-serious injuries (Helker et al. 2016). Since the 2012 event occurred in the area where the two stocks overlap, this injury was also assigned to the Western North Pacific stock. Three additional whales that were initially considered seriously injured due to entanglement in Hawaii crab pot gear (1 in 2013) and unidentified fishing gear (1 each in 2013 and 2014) were disentangled in Hawaii waters and released with non-serious injuries (NMFS-PIFSC, unpubl. data). None of the whales released with non-serious injuries in Alaska or Hawaii waters were included in the mean annual mortality and serious injury rate for 2010-2014.

The minimum average annual mortality and serious injury rate due to interactions with all fisheries in 2010-2014 is 16 Central North Pacific humpback whales (7.4 in commercial fisheries + 0.2 in subsistence fisheries + 0.3 in recreational fisheries + 7.7 in unknown fisheries).

Table 2. Summary of mortality and serious injury of Central North Pacific humpback whales reported to the NMFS Alaska Region marine mammal stranding network in 2010-2014 (Helker et al. 2016). Injury events lacking detailed information on the injury are assigned prorated values following injury determination guidelines described in NOAA (2012). A summary of information used to determine whether an injury was serious or non-serious, as well as a table of prorate values used for large whale reports with incomplete information, is reported in Helker et al. (2016).

Cause of injury	**2010**	**2011**	**2012**	**2013**	**2014**	**Mean annual mortality**
Entangled in ground tackle of Kodiak commercial Pacific cod jig vessel	0	0	0	1	0	0.2
Entangled in subsistence SE Alaska halibut longline gear	0	0	0.75	0	0	0.2
Entangled in Bering Sea pot gear*	0	0.75	0	0	0	0.2
Entangled in Prince William Sound shrimp pot gear*	0	0	0	0	1	0.2
Entangled in SE Alaska longline gear*	0	0.75	0	0	0	0.2
Entangled in SE Alaska golden king crab pot gear*	0	0.75	0	0	0	0.2
Entangled in SE Alaska pot gear*	1.5	0	0	0	0	0.3
Entangled in gillnet*	0	0.75	1	0	0	0.4
Entangled in unidentified net*	0	0	0	0.75	0	0.2
Entangled in marine debris	2.25	5.5	0.75	1.5	4.5	2.9
Ship strike	4	2	2.6	0.14	4.52	2.7
Total in commercial fisheries						0.2
Total in subsistence fisheries						0.2
*Total in unknown (commercial, recreational, or subsistence) fisheries						1.7
Total in marine debris						2.9
Total due to other sources (ship strike)						2.7

Table 3. Summary of mortality and serious injury of Central North Pacific humpback whales reported to the NMFS Pacific Islands Region stranding network in 2010-2014 (Bradford and Lyman 2015; NMFS-PIFSC, unpubl. data).

Cause of injury	2010	2011	2012	2013	2014	Mean annual mortality
Entangled in recreational troll gear	0	1.5	0	0	0	0.3
Entangled in Alaska king crab pot gear*	0	0.75	0	0	0	0.2
Entangled in Alaska tanner crab pot gear*	0	0	1	0	0	0.2
Entangled in Alaska shrimp pot gear*	0	0	0	0	1	0.2
Entangled in Alaska king crab, tanner crab, or finfish pot gear*	0	0	0	0	0.75	0.2
Entangled in longline gear*	0	0	0	1	1	0.4
Entangled in unidentified fishing gear*	5	3.25	4.25	5.25	6.25	4.8
Ship strike	2.0	1.72	1.72	3.56	1	2
Total in recreational fisheries						0.3
*Total in unknown (commercial, recreational, or subsistence) fisheries						6
Total due to other sources (ship strike)						2

However, these estimates of mortality and serious injury levels should be considered a minimum. No observers have been assigned to several fisheries that are known to interact with this stock, making the estimated mortality and serious injury rate unreliable. Further, due to limited Canadian observer program data, mortality and serious injury incidental to Canadian commercial fisheries (i.e., those similar to U.S. fisheries known to interact with humpback whales) is uncertain. Though interactions are thought to be minimal, data regarding the level of humpback whale mortality and serious injury related to commercial fisheries in northern British Columbia are not available, again indicating that the estimated mortality and serious injury incidental to commercial fisheries is underestimated for this stock.

Alaska Native Subsistence/Harvest Information

Subsistence hunters in Alaska are not authorized to take from this stock of humpback whales, and no takes have been reported.

Other Mortality

In 2015, increased mortality of large whales (including 11 fin whales, 14 humpback whales, 1 gray whale, and 4 unidentified cetaceans from May to mid-August 2015) was observed along the western Gulf of Alaska, including the areas around Kodiak Island, Afognak Island, Chirikof Island, the Semidi Islands, and the southern shoreline of the Alaska Peninsula (http://www.nmfs.noaa.gov/pr/health/mmume/faqs_2015_large_whale.html, accessed December 2016). On 20 August 2015, NMFS declared an Unusual Mortality Event for large whales in the western Gulf of Alaska; however, to date, no specific cause for the increased mortality has been identified.

Ship strikes and other interactions with vessels unrelated to fisheries occur frequently with humpback whales (Tables 2 and 3). Neilson et al. (2012) summarized 108 large whale ship-strike events in Alaska from 1978 to 2011, 25 of which are known to have resulted in the whale's death. Eighty-six percent of these reports involved humpback whales. The minimum mean annual mortality and serious injury rate due to ship strikes reported in Alaska (Table 2: 2.7) and Hawaii (Table 3: 2) in 2010-2014 is 4.7 humpback whales. Most ship strikes of humpback whales are reported from Southeast Alaska; however, there are also reports from the Southcentral and Kodiak areas of Alaska (Helker et al. 2016). Many of the ship strikes occurring off Hawaii are reported from waters near Maui (Bradford and Lyman 2015; NMFS-PIFSC, unpubl. data). It is not known whether the difference in ship-strike rates between Southeast Alaska and the northern portion of this stock is due to differences in reporting, amount of vessel traffic, densities of animals, or other factors. Entanglements in marine debris reported to the NMFS Alaska Region account for a minimum mean annual mortality and serious injury rate of 2.9 Central North Pacific humpback whales in 2010-2014 (Table 2; Helker et al. 2016).

HISTORICAL WHALING

Rice (1978) estimated that the number of humpback whales in the North Pacific may have been approximately 15,000 individuals prior to exploitation; however, this was based upon incomplete data and, given the level of known catches (legal and illegal) since World War II, may be an underestimate. Intensive commercial whaling removed more than 28,000 animals from the North Pacific during the 20th century. Humpback whales in the North Pacific were theoretically protected in 1965, but illegal catches by the U.S.S.R. continued until 1972 (Ivashchenko et al. 2007). From 1961 to 1971, 6,793 humpback whales were killed illegally by the U.S.S.R. Many animals during this period were taken from the Gulf of Alaska and Bering Sea (Doroshenko 2000); however, additional illegal catches were made across the North Pacific, from the Kuril Islands to the Queen Charlotte Islands, and other takes in earlier years may have gone unrecorded.

On the feeding grounds of the Central North Pacific stock after World War II, the highest densities of catches occurred around the western Aleutian Islands, in the eastern Aleutian Islands (and adjacent Bering Sea to the north and Pacific Ocean to the south), and British Columbia (Springer et al. 2006). Lower but still relatively high densities of catches occurred south of the Commander Islands, along the south side of the Alaska Peninsula, and around Kodiak Island. Lower densities of catches also occurred in the Gulf of Anadyr, in the central Aleutian Islands, in much of the offshore Gulf of Alaska, and in Southeast Alaska. No catches were reported in the winter grounds of the Central North Pacific stock in Hawaii nor in Mexican winter areas.

STATUS OF STOCK

NMFS recently concluded a global humpback whale Status Review (Bettridge et al. 2015). Although the estimated annual level of human-caused mortality and serious injury for the entire Central North Pacific stock (24 whales) is considered a minimum, it is unlikely that the total level of human-caused mortality and serious injury exceeds the PBR level (83) for the entire stock. The minimum estimate of the mean annual U.S. commercial fishery-related mortality and serious injury rate for this stock (7.4 whales) is less than 10% of the calculated PBR for the entire stock (10% of PBR = 8.3) and, therefore, can be considered to be insignificant and approaching a zero mortality and serious injury rate. The humpback whale ESA listing final rule (81 FR 62259, 8 September 2016) established 14 Distinct Population Segments (DPSs) with different listing statuses. The DPSs that occur in waters under the jurisdiction of the United States do not necessarily equate to the existing MMPA stocks. Some of the listed DPSs partially coincide with the currently defined Central North Pacific stock. Because we cannot manage one portion of an MMPA stock as ESA-listed and another portion of a stock as not ESA-listed, until such time as the MMPA stock delineations are reviewed in light of the DPS designations, NMFS considers this stock to be endangered and depleted for MMPA management purposes (e.g., selection of a recovery factor, stock status). As a result, the Central North Pacific stock of humpback whales is classified as a strategic stock. Humpback whale mortality and serious injury in Hawaii-based fisheries involves whales from the Hawaii DPS; this DPS is not listed as threatened or endangered under the ESA.

HABITAT CONCERNS

This stock is the focus of a large whale-watching industry in its wintering grounds (Hawaii) and summering grounds (Alaska). Regulations concerning minimum distance to keep from whales and how to operate vessels when in the vicinity of whales have been developed for Hawaii and Alaska waters in an attempt to minimize the impact of whale watching. Additional concerns have been raised in Hawaii about the impact of jet skis and similar fast waterborne tourist-related traffic, notably in nearshore areas inhabited by mothers and calves. In Alaska, NMFS issued regulations in 2001 to prohibit approaches to humpback whales within 100 yards (91.4 m; 66 FR 29502, 31 May 2001). In 2015, NMFS introduced a voluntary responsible viewing program called Whale SENSE to Juneau area whale-watch operators to provide additional protections for whales in Alaska (https://whalesense.org, accessed December 2016). The growth of the whale-watching industry is an ongoing concern as preferred habitats may be abandoned if disturbance levels are too high. Other potential concerns include elevated levels of sound from anthropogenic sources (e.g., shipping, military sonars), possible changes in prey distribution with climate change, entanglement in fishing gear, ship strikes due to increased vessel traffic (e.g., from increased shipping in higher latitudes), and oil and gas activities.

FIN WHALE (*Balaenoptera physalus*): Northeast Pacific Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Within the U.S. waters in the Pacific Ocean, fin whales are found seasonally off the coast of North America and in the Bering Sea during the summer (Fig. 1). Recent information on seasonal fin whale distribution has been gleaned from the reception of fin whale calls by bottom-mounted, offshore hydrophone arrays along the U.S. Pacific coast, in the central North Pacific, and in the western Aleutian Islands (Moore et al. 1998, 2006; Watkins et al. 2000; Stafford et al. 2007; Širović et al. 2013; Soule and Wilcock 2013). Moore et al. (1998, 2006), Watkins et al. (2000), and Stafford et al. (2007) documented high rates of fin whale calling along the U.S. Pacific coast beginning in August/September and lasting through February, suggesting that these may be important feeding areas during the winter. Širović et al. (2013) speculated that both resident and migratory fin whales may occur off southern California based on shifts in peaks in fin whale calling data. Širović et al. (2015) noted that fin whales were detected in the Southern California Bight year-round and found an increase in the fin whale call index from 2006 to 2012. Soule and Wilcock (2013) documented fin whale call rates in a presumed feeding area along the Juan de Fuca Ridge, offshore of northern Washington State, and found that some whales appear to head northwest from August to October. They speculate that some fin whales may migrate northward in fall and southward in winter. While peaks in call rates occurred during late summer, fall, and winter in the central North Pacific and the Aleutian Islands, fin whale calls were seldom detected during summer months even though fin whales are regularly seen in summer months in the Gulf of Alaska (Stafford et al. 2007). Fin whale calls were detected in the southeast Bering Sea using an instrument moored there, from April 2006 through April 2007, which showed peaks in fin whale call detections from September through November 2006 and also in February and March 2007 (Stafford et al. 2010). In addition, fin whale calls were detected in the northeastern Chukchi Sea using instruments moored there in July through October from 2007 through 2010 (Delarue et al. 2013). Call data collected from the Bering Sea suggest that several fin whale stocks may feed in the Bering Sea, but call data collected in the northeast Chukchi Sea suggest that only one of the putative Bering Sea stocks appears to migrate that far north to feed (Delarue et al. 2013). Some fin whale calls have also been recorded in the Hawaiian portion of the U.S. Exclusive Economic Zone in all months except June and July (Thompson and Friedl 1982, McDonald and Fox 1999). Sightings of fin whales in Hawaii are extremely rare: there was a sighting in 1976 (Shallenberger 1981), a sighting in 1979 (Mizroch et al. 2009), a sighting during an aerial survey in 1994 (Mobley et al. 1996), and five sightings during a survey in 2002 (Barlow 2006).

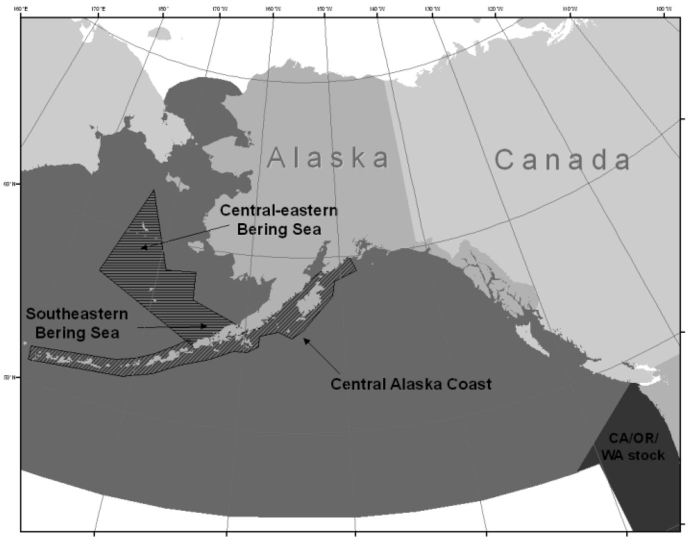

Figure 1. Approximate distribution of fin whales in the eastern North Pacific (dark shaded areas). Striped areas indicate where vessel surveys occurred in 1999-2000 (Moore et al. 2002) and 2001-2003 (Zerbini et al. 2006).

Surveys on the Bering Sea shelf in 1997, 1999, 2000, 2002, 2004, 2008, and 2010 and in coastal waters of the Aleutian Islands and the Alaska Peninsula from 2001 to 2003 provided information about the distribution and relative abundance of fin whales in these areas (Moore et al. 2000, 2002; Zerbini et al. 2006; Friday et al. 2012, 2013). Fin whales were the most common large whale sighted during the Bering Sea shelf surveys in all years except for 1997 and 2004 (Friday et al. 2012, 2013). Fin whales were consistently distributed both in the "green belt," an area of high productivity along the edge of the eastern Bering Sea (EBS) continental shelf (Springer et al. 1996), and in the middle shelf with the highest abundances occurring in the "green belt." Abundance estimates for fin whales in the Bering Sea were consistently higher in cold years than in warm years (Friday et al. 2012, 2013) indicating a shift in distribution. This is consistent with a fine-scale comparison of fin whale occurrence on the middle shelf between a cold year (1999) and a warm year (2002), which found that the group and individual encounter rates were 7-12 times higher in the cold year (Stabeno et al. 2012).

Based on historical whaling data, fin whales were found to range into the southern Sea of Okhotsk and Chukchi Sea. It was assumed that they passed through the Bering Strait into the southwestern Chukchi Sea during August and September. Many were taken as far west as Mys (Cape) Shmidta (68°55'N, 179°24'E) and as far north as 69°04'N, 171°06'W (Mizroch et al. 2009). Fin whale sightings have been increasing during sighting surveys in the U.S. portion of the northern Chukchi Sea in summer (Funk et al. 2010, Aerts et al. 2012, Clarke et al. 2013) and fin whale calls have been recorded each year from 2007 to 2010 in August and September on bottom-mounted hydrophones in the northeastern Chukchi Sea (Delarue et al. 2013), suggesting they may be re-occupying habitat used prior to large-scale commercial whaling. In August 2012, fin whale calls were recorded in the Alaska Chukchi Sea at a location 280 km northeast of the closest prior acoustic detection and 365 km northeast of the closest confirmed visual sighting of a fin whale, suggesting a possible range expansion over time as sea ice has retreated (Crance et al. 2015).

The following information was considered in classifying stock structure based on the Dizon et al. (1992) phylogeographic approach: 1) Distributional data: geographic distribution continuous in winter, possibly isolated in summer; 2) Population response data: unknown; 3) Phenotypic data: unknown; and 4) Genotypic data: unknown. Based on this limited information, the International Whaling Commission (IWC) considers fin whales in the North Pacific to all belong to the same stock (Mizroch et al. 1984), although those authors cited additional evidence that supported the establishment of subpopulations in the North Pacific. Further, Fujino (1960) described eastern and western groups, which are isolated though may intermingle around the Aleutian Islands. Discovery mark recoveries (Rice 1974, Mizroch et al. 2009) indicate that animals wintering off the coast of southern California range from central California to the Gulf of Alaska during the summer months.

Mizroch et al. (2009) provided a comprehensive summary of whaling catch data, Discovery mark recoveries, and opportunistic sightings data and found evidence that suggests there may be at least six populations of fin whales: two that are migratory (eastern and western North Pacific) and 2-4 more that are resident year-round in peripheral seas such as the Gulf of California, East China Sea, Sanriku-Hokkaido, and possibly the Sea of Japan. It appears likely that the two migratory stocks mingle in the Bering Sea in July and August, rather than in the Aleutian Islands as Fujino (1960) concluded (Mizroch et al. 2009). During winter months, fin whales have been seen over a wide geographic area from 23°N to 60°N, but winter distribution and location of primary wintering areas (if any) are poorly known and need further study. As a result, stock structure of fin whales remains uncertain.

For management purposes, three stocks of fin whales are currently recognized in U.S. Pacific waters: 1) Alaska (Northeast Pacific), 2) California/Washington/Oregon, and 3) Hawaii. Mizroch et al. (2009) suggest that this structure should be reviewed and updated, if appropriate, to reflect recent analyses, but the absence of any substantially new data on stock structure makes this difficult. The California/Oregon/Washington and Hawaii fin whale stocks are reported separately in the Stock Assessment Reports for the U.S. Pacific Region.

POPULATION SIZE

Reliable estimates of current and historical abundance for the entire Northeast Pacific fin whale stock are currently not available. Two studies provide some information on the distribution and occurrence of fin whales, although they do not provide estimates of population size. A survey conducted in August of 1994 covering 2,050 nautical miles of trackline south of the Aleutian Islands encountered only four fin whale groups (Forney and Brownell 1996). However, this survey did not include all of the waters off Alaska where fin whale sightings have been reported, thus no population estimate could be made.

Visual shipboard surveys for cetaceans were conducted on the eastern Bering Sea shelf during summer in 1997, 1999, 2000, 2002, 2004, 2008, and 2010 (Moore et al. 2000, 2002; Friday et al. 2012, 2013). These surveys were conducted in conjunction with the Alaska Fisheries Science Center echo-integrated trawl surveys for walleye pollock which determined the survey area and timing. The surveys included from 789 km to 3,752 km of effort depending on the year and whether the entire area was surveyed for cetaceans. Results of the surveys in 2002, 2008, and 2010, years when the entire pollock area was surveyed, provided provisional estimates of 419 (CV = 0.33), 1,368 (CV = 0.34), and 1,061 (CV = 0.38) fin whales (Friday et al. 2013). These estimates are considered provisional because they have not been corrected for animals missed on the trackline, animals submerged when the ship passed, and responsive movement; no data are currently available to make these corrections. However, they are expected to be robust as previous studies have shown that only small correction factors are needed for this species (Barlow 1995). This estimate cannot be used as an estimate of the entire Northeast Pacific stock of fin whales because it is based on a survey in only a small part of the stock's purported range.

Dedicated line-transect cruises were conducted in coastal waters (as far as 85 km offshore) of western Alaska and the eastern and central Aleutian Islands in July-August 2001-2003 (Zerbini et al. 2006). Over 9,053 km of tracklines were surveyed between the Kenai Peninsula (150°W) and Amchitka Pass (178°W). Fin whale sightings (n = 276) were observed from east of Kodiak Island to Samalga Pass, with high aggregations recorded near the Semidi Islands. Zerbini et al. (2006) estimated that 1,652 (95% CI: 1,142-2,389) fin whales occurred in the area.

Minimum Population Estimate

Although the full range of the Northeast Pacific stock of fin whales in Alaska waters has not been surveyed, a rough estimate of the size of the population west of the Kenai Peninsula has been calculated in previous Stock Assessment Reports by summing the estimates from Moore et al. (2002) and Zerbini et al. (2006) (n = 5,700). However, based on analyses presented in Mizroch et al. (2009), whales surveyed in the Aleutians (Zerbini et al. 2006) could migrate into the Bering Sea and be counted during the Bering Sea surveys. There are also indications that fin whale distribution in the Bering Sea is related to oceanographic conditions (Stabeno et al. 2012, Friday et al. 2013), making it possible that whales could be double counted when estimates from different years are summed (Moore et al. 2002). Therefore, our best provisional estimate of the fin whale population west and north of the Kenai Peninsula in U.S. waters would be 1,368, the greater of the minimum estimates from the 2008 and 2010 surveys (Friday et al. 2013). A minimum population estimate (N_{MIN}) for this stock can be calculated according to Equation 1 from the potential biological removal (PBR) guidelines (Wade and Angliss 1997): $N_{MIN} = N/\exp(0.842\times[\ln(1+[CV(N)]^2)]^{½})$. Using the best provisional estimate (N) of 1,368 from the 2010 surveys and the associated coefficient of variation CV(N) of 0.34 results in an N_{MIN} of 1,036 whales. However, this is an under-estimate for the entire stock because it is based on surveys which covered only a small portion of the stock's purported range.

Current Population Trend

Zerbini et al. (2006) estimated rates of increase of fin whales in coastal waters south of the Alaska Peninsula (Kodiak and Shumagin Islands). An annual increase of 4.8% (95% CI: 4.1-5.4%) was estimated for the period 1987-2003. This estimate is the first available for North Pacific fin whales and is consistent with other estimates of population growth rates of large whales. It should be used with caution, however, due to uncertainties in the initial population estimate for the first trend year (1987) and due to uncertainties about the population structure of fin whales in the area. Also, the study represented only a small fraction of the range of the Northeast Pacific stock.

Friday et al. (2013) estimated a 14% (95% CI: 1.0-26.5%) annual rate of change in abundance of fin whales during the period from 2002 to 2010. However, this apparent rate of change in abundance is higher than most plausible estimates of rates of change for large whale populations (see Zerbini et al. 2010 for a discussion of maximum rates of increase for humpback whale populations). It is likely that the apparent rate of change in abundance in the study area is due at least in part to changes in distribution and not just to changes in overall population size. Friday et al. (2013) found that the abundance of fin whales in the survey area increased in colder years, likely due to shifts in the distribution of prey. Stafford et al. (2010) provided evidence of prey-driven distribution where fin and right whale call rates in the vicinity of mooring M2 (approximate location: 57.9°N, 164.1°W) increased following peaks in euphausiid and copepod biomass.

Moore and Barlow (2011) analyzed trends in fin whale abundance from 1991 to 2008 from surveys conducted off California and found sufficient variability in trend estimates to conclude that the estimates were likely demonstrating dispersal of new individuals into the study area rather than actual population trends.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Zerbini et al. (2006) estimated an annual increase in coastal waters south of the Alaska Peninsula of 4.8% (95% CI: 4.1-5.4%) for the period 1987-2003. However, there are uncertainties in the initial population estimate from 1987, as well as uncertainties regarding fin whale population structure in this area. A reliable estimate of the maximum net productivity rate is currently unavailable for the Northeast Pacific fin whale stock. Hence, until additional data become available, it is recommended that the cetacean maximum net productivity rate (R_{MAX}) of 4% be employed for this stock (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the potential biological removal (PBR) is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: $PBR = N_{MIN} \times 0.5R_{MAX} \times F_R$. The recovery factor ($F_R$) for this stock is 0.1, the recommended value for cetacean stocks which are listed as endangered (Wade and Angliss 1997). Using the best provisional estimate of 1,368 (CV = 0.34) from the 2010 surveys and the associated N_{MIN} of 1,036, PBR is calculated to be 2.1 (1,036 × 0.02 × 0.1) fin whales. However, because the estimate of minimum abundance is for only a small portion of the stock's purported range, the calculated PBR is considered unreliable for the entire Northeast Pacific fin whale stock.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Detailed information (including observer programs, observer coverage, and observed incidental takes of marine mammals) for federally-managed and state-managed U.S. commercial fisheries in Alaska waters is presented in Appendices 3-6 of the Alaska Stock Assessment Reports.

One incidental mortality of a fin whale due to entanglement in the ground tackle of a commercial mechanical jig fishing vessel was reported to the NMFS Alaska Region in 2012 (Table 1; Helker et al. 2016). Since observer data are not available for this fishery, this mortality results in a mean annual mortality and serious injury rate of 0.2 fin whales in 2010-2014 (Table 1).

Table 1. Summary of mortality and serious injury of Northeast Pacific fin whales, by year and type, reported to the NMFS Alaska Region marine mammal stranding network in 2010-2014 (Helker et al. 2016). Only cases of serious injury were recorded in this table; animals with non-serious injuries have been excluded.

Cause of injury	2010	2011	2012	2013	2014	Mean annual mortality
Entangled in ground tackle of commercial mechanical jig fishing vessel	0	0	1	0	0	0.2
Ship strike	1	0	0	0	1	0.4
Total in commercial fisheries						0.2
Total due to other causes (ship strike)						0.4

Alaska Native Subsistence/Harvest Information

Subsistence hunters in Alaska and Russia have not been reported to take fin whales from this stock.

Other Mortality

In 2015, increased mortality of large whales (including 11 fin whales, 14 humpback whales, 1 gray whale, and 4 unidentified cetaceans from May to mid-August 2015) was observed along the western Gulf of Alaska, including the areas around Kodiak Island, Afognak Island, Chirikof Island, the Semidi Islands, and the southern shoreline of the Alaska Peninsula (http://www.nmfs.noaa.gov/pr/health/mmume/faqs_2015_large_whale.html, accessed December 2016). On 20 August 2015, NMFS declared an Unusual Mortality Event for large whales in the western Gulf of Alaska; however, to date, no specific cause for the increased mortality has been identified.

Between 1911 and 1985, 49,936 fin whales were reported taken in commercial whaling operations throughout the North Pacific (Mizroch et al. 2009), although newly revealed information about illegal Soviet catches indicates that the Soviets over-reported catches of about 1,200 fin whales, presumably to hide catches of other protected species (Doroshenko 2000). Fin whale mortality due to ship strikes in Alaska waters (one each in 2010 and 2014) has also been reported to the NMFS Alaska Region stranding network (Helker et al. 2016), resulting in a mean annual mortality and serious injury rate of 0.4 fin whales due to ship strikes in 2010-2014 (Table 1).

STATUS OF STOCK

The fin whale is listed as endangered under the Endangered Species Act of 1973, and therefore designated as depleted under the MMPA. As a result, the Northeast Pacific stock is classified as a strategic stock. While reliable estimates of the minimum population size and population trends are available for a portion of this stock, much of the North Pacific range has not been surveyed. Therefore the status of the stock relative to its Optimum Sustainable Population is currently not available. The total estimated annual level of human-caused mortality and serious injury for Northeast Pacific fin whales (0.6 whales) does not exceed the calculated PBR (2.1 whales), and the minimum mean annual rate of U.S. commercial fishery-related mortality and serious injury (0.2 whales) is less than

10% of the calculated PBR (10% of PBR = 0.21). However, the calculated PBR is considered unreliable for the entire stock because it is based on an estimate from surveys of only a small portion of the stock's purported range.

HABITAT CONCERNS

Changes in ocean conditions that affect the seasonal distribution and quality of prey may affect fin whale movements, distribution, and foraging energetics. Ship strikes are a known source of mortality, and reductions in sea-ice coverage may lead to range extension and concomitant exposure to increased shipping and oil/gas activities in the Chukchi and Beaufort seas. Ocean warming may increase the frequency of algal blooms that produce biotoxins known to be associated with large whale mortality. However, few or no data are available to assess the likelihood or extent of such impacts.

MINKE WHALE (*Balaenoptera acutorostrata*): Alaska Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

In the North Pacific, minke whales occur from the Bering and Chukchi seas south to near the Equator (Leatherwood et al. 1982). The following information was considered in classifying stock structure according to the Dizon et al. (1992) phylogeographic approach: 1) Distributional data: geographic distribution continuous; 2) Population response data: unknown; 3) Phenotypic data: unknown; and 4) Genotypic data: unknown. Based on this limited information, in 1991 the International Whaling Commission (IWC) recognized three stocks of minke whales in the North Pacific: one in the Sea of Japan/East China Sea, one in the rest of the western Pacific west of 180°N, and one in the "remainder" of the Pacific (Donovan 1991). The "remainder" stock designation reflects the lack of exploitation in the eastern Pacific and does not indicate that only one population exists in this area (Donovan 1991). In the "remainder" area, minke whales are relatively common in the Bering and Chukchi seas and in the inshore waters of the Gulf of Alaska (Moore et al 2000, Friday et al. 2012, Clarke et al. 2013) but are not considered abundant in any other part of the eastern Pacific (Leatherwood et al. 1982, Brueggeman et al. 1990). Recent visual and acoustic data found minke whales in the Chukchi Sea north of Bering Strait in July and August (Clarke et al. 2013), and minke whale "boing" sounds have been detected in the northeast Chukchi Sea in August, October, and November (Delarue 2013). There are two types of geographically distinct "boing" sounds produced by minke whales in the North Pacific (Rankin and Barlow 2005). Those recorded in the Chukchi Sea matched "central Pacific" boings leading the authors to hypothesize that minke whales from the Chukchi Sea might winter in the central North Pacific, not near Hawaii (Delarue et al. 2013).

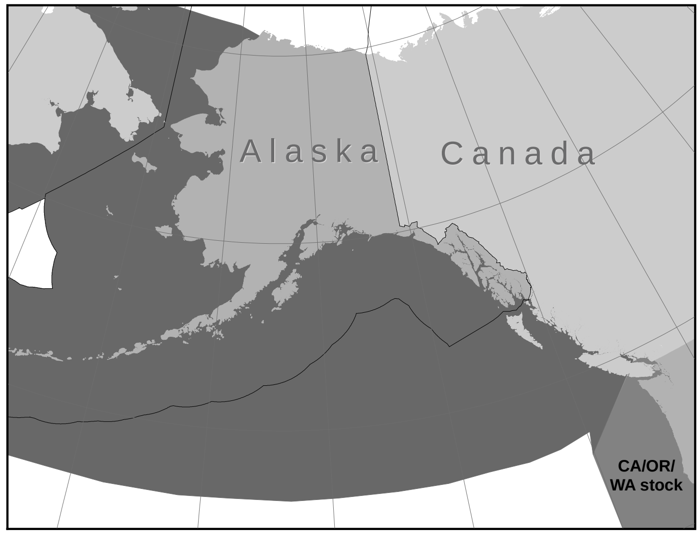

Figure 1. Approximate distribution of minke whales in the eastern North Pacific (dark shaded areas).

Ship surveys on the eastern Bering Sea shelf in 1999, 2000, 2002, 2004, 2008, and 2010 resulted in new information about the distribution and relative abundance of minke whales in this area (Moore et al. 2002; Friday et al. 2012, 2013). When comparing distribution and abundance in years when the entire study area was surveyed (2002, 2008, and 2010), Friday et al. (2013) found that minke whales were scattered throughout the study area in all oceanographic domains (coastal, middle shelf, and outer shelf/slope) in 2002 and 2008 but were concentrated in the outer shelf and slope in 2010. The highest minke whale abundance in the study area occurred in 2010 and abundance was greater in cold years (2008 and 2010) than a warm year (2002); however, changes in abundance were thought to be due at least in part to changes in distribution (Friday et al. 2013).

So few minke whales were seen during two offshore Gulf of Alaska surveys for cetaceans in 2009 and 2013 that a population estimate for this species in this area could not be determined (Rone et al. 2010, 2014).

In the northern part of their range, minke whales are believed to be migratory, whereas, they appear to establish home ranges in the inland waters of Washington and along central California (Dorsey et al. 1990). Because the "resident" minke whales from California to Washington appear behaviorally distinct from migratory whales farther north, minke whales in Alaska are considered a separate stock from minke whales in California, Oregon, and Washington (Dorsey et al. 1990). Accordingly, two stocks of minke whales are recognized in U.S. waters: 1) Alaska, and 2) California/Washington/Oregon (Fig. 1). The California/Oregon/Washington minke whale stock is reported separately in the Stock Assessment Reports for the U.S. Pacific Region.

POPULATION SIZE

No estimates have been made for the number of minke whales in the entire North Pacific. However, some information is available on the numbers of minke whales in some areas of Alaska. Visual surveys for cetaceans were conducted on the eastern Bering Sea shelf in 2002, 2008, and 2010 in cooperation with research on commercial fisheries (Friday et al. 2013). The surveys included 3,752 km, 3,253 km, and 1,638 km of effort in 2002, 2008, and 2010, respectively. Results of the surveys in 2002, 2008, and 2010 provide provisional abundance estimates of 389 (CV = 0.52), 517 (CV = 0.69), and 2,020 (CV = 0.73) minke whales on the eastern Bering Sea shelf, respectively (Friday et al. 2013). These estimates are considered provisional because they have not been corrected for animals missed on the trackline, animals submerged when the ship passed, or responsive movement. Additionally, line-transect surveys were conducted in shelf and nearshore waters (within 30-45 nautical miles of land) in 2001-2003 from the Kenai Fjords in the Gulf of Alaska to the central Aleutian Islands. Minke whale abundance was estimated to be 1,233 (CV = 0.34) for this area (Zerbini et al. 2006). This estimate has also not been corrected for animals missed on the trackline. The majority of the sightings were in the Aleutian Islands, rather than in the Gulf of Alaska, and in water shallower than 200 m. These estimates cannot be used as an estimate of the entire Alaska stock of minke whales because only a portion of the stock's range was surveyed.

Minimum Population

At this time, it is not possible to produce a reliable estimate of minimum abundance for this stock, as current estimates of abundance are not available.

Current Population Trend

There are no data on trends in minke whale abundance in Alaska waters.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

There are no estimates of the growth rate of minke whale populations in the North Pacific (Best 1993). Hence, until additional data become available, it is recommended that the cetacean maximum net productivity rate (R_{MAX}) of 4% be employed for this stock (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the potential biological removal (PBR) is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: $PBR = N_{MIN} \times 0.5R_{MAX} \times F_R$. Given the status of this stock is unknown, the appropriate recovery factor is 0.5 (Wade and Angliss 1997). However, because an estimate of minimum abundance is not available, the PBR for the Alaska minke whale stock is unknown at this time.

ANNUAL HUMAN-CAUSED MORTALITY

New Serious Injury Guidelines

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historical injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an "*injury that is more likely than not to result in mortality*." Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

Fisheries Information

Detailed information on U.S. commercial fisheries in Alaska waters (including observer programs, observer coverage, and observed incidental takes of marine mammals) is presented in Appendices 3-6 of the Alaska Stock Assessment Reports.

Six different commercial fisheries operating in Alaska waters within the range of the Alaska minke whale stock were monitored for incidental take by NMFS observers during 2009-2013: the Bering Sea/Aleutian Islands groundfish trawl, longline, and pot fisheries and the Gulf of Alaska groundfish trawl, longline, and pot fisheries. However, no mortality or serious injury of minke whales occurred in observed U.S. commercial fisheries in 2009-2013.

Alaska Native Subsistence/Harvest Information

No minke whales were ever taken by the modern shore-based whale fishery in the eastern North Pacific, which lasted from 1905 to 1971 (Rice 1974). Subsistence takes of minke whales by Alaska Natives are rare but have been known to occur. Only seven minke whales are reported to have been taken for subsistence by Alaska

Natives between 1930 and 1987 (C. Allison, International Whaling Commission, UK, pers. comm.). The most recent reported catches (two whales) in Alaska occurred in 1989 (Anonymous 1991), but reporting is likely incomplete. Based on this information, the average annual subsistence take was zero minke whales in 2009-2013.

Other Mortality

From 2009 to 2013, no human-related mortality or serious injury of minke whales was reported to the NMFS Alaska Region stranding database (Helker et al. 2015).

STATUS OF STOCK

Minke whales are not designated as "depleted" under the MMPA or listed as "threatened" or "endangered" under the Endangered Species Act. The greatest uncertainty regarding the status of the Alaska minke whale stock has to do with the uncertainty pertaining to the stock structure of this species in the eastern North Pacific. Because minke whales are considered common in the waters off Alaska and, because the number of human-related removals is currently thought to be minimal, this stock is presumed to not be a strategic stock. Reliable estimates of the minimum population size, population trends, PBR, and status of the stock relative to its Optimum Sustainable Population are currently not available. Because the PBR is unknown, the level of annual U.S. commercial fishery-related mortality and serious injury that can be considered insignificant and approaching zero mortality and serious injury rate is unknown.

HABITAT CONCERNS

Potential concerns include elevated levels of sound from anthropogenic sources (e.g., shipping, military sonars), possible changes in prey distribution with climate change, entanglement in fishing gear, ship strikes due to increased vessel traffic (e.g., from increased shipping in higher latitudes), and oil and gas activities.

NORTH PACIFIC RIGHT WHALE (*Eubalaena japonica*): Eastern North Pacific Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

A review of all 20th-century sightings, catches, and strandings of North Pacific right whales was conducted by Brownell et al. (2001). Data from this review were subsequently combined with historical whaling records to map the known distribution of the species (Fig. 1; Clapham et al. 2004, Shelden et al. 2005). Although whaling records initially indicated that right whales ranged across the entire North Pacific north of 35°N and occasionally as far south as 20°N (Fig. 1; Scarff 1986, 1991), recent analysis shows a pronounced longitudinally bimodal distribution (Josephson et al. 2008a). Before right whales in the North Pacific were heavily exploited by commercial whalers, concentrations were found in the Gulf of Alaska, eastern Aleutian Islands, south-central Bering Sea, Sea of Okhotsk, and Sea of Japan (Braham and Rice 1984). An analysis conducted on the North Pacific right whale fishery by Josephson et al. (2008b) showed that within the course of a decade (1840s), right whale abundance was severely depleted, particularly in the eastern portion of their range. Following large illegal catches (primarily from 1962 to 1968) by the U.S.S.R. (Ivashchenko and Clapham 2012, Ivashchenko et al. 2013), only 82 sightings of right whales in the entire eastern North Pacific were reported from 1962 to 1999, with the majority of these occurring in the Bering Sea and adjacent areas of the Aleutian Islands (Brownell et al. 2001). Additional sightings have been reported as far south as central Baja California and as far east as Yakutat Bay and Vancouver Island in the eastern North Pacific, as far south as Hawaii in the central North Pacific, and as far north as the subarctic waters of the Bering Sea and Sea of Okhotsk in the summer (Herman et al. 1980, Rowntree et al. 1980, Berzin and Doroshenko 1982, Salden and Mickelsen 1999, Brownell et al. 2001, Ford et al. 2016). However, most right whale sightings in the past 20 years have occurred in the southeastern Bering Sea, with a few in the Gulf of Alaska, near Kodiak, Alaska (Waite et al. 2003; Shelden et al. 2005; Wade et al. 2011a, 2011b).

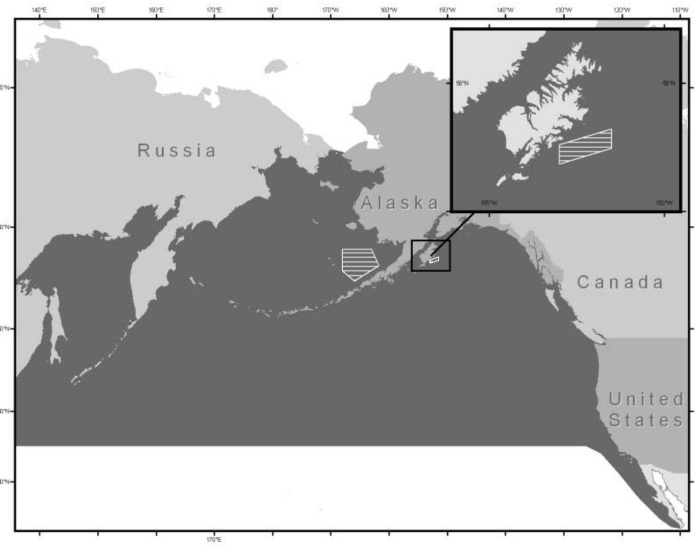

Figure 1. Approximate historical distribution of North Pacific right whales in the eastern North Pacific (dark shaded area). Striped areas indicate northern right whale critical habitat (71 FR 38277, 6 July 2006).

North Atlantic (*E. glacialis*) and Southern Hemisphere (*E. australis*) right whales calve in coastal waters during the winter months. However, in the eastern North Pacific no such calving grounds have been identified (Scarff 1986). Migratory patterns of North Pacific right whales are unknown, although it is thought they migrate from high-latitude feeding grounds in summer to more temperate waters during the winter, possibly well offshore (Braham and Rice 1984, Scarff 1986, Clapham et al. 2004). A right whale sighted off Maui in April 1996 (Salden and Michelsen 1999) was identified 119 days later and 4,111 km north in the Bering Sea (Kennedy et al. 2011). While the photographic match confirms that Bering Sea animals occasionally travel south, there is currently no reason to believe that either Hawaii or tropical Mexico have ever been anything except extra-limital habitats for this species (Brownell et al. 2001).

Passive acoustic monitoring from 2011 to 2014 of the northern Bering Sea revealed detections of calls matching the North Pacific right whale up call criterion in late winter (Wright 2015), suggesting that North Pacific right whales may occur in the northern Bering Sea during winter months. An individual North Pacific right whale was visually identified north of St. Lawrence Island in November 2012 (G. Sheffield, University of Alaska Fairbanks, Nome, AK), confirming their recent presence at higher latitudes late in the season. However, the winter upsweeps were observed during bowhead whale song and heavy ice conditions. As a result, these calls were termed ambiguous because there is some chance they were bowhead whale calls; further analysis is underway to clarify which species are making these calls (Wright 2015).

Information on the summer and autumn distribution of right whales is available from dedicated vessel and aerial surveys, bottom-mounted acoustic recorders, and vessel surveys for fisheries ecology and management that have also included dedicated marine mammal observers. Aerial and vessel surveys for right whales have occurred in a portion of the southeastern Bering Sea (Fig. 1) where right whales have been observed most summers since 1996 (Goddard and Rugh 1998, Rone et al. 2012). North Pacific right whales are observed consistently in this area, although it is clear from historical and Japanese sighting survey data that right whales often range outside this area and occur elsewhere in the Bering Sea (Moore et al. 2000, 2002; LeDuc et al. 2001; Clapham et al. 2004). Bottom-mounted acoustic recorders were deployed in the southeastern Bering Sea and the northern Gulf of Alaska starting in 2000 to document the seasonal distribution of right whale calls (Mellinger et al. 2004). Analysis of the data from those recorders deployed between October 2000 and January 2006 indicates that right whales remain in the southeastern Bering Sea from May through December with peak call detection in September (Munger and Hildebrand 2004). Data from recorders deployed between May 2006 and April 2007 show the same trends (Stafford and Mellinger 2009, Stafford et al. 2010). Recorders deployed from 2007 to the present time have not been fully analyzed, but 2012-2013 data indicate the presence of right whales in the southeastern Bering Sea in July-January, with a peak in September and a sharp decline in detections by mid-November (C. Berchok, NMFS-AFSC-MML, unpubl. data; Wright 2015). The probability of acoustically detecting right whales in the Bering Sea has been found to be strongly influenced by the abundance of the copepod *Calanus marshallae* (Baumgartner et al. 2013), and those authors propose that *C. marshallae* is the primary prey for right whales on the Bering Sea shelf. The seasonal development of these copepods into later life-history stages that can be exploited by right whales closely matches the peak timing of right whale call detections (Munger et al. 2008, Baumgartner et al. 2013). Additionally, right whale "gunshot" call detections increased shortly after peaks in copepod biovolume (Stafford et al. 2010). Baumgartner et al. (2013) suggest that the availability of *C. marshallae* on the middle shelf of the southeast Bering Sea is the reason right whales aggregate there annually. Satellite-telemetry data from four whales tagged in 2008 and 2009 provide further indication of this area's importance as foraging habitat for Eastern North Pacific right whales (Zerbini et al. 2015). Right whales were not observed outside the localized area in the southeastern Bering Sea during surveys conducted for fishery management purposes that covered a broader area of Bristol Bay and the Bering Sea (Moore et al. 2000, 2002; see Fig. 1 in the Northeast Pacific fin whale Stock Assessment Report for locations of tracklines for these surveys).

There are fewer recent sightings of right whales in the Gulf of Alaska than in the Bering Sea (Brownell et al. 2001); although, until the summer of 2015 there was little survey effort in this region, notably in the offshore areas where right whales commonly occurred during whaling days (Ivashchenko and Clapham 2012). Waite et al. (2003) summarized sightings from the Platforms of Opportunity Program from 1959 to 1997. Additional lone animals were observed off Kodiak Island in the Barnabas Canyon area from NOAA surveys in August 2004, 2005, and 2006 (A. Zerbini, NMFS-AFSC-MML, unpubl. data). A single right whale was reported in Pasagshak Bay by a kayaker in May of 2010, and one was sighted in December 2011 by humpback whale researchers in Uganik Bay (A. Kennedy, NMFS-AFSC-MML, pers. comm., 7 October 2012). A single right whale was sighted south of the Alaska Peninsula (53.5°N, 156.5°W) during a seismic survey in July 2011 (Davis et al. 2011). Acoustic monitoring from May 2000 to July 2001 at seven sites in the Gulf of Alaska detected right whale calls at only two sites: one off eastern Kodiak and the other in deep water south of the Alaska Peninsula (detection distance in 10s of kilometers) (Mellinger et al. 2004). More recently, right whale up and gunshot calls were detected in Unimak Pass in May-September and December-February on recorders deployed in 2009-2014. Similarly, gunshot calls were detected at Umnak Pass in July-September on a recorder deployed in 2009 (Wright 2015). Additionally, right whale up calls were detected on a recorder deployed near Quinn Seamount in the Gulf of Alaska on a few days each in June, July, August, and September 2013 (Širović et al. 2015).

A dedicated vessel survey for right whales was conducted by NMFS in August 2015 aboard the NOAA ship *Reuben Lasker*; the cruise used visual and acoustic survey techniques and followed tracklines on the shelf and in deeper waters to the south and east of Kodiak (B. Rone, NMFS-AFSC-MML, unpubl. data). Right whales were acoustically detected twice on the shelf, but none were visually observed.

Most of the illegal Soviet catches of right whales occurred in offshore areas, including a large area to the east and southeast of Kodiak (Doroshenko 2000, Ivashchenko and Clapham 2012); the Soviet catch distribution closely parallels that seen in plots of 19th-century American whaling catches by Townsend (1935). Whether this region remains an important habitat for this species, or whether cultural memory of its existence has been lost, is currently unknown. The sightings and acoustic detection of right whales in coastal waters east of Kodiak indicate at least occasional continuing use of this area; however, the lack of visual detections of right whales during the *Reuben Lasker* cruise in August 2015 adds to the concern that the Gulf of Alaska population may be extremely small.

In recent years, there have been two sightings of single right whales in the waters of British Columbia. The first was observed off Haida Gwaii on 9 June 2013 and the second, a large adult, was seen in the Strait of Juan de Fuca on 25 October 2013; this second animal had an apparently healed major wound across the rostrum, which may have been caused by a previous entanglement in fishing gear (Ford et al. 2016). Two right whale calls were detected on a bottom-mounted hydrophone off the Washington Coast on 29 June 2013. No right whale calls were detected in previous years at this site (Širović et al. 2015).

The following information was considered in classifying stock structure according to the Dizon et al. (1992) phylogeographic approach: 1) Distributional data: distinct geographic distribution; 2) Population response data: unknown; 3) Phenotypic data: unknown; and 4) Genotypic data: evidence for some isolation of populations. Based on this limited information, two stocks of North Pacific right whales are currently recognized: a Western North Pacific and an Eastern North Pacific stock (Rosenbaum et al. 2000, Brownell et al. 2001, LeDuc et al. 2012). The former is believed to feed primarily in the Sea of Okhotsk.

POPULATION SIZE

The former U.S.S.R. made illegal catches of an estimated 772 total right whales in the eastern and western North Pacific, with the majority (662) killed between 1962 and 1968. These takes severely impacted the two populations concerned, notably in the east (Ivashchenko and Clapham 2012, Ivashchenko et al. 2013). Based on sighting data, Wada (1973) estimated a total population of 100-200 in the North Pacific. Rice (1974) stated that only a few individuals remained in the Eastern North Pacific stock and that for all practical purposes the stock was extinct because no sightings of a mature female with a calf had been confirmed since 1900. However, confirmed sightings over the last 14 years, starting in 1996 (Goddard and Rugh 1998), have invalidated this view (Wade et al. 2006). Brownell et al. (2001) suggested from a review of sighting records that the abundance of this species in the western North Pacific was likely in the "low hundreds," including the population in the Okhotsk Sea.

There were several sightings of North Pacific right whales in the mid-1990s, which renewed interest in conducting dedicated surveys for this species that included the collection of photo-identifications and biopsies. Right whales can be individually identified by photographs of the unique callosity patterns on their heads. In April 1996, a right whale was sighted off Maui (Salden and Mickelsen 1999), and that same animal was identified 119 days later and 4,111 km north (in the Bering Sea); this represents the first high- to low-latitude match of a North Pacific right whale (Kennedy et al. 2011). The Maui sighting in April was the first documented sighting of a right whale in Hawaiian waters since 1979 (Herman et al. 1980, Rowntree et al. 1980) and, even though the photographic match confirms that Bering Sea animals occasionally travel south, there is little reason to believe that either Hawaii or tropical Mexico have ever been anything except extra-limital habitats for this species (Brownell et al. 2001).

A group of 3-4 right whales, that may have included a juvenile animal, was sighted in western Bristol Bay, southeastern Bering Sea, in July 1996 (Goddard and Rugh 1998). In July 1997, a group of 4-5 individuals was encountered one evening in Bristol Bay, followed by a second sighting of 4-5 whales the following morning in approximately the same location (Tynan 1999). During dedicated surveys in July 1998, July 1999, and July 2000, 5, 6, and 13 right whales were again found in the same general region of the southeastern Bering Sea (LeDuc et al. 2001). Biopsy samples of right whales encountered in the southeastern Bering Sea were taken in 1997 and 1999. Genetic analyses identified three individuals in 1997 and four individuals in 1999; of the animals identified, one was identified in both years, resulting in a total genetic count of six individuals (LeDuc et al. 2001). Genetic analyses of samples from all six whales sampled in 1999 determined that the animals were male (LeDuc et al. 2001). Two right whales were observed during a vessel-based survey in the central Bering Sea in July 1999 (Moore et al. 2000).

During the southeast Bering Sea survey in 2002, there were seven sightings of right whales (LeDuc 2004). One of the sightings in 2002 included a right whale calf; this is the first confirmed sighting of a calf in decades (a possible calf or juvenile sighting was also reported in Goddard and Rugh 1998). This concentration also included two probable calves. In the southeastern Bering Sea during September 2004, multiple right whales were acoustically located and subsequently sighted by another survey vessel approaching a near-real-time position of an individual located with a satellite tag (Wade et al. 2006). An analysis of photographs confirmed at least 17 individual whales (not including the tagged whales). Genetic analysis of biopsy samples identified 17 individuals: 10 males and 7 females. The discovery of seven females was significant as only one female had been identified previously, and at least two calves were present. From 2007 to 2011, 12 individual right whales were seen (some individuals were seen many times over all survey years).

Photographic and genotype data through 2008 were used to calculate the first mark-recapture estimates of abundance for right whales in the Bering Sea and Aleutian Islands, resulting in estimates of 31 (95% CL: 23-54; CV

= 0.22) and 28 (95% CL: 24-42), respectively (Wade et al. 2011a). The abundance estimates are for the last year of each study, corresponding to 2008 for the photo-identification estimate and 2004 for the genetic identification estimates. Wade et al. (2011a) also estimate the population consists of 8 females (95% CL: 7-18) and 20 males (95% CL: 17-37). Wade et al. (2011a) summarized the photo-identification and genetic-identification catalogues as follows: twenty-one individuals were identified from genotyping from the Aleutian Islands and Bering Sea from 1997 to 2004, comprising 15 males and 6 females. In aggregate, there were eight photo matches of individual whales across years involving five individuals. Wade et al. (2006) reported 17 individuals (including 7 females) identified from genotyping in 2004; that number was revised to 16 individuals (including 6 females) because a typographical error was subsequently discovered that masked a duplicate sample. There were four biopsies taken in 2008 and 2009 of two males and two females; three of these animals had been sampled in previous years. These samples were unavailable and not included in the Wade et al. (2011a) abundance estimate (A. Kennedy, NMFS-AFSC-MML, pers. comm., 21 September 2011).

The photo-identification catalogue, for purposes of abundance estimation, was restricted to aerial or left-side oblique photographs of good or excellent photo quality. After this restriction, there was a total of 18 unique individuals identified from photographs of callosity patterns and scars from 1998 to 2008, with 10 resightings across years involving 5 individuals.

Another seven individuals were observed in the summer of 2009, and one individual was seen in the summer of 2010 (A. Kennedy, NMFS-AFSC-MML, pers. comm., 3 November 2010). Four individuals were seen in the summer of 2011 (B. Rone, NMFS-AFSC-MML, pers. comm., 7 October 2012). The two sightings noted above of right whales (one in June and one in October) in British Columbia waters in 2013 were the first sightings of this species in this region in decades. Comparisons with the photo-identification catalogue curated at the Marine Mammal Laboratory showed that neither individual had been previously photographed elsewhere. Whether this indicates that right whales are returning to these coastal waters where they were once hunted is unclear.

LeDuc et al. (2012) analyzed 49 biopsy samples from right whales identified as being from 24 individuals, of which all but one were from the eastern North Pacific. The analysis revealed a male-biased sex ratio and a loss of genetic diversity that appeared to be midway between that observed for right whales in the North Atlantic and the Southern Hemisphere. The analysis also suggested a degree of separation between eastern and western populations, a male:female ratio of 2:1, and a low effective population size for the Eastern North Pacific stock, which LeDuc et al. (2012) considered to be at "extreme risk" of extirpation.

Detections of right whales have been very rare in the Gulf of Alaska, even though large numbers of whales were caught there in the 1800s and 1960s. With the exception of the Soviet catches, primarily in 1963-1964 (Ivashchenko and Clapham 2012), from the 1960s through 2002, only two sightings of right whales occurred in the Gulf of Alaska: an opportunistic sighting in March 1979 near Yakutat Bay in the eastern Gulf (Shelden et al. 2005) and a sighting during an aerial survey for harbor porpoise in July 1998 south of Kodiak Island (Waite et al. 2003). Both sightings occurred in shelf waters less than 100 m deep. However, from 2004 to 2006, four sightings of right whales occurred in the Barnabus Trough region on Albatross Bank, south of Kodiak Island (Wade et al. 2011b). Sightings of right whales occurred at locations within the trough with the highest density of zooplankton, as measured by active-acoustic backscatter. Photo-identification (of two whales) and genotyping (of one whale) failed to reveal a match to Bering Sea right whales. Fecal hormone metabolite analysis from one whale estimated levels consistent with an immature male, indicating either recent reproduction in the Gulf of Alaska or movements between the Bering Sea and Gulf of Alaska. The survey conducted off Kodiak in the summer of 2015 made two acoustic (and no visual) detections of right whales (B. Rone, NMFS-AFSC-MML, unpubl. data).

In recent decades, the only detections of right whales in pelagic waters of the Gulf of Alaska came from passive acoustic recorders. These detections of calls were exceptionally rare; instruments in seven widespread locations detected right whale calls from only two of the locations on only 6 days out of a total of 80 months of recordings (Mellinger et al. 2004) and on only 5 days out of a total of 70 months of recordings from the five deep-water stations. The calls were heard at the deep-water station in the Gulf of Alaska ~500 km southwest of Kodiak Island on 5 days in August and September of 2000, but no calls were detected from four other instruments deployed in deep water farther east during 2000 and 2001 (Mellinger et al. 2004). Calls classified as "probable" right whales were detected from an instrument deployed on the shelf at the location of the aerial visual detection on Albatross Bank on 6 September 2000 (Waite et al. 2003), but no calls were detected from two instruments deployed at the base of the continental slope off Albatross Bank just northeast of Barnabus Trough (Mellinger et al. 2004, Munger et al. 2008). Twenty sonobuoy deployments in 2004 throughout the Gulf of Alaska resulted in the detection of right whale calls only in Barnabus Trough, near the location of the visual sightings mentioned above (Wade et al. 2011b). Right whale up-calls were detected far offshore in the Gulf of Alaska in 2013 on a bottom-mounted recorder at Quinn Seamount during a total of 3 hours on 2 days (21 June and 3 August 2013). Right whale down calls were detected during 50 hours from 27 July to 5 September 2013 (Širović et al. 2015). The lack of detection of right whales from passive acoustic recorders does not provide indisputable evidence there were no right whales in the area, as the whales may not always vocalize or their calls may not always be detected by the automatic algorithms used or the call type targeted for detection. Until very recently, only a single call type, the "up call" was used to automatically detect right whales. The "gunshot" call has recently been identified as another candidate for right whale detections (Stafford et al. 2010, Rone et al. 2012). However, it is interesting to note the contrasting data from the southeastern Bering Sea, where similar instruments on the middle shelf (<100 m depth) detected right whale calls on >6 days per month in July-October (Munger et al. 2008), despite a population estimated to be only 31 whales (Wade et al. 2011a). The lack of detections of right whales in pelagic waters of the Gulf of Alaska may still be partially due to a lack of survey and recording effort in those areas, but the lack of calls in passive-acoustic monitoring suggests that right whales are very rare in at least the monitored pelagic areas today. More extensive coverage of shelf and nearshore waters of the Gulf of Alaska during previous ship and airplane surveys for cetaceans (summarized in Wade et al. 2011b) detected a single right whale near Kodiak Island (Waite et al. 2003) and two acoustic detections from the *Reuben Lasker* survey in August 2015 (B. Rone, NMFS-AFSC-MML, unpubl. data). Therefore, the Barnabus Trough/Albatross Bank area represents the only location in the Gulf of Alaska where right whales have been repeatedly detected in the last 4 decades, and those detections add only a minimum of two additional whales (from photo-identification in 2005 and 2006) to the total Eastern North Pacific population. However, with the exception of the August 2015 study off Kodiak, there has been virtually no survey coverage of the offshore waters in which right whales commonly occurred during historical and recent whaling periods (Townsend 1935, Ivashchenko and Clapham 2012).

Minimum Population Estimate

The minimum estimate of abundance of Eastern North Pacific right whales is 26 based on the 20th percentile of the photo-identification estimate of 31 (CV = 0.226; Wade et al. 2011a). The photo-identification catalogue used in the mark-recapture abundance estimate has a minimum of 20 unique individuals seen from 1998 to 2013, yet this number could be higher given that there are many animals with poor quality photos or poor coverage (one side only). The genetic-identification catalogue has a total of 23 individuals identified from 1997 to 2011 (LeDuc et al. 2012).

Current Population Trend

No estimate of trend in abundance is currently available.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Due to insufficient information, the default cetacean maximum net productivity rate (R_{MAX}) of 4% is used for this stock (Wade and Angliss 1997). However, given the small apparent size, male bias, and low observed calving rate of this population, this rate is likely to be unrealistically high.

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the potential biological removal (PBR) is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: PBR = $N_{MIN} \times 0.5R_{MAX} \times F_R$. The recovery factor ($F_R$) for this stock is 0.1, the recommended value for cetacean stocks which are listed as endangered (Wade and Angliss 1997). A reliable estimate of minimum abundance for this stock is 26 based on the mark-recapture estimate of 31 (CV = 0.226; Wade et al. 2011a). The calculated PBR level for this stock is therefore 0.05 which would be equivalent to one take every 20 years. However, because the Eastern North Pacific right whale population is far below historical levels and considered to include fewer than 30 mature females, the calculated value for PBR is considered unreliable.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Detailed information (including observer programs, observer coverage, and observed incidental takes of marine mammals) for federally-managed and state-managed U.S. commercial fisheries in Alaska waters is presented in Appendices 3-6 of the Alaska Stock Assessment Reports.

Gillnets were implicated in the death of a right whale off the Kamchatka Peninsula (Russia) in October of 1989 (Kornev 1994), which was presumably from the Western North Pacific population. No other incidental takes of right whales are known to have occurred in the North Pacific, although one photograph from the catalogue shows potential fishing gear entanglement (A. Kennedy, NMFS-AFSC-MML, pers. comm., 21 September 2011). The right whale photographed on 25 October 2013 off British Columbia and northern Washington State, showed potential fishing gear entanglement (Ford et al. 2016). Vessel collisions are considered the primary source of human-caused mortality and serious injury of right whales in the North Atlantic (Cole et al. 2005). Given the very small estimate of abundance, any mortality or serious injury incidental to commercial fisheries would be considered significant. Entanglement in fishing gear, including lobster pot and sink gillnet gear, is a significant source of mortality and serious injury for the North Atlantic right whale stock (Waring et al. 2004).

There are no records of mortality or serious injury of Eastern North Pacific right whales in any U.S. fishery. Overall, given the remote nature of the known and likely habitats of North Pacific right whales, it is very unlikely that any mortality in this population would be observed. Consequently, it is possible that the current absence of reported deaths in this stock is not a reflection of the true situation.

Alaska Native Subsistence/Harvest Information

Subsistence hunters in Alaska and Russia are not reported to take animals from this stock.

Other Mortality

Ship strikes are a significant source of mortality and serious injury for the North Atlantic stock of right whales, and it is possible that right whales in the North Pacific are also vulnerable to this source of mortality. However, due to their rare occurrence and scattered distribution, it is impossible to assess the threat of ship strikes to the Eastern North Pacific stock of right whales at this time. There is concern regarding the effects of increased shipping through arctic waters and the Bering Sea with retreating sea ice, which may increase the potential risk to right whales from shipping.

Overall, given the remote nature of the known and likely habitats of North Pacific right whales, it is very unlikely that any mortality in this population would be observed. Consequently, it is possible that the current absence of reported deaths in this stock is not a reflection of the true situation.

STATUS OF STOCK

The right whale is listed as endangered under the Endangered Species Act of 1973, and therefore designated as depleted under the MMPA. In 2008, NMFS relisted the North Pacific right whale as endangered as a separate species (*Eubalaena japonica*) from the North Atlantic species, *E. glacialis* (73 FR 12024, 06 March 2008). As a result, the stock is classified as a strategic stock. The abundance of this stock is considered to represent only a small fraction of its pre-commercial whaling abundance (i.e., the stock is well below its Optimum Sustainable Population). The total estimated annual level of human-caused mortality and serious injury is considered minimal for this stock. The reason(s) for the apparent lack of recovery for this stock is (are) unknown. Brownell et al. (2001) and Ivashchenko and Clapham (2012) noted the devastating impact of extensive illegal Soviet catches in the eastern North Pacific in the 1960s, and both suggested that the prognosis for right whales in this area was poor. Biologists working aboard the Soviet factory ships which killed right whales in the eastern North Pacific in the 1960s considered that the fleets had caught close to 100% of the animals they encountered (Ivashchenko and Clapham 2012); accordingly, it is quite possible that the Soviets wiped out the great majority of the animals in the population at that time. In its review of the status of right whales worldwide, the International Whaling Commission expressed “considerable concern” over the status of this population (IWC 2001), which is currently the most endangered stock of large whales in the world for which an abundance estimate is available.

HABITAT CONCERNS

NMFS conducted an analysis of right whale distribution in historical times and in recent years and stated that principal habitat requirements for right whales are dense concentrations of prey (Clapham et al. 2006) and, on this basis, proposed two areas of critical habitat: one in the southeastern Bering Sea and another south of Kodiak Island (70 FR 66332, 2 November 2005). In 2006, NMFS issued a final rule designating these two areas as northern right whale critical habitat, one in the Gulf of Alaska and one in the Bering Sea (71 FR 38277, 6 July 2006; Fig. 1). In 2008, NMFS redesignated the same two areas as Eastern North Pacific right whale critical habitat under the newly recognized species name, *E. japonica*.

Potential threats to the habitat of this population derive primarily from commercial shipping and fishing vessel activity. There is considerable fishing activity within portions of the critical habitat of this species, increasing the risk of entanglement, although photographs of right whales taken to date have shown no evidence of entanglement scars. The high volume of large vessels transiting Unimak Pass (e.g., 1,961 making 4,615 transits in 2012 (Nuka Research and Planning Group, LLC 2014a, 2014b), a subset of which continue north through the Bering

Sea, increases both the risk of ship strikes and the risk of a large or very large oil spill in areas in which right whales may occur. The risk of accidents in Unimak Pass, specifically, is predicted to increase in the coming decades, and studies indicate that more accidents are likely to involve container vessels (Wolniakowski et al. 2011). The U.S. Department of the Interior has designated areas within the southeastern Bering Sea, including areas designated as right whale critical habitat, as an outer continental shelf oil and gas lease area. This planning area, referred to as the North Aleutian Basin, was not included in the current 2012-2017 national lease schedule by the Bureau of Ocean Energy Management, and there are no residual active leases from past sales. On December 16, 2014, President Obama announced that, under authority granted him by Section 12(a) of the Outer Continental Lands Act (OCSLA), he was withdrawing the North Aleutian Basin from future oil and gas leasing, development or production "for a time period without specific expiration." Thus, oil and gas leasing in federal waters in this area is not likely for the foreseeable future.

BOWHEAD WHALE (*Balaena mysticetus*): Western Arctic Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Western Arctic bowhead whales are distributed in seasonally ice-covered waters of the Arctic and near-Arctic, generally north of 60°N and south of 75°N in the western Arctic Basin (Braham 1984, Moore and Reeves 1993). For management purposes, four stocks of bowhead whales have been recognized worldwide by the International Whaling Commission (IWC 2010). Small stocks, comprised of only a few hundred individuals occur in the Sea of Okhotsk and the offshore waters of Spitsbergen (Zeh et al. 1993, Shelden and Rugh 1995, Wiig et al. 2009, Shpak et al. 2014, Boertmann et al. 2015). Bowhead whales occur in western Greenland (Hudson Bay and Foxe Basin) and eastern Canada (Baffin Bay and Davis Strait), and evidence suggests that these should be considered one stock based on genetics (Postma et al. 2006, Bachmann et al. 2010, Heide-Jørgensen et al. 2010, Wiig et al. 2010), aerial surveys (Cosens et al. 2006), and tagging data (Dueck et al. 2006; Heide-Jørgensen et al. 2006; IWC 2010, 2011). This stock, previously thought to include only a few hundred animals, may number over a thousand (Heide-Jørgensen et al. 2006, Wiig et al. 2011), and perhaps over 6,000 (IWC 2008). The only stock found within U.S. waters is the Western Arctic stock (Figs. 1 and 2), also known as the Bering-Chukchi-Beaufort stock (Rugh et al. 2003) or Bering Sea stock (Burns et al. 1993). Although Jorde et al. (2007) suggested there might be multiple stocks of bowhead whales in U.S. waters, several studies (George et al. 2007, Taylor et al. 2007, Rugh et al. 2009) and the IWC Scientific Committee concluded that data are most consistent with one stock that migrates throughout waters of northern and western Alaska (IWC 2008).

The majority of the Western Arctic stock migrates annually from wintering areas (December to March) in the northern Bering Sea, through the Chukchi Sea in the spring (April through May), to the eastern Beaufort Sea (Fig. 1) where they spend much of the summer (June through early to mid-October) before returning again to the Bering Sea (Fig. 2) in the fall (September through December) to overwinter (Braham et al. 1980, Moore and Reeves 1993, Quakenbush et al. 2010a, Citta et al. 2015). Some bowhead whales are found in

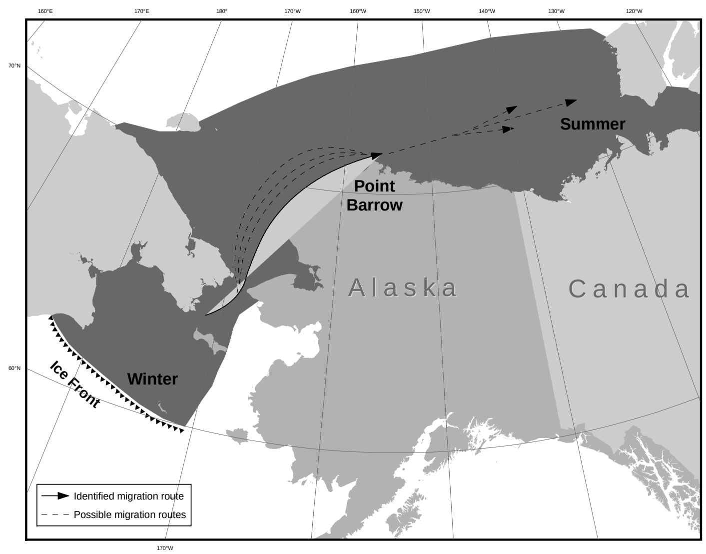

Figure 1. Dark areas depict the approximate distribution of the Western Arctic stock of bowhead whales. The spring migration represented here by lines and arrows follows a route from the Bering Sea wintering area to the Beaufort Sea summering area, mostly along a coastal tangent that constricts somewhat as it goes east past Point Barrow.

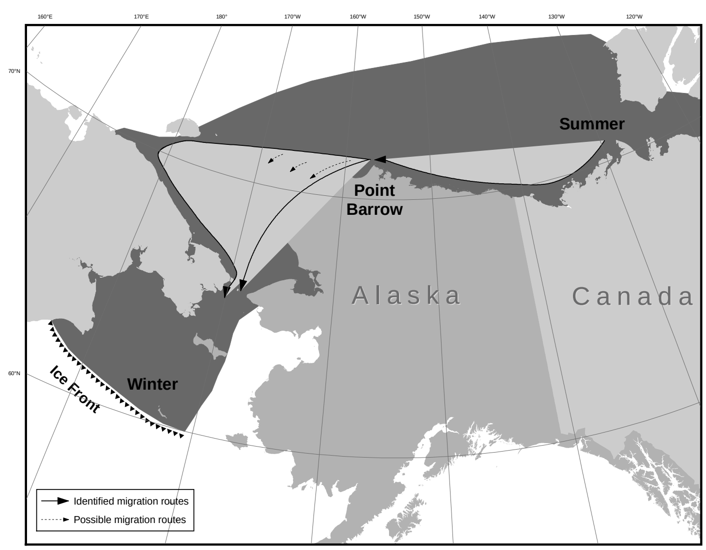

Figure 2. Dark areas depict the approximate distribution of the Western Arctic stock of bowhead whales. The fall migration is represented here by lines and arrows showing generalized routes used to travel from the Beaufort Sea (summering area) to the Bering Sea (wintering area).

the western Beaufort, Chukchi, and Bering seas in summer, and these are thought to be a part of the expanding Western Arctic stock (Rugh et al. 2003; Clarke et al. 2013, 2014, 2015; Citta et al. 2015).

During winter and spring, bowhead whales are closely associated with sea ice (Moore and Reeves 1993, Quakenbush et al. 2010a, Citta et al. 2015). The bowhead whale spring migration follows fractures in the sea ice around the coast of Alaska, generally in the shear zone between the shorefast ice and the mobile pack ice. During summer, most of the population is in relatively ice-free waters in the southeastern Beaufort Sea (Citta et al. 2015), an area often exposed to industrial activity related to petroleum exploration (e.g., Richardson et al. 1987, Davies 1997). Summer aerial surveys conducted in the western Beaufort Sea during July and August of 2012-2014 have had relatively high sighting rates of bowhead whales, including cows with calves and feeding animals (Clarke et al. 2013, 2014; MML, unpubl. data, available online: http://www.afsc.noaa.gov/nmml/cetacean/bwasp/flights_2014.php, accessed December 2016). During the autumn migration through the Beaufort Sea, bowhead whales select shelf waters in all but "heavy ice" conditions, when they select slope habitat (Moore 2000). Heavy ice years in autumn in the Beaufort Sea are becoming less common because of climate change and the resulting trend of delayed seasonal sea ice formation and dramatic reduction in volume of multi-year ice. In winter in the Bering Sea, bowhead whales often use areas with ~100% sea-ice cover, even when polynas are available (Quakenbush et al. 2010a, Citta et al. 2015).

Evidence suggests that bowhead whales feed on concentrations of zooplankton throughout their range. Likely or confirmed feeding areas include Amundsen Gulf and the eastern Canadian Beaufort Sea; the central and western U.S. Beaufort Sea; Wrangel Island; and the coast of Chukotka, between Wrangel Island and the Bering Strait (Lowry et al. 2004; Ashjian et al. 2010; Clarke and Ferguson 2010a; Quakenbush et al. 2010a, 2010b; Okkonen et al. 2011; Clarke et al. 2012, 2013, 2014, 2015; MML, unpubl. data, available online: http://www.afsc.noaa.gov/nmml/cetacean/bwasp/flights_2014.php, accessed December 2016). Bowhead whales have also been observed feeding during the summer in the northeastern Chukchi Sea (Clarke and Ferguson 2010b).

POPULATION SIZE

All stocks of bowhead whales were severely depleted during intense commercial whaling, starting in the early 16th century near Labrador (Ross 1993) and spreading to the Bering Sea in the mid-19th century (Braham 1984, Bockstoce and Burns 1993, Bockstoce et al. 2007). Woodby and Botkin (1993) summarized previous efforts to estimate bowhead whale population size prior to the onset of commercial whaling. They reported a minimum worldwide population estimate of 50,000, with 10,400-23,000 in the Western Arctic stock (dropping to less than 3,000 at the end of commercial whaling). Brandon and Wade (2006) used Bayesian model averaging to estimate that the Western Arctic stock consisted of 10,960 (9,190-13,950; 5th and 95th percentiles, respectively) bowhead whales in 1848 at the start of commercial whaling.

Since 1978, systematic counts of bowhead whales have been conducted from sites on sea ice near Point Barrow during the whales' spring migration (Krogman et al. 1989). These counts have been corrected for whales missed due to distance offshore (since the mid-1980s, using acoustical methods described in Clark et al. 1994), whales missed when no watch was in effect (through interpolations from sampled periods), and whales missed during a watch (estimated as a function of visibility, number of observers, and distance offshore: Zeh et al. 1993). A summary of the resulting abundance estimates is provided in Table 1 and Figure 3. These estimates of abundance have not been

Table 1. Summary of abundance estimates for the Western Arctic stock of bowhead whales. The historical estimates were made by back-projecting using a simple recruitment model. All other estimates were developed by corrected ice-based census counts. Historical estimates are from Woodby and Botkin (1993); 1978-2001 estimates are from George et al. (2004) and Zeh and Punt (2004). The 2011 estimate is reported in Givens et al. (2013).

Year	Abundance estimate (CV)	Year	Abundance estimate (CV)
Historical estimate	10,400-23,000	1985	5,762 (0.253)
End of commercial whaling	1,000-3,000	1986	8,917 (0.215)
1978	4,765 (0.305)	1987	5,298 (0.327)
1980	3,885 (0.343)	1988	6,928 (0.120)
1981	4,467 (0.273)	1993	8,167 (0.017)
1982	7,395 (0.281)	2001	10,545 (0.128)
1983	6,573 (0.345)	2011	16,892 (0.058)

corrected for a small portion of the population that may not migrate past Point Barrow during the period when counts are made. Attempts to count migrating whales near Point Barrow in 2009 and 2010 were unsuccessful due to sea-ice conditions (IWC 2010, George et al. 2011) but were successful in 2011.

Bowhead whales were identified from aerial photographs taken in 1985 and 1986, and the results were used in a sight-resight analysis. This approach provided estimates of 4,719 (95% CI: 2,382-9,343; SE 1,696) to 7,022 (95% CI: 4,701-12,561; SE 2,017), depending on the model used (daSilva et al. 2000). These population estimates and their associated error ranges are comparable to the estimates obtained from the combined ice-based visual and acoustic data for 1985 (6,039; 95% CI: 2,286-9,792; SE 1,915) and 1986 (7,734; 95% CI: 4,892-10,576; SE 1,450; Raftery and Zeh 1998). Aerial photographs provided another sampling of the bowhead whale population in 2003 and 2004. Sight-resight results provided estimates of 8,250 whales (95% CI: 3,150-15,450) in 2001 (Schweder et al. 2009) and 12,631 whales (95% CI: 7,900-19,700) in 2004 (Koski et al. 2010), which are consistent with trends in abundance estimates made from ice-based counts. An aerial photographic survey was conducted near Point Barrow concurrently with the ice-based spring census in 2011; these data are currently being analyzed to produce a revised abundance estimate based on sight-resight data (Mocklin et al. 2012).

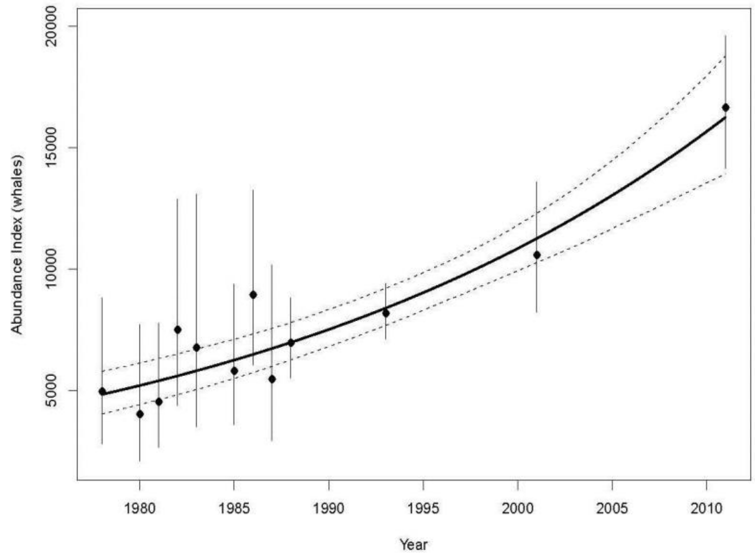

Figure 3. Abundance estimates for the Western Arctic stock of bowhead whales, 1978-2011 (Givens et al. 2013), as computed from ice-based counts, acoustic data, and aerial transect data collected during bowhead whale spring migrations past Point Barrow, Alaska.

Minimum Population Estimate

The minimum population estimate (N_{MIN}) for this stock is calculated from Equation 1 from the potential biological removal (PBR) guidelines (Wade and Angliss 1997): $N_{MIN} = N/\exp(0.842\times[\ln(1+[CV(N)]^2)]^{½})$. Using the 2011 population estimate (N) of 16,892 and its associated coefficient of variation CV(N) of 0.058, N_{MIN} for the Western Arctic stock of bowhead whales is 16,091.

Current Population Trend

Based on concurrent passive acoustic and ice-based visual surveys, Givens et al. (2013) reported that the Western Arctic stock of bowhead whales increased at a rate of 3.7% (95% CI = 2.8-4.7%) from 1978 to 2011, during which time abundance tripled from approximately 5,000 to approximately 16,000 whales (Givens et al. 2013). Schweder et al. (2009) estimated the yearly growth rate to be 3.2% (95% CI = 0.5-4.8%) between 1984 and 2003 using a sight-resight analysis of aerial photographs.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

The current estimate for the rate of increase for this stock of bowhead whales (3.2-3.7%) should not be used as an estimate of (R_{MAX}) because the population is currently being harvested. It is recommended that the cetacean maximum theoretical net productivity rate (R_{MAX}) of 4% be used for the Western Arctic stock of bowhead whales (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Under the 1994 reauthorized Marine Mammal Protection Act (MMPA), the PBR level is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: $PBR = N_{MIN} \times 0.5R_{MAX} \times F_R$. The recovery factor ($F_R$) for this stock has been set at 0.5 rather than the default value of 0.1 for endangered species because population levels are increasing in the presence of a known take (see Wade and Angliss 1997, p. 27-28). Thus, PBR = 161 animals (16,091 × 0.02 × 0.5). The calculation of a PBR level for the Western Arctic bowhead whale stock is required by the MMPA even though the subsistence harvest quota is established under the authority of the IWC based on an extensively tested strike limit algorithm (IWC 2003). The quota is based on subsistence need or the ability of the bowhead whale population to sustain a harvest, whichever is smaller. The IWC bowhead whale quota takes precedence over the PBR estimate for the purpose of managing the Alaska Native subsistence harvest from this stock. For 2013-2018, the IWC established a block quota of 306 landed bowhead whales. Because some whales are struck and lost, a strike limit of 67 (plus up to 15 previously unused strikes) is permitted each year. This quota includes an allowance of five animals to be taken by Chukotka Natives in Russia. The 2013-2018 quota maintains the *status quo* of the previous 5-year block quota (2008-2012) but was extended for 6 years.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Detailed information (including observer programs, observer coverage, and observed incidental takes of marine mammals) for federally-managed and state-managed U.S. commercial fisheries in Alaska waters is presented in Appendices 3-6 of the Alaska Stock Assessment Reports.

Several cases of line or net entanglement have been reported from whales taken in the subsistence hunt (Philo et al. 1993). George et al. (2015b) examined records for 904 bowhead whales harvested between 1990 and 2012. Of these, 521 records were examined for at least one of the three types of scars indicating injuries from line entanglement wounds (515 records), attacks by killer whales (378 records), and ship strikes (and/or propeller injuries) (505 records). Their best estimate of the occurrence of entanglement scars was ~12.1% (59/486; an additional 29 records with possible entanglement scars were excluded from the analysis) with the cause most likely from fishing/crab gear in the Bering Sea. Most entanglement injuries occurred on the peduncle and were rare on smaller subadult and juvenile whales (<10 m).

There are no observer program records of bowhead whale mortality incidental to U.S. commercial fisheries in Alaska. However, some bowhead whales have had interactions with crab pot gear and fishing nets. One dead whale was found floating in Kotzebue Sound in early July 2010, entangled in crab pot gear similar to that used by commercial crabbers in the Bering Sea (Table 2; Suydam et al. 2011), and one entangled bowhead whale was photographed during the 2011 spring aerial photographic survey of bowhead whales near Point Barrow (Mocklin et al. 2012), but it was not considered to be seriously injured. More recently, Citta et al. (2014) found that the distribution of satellite-tagged bowhead whales in the Bering Sea spatially and temporally overlapped areas where commercial pot fisheries occurred and noted the potential risk of entanglement in lost gear. The minimum estimated average annual mortality and serious injury rate in U.S. commercial fisheries in 2010-2014 is 0.2 bowhead whales; however, the actual rate is currently unknown.

Table 2. Summary of mortality and serious injury of Western Arctic bowhead whales, by year and type, reported to the NMFS Alaska Region marine mammal stranding network in 2010-2014 (Helker et al. 2016). Only cases of mortality and serious injury were recorded in this table; animals with non-serious injuries have been excluded.

Cause of injury	2010	2011	2012	2013	2014	Mean annual mortality
Entangled in commercial pot gear	1	0	0	0	0	0.2
Total in commercial fisheries						0.2

Alaska Native Subsistence/Harvest Information

Eskimos have been taking bowhead whales for subsistence purposes for at least 2,000 years (Marquette and Bockstoce 1980, Stoker and Krupnik 1993). Subsistence takes have been regulated by a quota system under the authority of the IWC since 1977. Alaska Native subsistence hunters, primarily from 11 Alaska communities, take approximately 0.1-0.5% of the population per annum (Philo et al. 1993, Suydam et al. 2011). Under this quota, the number of kills in any one year has ranged between 14 and 72. The maximum number of strikes per year is set by a quota which is determined by subsistence needs and bowhead whale abundance and trend estimates (Stoker and Krupnik 1993). Suydam and George (2012) summarized Alaska subsistence harvests of bowhead whales from 1974 to 2011 and reported a total of 1,149 whales landed by hunters from 12 villages, with Barrow landing the most whales (n = 590) and Shaktoolik landing only one. Alaska Natives landed 45 whales in 2010 (Suydam et al. 2011), 38 in 2011 (Suydam et al. 2012), 55 in 2012 (Suydam et al. 2013), 46 in 2013 (George and Suydam 2014, Suydam et al. 2014), and 38 in 2014 (Suydam et al. 2015). The number of whales landed at each village varies greatly from year to year, as success is influenced by village size and ice and weather conditions. The efficiency of the hunt (the percent of whales struck that are retrieved) has increased since the implementation of the bowhead whale quota in 1978. In 1978, the efficiency was about 50%. In 2014, 38 of 53 whales struck were landed, resulting in an efficiency of 72% (Suydam et al. 2015). Suydam et al. (2015) reported that the current mean efficiency, from 2005 through 2014, is 76.5%.

Canadian and Russian Natives also take whales from this stock. Hunters from the western Canadian Arctic community of Aklavik harvested one whale in 1991 and one in 1996. No catches for Western Arctic bowhead whales were reported by either Canadian or Russian hunters for 2006-2007 (IWC 2008, 2009) or by Russia in 2009, 2011, 2012, or 2014 (IWC 2011, Ilyashenko 2013, Ilyashenko and Zharikov 2015), but two bowhead whales were taken in Russia in 2008 (IWC 2010), two in 2010 (IWC 2012), and one in 2013 (Ilyashenko and Zharikov 2014). The average annual subsistence take (by Natives of Alaska, Russia, and Canada) during the 5-year period from 2010 through 2014 is 44 bowhead whales.

Other Mortality

Pelagic commercial whaling for bowhead whales was conducted from 1849 to 1914 in the Bering, Chukchi, and Beaufort seas (Bockstoce et al. 2007). During the first two decades of the fishery (1850-1870), over 60% of the estimated pre-whaling population was killed, and effort remained high into the 20th century (Braham 1984). Woodby and Botkin (1993) estimated that the pelagic whaling industry harvested 18,684 whales from this stock. During 1848-1919, shore-based whaling operations (including landings as well as struck and lost estimates from the U.S., Canada, and Russia) took an additional 1,527 animals (Woodby and Botkin 1993). An unknown percentage of the animals taken by the shore-based operations were harvested for subsistence and not commercial purposes. Historical harvest estimates likely underestimate the actual harvest as a result of under-reporting of the Soviet catches (Yablokov 1994) and incomplete reporting of struck and lost animals.

Transient killer whales are the only known predators of bowhead whales. In a study of marks on bowhead whales taken in the subsistence harvest between spring 1976 and fall 1992, 4.1% to 7.9% had scars indicating that they had survived attacks by killer whales (George et al. 1994). Of 378 complete records for killer whale scars collected from 1990 to 2012, 30 whales (7.9%) had scarring "rake marks" consistent with orca/killer whale injuries and another 10 had possible injuries (George et al. 2015b). A higher rate of killer whale rake mark scars occurred during 2002-2012 than in the previous decade. George et al. (2015b) noted this may be due to better reporting and/or sampling bias, an increase in killer whale population size, an increase in occurrence of killer whales at high latitudes (Clarke et al. 2013), or a longer open water period offering more opportunities to attack bowhead whales.

With increasing ship traffic and oil and gas activities in the Chukchi and Beaufort seas, bowhead whales may become increasingly at risk from ship strikes. Currently, ship-strike injuries appear to be uncommon on bowhead whales in Alaska (George et al. 2015b). Only 10 whales harvested between 1990 and 2012 (~2% of the total sample) showed clear evidence of scarring from ship propeller injuries.

STATUS OF STOCK

Based on currently available data, the estimated mean annual mortality and serious injury rate incidental to U.S. commercial fisheries (0.2 whales) is not known to exceed 10% of the PBR (10% of PBR = 16.1) and, therefore, can be considered to be insignificant. The total annual level of human-caused mortality and serious injury (44 whales) is not known to exceed the PBR (161) nor the IWC annual maximum strike limit (67). The Western Arctic bowhead whale stock has been increasing; the estimate of 16,892 from 2011 is between 31% and 170% of the pre-exploitation abundance of 10,000 to 55,000 estimated by Brandon and Wade (2004, 2006). However, the stock is classified as a strategic stock because the bowhead whale is listed as endangered under the U.S. Endangered Species Act and is therefore also designated as depleted under the MMPA.

HABITAT CONCERNS

Vessel traffic in arctic waters is increasing, largely due to an increase in oil and gas activities and commercial shipping. This increase in vessel traffic could result in an increased number of vessel collisions with bowhead whales (Huntington et al. 2015).

Increasing oil and gas development in the Arctic has led to an increased risk of various forms of pollution in bowhead whale habitat, including oil spills. Also of concern is noise produced by seismic surveys and vessel traffic resulting from shipping and offshore energy exploration, development, and production operations. Evidence indicates that bowhead whales are sensitive to noise from offshore drilling platforms and seismic survey operations (Richardson and Malme 1993, Richardson 1995, Davies 1997) and that bowhead whales often avoid sound sources associated with active drilling (Schick and Urban 2000) and seismic operations (Miller et al. 1999). Studies in the

1980s indicated that bowhead whales reacting to seismic activity in feeding areas appeared to recover from behavioral changes within 30-60 minutes following the end of the activity (Richardson et al. 1986, Ljungblad et al. 1988). However, more recent monitoring studies of 3-D seismic exploration in the nearshore Beaufort Sea during 1996-1998 demonstrated that nearly all fall-migrating bowhead whales avoided an area within 20 km of an active seismic source (Richardson et al. 1999). Furthermore, the studies also suggested that the bowhead whales' offshore displacement may have begun roughly 35 km (19 nautical miles or 22 statute miles) east of the activity and may have persisted more than 30 km to the west (Richardson et al. 1999). Richardson et al. (1986) observed that some feeding bowhead whales started to turn away from a 30-airgun array with a source level of 248 dB re 1 μPa at a distance of 7.5 km (4.7 mi) and swam away when the vessel was within about 2 km (1.2 mi); other whales in the area continued feeding until the seismic vessel was within 3 km (1.9 mi). More recent studies have similarly shown that feeding bowhead whales had a greater tolerance of higher sound levels than did migrating whales (Miller et al. 2005, Harris et al. 2007). Data from an aerial monitoring program in the Alaska Beaufort Sea during 2006-2008 also indicated that bowhead whales feeding during late summer and autumn did not exhibit large-scale distribution changes in relation to seismic operations (Funk et al. 2010). Persistent feeding behavior in the presence of seismic survey noise does not necessarily mean that the feeding bowhead whales are unaffected by the noise. Feeding bowhead whales may be sufficiently motivated to continue feeding in a given area despite noise-induced stress or physiological effects (MMS 2008). A study by Blackwell et al. (2015) found that bowhead whales react differently to different thresholds of seismic noise. At relatively low cumulative exposure levels (as soon as airguns were just detectable), bowhead whales almost doubled their call rates. Once cumulative exposure levels exceeded 127 dB re 1 μPa^2-s, call rates decreased. Bowhead whales went completely silent at received levels over 160 dB re 1 μPa^2-s. These authors note that the existence of two behavioral thresholds for calling by bowhead whales can explain results of previous studies that found variability in bowhead whale call rates in the presence or absence of airgun pulses (i.e., Greene et al. 1998).

Climate change is resulting in warming of northern latitudes at about twice the rate of more temperate latitudes, increasing the immediacy of this threat for bowhead whales and other arctic species. Global climate model projections for the next 50-100 years consistently show pronounced warming over the Arctic, accelerated sea-ice loss, and continued permafrost degradation (IPCC 2007, USGS 2011, Jeffries et al. 2015). Within the Arctic, some of the largest changes are projected to occur in the Bering, Beaufort, and Chukchi seas (Chapman and Walsh 2007, Walsh 2008). Ice-associated animals, including the bowhead whale, may be sensitive to changes in arctic weather, sea-surface temperatures, sea-ice extent, and the concomitant effect on prey availability. Laidre et al. (2008) concluded that on a worldwide basis, bowhead whales were likely to be moderately sensitive to climate change based on an analysis of various life-history features that could be affected by climate. Currently, there are insufficient data to make reliable projections of the effects of arctic climate change on bowhead whales. George et al. (2006) showed that landed bowhead whales had better body condition during years of light ice cover. Similarly, George et al. (2015a) found an overall improvement in bowhead whale body condition and a positive correlation between body condition and summer sea ice loss over the last 2.5 decades in the Pacific Arctic. George et al. (2015a) speculated that sea ice loss has positive effects on secondary trophic production within the Western Arctic bowhead whale's summer feeding region.

Appendix 1. Summary of changes to the 2016 stock assessments (last revised 12/30/2016). An 'X' indicates sections where the information presented has been updated since the 2015 stock assessments were released. Stock Assessment Reports for those stocks in boldface were updated in 2016.

Stock	Stock definition	Population size	PBR	Fishery mortality	Subsistence mortality	Status
Steller sea lion (Western U.S.)	X	X	X	X	X	X
Steller sea lion (Eastern U.S.)	X	X	X	X	X	X
Northern fur seal (Eastern Pacific)	X	X	X	X	X	X
Harbor seal (Aleutian Islands)						
Harbor seal (Pribilof Islands)						
Harbor seal (Bristol Bay)						
Harbor seal (North Kodiak)						
Harbor seal (South Kodiak)						
Harbor seal (Prince William Sound)						
Harbor seal (Cook Inlet/Shelikof Strait)						
Harbor seal (Glacier Bay/Icy Strait)						
Harbor seal (Lynn Canal/Stephens Passage)						
Harbor seal (Sitka/Chatham Strait)						
Harbor seal (Dixon/Cape Decision)						
Harbor seal (Clarence Strait)						
Spotted seal (Alaska)						
Bearded seal (Alaska)			X	X	X	X
Ringed seal (Alaska)	X	X	X	X	X	X
Ribbon seal (Alaska)						
Beluga whale (Beaufort Sea)						
Beluga whale (Eastern Chukchi Sea)						
Beluga whale (Eastern Bering Sea)						
Beluga whale (Bristol Bay)						
Beluga whale (Cook Inlet)	X	X		X	X	X
Narwhal (Unidentified)	X			X		
Killer whale (ENP Alaska Resident)				X		X
Killer whale (ENP Northern Resident)						
Killer whale (ENP Gulf of Alaska, Aleutian Islands, and Bering Sea Transient)				X		X
Killer whale (AT1 Transient)		X				
Killer whale (West Coast Transient)						
Pacific white-sided dolphin (North Pacific)						
Harbor porpoise (Southeast Alaska)	X	X	X	X		X
Harbor porpoise (Gulf of Alaska)	X	X		X		X
Harbor porpoise (Bering Sea)	X	X		X		X
Dall's porpoise (Alaska)						
Sperm whale (North Pacific)	X			X		X
Baird's beaked whale (Alaska)						
Cuvier's beaked whale (Alaska)						
Stejneger's beaked whale (Alaska)						
Humpback whale (Western North Pacific)	X			X	X	X
Humpback whale (Central North Pacific)	X	X		X		X
Fin whale (Northeast Pacific)	X	X	X	X		X
Minke whale (Alaska)						
North Pacific right whale (Eastern North Pacific)	X	X		X		X
Bowhead whale (Western Arctic)	X	X		X	X	X

Appendix 2. Stock summary table (last revised 12/30/2016). Stock Assessment Reports for those stocks in boldface were updated in 2016. N/A indicates data are unknown. UNDET (undetermined) PBR indicates data are available to calculate a PBR level but a determination has been made that calculating a PBR level using those data is inappropriate (see stock assessment for details).

Species	Stock	N_{EST}	CV	N_{MIN}	Year of last survey	R_{MAX}	F_R	PBR	Commer. fishery mort.	Native subsist. mort.	Total mort.	Status

N_{EST} = the AFSC Marine Mammal Laboratory's best estimate of the size of the population.
Status: S = Strategic, NS = Not Strategic.

[a]N_{EST} is the best estimate of pup and non-pup counts, which have not been corrected to account for animals at sea during abundance surveys.
[b]See text in Stock Assessment Report.
[c]N_{EST} is based on counts of individual animals identified from photo-identification catalogues. Surveys for abundance estimates of these stocks are conducted infrequently.

Appendix 3. Summary table for Alaska **Category 2** commercial fisheries (last updated 12/30/2016). Notice of continuing effect of list of fisheries.

Fishery (area, target species, and gear type)	Mngmt	Active Permits/Vessels[1]	Soak time	Landings per day	Sets per day	Season duration	Fishery trends (2012-2016)
AK Southeast salmon drift gillnet	State	451	20 min - 3 hrs; day/night	1	6 - 20	June 18 to Early Oct	# vessels stable but may vary with price of salmon; catch - high
AK Yakutat salmon set gillnet	State	149	continuous soak during opener; day/night	1	net picked every 2 - 4 hrs/day or continuous during peak	June 4 to mid-Oct	# sites fished stable; catch - variable
AK Prince William Sound salmon drift gillnet	State	529	15 min - 3 hrs; day/night	1 or 2	10 - 14	mid-May to end of Sept	# vessels stable; catch - stable
AK Cook Inlet salmon drift gillnet	State	548	15 min - 3 hrs or continuous; day only	1	6 - 18	June 25 to end of Aug	# vessels stable; catch - variable
AK Cook Inlet salmon set gillnet	State	717	continuous soak during opener, but net dry with low tide; upper CI - day/night lower CI - day only except during fishery extensions	1	upper CI - picked on slack tide lower CI - picked every 2 - 6 hrs/day	June 2 to mid-Sept	# sites fished stable; catch - up for sockeye and kings, down for pinks
AK Kodiak salmon set gillnet	State	182	continuous during opener; day only	1 or 2	picked 2 or more times	June 9 to end of Sept	# sites fished stable; catch - variable
AK Peninsula/Aleutian Islands salmon drift gillnet	State	150	2 -5 hrs; day/night	1	3 - 8	mid-June to mid-Sept	# vessels stable; catch up
AK Peninsula/Aleutian Islands salmon set gillnet	State	108	continuous during opener; day/night	1	every 2 hrs	June 18 to mid-Aug	# sites fished stable; catch - up since 90; down in 96
AK Bristol Bay salmon drift gillnet	State	1,811	continuous soaking of part of net while other parts picked; day/night	2	continuous	June 17 to end of Aug or mid-Sept	# vessels stable; catch - variable
AK Bristol Bay salmon set gillnet	State	941	continuous during opener, but net dry during low tide; day/night	1	2 or continuous	June 17 to end of Aug or mid-Sept	# sites fished stable; catch - variable
AK Bering Sea, Aleutian Islands flatfish trawl	Federal	31	near continuous, 3-4 hours; day/night	NA	~ 4 per day	Jan 20 to end of Dec	# of vessels stable, catch variable
AK Bering Sea, Aleutian Islands pollock trawl	Federal	100	near continuous, 3-4 hours; day/night	NA	~ 3 per day	Jan 20 to Nov 1	# of vessels stable, catch variable
AK Bering Sea, Aleutian Islands rockfish trawl	Federal	18	near continuous, 2-3 hours; day/night	NA	~ 3 per day	Jan 20 to end of Dec	# of vessels stable, catch variable
AK Bering Sea, Aleutian Islands Pacific cod longline	Federal	34	near continuous, 1-hours; day/night	1	~ 3 per day	Year-round	# of vessels stable, catch variable

[1]For state-managed fisheries, this is the number of active permits in 2016. For federally-managed fisheries, this is the number of active vessels participating in the fishery in 2015.

Appendix 4. Interaction table for Alaska **Category 2** commercial fisheries (last revised 12/30/2016). Notice of continuing effect of list of fisheries.

Fishery Name (area, target species, and gear type)	Mngmt	Active Permits/Vessels[1]	Observer data[2]	Species recorded as taken incidentally in this fishery (records dating back to 1988)	Data type
AK Southeast salmon drift gillnet	State	451	2012 - 2013	Steller sea lion, harbor seal, harbor porpoise, Dall's porpoise, Pacific white-sided dolphin, humpback whale, sea otter	logbook, observer, stranding data, self-reports
AK Yakutat salmon set gillnet	State	149	2007 - 2008	harbor seal, harbor porpoise (obs), humpback whale, gray whale (stranding)	logbook, observer, stranding
AK Prince William Sound salmon drift gillnet	State	529	1990 - 1991	Steller sea lion (obs), northern fur seal, harbor seal (obs), harbor porpoise (obs), Dall's porpoise, Pacific white-sided dolphin, sea otter	logbook, observer, stranding
AK Cook Inlet salmon drift gillnet	State	548	1999 - 2000	Steller sea lion, harbor seal, harbor porpoise, Dall's porpoise, Cook Inlet beluga whale (Note: observer program in 1999 and 2000 recorded one incidental mortality/serious injury of a harbor porpoise)	observer, logbook
AK Cook Inlet salmon set gillnet	State	717	1999 - 2000	harbor seal, harbor porpoise, Dall's porpoise, Cook Inlet beluga whale, humpback whale, Steller sea lion, sea otter (Note: observer program in 1999 and 2000 recorded one incidental mortality/serious injury of a harbor porpoise)	observer, logbook
AK Kodiak salmon set gillnet	State	182	2002, 2005	harbor seal, harbor porpoise, sea otter, Steller sea lion	observer, logbook
AK Peninsula/Aleutian Islands salmon drift gillnet	State	150	1990-1991	northern fur seal, harbor seal, harbor porpoise, Dall's porpoise (obs)	observer, logbook
AK Peninsula/Aleutian Islands salmon set gillnet	State	108	never observed	Steller sea lion, harbor porpoise, northern sea otter	logbook
AK Bristol Bay salmon drift gillnet	State	1,811	never observed	Steller sea lion, northern fur seal, harbor seal, spotted seal, Pacific white-sided dolphin, beluga whale, gray whale	logbook
AK Bristol Bay salmon set gillnet	State	941	never observed	northern fur seal, harbor seal, spotted seal, beluga whale, gray whale	logbook
AK Bering Sea, Aleutian Islands flatfish trawl	Federal	31	1976 - 2015	bearded seal, harbor porpoise (Bering Sea), harbor seal (Bering Sea), killer whale (Alaska Resident), killer whale (GOA, Aleutian Islands, and Bering Sea Transient), northern fur seal, spotted seal, ringed seal, ribbon seal, gray whale, Steller sea lion (Western U.S.), walrus, humpback whale	observer
AK Bering Sea, Aleutian Islands pollock trawl	Federal	100	1976 - 2015	Dall's porpoise, harbor seal, humpback whale (Central North Pacific), humpback whale (Western North Pacific), fin whale, killer whale (GOA, Aleutian Islands, and Bering Sea Transient), minke whale, ribbon seal, spotted seal, ringed seal, bearded seal, northern fur seal, Steller sea lion (Western U.S.), beluga whale	observer
AK Bering Sea, Aleutian Islands rockfish trawl	Federal	18	1976 - 2015	killer whale (Alaska Resident), killer whale (GOA, Aleutian Islands, and Bering Sea Transient)	observer
AK Bering Sea, Aleutian Islands Pacific cod longline	Federal	34	1976 - 2015	killer whale (Alaska Resident), killer whale (GOA, Aleutian Islands, and Bering Sea Transient), ribbon seal, northern fur seal, ringed seal, spotted seal, Steller sea lion (Western U.S.), Dall's porpoise	observer

[1]For state-managed fisheries, this is the number of active permits in 2016 and for federally-managed fisheries, this is the number of active vessels participating in the fishery in 2015.
[2]Observer data indicates the years of observer data included in these reports.

Note: Only species with positive records of being taken incidentally in a fishery since 1988 (the first year of the Marine Mammal Protection Act interim exemption program) have been included in this table. A species' absence from this table does not necessarily mean it is not taken in a particular fishery. Rather, in most fisheries, only logbook or stranding data are available which resulted in many reports of unidentified or misidentified marine mammals. Observer program indicates most recent year of observer data included in these reports.

AK herring spawn-on-kelp (hand pick/dive)	State	226	never observed	none documented	none
AK urchin and other fish/shellfish (hand pick/dive)	State	214	never observed	none documented	none
AK commercial passenger fishing vessel	State	1006	never observed	killer whale (stock unknown), Steller sea lion (Western U.S.), Steller sea lion (Eastern U.S.)	n/a
AK abalone	State	0	never observed	none documented	none
AK clam	State	87	never observed	none documented	none

[1]For state-managed fisheries, this is the number of active permits in 2016. For federally-managed fisheries, this is the number of active vessels participating in the fishery in 2015. For 'AK commercial passenger fishing vessel', this is the number of active vessels in the commercial passenger fishing vessel in 2014, the most current year of data available.
[2]Observer data indicates most recent year of observer data included in these reports. Prior to 2013, there were no observer data from vessels less than 60 feet in length, regardless of fishery. Also prior to 2013, there were no observer data for the halibut Individual Fishing Quota (IFQ) fishery, regardless of vessel size.

Note: Only species with positive records of being taken incidentally in a fishery since 1990 (the first year of the MMPA interim exemption logbook program) have been included in this table. A species' absence from this table does not necessarily mean it is not taken in a particular fishery. Rather, in most fisheries, only logbook or stranding data are available which resulted in many reports of unidentified or misidentified marine mammals.

Note: Observer coverages in the groundfish fisheries (trawl, longline, and pots) were determined by the percentage of tons caught which were observed. Observer coverage in the groundfish fisheries is assigned according to vessel length; where vessels greater than 125 feet have 100% coverage, vessels 60-125 feet have 30% coverage, and vessels less than 60 feet are not observed. Observer coverage in the groundfish fisheries varies by statistical area; the pooled percent coverage for all areas is provided here. Observer coverages in the drift gillnet fisheries were calculated as the percentage of the estimated sets that were observed. Observer coverages in the set gillnet fishery were calculated as the percentage of estimated setnet hours (determined by number of permit holders and the available fishing time) that were observed.

Appendix 7. Self-reported fisheries information.

The Marine Mammal Exemption Program (MMEP) was initiated in mid-1989 as a result of the 1988 amendments to the Marine Mammal Protection Act (MMPA). The MMEP required fishers involved in Category I and II fisheries to register with NMFS and to complete annual logbooks detailing each day's fishing activity, including: date fished, hours fished, area fished, marine mammal species involved, injured and killed due to gear interactions, and marine mammal species harassed, injured and killed due to deterrence from gear or catch. If the marine mammal was deterred, the method of deterrence was required, as well as indication of its effectiveness. Fishers were also required to report whether there were any losses of catch or gear due to marine mammals. These logbooks were submitted to NMFS on an annual basis, as a prerequisite to renewing their registration. Fishers participating in Category III fisheries were not required to submit complete logbooks, but only to report mortalities of marine mammals incidental to fishing operations. Logbook data are available for part of 1989 and for the period covering 1990-1993. Logbook data received during the period covering part of 1994 and all of 1995 was not entered into the MMEP logbook database in order for NMFS personnel to focus their efforts on implementing the 1994 amendments to the MMPA. Thus, aside from a few scattered reports from the Alaska Region, self-reported fisheries information is not available for 1994 and 1995.

In 1994, the MMPA was amended again to implement a long-term regime for managing mammal interactions with commercial fisheries (the Marine Mammal Authorization Program, or MMAP). Logbooks are no longer required. Instead, vessel owners/operators in any commercial fishery (Category I, II, or III) are required to submit one-page pre-printed reports for all interactions resulting in an injury or mortality to a marine mammal. The report must include the owner/operator's name and address, vessel name and ID, where and when the interaction occurred, the fishery, species involved, and type of injury (if animal was released alive). These postage-paid report forms are mailed to all Category I and II fishery participants that have registered with NMFS, and must be completed and returned to NMFS within 48 hours of returning to port for trips in which a marine mammal injury or mortality occurred. This reporting requirement was implemented in April 1996. During 1996, only 5 mortality/injury reports were received by fishers participating in all of Alaska's commercial fisheries. This level of reporting was a drastic drop in the number of reports compared to the numbers of interactions reported in the annual logbooks. As a result, the Alaska Scientific Review Group (SRG) considers the MMAP reports unreliable and has recommended that NMFS not utilize the reports to estimate marine mammal mortality (see June 1998 Alaska SRG meeting minutes; DeMaster 1998). As of the stock assessment reports for 2006, these records are no longer used to estimate annual fishery-related mortalities.

Appendix 8. Stock Assessment Reports published by the U.S. Fish and Wildlife Service.

POLAR BEAR (*Ursus maritimus*): Chukchi/Bering Seas Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

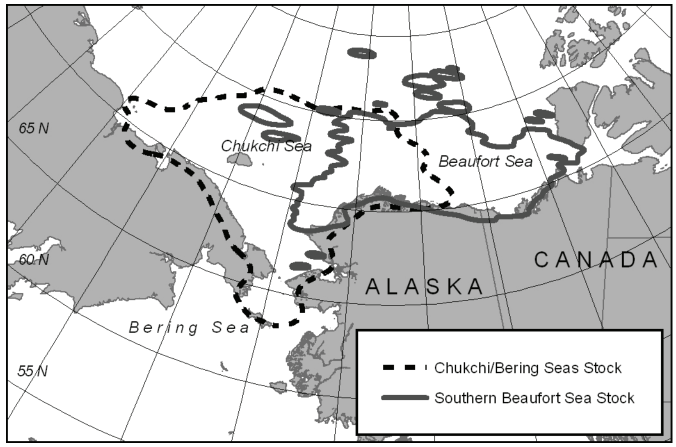

Figure 1. Map of the Southern Beaufort Sea and the Chukchi/Bering seas polar bear stocks.

Polar bears are circumpolar in their distribution in the northern hemisphere. They occur in several largely discrete stocks or populations (Harington 1968). Polar bear movements are extensive and individual activity areas are enormous (Garner *et al.* 1990, Amstrup *et al.* 2000). The parameters used by Dizon *et al.* (1992) to classify stocks based on the phylogeographic approach were considered in the determination of stock separation in Alaska. Several polar bear stocks are known to be shared between countries (Amstrup *et al.* 1986, Amstrup and DeMaster 1988). Lentfer hypothesized that in Alaska two stocks exist, the Southern Beaufort Sea (SBS) and the Chukchi/Bering seas (CBS), based upon: (a) variations in levels of heavy metal contaminants of organ tissues (Lentfer 1976, Lentfer and Galster 1987); (b) morphological characteristics (Manning 1971, Lentfer 1974, Wilson 1976); (c) physical oceanographic features which segregate the Chukchi Sea and Bering Sea stock from the Beaufort Sea stock (Lentfer 1974); and (d) movement information collected from mark and recapture studies of adult female bears (Lentfer 1974, 1983) (Figure 1). Information on contaminants (Woshner *et al.* 2001, Evans 2004a, Evans 2004b, Kannan *et al.* 2005, Smithwick *et al.* 2005, Verreault *et al.* 2005, Muir *et al.* 2006, Smithwick *et al.* 2006, Kannan *et al.* 2007, Rush *et al.* 2008) and movement data using satellite collars (Amstrup *et al.* 2004, Amstrup *et al.* 2005) continue to support the presence of these two stocks.

The CBS population is widely distributed on the pack ice in the Chukchi Sea and northern Bering Sea and adjacent coastal areas in Alaska and Russia. The northeastern boundary of the Chukchi/Bering seas stock is near the Colville Delta in the central Beaufort Sea (Garner *et al.*1990, Amstrup 1995, Amstrup *et al.* 2005) and the western boundary is near Chauniskaya Bay in the Eastern Siberian Sea. The boundary between the Eastern Siberian Sea stock and the Chukchi Sea stock is designated based on movements of adult female polar bears captured in the Bering and Chukchi seas region. Female polar bears initially captured and radio collared on Wrangel Island exhibited no movement into the Eastern Siberian Sea, while female polar bears captured and radio collared in the Eastern Siberian Sea, exhibited only limited short term movement into the western Chukchi Sea (Garner *et al.* 1990). The Chukchi/Bering seas stock extends into the Bering Sea and its southern boundary is determined by the annual extent of pack ice (Garner *et al.* 1990). Adult female polar bears captured from the Southern Beaufort Sea stock may make seasonal movements into the Chukchi Sea in an area of overlap located between Point Hope and Colville Delta, centered near Point Lay (Garner *et al.* 1990, Garner *et al.* 1994, Amstrup 1995, Amstrup *et al.* 2002, Amstrup *et al.* 2005). Probabilistic distribution information for zones of overlap between the Chukchi/Bering seas and the Southern Beaufort Sea population exist (Amstrup *et al.* 2004, Amstrup *et al.* 2005). Telemetry data indicate that these bears, marked in the Beaufort Sea, spend about 25% of their time in the northeastern Chukchi Sea, whereas females captured in the Chukchi Sea spend only 6% of their time in the Beaufort Sea (Amstrup 1995). Average activity areas of females in the Chukchi/Bering seas from 1986–1988 (244,463 km^2, range 144,659–351,369 km^2) (Garner *et al.* 1990) were more extensive than the Beaufort Sea from 1983– 1985 (96,924 km^2, range 9,739–269,622 km^2) (Amstrup 1986) or from 1985–1995 (166,694 km^2, range 14,440–616,800 km^2) (Amstrup *et al.* 2000). Radio collared adult females spent a greater proportion of their time in the Russian region than in the American region (Garner *et al.* 1990). Historically polar bears ranged as far south as St. Matthew Island (Hanna 1920) and the Pribilof Islands (Ray 1971) in the Bering Sea.

Analysis of mitochondrial DNA indicates little differentiation of the Alaska polar bear stocks (Cronin *et al.* 1991, Scribner *et al.* 1997, Cronin *et al.* 2006). Using 16 highly variable micro-satellite loci, Paetkau *et al.* (1999) determined that polar bears throughout the arctic (19 populations) are genetically similar. Genetically, polar bears in the southern Beaufort Sea differed more from polar bears in the Chukchi/Bering seas than from polar bears in the northern Beaufort Sea (Paetkau *et al.* 1999).

While genetically similar, demographic and movement data of the CBS population, indicates a high degree of site fidelity, suggesting that the stocks should be managed separately (Amstrup 2000, Amstrup *et al.* 2000, Amstrup *et al.* 2001a, Amstrup *et al.* 2002, Amstrup *et al.* 2004, Amstrup *et al.* 2005).

Past management has consistently distinguished between the southern Beaufort Sea and the Chukchi/Bering seas stocks. The Inuvialuit of the Inuvialuit Game Council (IGC), Northwest Territories, and the Inupiat of the North Slope Borough (NSB), Alaska, polar bear management agreement for the Southern Beaufort Sea stock was based on stock boundaries described previously (Brower *et al.* 2002, Nageak *et al.* 1991, Treseder and Carpenter 1989) and reaffirmed by the information in this stock assessment report.

POPULATION SIZE

Polar bears typically occur at low densities throughout their circumpolar range (DeMaster and Stirling 1981). It has been difficult to obtain a reliable population estimate for this population due to the vast and inaccessible nature of the habitat, movement of bears across international boundaries, logistical constraints of conducting studies in Russian territory, and budget limitations (Amstrup and DeMaster 1988, Garner *et al.* 1992, Garner *et al.* 1998, Evans *et al.* 2003). The Chukchi Sea population is estimated to comprise 2,000 animals, based on extrapolation of aerial den surveys (Lunn *et al.* 2002). Estimates of the population have been derived from observations of dens and aerial surveys (Chelintsev 1977, Stishov 1991a, Stishov 1991b, Stishov *et al.* 1991); however, these estimates (see below) have wide confidence intervals and are considered to be of little value for management and cannot be used to evaluate status and trends for this population.

Minimum Population Estimate

A reliable population estimate for the Chukchi/Bering seas stock currently does not exist. Lentfer, in the Administrative Law Judge (ALJ) proceeding to waive the Marine Mammal Protection Act of 1972 (MMPA) moratorium on taking and return management to the State of Alaska (ALJ 1977), estimated the size of the Chukchi/Bering seas population stock (Wrangel Island to western Alaska) at 7,000, and Chapman estimated the Alaska population (both stocks) at 5,550 to 5,700 (ALJ 1977). Lentfer and Chapman's estimates (ALJ 1977), however, were not based on rigorous statistical analysis of population data and variance estimates could not be calculated. Amstrup *et al.* (1986) estimated densities (1976–129 km^2/bear, 1981–211 km^2/bear) based on mark and recapture of 266 polar bears near Cape Lisburne on the Chukchi Sea, but a population estimate for the Chukchi Sea was not developed at that time. An August 2000 aerial survey of polar bears in the Eastern Chukchi Sea resulted in density estimates of (0.00748 bear/km^2, or 147 km^2/bear, C.V. = 0.38) (Evans *et al.* 2003). A population estimate was not derived from this density since the study area included only a portion of the total area used by the population.

Amstrup and DeMaster (1988) estimated the Alaska population (both stocks) at 3,000 to 5,000 animals based on densities calculated previously by Amstrup *et al.* (1986). The area that the estimate applied to and the variance associated with the estimate were not provided for in the 1988 population estimate (Amstrup and DeMaster 1988). A crude population estimate for the Chukchi/Bering seas stock of 1,200 to 3,200 animals was derived by subtracting the Beaufort Sea population estimate of 1,800 animals (Amstrup 1995) from the total Alaska statewide estimate of 3,000 to 5,000 (Amstrup and DeMaster 1988). The IUCN Polar Bear Specialist Group (IUCN 2006) estimated this population to be approximately 2,000 animals based on extrapolation of multiple years of denning data for Wrangel Island, assuming that 10% of the population dens annually as adult females. However, confidence in this estimate is low due to the lack of current denning estimates and reliable data with measurable levels of precision (IUCN 2006). Nonetheless, an N_{MIN} of 2,000 is the best available information we have at this time.

Current Population Trend

Prior to the 20th century, when Alaska's polar bears were hunted primarily by Alaskan Natives, both stocks probably existed at near carrying capacity (K). The size of the Beaufort Sea stock declined substantially in the late 1960's and early 1970's (Amstrup *et al.* 1986) due to excessive sport harvest. Similar declines could have occurred in the Chukchi Sea, although there are no population data to support this assumption. Since passage of the MMPA, the southern Beaufort Sea population grew during the late 1970's and 1980's and then stabilized during the 1990's (Amstrup *et al.* 2001b). Based on demographic data 2001 to 2006, the overall population growth rate in the Southern Beaufort Sea population declined approximately 0.3% per year (Hunter *et al.* 2007). Until 1992 it is likely that the Chukchi/Bering seas stock mimicked the growth pattern and later stability of Southern Beaufort Sea stock, since both stocks experienced similar management and harvest histories. However, since 1992 the CBS population has faced different stressors than the SBS population. These include increased harvest in Russia (150 – 250 bears/yr) (Kochnev 2006, Ovsyanikov 2006, Eduard Zdor personal communication) and greater loss of summer sea ice habitat from global warming (Overland and Wang 2007), which suggest that using the growth rate for the Southern Beaufort Sea may not be applicable. The status of the Chukchi/Bering seas stock was listed as data deficient (Aars *et al.* 2006) due to the lack of abundance estimates with measurable levels of precision. The population is believed to be declining and the status relative to historical levels is believed to be reduced based on harvest levels that were demonstrated to be unsustainable in the past.

MAXIMUM NET PRODUCTIVITY RATES

Polar bears are long lived, mature at a relatively old age, have an extended breeding interval, and have small litters (Lentfer *et al.* 1980, DeMaster and Stirling 1981). Population/stock specific data to estimate R_{MAX} are not available for the Chukchi/Bering seas polar bear stock. The Southern Beaufort Sea is one of four polar bear populations with long-term data sets and as it overlaps with the Chukchi/Bering seas stock using the default value for R_{MAX} for the Southern Beaufort Sea seems reasonable as it is based on empirical data. Survival rates for the Southern Beaufort Sea stock (Regehr *et al.* 2006), which can be used in a Leslie matrix model, suggest that under optimal conditions and in the absence of human perturbations the population could increase at a rate of between 4 and 6%. Amstrup (1995) projected an annual intrinsic growth rate (including natural mortality but not human-caused mortality) of 6.03% for the Southern Beaufort Sea stock using a Leslie type matrix of recapture data. Since the Chukchi/Bering seas area is one of the most productive areas in the Arctic using the 6.03% for the Chukchi/Bering seas polar bear stock seems reasonable.

POTENTIAL BIOLOGICAL REMOVAL (PBR)

Under the 1994 reauthorized MMPA, the potential biological removal (PBR) level is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: PBR = $(N_{MIN})(½\ R_{MAX})(F_R)$. Wade and Angliss (1997) recommend a default recovery factor (F_R) of 0.5 for a threatened population or when the status of a population is unknown. We used 0.5 as the recovery factor since reliable population estimates to assess population trends are not available. In the following calculation: $(N_{MIN})(½\ R_{MAX})(F_r)$ = PBR (Wade and Angliss 1997) the minimum population estimate, N_{MIN} was 2,000; the maximum rate of increase R_{MAX} was 6.03%; and the recovery factor F_R was 0.50. Therefore, the PBR level for the Chukchi/Bering seas stock is 30 bears per year. However, confidence in these numbers is low due to dated and extrapolated population information and, therefore, the PBR value has little utility for management purposes.

ANNUAL HUMAN CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Polar bear stocks in Alaska have no direct interaction with commercial fisheries activities. Consequently, the total fishery mortality and serious injury rate for the Chukchi/Bering seas stock is zero.

Alaska Native Subsistence Harvest

Historically, polar bears have been killed for subsistence, handicrafts, and recreation. Based on records of skins shipped from Alaska for 1925–53, the estimated annual statewide harvest averaged 120 bears, taken primarily by Native hunters. Recreational hunting by non-native sports hunters using aircraft was common from 1951–72, increasing statewide annual harvest to 150 during 1951–60 and to 260 during 1960–72 (Amstrup *et al.* 1986, Schliebe *et al.* 1995). Hunting by non-Natives has been prohibited since 1973 when provisions of the MMPA went into effect. This reduced the mean annual statewide harvest for both populations to 98 during 1980–2007 (SD=40; range 48–242) (USFWS unpublished data). The annual harvest from the Chukchi/Bering seas stock was 92/year in the 1980s, 49/year in the 1990s, and 43/year in the 2000s. More recently, the 2003−2007 average Alaska harvest for the Chukchi/Bering seas stock in Alaska was 37 and the sex ratio was 66M:34F.

Under the MMPA, an exemption was made for Alaska Natives living in coastal communities to allow them to hunt polar bears for subsistence and making of handicrafts provided that the hunt was not done in a wasteful manner. Recently, harvest levels by Alaska Natives from the Chukchi/Bering seas stock have been declining (Figure 2). The sex ratio of known-sex bears harvested since 1980 has remained relatively consistent at 66% males and 34% females (Schliebe *et al.* 2006).

The number of unreported kills in Alaska since 1980 to the present time is approximately 7% based on: (a) tagging information; (b) interviews with local hunters; and (c) law enforcement investigations. No user agreement, similar to that between the Inuvialuit and Inupiat for the Beaufort Sea stock, exists for the Bering/Chukchi stock. Harvest levels are not limited at this time.

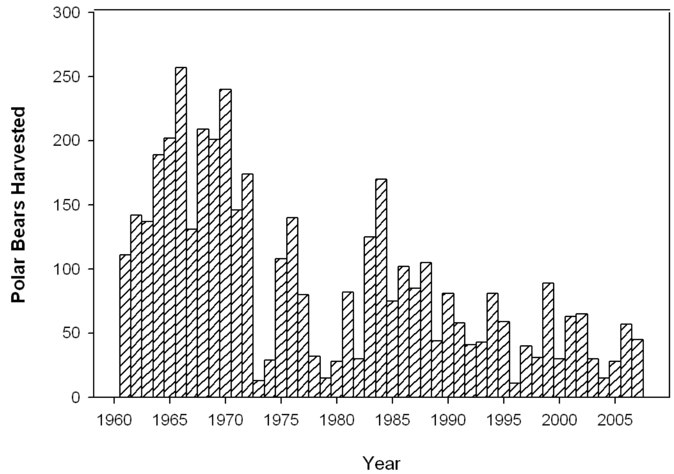

Figure 2. Annual Alaska polar bear harvest from the Chukchi/Bering Seas stock, 1961-2007.

Other Removals

Russia prohibited all hunting of polar bears in 1956 in response to perceived population declines caused by over-harvest. In Russia, only a small number of animals, less than 3–5 per year, were removed for placement in zoos prior to 1986 (Uspenski 1986) and a few were killed in defense of life. No bears were taken for zoos or circuses from 1993 to 1995 (Belikov 1998). The occurrence of increased takes of problem bears in Chukotka was acknowledged in 1992, and Belikov (1993) estimated that up to 10 problem bears were killed annually in all of the Russian Arctic. Increased illegal hunting of polar bears in the Russian Arctic was also recognized to have begun in 1992. While the magnitude of the illegal harvest in Russia from the Chukchi/Bering seas stock is unquantified, reports indicate that a substantial number of bears, 150–250/yr (Kochnev 2006), or alternatively 120–150/yr (Eduard Zdor pers. comm.), are being harvested. Combining the reported Chukotka harvest with the documented Alaska harvest indicates that up to 200 bears may have been harvested from this population in many years. Harvest levels similar to these are believed to have caused population depletion by the early 1970s. Belikov *et al.* (2006) indicated that the current level of poaching in Russia poses a serious threat to the population. No serious injuries, other than the mortalities discussed here, have been reported for the Chukchi/Bering seas stock.

No orphaned cubs from the Alaskan Chukchi/Bering seas stock were placed in zoos since 2002. Illegal harvest has not been detected in Alaska. Oil and gas exploration in the Bering/Chukchi region of Alaska, began again in 2006, primarily during the open water season has resulted in minimal interaction with polar bears; there was no evidence of mortality or serious injury.

STATUS OF STOCK

Polar bears in the Chukchi/Bering seas stock are currently classified as depleted under the MMPA and listed as threatened under the U.S. Endangered Species Act of 1973 (ESA) as amended. Reliable estimates of the minimum population, PBR level, and human-caused mortality or serious injury in Chukotka are currently not available

The ongoing level of the subsistence hunting in western Alaska and Chukotka is a concern. There is no incidental mortality or serious injury of polar bear in any U.S. commercial fishery. The primary concerns for this population are habitat loss resulting from climate change, potential over-harvest, human activities including industrial activities occurring within the near-shore environment, and potential effects of contaminants on nutritionally stressed populations. The Chukchi/Bering seas polar bear stock is designated as a strategic stock because the population is listed as threatened under the ESA.

Conservation Issues and Habitat Concerns

Oil and Gas Exploration

In 2008, the Minerals Management Service held an oil and gas lease sale for offshore blocks in the eastern Chukchi Sea. Polar bears from Chukchi/Bering seas stock seasonally use the shallow, productive, ice-covered waters of the eastern Chukchi Sea for feeding, breeding, and movements. The Fish and Wildlife Service (USFWS) works to monitor and mitigate potential impacts of oil and gas activities on polar bears through incidental take regulations (ITR) as authorized under the Marine Mammal Protection Act. Activities operating under these regulations must adopt measures to: ensure that the total of such incidental taking of polar bears remains negligible; minimize impacts to their habitat; and ensure no unmitigable adverse impact on their availability for Alaska Native subsistence use. ITR also specify monitoring requirements that provide a basis for evaluating potential impacts of current and future activities on marine mammals.

Climate Change

Polar bears evolved over thousands of years to life in a sea ice environment. They depend on the sea ice-dominated ecosystem to support essential life functions. Sea ice provides a platform for hunting and feeding, for seeking mates and breeding, for movement to terrestrial maternity denning areas and occasionally for maternity denning, for resting, and for long-distance movements. The sea ice ecosystem supports ringed seals, the primary prey for polar bears, and other marine mammals that are also part of their prey base.

Sea ice is rapidly diminishing throughout the Arctic and large declines in optimal polar bear habitat have occurred in the Southern Beaufort and Chukchi Seas between the two time periods, 1985–1995 and 1996–2006 (Durner et al 2009). In addition, it is predicted that the greatest declines in 21st century optimal polar bear habitat will occur in Chukchi and Southern Beaufort Seas (Durner *et al.* 2009a). Patterns of increased temperatures, earlier onset of and longer melting periods, later onset of freeze-up, increased rain-on-snow events, and potential reductions in snowfall are occurring. In addition, positive feedback systems (i.e., the sea-ice albedo feedback mechanism) and naturally occurring events, such as warm water intrusion into the Arctic and changing atmospheric wind patterns, can operate to amplify the effects of these phenomena. As a result, there is fragmentation of sea ice, a dramatic increase in the extent of open water areas seasonally, reduction in the extent and area of sea ice in all seasons, retraction of sea ice away from productive continental shelf areas throughout the polar basin, reduction of the amount of heavier and more stable multi-year ice, and declining thickness and quality of shore-fast ice (Parkinson et al 1999, Rothrock *et al.* 1999, Comiso 2003, Fowler *et al.* 2004, Lindsay and Zhang 2005, Holland *et al.* 2006, Comiso 2006, Serreze *et al.* 2007, Stroeve *et al.* 2008).

The Chukchi/Bering seas and the Southern Beaufort Sea population stocks are currently experiencing the initial effects of changes in sea ice conditions (Rode *et al.* 2007, Regehr *et al.* 2007, Hunter *et al.* 2007). These populations are vulnerable to large-scale dramatic seasonal fluctuations in ice movements, decreased abundance and access to prey, and increased energetic costs of hunting. The USFWS is working on measures to protect polar bears and their habitat.

Subsistence Harvest

Past differences in management regimes between the United States and Russia have made coordination of studies on the shared Alaska-Chukotka polar bear population difficult. In the former Soviet Union, hunting of polar bears was banned nationwide in 1956. Recently, Russia's ability to enforce that ban has been difficult due to logistical and financial constraints. In Alaska, subsistence hunting of polar bears by Alaska Natives is currently unrestricted under section 101(b) of the MMPA provided that the take is for subsistence purposes or creating authentic articles of Alaska Native handicrafts and conducted in a non-wasteful manner. While several joint research and management projects have been successfully undertaken in the past between the United States and Russia, today comparable efforts are either no longer occurring or are unilateral in scope.

The bilateral "Agreement between the United States and the Russian Federation on the Conservation and Management of the Alaska-Chukotka Polar Bear Population (Agreement)" was signed by the governments of the United States and the Russian Federation on October 16, 2000, with subsequent advice and consent provided by the U.S. Senate. Among other provisions the Agreement recognizes the needs of Native people to harvest polar bears for subsistence purposes and includes provisions for developing sustainable harvest limits, allocation of the harvest between jurisdictions, and compliance and enforcement. Each jurisdiction is entitled to up to one-half of a harvest limit to be determined by a future the joint Commission. The Agreement reiterates requirements of the 1973 multi-lateral agreement and includes restrictions on harvesting denning bears, females with cubs, or cubs less than one year old, and prohibitions on the use of aircraft, large motorized vessels, and snares or poison for hunting polar bears.

On January 12, 2007, President Bush signed into law H.R. 5946, the "Magnuson-Stevens Fishery Conservation and Management Reauthorization Act of 2006." This Act includes Title X implementing the Agreement. This action allows for the establishment of the commission and development of enforceable harvest management agreements. The Russian Federation and the United States have completed documents necessary to implement the Agreement within Russia and the United States. The USFWS is currently developing recommendations for the Bilateral Commission that will direct research and establish sustainable and enforceable harvest limits needed to address current potential population declines due to over-harvest of the population.

POLAR BEAR (*Ursus maritimus*): Southern Beaufort Sea Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Polar bears are circumpolar in their distribution in the northern hemisphere. They occur in several largely discrete stocks or populations (Harington 1968). Polar bear movements are extensive and individual activity areas are enormous (Garner et al. 1990, Amstrup et al. 2000). The parameters used by Dizon et al. (1992) to classify stocks based on the phylogeographic approach were considered in the determination of stock separation in Alaska. Several polar bear stocks are known to be shared between countries (Amstrup et al. 1986, Amstrup and Demaster 1988). Lentfer hypothesized that two Alaska stocks exist, the Southern Beaufort Sea, and the Chukchi/Bering Seas, based upon: (a) variations in levels of heavy metal contaminants of organ tissues (Lentfer 1976, Lentfer and Galster 1987); (b) morphological characteristics (Manning 1971; Lentfer 1974; Wilson 1976); (c) physical oceanographic features which segregate stocks (Lentfer 1974) and; (d) movement information collected from mark and recapture studies of adult female bears (Lentfer 1983) (Figure 1). Information on contaminants (Woshner et al. 2001, Evans 2004a, Evans 2004b, Kannan et al. 2005, Smithwick et al. 2005, Verreault et al. 2005, Muir et al. 2006, Smithwick et al. 2006, Kannan et al. 2007, Rush et al. 2008) and movement data using satellite collars (Amstrup et al. 2004, Amstrup et al. 2005) continue to support the existence of these two stocks.

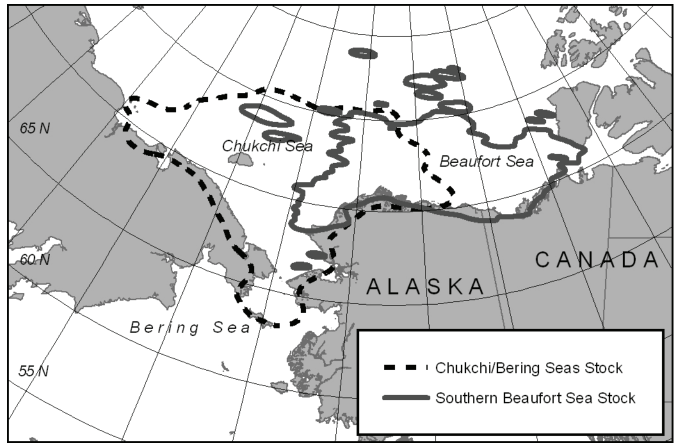

Figure 1. Map of the Southern Beaufort Sea and the Chukchi/Bering seas polar bear stocks.

Amstrup et al. (2000) demonstrated that the eastern boundary of the Southern Beaufort Sea stock occurs south of Banks Island and east of the Baillie Islands, Canada. The bears in the Northern Beaufort Sea and Southern Beaufort Sea populations spend the summer on pack ice and move toward the coast during fall, winter, and spring (Durner et al. 2004). The range of the two populations previously overlapped extensively in the vicinity of the Baille Islands, Canada (Amstrup 2000) but recent data no longer support this degree of overlap (Amstrup et al. 2005). Recent analysis of polar bear movements using satellite telemetry from 2000 to 2006 (Amstrup et al. 2004, Amstrup et al. 2005), capture and recapture data (Regehr et al. 2006, Stirling et al. 2007), and harvest information suggest that the eastern population boundary has shifted westward to near the village of Tuktoyaktuk, Canada. The assignment of this new boundary could be adjusted somewhat based on local management considerations; however, it will probably necessitate a downward readjustment of the population size of the Southern Beaufort Sea stock to correspond with the smaller geographic area. The proposed boundary change is under consideration and has not been accepted by the parties to the Polar Bear Management Agreement for the Southern Beaufort Sea between the Inuvialuit Game Council of Canada and the North Slope Borough of Alaska. For the purposes of this report, we continue to use the previously published boundaries for the Southern Beaufort Sea population delineated by Amstrup et al. (2000). The western boundary is near Point Hope. An extensive area of overlap between the Southern Beaufort Sea stock and the Chukchi/Bering seas stock occurs between Point Barrow and Point Hope, centered near Point Lay (Garner et al. 1990, Garner et al. 1994, Amstrup et al. 2000). The southern boundary of the Northern Beaufort Sea stock in the Canadian Arctic was delineated by Bethke et al. (1996). Telemetry data indicates that adult female polar bears marked in the Southern Beaufort Sea spend about 25% of their time in the northeastern Chukchi Sea, whereas females captured in the Chukchi Sea spend only 6% of their time in the Southern Beaufort Sea (Amstrup 1995). However, polar bears are not dispersed evenly throughout their range. To access ringed and bearded seals, polar bears in the Southern Beaufort Sea concentrate in shallow waters less that 300 m deep over the continental shelf and in areas with >50% ice cover (Stirling et al. 1999, Durner et al. 2004, Durner et al. 2006a, Durner et al. 2009). Polar bears from this population have historically denned on both the sea ice and land. Thinning of the sea ice in recent years has caused a decline in the number of polar bears denning on the sea ice. Fischbach et al. (2007) found that the proportion of dens on the pack ice declined from 62% from 1985—1994 to 37% in 1998-2004. The main terrestrial denning areas for the Southern Beaufort Sea population in Alaska occur on the barrier islands from Barrow to Kaktovik and along coastal areas up to 25 miles inland including the Arctic National Wildlife Refuge to Peard Bay, west of Barrow (Amstrup and Gardner 1994, Amstrup 2000, Durner et al. 2001, Durner et al. 2006b).

In response to changes in the sea ice characteristics and declines in sea ice habitat over the continental shelf during the summer and late fall, some polar bears have changed distribution to search for seals and to access the remains of subsistence harvested bowhead whales (Schliebe et al. 2008). It is expected that changes in the distribution and movements may occur with increasing frequency in the future (Durner et al. 2009, Schliebe et al. 2008) Polar bears may also become more nutritionally stressed due to global climate changes in the Arctic (Stirling and Parkinson 2006) and, thus, continued monitoring is required to document these changes.

Analysis of mitochondrial DNA and microsatellite DNA loci indicates little differentiation of the Alaska polar bear stocks (Cronin et al. 1991, Scribner et al. 1997, Cronin et al. 2006). Using 16 highly variable micro satellite loci, Paetkau et al. (1999) determined that polar bears throughout the arctic (19 populations) were genetically very similar. Genetically, polar bears in the Southern Beaufort Sea differed more from polar bears in the Chukchi/Bering Seas than from polar bears in the Northern Beaufort Sea (Paetkau et al. 1999, Thiemann et al. 2008). While genetically similar, demographic and movement data indicates a high degree of site fidelity, suggesting that the stocks should be managed separately (Amstrup 2000, Amstrup et al. 2000, Amstrup et al. 2001a, Amstrup et al. 2002, Amstrup et al. 2004, Amstrup et al. 2005).

POPULATION SIZE

Polar bears occur at low densities throughout their circumpolar range (DeMaster and Stirling 1981). They are long lived, mature late, have an extended breeding interval, and have small litters (Lentfer et al. 1980, DeMaster and Stirling 1981, Amstrup 2003). Accurate population estimates for the Alaskan populations have been difficult to obtain because of low population densities, inaccessibility of the habitat, movement of bears across international boundaries, and budget limitations (Amstrup and DeMaster 1988, Garner et al. 1992). Research on the Southern Beaufort Sea population began in 1967 and is one of only four polar bear populations with long term (>20 yrs) data.

Amstrup et al. (1986) estimated the Southern Beaufort Sea stock at 1,778 (S.D. ± 803; C.V. = 0.45) during the 1972-83 period. Amstrup (1995) estimated the Southern Beaufort Sea stock near 1,480 animals in 1992. Amstrup (USGS unpublished data) using data for the 1986-98 period (excluding 4 unsampled years), estimated the population at 2,272 in 2001. This total population estimate was based on as estimate of 1,250 females (C.V. = 0.17) and a sex ratio of 55% females (Amstrup et al. 2001b). The population estimate of 1,526 (95% CI =1211−1841; C.V. = 0.106) (Regehr et al. 2006), which is based on open population capture-recapture data collected from 2001 to 2006, is considered the most current and valid population estimate.

Minimum Population Estimate

N_{MINn} is calculated as follows $N/exp(0.842 * (ln(1+CV(N)^2))^{½})$ and is 1,397 bears for population size of 1,526 and C.V. of 0.106. This population estimate applies to an area that extends from Pt. Barrow in the west, east to the Baillie Islands in Canada.

Current Population Trend

Prior to the 20th century, when Alaska's polar bears were hunted primarily by Natives, both the Chukchi/Bering seas and Southern Beaufort Sea stocks probably existed near carrying capacity (K). Once harvest by non-Natives became common in the Southern Beaufort Sea in the early 1960s, the size of these stocks declined substantially (Amstrup et al. 1986, Amstrup 1995). Since passage of the Marine Mammal Protection Act (MMPA) in 1972, both Alaska polar bear stocks seem to have increased; this is based on: (a) mark and recapture data; (b) observations by Natives and residents of coastal Alaska and Russia; (c) catch per unit effort indices (USGS unpublished data); (d) reports from Russian scientists (Uspenski and Belikov 1991); and (e) harvest statistics on the age structure of the population. Recapture data from the stock indicated a population growth rate of 2.4% from 1981 to 1992 (Amstrup 1995).

The Southern Beaufort Sea stock experienced little or no growth during the 1990's (Amstrup et al. 2001b). Declining survival, recruitment, and body size (Regehr et al. 2006, Regehr et al. 2007), and low growth rates (λ) during years of reduced sea ice during the summer and fall (2004 and 2005), and an overall declining growth rate of 3% per year from 2001-2005 (Hunter et al. 2007) indicates that the Southern Beaufort Sea population is now declining.

MAXIMUM NET PRODUCTIVITY RATES

Population/stock specific data to estimate R_{MAX} are not available for the stock. Taylor et al. (1987) estimated the sustainable yield of the female component of the population at < 1.6% per annum. The following information is used to understand the R_{MAX} determination. From 1981-92, when the population was increasing, vital rates of polar bears in the Southern Beaufort Sea were as follows: average age of sexual maturity (females) was 6 years; average COY litter size was 1.67; average reproductive interval was 3.68 years; and average annual natural mortality (nM), which varies by age class, ranged from 1-3% for adults (Amstrup 1995).

Amstrup (1995) projected an annual intrinsic growth rate (including natural mortality but not human-caused mortality) of 6.03% for the Southern Beaufort Sea stock using a Leslie type matrix of recapture data. This analysis mimics a life history scenario where environmental resistance is low and survival high.

POTENTIAL BIOLOGICAL REMOVAL (PBR)

Under the 1994 reauthorized MMPA, the potential biological removal (PBR) level is defined as the product of the minimum population estimate, one-half the maximum theoretical net productivity rate, and a recovery factor: PBR = $(N_{MIN})(\frac{1}{2} R_{MAX})(F_R)$. Wade and Angliss (1997) recommend a default recovery factor (F_R) of 0.5 for a threatened population or when the status of a population is unknown. In the following calculation: $(N_{MIN})(\frac{1}{2} R_{MAX})(F_r)$ = PBR (Wade and Angliss 1997) the minimum population estimate, N_{MIN} was 1,397; the maximum rate of increase R_{MAX} was 6.03%; and the recovery factor F_R was 0.5. Therefore, the PBR level for the Southern Beaufort Sea stock is 22 bears per year.

ANNUAL HUMAN CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Polar bear stocks in Alaska have no direct interaction with commercial fisheries activities. Consequently, the total fishery mortality and serious injury rate for the Southern Beaufort Sea stock is zero.

Alaska Native Subsistence Harvest

Historically, polar bears have been killed for subsistence, handicrafts, and recreation (sport hunting). Based upon records of skins shipped from Alaska, the estimated annual statewide harvest (both stocks) for 1925−53 averaged 120 bears taken primarily by Native hunters. Sport hunting using aircraft was common from 1951−72, increasing annual harvest in Alaska to 150 during 1951-60 and to 260 during 1960−72 (Amstrup et al. 1986; Schliebe et al.1995). The annual harvest for the Southern Beaufort Sea stock was 81/year from 1960−1972. Although polar bear hunting was prohibited by the MMPA, an exemption was made for Alaska Natives living in coastal communities to allow them to hunt polar bears for subsistence and making of handicrafts provided that the hunt was not done in a wasteful manner. The cessation of sport hunting in 1972 reduced the mean annual combined harvest for both Alaskan stocks to 98 during 1980−2007 (SD=40; range 48−242) (USFWS unpublished data). The annual harvest from the Southern Beaufort Sea was 39/year in the 1980s, 33/year in the 1990s, and 32/year in the 2000s. More recently, the 2003−2007 average Alaska harvest for the Southern Beaufort Sea in Alaska was 33 and the sex ratio was 67M:33F. During the same time period the average Canadian harvest for the Southern Beaufort Sea was 21.0 and the sex ratio was 45M:55F. The combined average annual Alaska and Canada harvest during the past five years was 53.6. Figure 2 illustrates the annual Alaska polar bear harvest and trend for the Southern Beaufort Sea stock from 1961−2007. No serious injuries, other than the mortalities discussed here, have been reported for the Southern Beaufort Sea stock.

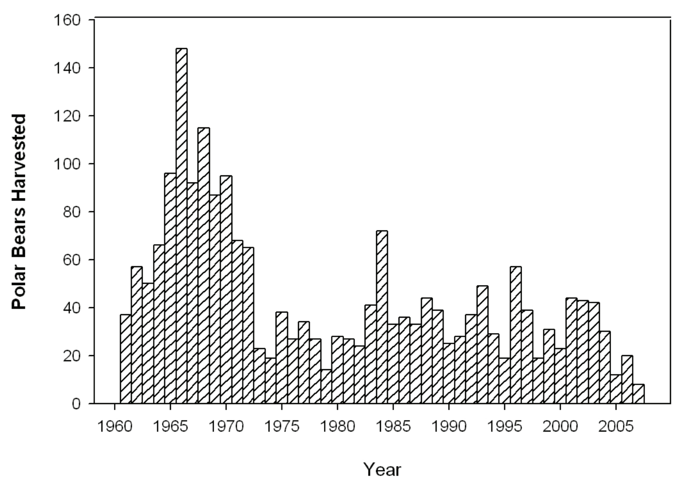

Figure 2. Annual Alaska polar bear harvest from the Southern Beaufort Sea stock, 1961-2007.

During the 1980–2007 period the Alaska harvest from the Southern Beaufort Sea accounted for 34% of the total Alaska kill (annual mean=33 bears) with the remaining 66% occurring in the Chukchi Sea. The sex ratio of the harvest from 1980–2007 in the Southern Beaufort Sea was 69M:31F.

Other Removals

Orphaned cubs are occasionally removed from the wild and placed in zoos; no cubs were placed into public display facilities during the past five years. One bear died as a result of research mortality and two bears were euthanized during the last five years. Activities operating under "incidental take" regulations, associated with the oil and gas industry, have the potential to impact polar bears and their habitat. During the past five years no lethal takes related to industrial activities of polar bears have occurred. Three lethal takes related to oil and gas activities have been documented in the Southern Beaufort Sea: one at an offshore drilling site in the Canadian Beaufort Sea (1968); one bear at the Stinson site in the Alaska Beaufort Sea (1990); and one bear that ingested ethylene glycol stored at an offshore island in the Alaska Beaufort Sea (1988). In 1993, a polar bear was killed at the Oliktok remote radar defense site when it broke into a residence and severely mauled a worker.

STATUS OF STOCK

The Southern Beaufort Sea Stock is currently classified as depleted under the MMPA and listed as threatened under the U.S. Endangered Species Act of 1973 (ESA), as amended. The primary concerns for this population are loss of the sea ice habitat due in part to climate changes in the Arctic, potential overharvest, and current and proposed human activities including industrial activities occurring in the nearshore and offshore environment. Recent data on the vital rates, population estimate, and growth rates for the Southern Beaufort Sea suggests that this population stock is declining. Because of its status as a threatened species under the ESA, the Southern Beaufort Sea population is designated as a strategic stock.

Conservation Issues and Habitat Concerns

Oil and Gas Exploration

The Minerals Management Service (MMS) (2004) estimated an 11 percent chance of a marine spill greater than 1,000 barrels in the Beaufort Sea from the Beaufort Sea Multiple Lease Sale in Alaska. Amstrup et al. (2006) evaluated the potential effects of a hypothetical 5,912-barrel oil spill (the largest spill thought possible from a pipeline spill) on polar bears from the Northstar offshore oil production facility in the southern Beaufort Sea, and found that there is a low probability that a large number of bears (i.e., 25–60) might be affected by such a spill. For the purposes of this scenario, it was assumed that a polar bear would die if it came in contact with the oil. Amstrup et al. (2006) found that 0–27 bears could potentially be oiled during the open water conditions in September; and from 0–74 bears in mixed ice conditions during October. If such a spill occurred, particularly during the broken ice period, the impact of the spill could be significant to the Southern Beaufort Sea polar bear population (Amstrup et al. 2006, 65 FR 16828; March 30, 2000). At the time that Amstrup did this analysis, the sustainable harvest yield per year for the Southern Beaufort Sea polar bear population, based on a stable population size of 1,800 bears, was estimated to be 81.1 bears (1999–2000 to 2003–2004) (Lunn et al. 2005). For the same time period, the average harvest was 58.2 bears, leaving an additional buffer of 23 bears that could have been removed from the population. Therefore, an oil spill that resulted in the death of greater than 23 bears, which was possible based on the range of oil spill-related mortalities from the previous analysis, could have had population level effects for polar bears in the southern Beaufort Sea. However, the harvest figure of 81 bears may no longer be sustainable for the Southern Beaufort Sea population so, given the average harvest rate cited above, fewer than 23 oil spill-related mortalities could result in a population decline or increase the time required for recovery.

The Fish and Wildlife Service (USFWS) works to monitor and mitigate potential impacts of oil and gas activities on polar bears through incidental take regulations (ITR) as authorized under the Marine Mammal Protection Act. Activities operating under these regulations must adopt measures to: ensure that the total taking of polar bears remains negligible; minimize impacts to their habitat; and ensure no unmitigable adverse impact on their availability for Alaska Native subsistence use. ITR also specify monitoring requirements that provide a basis for evaluating potential impacts of current and future activities on marine mammals.

Climate Change

Polar bears evolved over thousands of years to life in a sea ice environment. They depend on the sea ice-dominated ecosystem to support essential life functions. Sea ice provides a platform for hunting and feeding, for seeking mates and breeding, for movement to terrestrial maternity denning areas and occasionally for maternity denning, for resting, and for long-distance movements. The sea ice ecosystem supports ringed seals, the primary prey for polar bears, and other marine mammals that are also part of their prey base.

Sea ice is rapidly diminishing throughout the Arctic and large declines in optimal polar bear habitat have occurred in the Southern Beaufort and Chukchi Seas between the two time periods, 1985–1995 and 1996–2006 (Durner et al. 2009). In addition, it is predicted that the greatest declines in 21st century optimal polar bear habitat will occur in Chukchi and Southern Beaufort Seas (Durner et al. 2009). Patterns of increased temperatures, earlier onset of and longer melting periods, later onset of freeze-up, increased rain-on-snow events, and potential reductions in snowfall are occurring. In addition, positive feedback systems (i.e., the sea-ice albedo feedback mechanism) and naturally occurring events, such as warm water intrusion into the Arctic and changing atmospheric wind patterns, can operate to amplify the effects of these phenomena. As a result, there is fragmentation of sea ice, a dramatic increase in the extent of open water areas seasonally, reduction in the extent and area of sea ice in all seasons, retraction of sea ice away from productive continental shelf areas throughout the polar basin, reduction of the amount of heavier and more stable multi-year ice, and declining thickness and quality of shore-fast ice (Parkinson et al 1999, Rothrock et al. 1999, Comiso 2003, Fowler et al. 2004, Lindsay and Zhang 2005, Holland et al. 2006, Comiso 2006, Serreze et al. 2007, Stroeve et al. 2008).

The Chukchi/Bering Seas and the Southern Beaufort Sea population stocks are currently experiencing the initial effects of changes in sea ice conditions (Rode et al. 2007, Regehr et al. 2007, Hunter et al. 2007). These populations are vulnerable to large-scale dramatic seasonal fluctuations in ice movements, decreased abundance and access to prey, and increased energetic costs of hunting. The USFWS is working on measures to protect polar bears and their habitat.

Subsistence Harvest

Recognition that the polar bears in the southern Beaufort Sea were shared between Canada and the Alaska led to the development of the Polar Bear Management Agreement for the Southern Beaufort Sea between the Inuvialuit of the Inuvialuit Game Council (IGC), Canada and the Inupiat of the North Slope Borough (NSB) Alaska in 1988 (Nageak et al. 1991, Treseder and Carpenter 1989, Prestrud and Stirling 1994, Brower et al. 2002). Since initiation of this local user agreement in 1988, the combined Alaska/Canada mean harvest from this stock has been 56.9 bears per year (1988-2007). The harvest in Canada is limited primarily to Native hunters and is regulated by a quota system (Prestrud and Stirling 1994, Brower et al. 2002). Canada has a well regulated and controlled harvest, which has resulted in accurate harvest reporting, strict controls on the harvest, and efficient monitoring and enforcement. The harvest management system in Alaska is voluntary and is less efficient overall than the Canadian system (Brower et al 2002).

The calculation of a PBR level for the Southern Beaufort Sea stock is required by the MMPA even though the subsistence harvest quota is managed under the authority of the Polar Bear Agreement between the NSB and the IGC. Accordingly, the quota from the Board of Commissioners for the Polar Bear Agreement takes precedence over the PBR estimate for the purposes of managing the Alaska Native subsistence harvest from this stock. The Southern Beaufort Sea population is currently thought to be declining; therefore, overharvest could hasten the decline or prevent and/or slow the recovery. Analysis is currently underway to evaluate the effects of different harvest levels on the population dynamics of the Southern Beaufort Sea population.

PACIFIC WALRUS (*Odobenus rosmarus divergens*):

Alaska Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

The family Odobenidae is represented by a single modern species, *Odobenus rosmarus,* of which two subspecies are generally recognized: the Atlantic walrus (*O. r. rosmarus*) and the Pacific walrus (*O. r. divergens*). The two subspecies occur in geographically isolated populations. The Pacific walrus is the only stock occurring in United States waters and considered in this account.

Pacific walruses range throughout the continental shelf waters of the Bering and Chukchi Seas, occasionally moving into the East Siberian Sea and the Beaufort Sea (Figure 1). During the summer months most of the population migrates into the Chukchi Sea; however, several thousand animals, primarily adult males, aggregate near coastal haulouts in the Gulf of Anadyr, Russia; Bering Strait, and Bristol Bay, Alaska. During the winter breeding season walruses are found in three concentration areas of the Bering Sea where open leads, polynyas, or thin ice occur (Fay *et al.* 1984, Garlich-Miller *et al.* 2011a). While the specific location of these groups varies annually and seasonally depending upon the extent of the sea ice, generally one group occurs near the Gulf of Anadyr, another south of St. Lawrence Island, and a third in the southeastern Bering Sea south of Nunivak Island into northwestern Bristol Bay. However, Pacific walruses are currently managed as a single panmictic population. Scribner *et al.* (1997) found no difference in mitochondrial and nuclear DNA among walruses sampled shortly after the breeding season from four areas of the Bering Sea (Gulf of Anadyr, Koryak Coast, Southeast Bering Sea, and St. Lawrence Island).

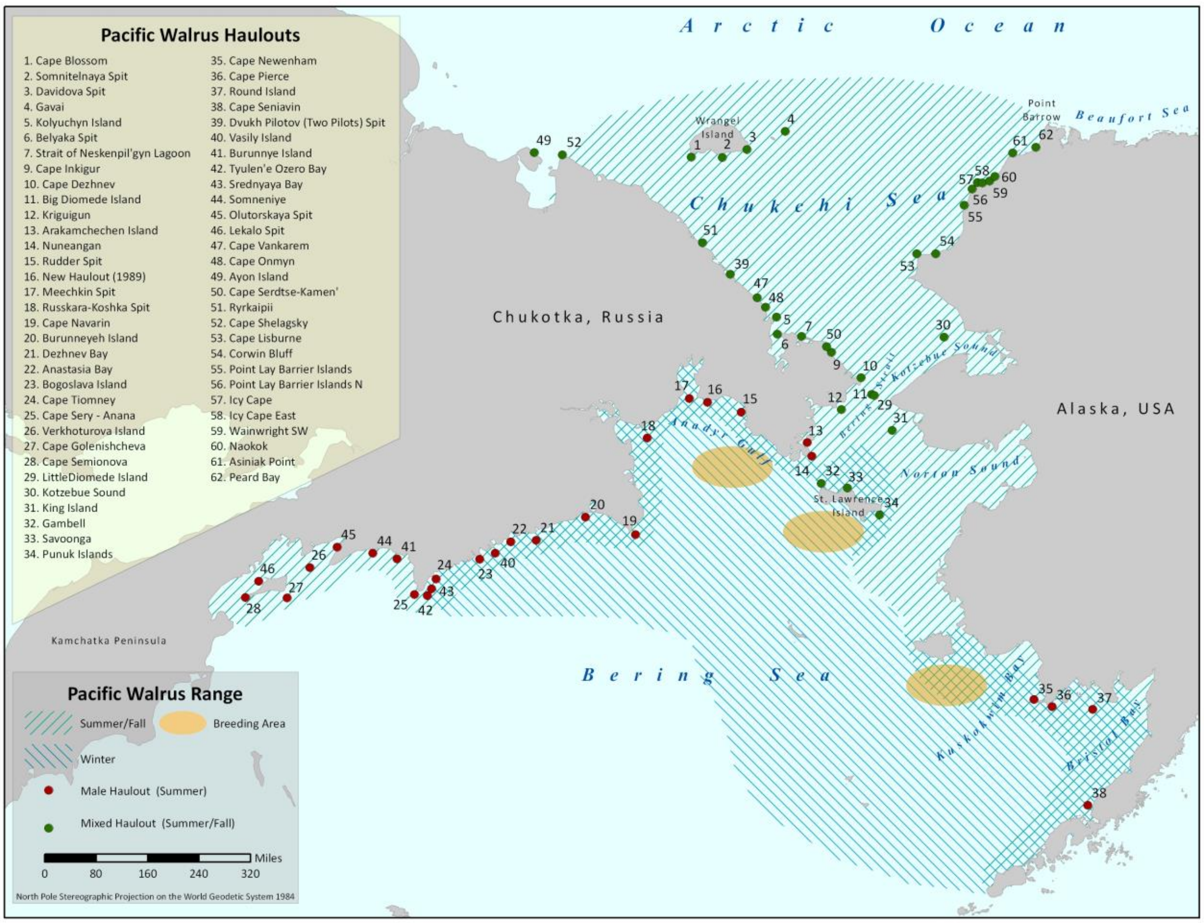

Figure 1. Seasonal distribution, breeding areas, and coastal haulouts of Pacific walruses in the Bering and Chukchi Seas. Modified from Smith 2010.

Pacific walruses typically use sea-ice as a resting platform between feeding dives, as a birthing substrate, for shelter from storms, isolation from predators, and passive transportation (Fay 1982). Historically, the summer distribution of walruses in the Chukchi Sea occurred primarily on sea ice over the continental shelf from the Alaska to Chukotka coasts with large numbers of animals near Hanna Shoal in the United States and Wrangel Island in the Russian Federation. A few animals would be observed utilizing haulouts along both the Alaska and Chukotka coasts, particularly in the fall. While the overall geographic range of Pacific walruses has not changed, over the past decade the number of walruses coming to shore along the coastline of the Chukchi Sea in both Alaska and Chukotka has increased from the hundreds to thousands to greater than 100,000 (Kavry *et al.* 2008, Garlich-Miller *et al.* 2011*a*, Jay *et al.* 2011). Additionally, adult female and young walruses are arriving at these coastal haulouts as much as a month earlier and staying at the coastal haulouts a week or two longer. In fall 2007, 2009, 2010, and 2011 large walrus aggregations (3,000 to 20,000) were observed along the Alaska coast (Garlich-Miller *et al*. 2011*a*). This increased use of coastal haulouts is a function of the loss of summer sea ice over the continental shelf (Garlich-Miller *et al.* 2011*a*). Summer sea-ice extent in the Chukchi Sea has decreased by about 12% per decade (NSIDC 2012); retreating off the shallow continental shelf and remaining only over deep Arctic Ocean waters where walruses cannot reach the benthos to feed. Declines in Chukchi Sea ice extent, duration, and thickness are projected to continue in a linear fashion into the foreseeable future (Douglas 2010).

POPULATION SIZE

The size of the Pacific walrus population has never been known with certainty. Based on large sustained harvests in the 18th and 19th centuries, Fay (1982) speculated that the pre-exploitation population was represented by a minimum of 200,000 animals. Since that time, population size has fluctuated markedly in response to varying levels of human exploitation (Fay *et al*. 1989). Large-scale commercial harvests reduced the population to 50,000 to 100,000 animals in the mid-1950s (Fay *et al.* 1997). The population is believed to have increased rapidly in size during the 1960s and 1970s in response to reductions in hunting pressure (Fay *et al.* 1989).

Between 1975 and 1990, aerial surveys were carried out by the United States and Russia at five-year intervals, producing mean population estimates ranging from 201,039 to 234,020 animals with 95% confidence intervals that include zero (Table 1). The estimates generated from these surveys are considered minimum values and because of the large associated variances they are not suitable for detecting population trends (Hills and Gilbert 1994, Gilbert *et al.* 1992). Further, these earlier figures largely underestimate the population because they were not adjusted for walruses in the water, a proportion of the population that may be as high as 65 to 87 percent (Born and Knutsen 1997, Gjertz *et al*. 2001, Jay *et al*. 2001, Born *et al*. 2005, Acquarone *et al*. 2006, Lydersen *et al*. 2008) and, because walrus tend to aggregate in large closely packed groups when hauled out on ice or land, it was difficult to obtain accurate counts of animals observed. Efforts to survey the Pacific walrus population were suspended at that time due to unresolved problems with survey methods, which produced population estimates with unknown bias and unknown or large variances that severely limited their utility (Gilbert *et al.* 1992, Gilbert 1999).

An international workshop on walrus survey methods in 2000 concluded that it would not be possible to obtain a population estimate with adequate precision for tracking trends using the existing aerial survey methods and any feasible amount of survey effort (Garlich-Miller and Jay 2000). Two major problems were identified: (1) accurately counting walruses in large groups, and (2) accounting for walruses in the water that were not available to be counted. Remote sensing systems were viewed as having great potential to address the first problem (Udevitz *et al.* 2001) as well as being able to sample larger areas per unit of time (Burn *et al*. 2006). To address the second problem U.S. Geological Survey (USGS) scientists developed satellite transmitters that recorded the haul-out status (in water or out) of individual walruses, which was used to estimate the proportion of animals in the water and correct walrus counts (Udevitz *et al.* 2009). These technological advances led to a joint United States-Russian Federation survey in March and April of 2006. This survey effort was timed to occur when the majority of Pacific walrus were hauled out on sea ice habitats across the continental shelf of the Bering Sea in order to capture as much of the population as possible.

The goal of the 2006 survey was to estimate the size of the Pacific walrus population (Speckman *et al.* 2011). However, some areas known to be important to walruses were not surveyed in 2006 because of poor weather and therefore the 2006 estimate is also considered to be an underestimate. The number of Pacific walruses within the area surveyed in 2006 was estimated at 129,000 with a 95% confidence interval of 55,000 to 507,000 (Speckman *et al.* 2011).

Table 1. Point estimates (95% confidence interval) of Pacific walrus population size, 1975-2006 from cooperative United States – Russian aerial surveys and original references.

Year	Population Estimate	References
1975	221,350 (–20,000-480,000)[a]	Gol'tsev 1976, Estes and Gilbert 1978, Estes and Gol'tsev 1984
1980	246,360 (–20,000-540,000)[a]	Johnson *et al.* 1982, Fedoseev 1984
1985	234,020 (–20,000-510,000)[a]	Gilbert 1986, 1989a, 1989b; Fedoseev and Razlivalov 1986
1990	201,039 (–19,000-460,000)[a]	Gilbert *et al.* 1992
2006	129,000 (55,000-507,000)	Speckman *et al*. 2011

[a]95% confidence intervals are from Figure 1 in Hills and Gilbert (1994).

Minimum Population Estimate

Under section 3(27) of the Marine Mammal Protection Act (MMPA), a "minimum population estimate" is defined as "an estimate of the number of animals in a stock that (A) is based on the best available scientific information on abundance, incorporating the precision and variability associated with such information and (B) provides reasonable assurance that the stock size is equal to or greater than the estimate." The estimate derived from the joint United States-Russian Federation survey conducted in March and April 2006 (Speckman *et al*. 2011) represents the minimum population estimate for the Pacific walrus. Because the 2006 survey used the most advanced technologies developed to address the problems identified in earlier aerial survey methods and was timed to capture as much of the population as possible (see above discussion under **POPULATION SIZE**), the survey's estimate of 129,000 individuals, with a 95%

confidence interval of 55,000 to 507,000 (Speckman *et al*. 2011), constitutes the best available scientific information on the size of the Pacific walrus population, taking into account the precision and variability associated with such estimates on abundance. The estimate from the 2006 survey is also negatively biased (Speckman *et al*. 2011), which provides reasonable assurance that the walrus population size is greater.

Current Population Trend

The 2006 estimate is lower than previous estimates of Pacific walrus population size (Table 1) and is known to be biased low to an unknown degree (Garlich-Miller *et al.* 2011*a*). However, estimates of population size from 1975 to the present (Table 1) are not directly comparable (Fay *et al.* 1997, Gilbert 1999) because of differences in survey methods, timing of surveys, and segments of the population surveyed. Therefore, while these estimates do not provide a good basis for inference with respect to population trends, there is other evidence supporting the hypothesis that the Pacific walrus population has declined from a peak in the late 1970s and 1980s.

Walrus researchers in the 1970s and 1980s were concerned that the population had reached or exceeded carrying capacity, and predicted that density-dependent mechanisms would begin to cause a decrease in population size (Fay and Stoker 1982b, Fay *et al*. 1986, Sease 1986, Fay *et al*. 1989). Estimates of demographic parameters from the late 1970s and 1980s support the idea that population growth was slowing (Fay and Stoker 1982a, Fay *et al*. 1986, Fay *et al*. 1989). Garlich-Miller *et al*. (2006) found that the median age of first reproduction for female walruses decreased in the 1990s, which is consistent with a reduction in density-dependent pressures. In addition, data on calf/cow ratios collected from harvested animals is consistent with a population peak in the late 1970s (i.e., low estimates in the late 1970s and 1980s) and subsequent population decline, and indicates that the population is currently below carrying capacity (MacCracken 2012).

The current working hypothesis, based on the available data, is that commercial and subsistence harvests prior to the 1960s limited the population; adoption of harvest quotas in the 1960s resulted in a population increase until the carrying capacity (about 300,000; according to Fay *et al.* (1997)) was reached in the 1970 to 1980s and productivity began to decline. The subsequent lack of harvest quotas in the United States beginning in 1979 and the reduced productivity levels resulted in another population decline, and the population is once again likely limited primarily by subsistence harvest, although other factors such as haulout mortalities may also be important (Udevitz et al. 2013). Garlich-Miller *et al*. (2011*a*) predicted that changing sea ice dynamics will result in further population declines in the future, but could not specify the magnitude or rate of decline. Given the suite of challenges associated with walrus aerial surveys, many of which cannot be overcome (e.g., poor weather, extensive area, estimate imprecision), it is clear that new approaches to evaluate population status and trend need to be explored. The U.S. Fish and Wildlife Service (Service) is developing a project to test the feasibility of genetic mark-recapture methods to estimate population size and trend. The successful development of a repeatable, unbiased, and precise estimate of population size will greatly facilitate our walrus conservation efforts including those directed at harvest management (USFWS 1994).

MAXIMUM NET PRODUCTIVITY RATES

Estimates of net productivity rates for walrus populations have ranged from 3 to 13% per year with most estimates between 5-10% (Chapskii 1936; Mansfield 1959; Krylov 1965, 1968; Fedoseev and Gol'tsev 1969; Sease 1986; DeMaster 1984; Sease and Chapman 1988; Fay *et al.* 1997). Chivers (1999) developed an individual age-based model of the Pacific walrus population using published estimates of survival and reproduction. The model yielded a maximum population growth rate (R_{MAX}) of 8%, which we use as the maximum net productivity rate in this assessment. Empirical estimates of age-specific survival rates for free ranging walruses are not available.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) of a marine mammal stock is defined in the MMPA as the maximum number of animals, not including natural mortalities that may be removed from a marine mammal stock while allowing that stock to reach or maintain its optimal sustainable population. The PBR is the product of the following factors: (A) the minimum population estimate of the stock, (B) one-half the maximum theoretical or estimated net productivity rate of the stock at a small population size, and (C) a recovery factor between 0.1-1.0 (MMPA §3(20)). Mathematically, PBR = N_{MIN} x 0.5 R_{MAX} x F_R; where N_{MIN} is minimum populations size, R_{MAX} the net productivity rate, and F_R a recovery factor. The F_R for the Pacific walrus is 0.5 (NMFS 2005) because the population is a candidate for listing under the U.S. Endangered Species Act of 1973, as amended (ESA) (USFWS 2011). The net productivity rate is estimated as 0.08 (Chivers 1999). Therefore, for the Pacific walrus population:

$$N_{MIN} = 129{,}000$$

$$R_{MAX} = 0.08$$

$$F_R = 0.5$$

$$PBR = (129{,}000 \times [0.5*0.08]*0.5) = 2{,}580$$

HUMAN CAUSED MORTALITY AND SERIOUS INJURY

Human Caused Mortalities

Subsistence Harvest

Over the past 60 years the Pacific walrus population has sustained estimated annual harvest removals ranging from 3,184 to 16,127 animals (mean = 6,440; Figure 2). Harvest levels since 2006 are 5 to 68% lower than this long-term average. It is not known whether recent reductions in harvest levels reflect changes in walrus abundance or hunting opportunities, but hunters consistently state that more frequent and severe storms are affecting hunting effort (EWC 2003, Oozeva *et al.* 2004). Other factors affecting harvest levels included: 1) the cessation of Russian commercial walrus harvests after 1990; and 2) changes in political, economic, and social conditions of subsistence hunters in Alaska and Chukotka.

The Service uses the average annual harvest over the past five years as an estimate of current harvest levels in the United States and Russia. Total U.S. annual harvest is estimated using data collected by direct observation in selected communities and through the statewide regulatory Marking, Tagging, and Reporting Program. The two sources of data are combined to calculate annual reporting compliance and to correct for any unreported harvest. Total U.S. subsistence harvest is estimated as the sum of reported and estimated unreported harvests. Harvest estimates in Russia were collected through both an observer program and a reporting program instituted by the Russian Federation.

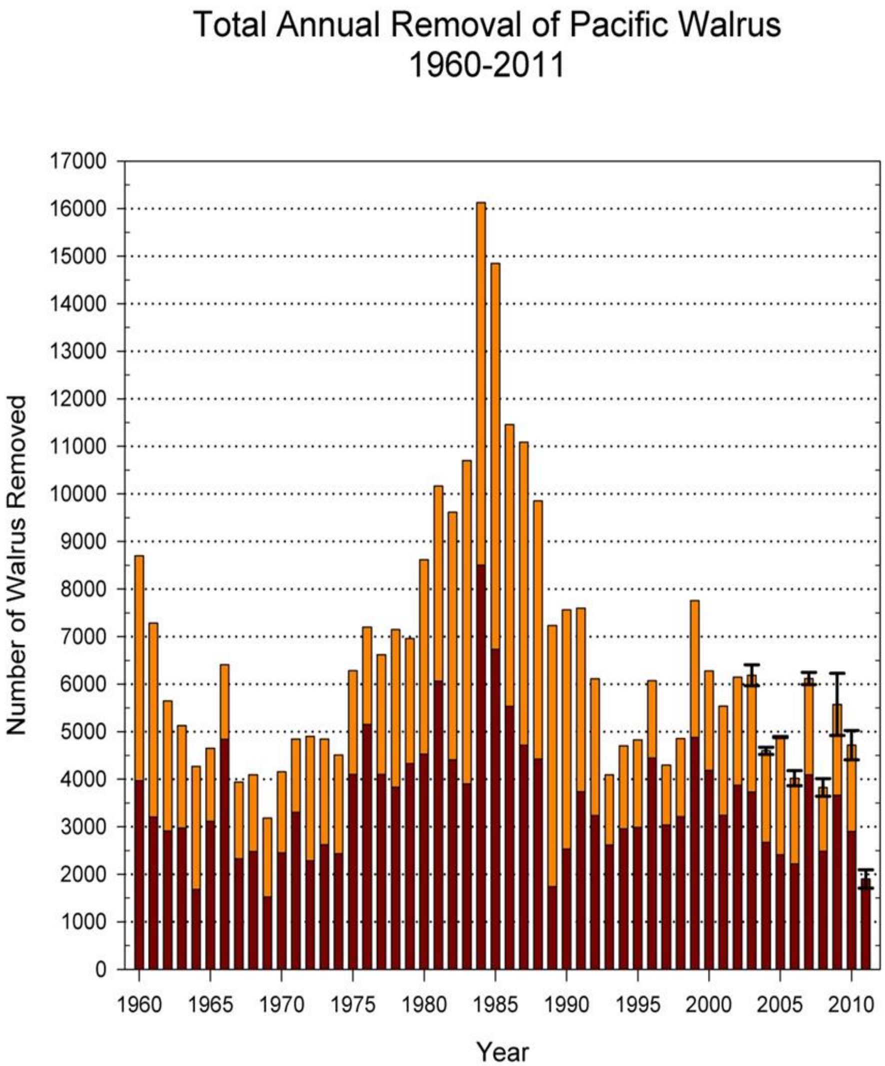

Figure 2. Total annual harvest removals for the Pacific walrus population from 1960 to 2011. Error bars for 2003-2011 denote the standard error around the estimate. Russian data for 2011 not included.

Using data collected between 1952 and 1972, Fay *et al*. (1994) estimated that 42% of walruses that were shot at were lost after being hit. All walruses that have been shot with a firearm are either killed immediately or assumed to be mortally wounded; however, they are often not retrievable if they die in the water and sink or if they are wounded and escape (Fay *et al.* 1994). We recognize that hunting equipment and techniques have improved since Fay *et al.* (1994) published their estimate; however, that estimate is still the best available. We therefore multiply the estimated harvest by 1.42 to adjust for walruses shot but not retrieved (i.e., struck and lost), resulting in a more accurate estimate of total number of walruses harvested.

Harvest mortality levels from 2006 to 2010 are estimated at 3,828 to 6,119 walruses per year (Table 2). The sex-ratio of the reported U.S. walrus harvest over this time period was 1.3:1 males to females. The sex-ratio of the reported Russian walrus harvest was 3.1:1 males to females based on harvest information collected by ChukotTINRO from 1999 to 2009 (Kochnev 2010).

Impacts of climate change on future subsistence harvests of walruses are difficult to predict (Holversrud 2008). Changes in walrus distribution, abundance, and health; sea ice characteristics and distribution; length and timing of the hunting season; and weather and sea state during the hunting season can all influence hunting success. Recent harvests are lower than historic levels and more frequent storms during the traditional hunting season, which limit hunting opportunities, appear to be a contributing factor. Holversrud (2008) predicted that climate change would result in a decline in the subsistence harvest of marine mammals. Garlich-Miller *et al*. (2011a) predicted that walrus harvest levels would remain relatively stable. Since 2006, the estimated total removal of walruses has fluctuated from year to year by an average of 3%, but is highly variable (e.g., 2006 to 2007, a 52% increase; and 2007 to 2008, a 60% decline).

Although fewer walruses are currently being harvested overall, of those animals harvested more are being harvested earlier in the spring and earlier in the winter than during the previous 20 years demonstrating that hunters will likely adapt to changing hunting and sea ice conditions. Harvest levels must be assessed within the context of the best available information on walrus population size, weather and climate, and political, economic, and social conditions of subsistence hunters in Alaska and Chukotka. Garlich-Miller et al. (2011a) assumed that summer sea ice loss would result in a reduced walrus population over time and that subsistence harvests could become unsustainable if not reduced in concert with any decline in the population. The recent adoption of trip limit ordinances by the Native Villages of Gambell and Savoonga and the acquisition of a Tribal Wildlife Grant to ensure administration of those ordinances is a positive development in this arena.

Table 2. Mean (standard error) harvest of Pacific walruses, 2006-2010. Russian harvest information was provided by ChukotTINRO and the Russian Agricultural Department. United States harvest information was collected by the U.S. Fish and Wildlife Service, and adjusted for unreported walruses using a mark-recapture method. Total harvest includes a struck and lost factor of 42% (Fay *et al*. 1994).

Year	Total harvest	United States harvest	Russian harvest
2006	4,022(157)	1,286(91)	1,047
2007	6,119(127)	2,376(74)	1,173
2008	3,828(185)	1,442(107)	778
2009	5,547(654)	2,123(379)	1,110
2010	4,716(308)	1,682(178)	1,053
Five year mean	4,852(346)	1,782(200)	1,032(67)

Cooperative Agreements have been developed annually between the Service and the Eskimo Walrus Commission since 1997 to facilitate the participation of subsistence hunters in activities related to the conservation and management of the walrus in Alaska. This co-management process is on-going. Ensuring that harvest levels remain sustainable is a goal shared by subsistence hunters and resource managers in the United States and Russian Federation. Achieving this management goal will require continued investments in co-management relationships, harvest monitoring programs, international coordination, and research.

Fisheries Related Mortalities and Injuries

A complete list of fisheries and marine mammal interactions is published annually by the National Oceanic and Atmospheric Administration (NOAA)-Fisheries, the most recent of which was published on August 29, 2013 (NOAA 2013). Pacific walruses occasionally interact with trawl and longline gear of groundfish fisheries. No data are available on incidental catch of walruses in fisheries operating in Russian waters, although trawl and longline fisheries are known to operate there. In Alaska each year, fishery observers monitor a percentage of commercial fisheries and report injury and mortality of marine mammals incidental to these operations. Overall, 13 fisheries, with observers, operate in Alaska within the range of the Pacific walrus in the Bering Sea, and could potentially interact with them.

Mortalities

Incidental mortality during 2006-2010 was observed in only one fishery, the Bering Sea/Aleutian Island flatfish non-pelagic trawl (Table 3); which, according to NOAA-Fisheries is a Category II Commercial Fishery with an estimated 34 vessels and/or persons participating. Observer coverage for this fishery averaged 88% during 2006-2010. The mean number of observed mortalities was one walrus per year, with a range of zero to three (Table 3). The total estimated annual fishery-related incidental mortality in Alaska was two walruses per year. We consider fishery related mortality to be insignificant.

Table 3. Summary of incidental mortality of Pacific walruses in the Bering Sea/Aleutian Islands flatfish trawl fishery from 2006-2010 and estimated mean annual mortality. Data provided by the National Marine Fisheries Service.

Year	Observer coverage (%)	Observed mortality	Estimated mortality	95% CI
2006	68	2	3	1 – 6
2007	72	1	3	1 – 5
2008	100	1	1	0.6 – 1.4
2009	100	0	0	
2010	100	2	2	1 – 3
Five year mean(SE[a])	88(7)	1(0.4)	2(0.6)	

[a]standard error.

Injuries

No incidental injury was observed during this time period; therefore, annual serious injury is estimated to be zero.

Other Removals

Between 2006-2011, satellite transmitters were affixed to 348 walruses, and collections of skin and blubber samples with biopsy darts were attempted from 183 walruses. No mortalities or serious injuries were directly associated with those research activities. However, in 2011, walruses at the Point Lay, Alaska haulout cleared the beach as USGS researchers, ferried by local guides, boated past resulting in the death of one calf (Jay 2012).

Up to 52 orphaned walrus calves were captured in Russia and placed on public display between 2006-2010. In addition, 3 calves were found on the beach near Barrow, Alaska in 2012 and taken into captivity. Based on this information, about 19 (standard error = 17) walruses per year were removed from the wild due to other human activities.

Total Estimated Human-Caused Mortality and Serious Injury

The average (standard error) total annual human-caused mortality or removal is 4,873 (346) walruses (2 due to fisheries interactions, 4,852 due to harvest, and 19 due to other human activities). There is no evidence that levels of human-caused serious injury are significant at this point.

Mortalities at coastal haulouts are due to several natural sources (poor condition, old age, injuries, predation, etc.) and occur at all haulouts at an unknown background level. Mortalities due to human caused stampedes also occur but are hard to quantify – most events are observed after the fact (Fay and Kelley 1980, Fischbach *et al.* 2009), some may go undetected, and carcasses can be redistributed during storms and consumed by predators. In 2007, more than 3,200 haulout mortalities were attributed to disturbance events along the Russian coast, but none were noted in Alaska. In 2008, few haulout mortalities were observed (0 in the United States, 165 in Russia) as remnant ice in the Chukchi Sea allowed walruses to stay offshore. In 2009, 131 calves were apparently trampled in a disturbance event at Icy Cape, Alaska (Fischbach *et al.* 2009) and another 53 were reported from other locations in Alaska with 453 counted in Russia. In 2010, 680 carcasses were counted at four haulouts in Russia (A. Kochnev, pers. comm.) and less than 200 were observed at Point Lay, Alaska (USFWS, unpubl. data). In 2011, 376 carcasses were counted in Russia (A. Kochnev, pers. comm.) and about 100 carcasses were found at the Point Lay haulout (USFWS, unpubl. data). Haulout management programs in Russia and the United States may be a successful management tool in reducing disturbance related mortalities compared to the extreme event in 2007.

STATUS OF STOCK

Pacific walrus are not designated as depleted under the MMPA; however, we have determined that listing the Pacific walrus as endangered or threatened under the ESA is warranted, but precluded by higher priority listing actions (USFWS 2011). Based on the best available information, the estimated incidental mortality and serious injury related to commercial fisheries (two walruses per year) is less than one percent of PBR and therefore can be considered insignificant and approaching a zero mortality and serious injury rate. However, the total human-caused removals exceed the PBR of 2,580. Therefore, the Pacific walrus is classified as a strategic stock.

EMERGING CONSERVATION ISSUES

A status review for the Pacific walrus was completed in 2011 in response to the ESA listing petition (Garlich-Miller *et al.* 2011*a*, and is available at: *http://alaska.fws.gov/fisheries/mmm/walrus/pdf/review_2011.pdf*. That review provides a comprehensive analysis of the stressors currently affecting the Pacific walrus population. The major findings of that analysis have been incorporated into this document in the appropriate sections. Readers should refer to Garlich-Miller *et al.* (2011*a*) for additional information on topics not covered by this stock assessment report.

Chukchi Coast Haulout Use

Over the past decade, the number of walruses coming to shore in summer and fall along the coastline of the Chukchi Sea in both Alaska and Russia has increased (Kavry *et al.* 2008, Garlich-Miller *et al.* 2011*a*) coincident with the earlier and more extensive melting of sea ice. In fall 2007, 2009, 2010, and 2011, large aggregations of females and young (about 3,000 to 30,000) were observed along the Alaska coast. An area of concern is the amount of walrus prey within the foraging range of coastal haulouts (Garlich-Miller *et al*. 2011*a*). As more walruses use coastal haulouts more frequently and for longer periods each year, prey populations could be depleted. Malnourished walruses have been reported from Chukotka (Ovsyanikov *et al*. 2008, A.A. Kochnev personal communication) and they are also regularly observed in Alaska (Garlich-Miller *et al.* 2011a); however, the majority of walruses observed at fall haulouts in Alaska in 2010 and 2011 were in good physical condition.

Ocean Acidification

The effect of ocean acidification (OA) on walrus prey is another issue of concern because lower pH levels can interfere with invertebrate shell formation and erode existing shells. No information is available about potential impacts on specific walrus prey species. Uncertainty regarding the general effects of ocean acidification has been summarized by the National Research Council (2010:1): "The major changes in ocean chemistry caused by increasing atmospheric CO_2 are well understood and can be precisely calculated, despite some uncertainty resulting from biological feedback processes. However, the direct biological effects of ocean acidification are less certain and will vary among organisms, with some coping well and others not at all." Consequently, although we recognize that effects to calcifying organisms that are important prey items for Pacific walruses may occur in the foreseeable future from ocean acidification, we do not know which species may be able to adapt and thrive, which may decline, or the ability of the walrus to depend on alternative prey items. The prey base of walrus includes over 100 taxa of benthic invertebrates from all major phyla (Sheffield and Grebmeier 2009). Although walruses are highly adapted for obtaining bivalves, they also have the potential to switch to other prey items if bivalves and other calcifying invertebrate populations decline. Whether other prey items would fulfill walrus nutritional needs over their life span is unknown (Sheffield and Grebmeier 2009), and there also is uncertainty about the extent to which other suitable non-bivalve prey might be available, due to uncertainty about the effects of ocean acidification and the effects of ocean warming.

Subsistence Harvest

Recent subsistence harvests are lower than historic levels due to a faster spring migration and more frequent severe storms that have limited hunting opportunities during the spring migration (Kapsch *et al.* 2010). Garlich-Miller *et al.* (2011*a*) predicted that walrus harvest levels would remain relatively stable as hunters adapt to changing hunting conditions, but that summer sea ice loss will result in a reduced walrus population over time, and therefore subsistence harvests could become unsustainable if not reduced similarly. The Service, in cooperation with the Russian Federation, has a comprehensive harvest monitoring program in place that provides detailed information on harvest trends and characteristics. We will continue to cooperatively monitor harvest levels into the future, a key component to maintaining a sustainable harvest.

Oil and Gas Exploration

In 2008, the Minerals Management Service (now the Bureau of Ocean Energy Management) held an oil and gas lease sale for offshore blocks in the eastern Chukchi Sea. In 2009, 2010, and 2011 a number of seismic surveys were conducted in the lease sale area. A significant portion of the Pacific walrus population migrates into the Chukchi Sea region each summer, and the shallow, productive, ice covered waters of the eastern Chukchi Sea are considered particularly important habitat for female walruses and their dependent young. The Hanna Shoal area seems to be particularly attractive to walruses summering in the Chukchi Sea likely due to both high prey abundance and shallow waters. The Service works to monitor and mitigate potential impacts of oil and gas activities on walruses through Incidental Take Regulations (ITR) as authorized under the MMPA. Entities operating under these regulations must adopt measures to ensure that impacts to walruses remain negligible, minimize impacts to their habitat, and ensure no unmitigable adverse impact on their availability for Alaska Native subsistence use. These regulations also specify monitoring requirements that provide a basis for evaluating potential impacts of current and future activities on marine mammals. The current ITRs were renewed in 2013 for another five years. The Service included a thorough analysis of the monitoring data collected in association with previous ITRs when it issued the current ITRs.

The Service (2011) concluded that at current levels, oil and gas exploration posed a relatively minor threat to the Pacific walrus population. However, we noted that a large oil spill could significantly impact the population depending on timing, location, amount and type of oil, efficacy of response efforts, etc.; the current ITRs also provided special considerations to limit potential impacts to walrus utilizing the Hanna Shoal area.

International Commercial Shipping

As summer sea ice melts earlier in the year and the open water extends further north, opportunities for commercial shipping through the arctic increase (Garlich-Miller *et al.* 2011*a*). Transits through the Bering Strait increased significantly between 2009 and 2010 (M. Williams, pers. comm.) and are currently outpacing regulatory efforts to define shipping channels, seasons of use, and mitigation measures to reduce ship strikes, etc. Commercial shipping is expected to increase in the future, but several scenarios are possible depending on economics and international regulatory efforts. Shipping is not currently impacting the Pacific walrus population and not expected to be a major source of mortality in the future.

Disease

During summer and fall 2011, about 130 ringed seals (*Pusa hispida*) were found on the beaches on northwest Alaska with skin lesions and hair loss suggestive of a viral infection. About 48% of those seals were found dead and the others were lethargic. During September 2011, 6% of the walruses at the Point Lay haulout had similar skin lesions, but were otherwise in good physical condition. The majority of affected walruses were subadults and some of those had healed lesions, indicating that the disorder is not necessarily fatal. However, a number of dead calves at the haulout had both skin lesions and signs of trampling trauma (Garlich-Miller *et al.* 2011*b*) and the ultimate cause of death is not known at this time.

In December 2011, the National Marine Science Fisheries (NMFS) declared the seal mortalities an unusual mortality event (UME) and, with the Service concurrence, included walrus in the UME, due to the similarities of the lesions. No causative agent has been identified and it is not known if the same agent is infecting both species. The symptoms appear to be less severe in walruses than in ringed seals in terms of prevalence and mortalities. Sampling of Pacific walrus' tissues and comprehensive laboratory analyses is continuing as part of the UME investigation.

NORTHERN SEA OTTER (*Enhydra lutris kenyoni*):

Southeast Alaska Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Sea otters occur in nearshore coastal waters of the U.S. along the North Pacific Rim from the Aleutian Islands to California. The species is most commonly observed within the 40-meter (m) (approximately 12.2 feet) depth contour because the animals require frequent access to benthic foraging habitat in subtidal and intertidal zones (Reidman and Estes 1990). Sea otters are not migratory and generally do not disperse over long distances, although movements of tens of kilometers (km) (tens of miles [mi]) are common (Garshelis and Garshelis 1984). Annual home range sizes of adult sea otters are relatively small, with male territories ranging from 4 to 11 square kilometers (km^2) (approximately 10.5 to 28.5 square miles [mi^2]) and adult female home ranges from a few to 24 km^2 (approximately 62 mi^2) (Garshelis and Garshelis 1984; Ralls *et al*. 1988; Jameson 1989). Due to their benthic foraging, sea otter distribution is largely limited by their ability to dive to the sea floor (Bodkin *et al*. 2004).

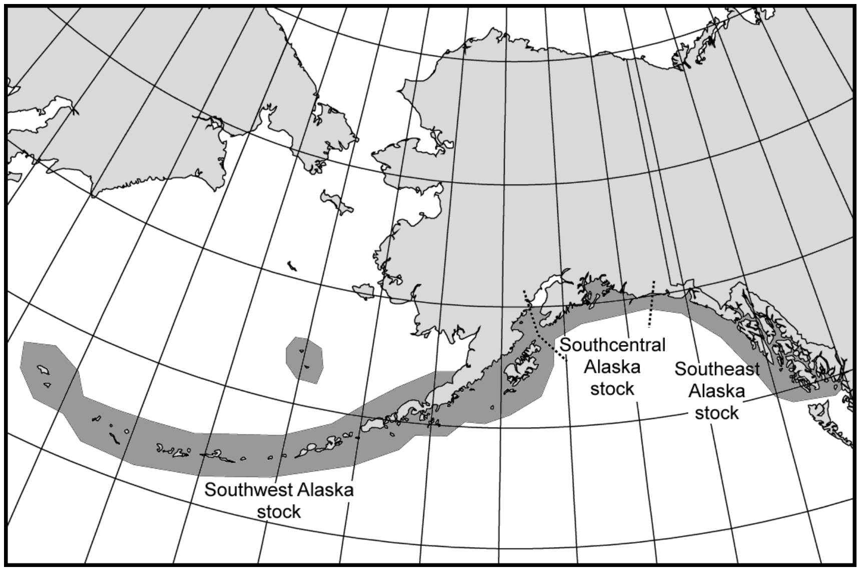

Figure 1. Approximate distribution and stock boundaries of northern sea otters in Alaska waters (shaded area).

The spatial scale at which sea otter populations are managed remains an important, although largely unexplored issue (Bodkin and Ballachey 2010) deserving further study. Bodkin and Ballachey (2010) used models of sea otter mortality to show that range-wide reductions and extirpations during the commercial fur trade of the 18th and 19th centuries occurred not simply because of excessive harvest, but because the harvest was not allocated proportional to the abundance and distribution of sea otters. This process of serial depletion was facilitated by the relatively sedentary nature of sea otters. To reduce the risk of overexploitation, sea otters must be managed on a spatial scale compatible with their well-known behavioral and reproductive biology (Bodkin and Monson 2002), incorporating traits such as home range and movements. These proposed scales for management are much smaller than the currently recognized stocks.

Gorbics and Bodkin (2001) applied the phylogeographic approach of Dizon *et al.* (1992) and used the best available data at the time to identify three sea otter stocks in Alaska: Southeast, Southcentral, and Southwest. The ranges of these stocks are defined as follows: (1) Southeast

Alaska stock extends from Dixon Entrance to Cape Yakataga; (2) Southcentral Alaska stock extends from Cape Yakataga to Cook Inlet including Prince William Sound, the Kenai Peninsula coast, and Kachemak Bay; and (3) Southwest Alaska stock includes the Alaska Peninsula and Bristol Bay coasts, and the Aleutian, Barren, Kodiak, and Pribilof Islands (Figure 1). This stock assessment report is focused on the Southeast stock of sea otters in Alaska.

POPULATION SIZE

Historically, sea otters occurred across the North Pacific Rim, ranging from Hokkaido, Japan, through the Kuril Islands, the Kamchatka Peninsula, the Commander Islands, the Aleutian Islands, peninsular and south coastal Alaska, and south to Baja California, Mexico (Kenyon 1969). In the early 1700s, the worldwide population was estimated to be between 150,000 (Kenyon 1969) and 300,000 individuals (Johnson 1982). Prior to large-scale commercial exploitation, indigenous peoples of the North Pacific hunted sea otters. Although it appears that harvests may have periodically led to local reductions of sea otters (Simenstad *et al.* 1978), the species remained abundant throughout its range until the mid-1700s. Following the arrival in Alaska of Russian explorers in 1741, extensive commercial harvest of sea otters over the next 150 years resulted in the near extirpation of the species. When sea otters were afforded protection by the International Fur Seal Treaty in 1911, probably fewer than 2,000 animals remained in thirteen remnant colonies (Kenyon 1969).

Although population recovery began following legal protection, no remnant colonies of sea otters existed in Southeast Alaska. As part of efforts to re-establish sea otters in portions of their historical range, otters from Amchitka Island and Prince William Sound were translocated to other areas (Jameson *et al.* 1982). These translocation efforts met with varying degrees of success. From 1965 to 1969, 412 otters (89% from Amchitka Island in southwest Alaska, and 11% from Prince William Sound in southcentral Alaska) were translocated to six sites in southeast Alaska (Jameson *et al.* 1982). In the first 20 years following translocation, these populations increased in numbers and expanded their range (Pitcher 1989).

Nearly all of the current population estimates for the Southeast Alaska stock were developed using the aerial survey methods of Bodkin and Udevitz (1999). The lone exception was a survey of the outer coastline from the western boundary of the stock at Cape Yakataga to Cape Spencer conducted by U.S. Geological Survey (USGS) in 2000. Thirty-two otters were estimated to be in that area (coefficient of variation [CV]=0.378). In 2005, the U.S. Fish and Wildlife Service (Service) surveyed Yakutat Bay (estimate number of otters [N]=1,582; CV=0.33; Gill and Burn 2007). In 2010, the Service surveyed the southern half (Kuiu and Kupreanof Islands south to the Canadian border) of Southeast Alaska (SSE) (N=12,873; CV=0.18; Gill and Burn unpublished data). The northern half (Admiralty and Baranof Islands north to Glacier Bay) of Southeast Alaska (NSE) was surveyed by the Service in 2011 (N=2,717; CV=0.22; Gill and Burn unpublished data). Glacier Bay (GB) National Park (NSE) was not included in the 2011 survey as USGS had separate plans to conduct replicate surveys in the Bay in 2012 to add to a long-term data set for the National Park (NP). The estimate from that 2012 survey is N=8,508; CV=0.20 (Esslinger *et al.* 2013). The most recent population estimates for the Southeast Alaska stock are presented in Table 1, which shows a total estimate of 25,712 sea otters for the stock.

Table 1. Abundance estimates for the Southeast Alaska stock of northern sea otters.

Survey Area	**Year**	**Unadjusted count**	**Adjusted Estimate**	**CV**	**N_{MIN}**	**Reference**
North Gulf of Alaska	2000	15	32	0.38	24	USGS unpublished data
Glacier Bay (NP)	2012		8,508	0.20	7,201	Esslinger, Bodkin, & Weitzman (2013)
Northern Southeast Alaska (NSE)	2011		2,717	0.22	2,270	Gill and Burn unpublished data
Southern Southeast Alaska (SSE)	2010		12,873	0.18	11,099	Gill and Burn unpublished data
Yakutat Bay	2005		1,582	0.33	1,203	Gill and Burn (2007)
Current Total			**25,712**		**21,798**	
2008 SAR Total			10,563		9,136	

Minimum Population Estimate

The minimum population estimate (N_{MIN}) for this stock is calculated using Equation 1 from the Potential Biological Removal Guidelines (Wade and Angliss 1997): $N_{MIN} = N/\exp(0.842 \times [\ln(1+[CV(N)]^2)]^{½})$. The N_{MIN} for each survey area is presented in Table 1. The estimated N_{MIN} for the entire Southeast Alaska stock is 21,798 sea otters.

Current Population Trend

The trend for this stock of sea otters has generally been one of growth (Pitcher 1989, Agler *et al.* 1995, Esslinger and Bodkin 2009). Comparing the current population estimate with that of the previous stock assessment reports suggests that this growth trend is continuing. The estimated population size (25,712) of this stock currently is more than double what was estimated in the previous (2008) stock assessment report (10,563). However, it is important to note that the population estimate published in the 2008 stock assessment report was based on survey data from 2002 and 2003. Therefore, we can only conclude that the Southeast population stock has doubled since 2003.

The 2010-2011 survey followed the same Bodkin and Udevitz (1999) methods as the 2002-2003 survey effort (Esslinger and Bodkin 2009) so results of those two surveys can be directly compared. In addition, all surveys in the GBNP time series followed the Bodkin and Udevitz (1999) method. The Service's 2010 survey of SSE showed an average annual increase of 12% per year over the last seven years and the Service's 2011 survey of NSE Alaska (minus GBNP) showed an average annual increase of 4% per year over the last nine years. The USGSs' survey of GBNP showed an average annual increase of 20% per year over the last six years. If we include the 2012 GBNP estimate with the estimate for the 2011 NSE Alaska the growth rate is about 14% per year in NSE Alaska which is in line with the growth rate for SSE Alaska. Hence, the northern and southern portions of Southeast Alaska appear to be growing at the same average annual rate; between 12-14% per year.

When compared to SSE, the sea otter population has also not appreciably expanded its range in NSE outside of GBNP since 2002 (Esslinger and Bodkin 2009, Gill and Burn unpublished data). However, otters have occupied appreciable new habitat in SSE since 2003 (Esslinger and Bodkin 2009, Gill and Burn unpublished data). There appear to be two major areas of expansion in SSE; otters have moved in large numbers along the northwest coast of Kuiu Island up into Keku Strait and then animals from this area have crossed Frederick Sound to the southern tip of Admiralty Island, and finally otters have expanded northward from the Barrier Islands through Tlevak Strait.

Sea otter abundance in Yakutat Bay has also increased, by an estimated 14.6% per year, over the last decade, likely through reproduction, although some amount of immigration cannot be ruled out (Gill and Burn 2007). During this process, otters appear to have expanded their range to include the western shores of Yakutat Bay.

Based on this information the current population trend for the Southeast Alaska stock is increasing.

MAXIMUM NET PRODUCTIVITY RATE

Estes (1990) estimated a population growth rate of 17 to 20% per year for northern sea otter populations expanding into unoccupied habitat in the Aleutian Islands, southeast Alaska, British Columbia, Washington State, and central California. Although maximum productivity rates (R_{MAX}) have not been measured through much of the sea otter's range in Alaska, in the absence of more detailed information, the rate of 20% calculated by Estes (1990) is considered the best available estimate of R_{MAX}. The Service's 2010 survey of SSE and 2011 survey of NSE shows a current growth rate of 12% and 4% respectively per year (minus GBNP). The USGS' 2012 survey of GBNP shows a current growth rate of 20% per year. Combining the data from NSE AK indicates that area is growing at a rate of 14% per year which compares to the rate of 12% per year in SSE AK. Consequently, we estimate the current net productivity rate for the entire Southeast Alaska population stock to be between 12-14% per year.

POTENTIAL BIOLOGICAL REMOVAL

Under the Marine Mammal Protection Act (MMPA), the potential biological removal (PBR) is defined as *the maximum number of animals, not including natural mortalities, that may be removed from a marine mammal stock while allowing that stock to reach or maintain its optimal sustainable population.* Potential biological removal is the product of the minimum population estimate (N_{MIN}), one-half the maximum theoretical net productivity rate, and a recovery factor (F_R): PBR = N_{MIN} x 0.5 R_{MAX} x F_R. The recovery factor for this stock is 1.0 (Wade and Angliss 1997) as population levels have been stable or increasing with a known human take. Thus, for the Southeast stock of sea otters, PBR = 2,179 animals (21,798 x 0.5(0.2) x 1.0).

ANNUAL HUMAN CAUSED MORTALITY

Fisheries Information

A complete list of fisheries and marine mammal interactions is published annually by the National Oceanic and Atmospheric Administration (NOAA) Fisheries, the most recent of which was published on August 29, 2013 (78 FR 53336). Fisheries that have been known to interact with sea otters in the Southwest and Southcentral Alaska stocks do occur in Southeast Alaska, specifically the Southeast Alaska salmon drift gillnet (474 vessels) and the Yakutat salmon set gillnet (167 participants) fisheries. Sea otters are also known to interact with pot fisheries in California (Hatfield *et al*. 2011); in Southeast Alaska, there are 415 crab pot fishery participants and 274 shrimp pot participants. There are also 243 miscellaneous finfish pot fishery participants across the entire state (numbers are not available for specific areas). Available information suggests that fisheries using other types of gear, such as trawl, longline, and purse seine, are less likely to have interactions with sea otters across their entire range in Alaska due to either the areas where such fisheries operate (i.e., outside of sea otter habitat), the specific gear used (i.e., otters are not going to tangle or get trapped in a longline), or both.

Although commercial fisheries in Alaska have observer programs that monitor and report injury and mortality of marine mammals incidental to their operations, a reliable estimate of the levels of commercial fisheries incidental mortality and serious injury relative to the southeast sea otter stock cannot be made because observer coverage is not sufficient and data are not collected consistently over time. Of the observer programs in operation within the stock, no incidents of sea otter incidental take were observed in trawl, longline, or pot groundfish fisheries in Southeast Alaska from 1989 to 2010 (Perez 2003, Perez 2006, Perez 2007, Manly 2009, Bridget Mansfield 2011 personal communication). However, there has been no observer effort to document by-catch in the salmon set or drift gillnet fisheries or in the crab or shrimp pot fisheries in Southeast Alaska. Hatfield *et al*. (2011) contend that significant sea otter mortality from pot fishery by-catch might easily go undetected, even when seemingly high levels of observer effort exist.

An additional source of information on the number of sea otters killed or injured incidental to commercial fishery operations in Alaska is found in fisher self-reports required of vessel owners by NOAA Fisheries. From 1990 to 1993, self-reported fisheries data showed no sea otter kills or injuries in Southeast Alaska. Self-reports were incomplete for 1994 and not available for 1995 or 1996. Between 1997 and 2010, there were no records of incidental take of sea otters by commercial fisheries in this region. Credle *et al.* (1994) considered fisher self-reports to be a minimum estimate of incidental take as these data are most likely negatively biased. Indeed, anecdotal observations have been reported to the Service within the last five years suggesting that sea otters do interact with crab pots in Southeast Alaska. As sea otters reoccupy portions of their former habitat in Southeast Alaska, co-occurrence with pot fisheries will increase and so will the likelihood of mortalities or serious injury.

Information is insufficient to determine whether or not the total fishery mortality and serious injury for the Southeast Alaska stock of the northern sea otter is insignificant and is approaching a zero mortality and serious injury rate.

Oil Spills

Activities associated with exploration, development, and transport of oil and gas resources can adversely impact sea otters and nearshore coastal ecosystems in Alaska. Sea otters rely on air trapped in their fur for conserving body heat and buoyancy. Contamination with oil drastically reduces the insulative value of the pelage, and consequently, sea otters are among the marine mammals most likely to be detrimentally affected by contact with oil. It is believed that sea otters can survive low levels of oil contamination (< 10% of body surface), but that greater levels (>25%) will lead to death (Costa and Kooyman 1981, Siniff *et al.* 1982). Vulnerability of sea otters to oiling was demonstrated by the 1989 *Exxon Valdez* oil spill in Prince William Sound. Total estimates of mortality caused by the spill for the Prince William Sound area vary from 750 (range 600-1,000) (Garshelis 1997) to 2,650 (range 500-5,000) (Garrot *et al.* 1993) otters. Statewide, it is estimated that 3,905 sea otters (range 1,904-11,257) died in Alaska as a result of the spill (DeGange *et al.* 1994), but none of these were from the Southeast Alaska stock.

There is currently no oil and gas development in Southeast Alaska. Tankers carrying oil south from the Trans-Alaska Pipeline typically travel offshore of Southeast Alaska. Information on oil spills compiled by the Alaska Department of Environmental Conservation from 2006 to 2010 indicates that there were no reported spills of crude oil in Southeast Alaska. In addition to spills that may occur in association with the development, production, and transport of crude oil, each year numerous spills of non-crude oil products in the marine environment occur from ships and shore facilities throughout Southeast Alaska. During that same time period, there was an average of 133 spills each year, ranging in size from less than 1 and up to 17,800 gallons (approximately 4 to 64,600 liters). The vast majority of these spills were small, with a mean size of 46 gallons (1,748 liters), and there is no indication that these small-scale spills have had an impact on the Southeast Alaska stock of northern sea otters at the population level.

Subsistence/Native Harvest Information

The MMPA exempts Alaska Natives from the prohibition on take of marine mammals, provided such taking is not wasteful and is done for subsistence use or for creating and selling authentic handicrafts or clothing. According to the Service's Law Enforcement records from 2006 to 2010, individuals were prosecuted for unlawful possession, transport, or sale of 208 sea otter hides or skulls taken within the range of the Southeast Alaska stock. During the same time period, there was one prosecution for unlawful take of a single sea otter hide. Data for subsistence harvest of sea otters in Southeast Alaska are collected by a mandatory Marking, Tagging and Reporting Program administered by the Service since 1988. Figure 2 provides a summary of subsistence harvest information for the Southeast stock from 1989 to 2010. The mean reported annual subsistence take during the past five complete calendar years (2006-2010) was 447 animals. This is an increase from the annual average of 322 sea otters hunted during the previous five-year period. Reported age composition from 2006 to 2010 was the same as the previous five years; 83% adults, 14% subadults, and 3% pups. Reported sex composition from 2006 to 2010 was also the same as the previous five years; 72% males, 27% females, and 1% of unknown sex.

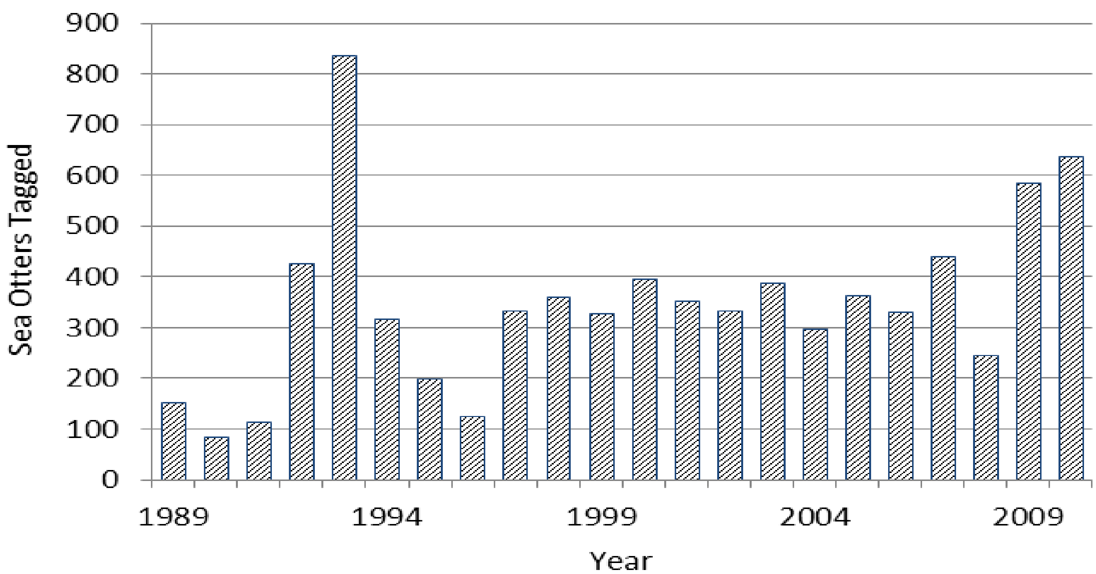

Figure 2. Reported subsistence harvest of northern sea otters from the Southeast Alaska stock, 1989 to 2010.

Research and Public Display

In the past five years, no sea otters were removed from the Southeast Alaska stock for public display. In 2011, 93 sea otters were captured and released for scientific research in the Southeast Alaska stock; the Service captured and released 31 sea otters in the Keku Strait region and the USGS captured and released 62 sea otters in Cross Sound and off of southern Baranof Island. There were no mortalities and serious injuries reported from either of these research efforts.

Other Factors

Since 2002 the Service has undertaken a health and disease study of northern sea otters from all three Alaskan stocks. On average, the Service conducts about 100 necropsies a year on sea otter carcasses to determine cause of death, disease incidence and status of general health parameters. Boat strike is a recurring cause of death across all three stocks. However, it has been determined in most of these cases that although trauma was the ultimate cause of death, there was a contributing factor, such as disease or biotoxin exposure, which incapacitated the animal and made it more vulnerable to boat strike.

In August 2006, the Working Group on Marine Mammal Unusual Mortality Events reviewed information provided by the Service, and declared that a dramatic increase in sea otter strandings in Kachemak Bay, in the Southcentral Alaska stock, since 2002 constituted an Unusual Mortality Event (UME) in accordance with section 404 of the MMPA. The disease that typifies this UME is caused by a *Streptococcus infantarius* infection and has been observed over a broad geographic range in Alaska, including a few cases from Southeast Alaska; however, the majority of cases have come from Kachemak Bay in the Southcentral Alaska stock. It is not clear if the observed stranding pattern is representative of overall sea otter mortality, or an artifact of having a well-developed stranding network in the Kachemak Bay area. The Service will continue to work with NOAA Fisheries and the Alaska SeaLife Center to develop the infrastructure for a statewide marine mammal stranding network in Alaska.

STATUS OF STOCK

The known level of direct human-caused mortality within the Southeast Alaska stock does not exceed the PBR level, and the Southeast Alaska stock is neither listed as "depleted" under the MMPA or listed as "threatened" or "endangered" under the Endangered Species Act of 1973, as amended, nor is it likely to be listed as such in the foreseeable future. The known level of direct human-caused mortality is 447 otters per year. It would require an annual rate of human-caused mortality from additional hunting or fisheries interactions of 1,733 more otters per year for the total amount of direct human-caused mortality to exceed PBR for this stock. Despite uncertainties regarding fishery mortality, we believe that it is unlikely this level is occurring at present. Therefore, the Southeast Alaska stock of the northern sea otter is classified as non-strategic. In addition, although the Service does not currently know the OSP for this stock, based on the known population level and our estimate of growth and considering the known level of human-caused mortality, we have determined that this stock is increasing and that human-caused mortality and serious injury is not likely to cause the stock to be reduced or to decrease its growth rate. Therefore, we would not expect the current level of human-caused mortality and serious injury to cause this stock to be reduced below its plausible OSP.

NORTHERN SEA OTTER (*Enhydra lutris kenyoni*):

Southcentral Alaska Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Sea otters occur in nearshore coastal waters of the U.S. along the North Pacific Rim from the Aleutian Islands to California. The species is most commonly observed within the 40-meter (approximately 12.2 feet [ft]) depth contour because the animals require frequent access to benthic foraging habitat in subtidal and intertidal zones (Reidman and Estes 1990). Sea otters are not migratory and generally do not disperse over long distances, although movements of tens of kilometers (km) (tens of miles [mi]) are common (Garshelis and Garshelis 1984). Annual home range sizes of adult sea otters are relatively small, with male territories ranging from 4 to 11 square kilometers (km^2) (approximately 10.5 to 28.5 square miles[mi^2]) and adult female home ranges from a few to 24 km^2 (approximately 62 mi^2) (Garshelis and Garshelis 1984; Ralls *et al*. 1988; Jameson 1989). Due to their benthic foraging, sea otter distribution is largely limited by their ability to dive to the sea floor (Bodkin *et al*. 2004).

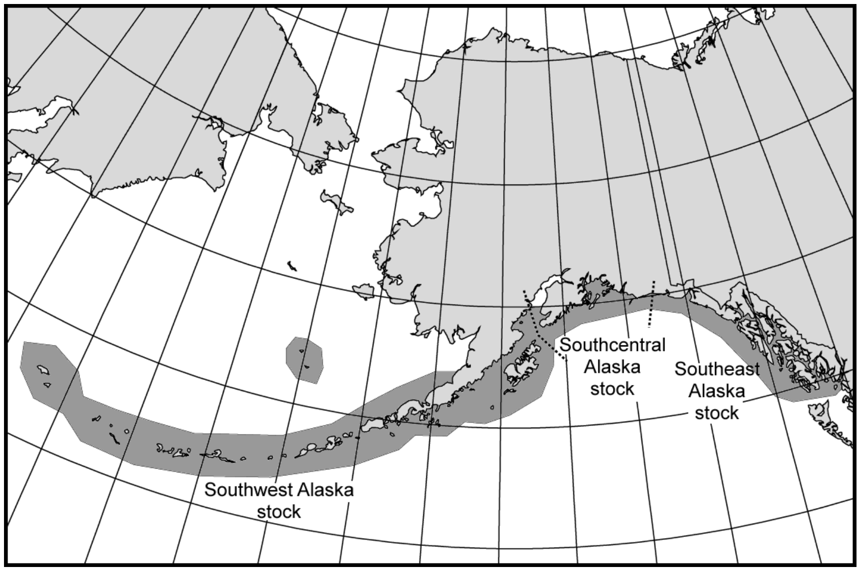

Figure 1. Approximate distribution and stock boundaries of northern sea otters in Alaska waters (shaded area).

The spatial scale at which sea otter populations are managed remains an important, although largely unexplored issue (Bodkin and Ballachey 2010) deserving further study. Bodkin and Ballachey (2010) used models of sea otter mortality to show that range-wide reductions and extirpations during the commercial fur trade of the 18th and 19th centuries occurred not simply because of excessive harvest, but because the harvest was not allocated proportional to the abundance and distribution of sea otters. This process of serial depletion was facilitated by the relatively sedentary nature of sea otters. To reduce the risk of overexploitation, sea otters must be managed on a spatial scale compatible with their well-known behavioral and reproductive biology (Bodkin and Monson 2002), incorporating traits such as home range and movements. These proposed scales for management are much smaller than the currently recognized stocks.

Gorbics and Bodkin (2001) applied the phylogeographic approach of Dizon *et al.* (1992) and used the best available data at the time to identify three sea otter stocks in Alaska: Southeast, Southcentral, and Southwest. The ranges of these stocks are defined as follows: (1) Southeast

Alaska stock extends from Dixon Entrance to Cape Yakataga; (2) Southcentral Alaska stock extends from Cape Yakataga to Cook Inlet including Prince William Sound, the Kenai Peninsula coast, and Kachemak Bay; and (3) Southwest Alaska stock includes the Alaska Peninsula and Bristol Bay coasts, and the Aleutian, Barren, Kodiak, and Pribilof Islands (Figure 1). This stock assessment report is focused on the Southcentral stock of sea otters in Alaska.

POPULATION SIZE

Historically, sea otters occurred across the North Pacific Rim, ranging from Hokkaido, Japan, through the Kuril Islands, the Kamchatka Peninsula, the Commander Islands, the Aleutian Islands, peninsular and south coastal Alaska, and south to Baja California, Mexico (Kenyon 1969). In the early 1700s, the worldwide population was estimated to be between 150,000 (Kenyon 1969) and 300,000 individuals (Johnson 1982). Prior to large-scale commercial exploitation, indigenous peoples of the North Pacific hunted sea otters. Although it appears that harvests may have periodically led to local reductions of sea otters (Simenstad *et al.* 1978), the species remained abundant throughout its range until the mid-1700s. Following the arrival in Alaska of Russian explorers in 1741, extensive commercial harvest of sea otters over the next 150 years resulted in the near extirpation of the species. When sea otters were afforded protection by the International Fur Seal Treaty in 1911, probably fewer than 2,000 animals remained in thirteen remnant colonies (Kenyon 1969). Population recovery began following legal protection. As part of efforts to re-establish sea otters in portions of their historical range, otters from Amchitka Island and Prince William Sound were translocated to other areas in the

1960s and 1970s, including to southeast Alaska (Jameson *et al.* 1982). Sea otters have since recolonized much of their historical range in Alaska.

The most recent abundance estimates for survey areas within the Southcentral Alaska stock are presented in Table 1. Estimates for Kenai Fjords and Kachemak Bay have been updated since the previous stock assessment report. In 2008, an aerial survey using the methods described in Bodkin and Udevitz (1999) was conducted within Kachemak Bay, resulting in an estimate of 3,596 sea otters (CV = 0.50; USFWS unpublished data). This method included a survey-specific correction factor to account for undetected animals. A 2010 aerial survey using the Bodkin-Udevitz method in Kenai Fjords National Park resulted in an estimate of 1,322 sea otters (CV = 0.37; Coletti *et al*. 2011). Eastern lower Cook Inlet was surveyed as part of a larger area in 2002, yielding an estimate of 962 sea otters (CV = 0.54; Bodkin *et al*. 2003b) for the areas not covered in 2008 and 2010.

In 2003, an aerial survey of Prince William Sound resulted in an abundance estimate of 11,989 sea otters (CV = 0.18; Bodkin *et al.* 2003a). Finally, an aerial survey of the northern Gulf of Alaska coastline flown in 2000 provided a minimum uncorrected count of 198 sea otters between Cape Hinchinbrook and Cape Yakataga (USGS unpublished data). Applying a correction factor of 2.16 (CV = 0.38) for this observer conducting sea otter aerial surveys produces an adjusted estimate of 428 (CV = 0.38).

The most recent population estimates for survey areas within the Southcentral Alaska stock are presented in Table 1. Combining the adjusted estimates for these areas results in a total estimate of 18,297 sea otters for the Southcentral Alaska stock.

Table 1. Population estimates for the Southcentral Alaska stock of northern sea otters. The previous stock assessment report (SAR) total is from 2008.

Survey Area	Year	Unadjusted Estimate	Adjusted Estimate	CV	N_{MIN}	Reference
Cook Inlet, Kachemak Bay excluded	2002		962	0.54	629	Bodkin *et al.* (2003b)
Kachemak Bay	2008		3,596	0.50	2,416	USFWS unpublished data
Kenai Fjords	2010		1,322	0.37	978	Coletti *et al.* (2011)
Prince William Sound	2003		11,989	0.18	10,324	Bodkin *et al.* (2003a)
North Gulf of Alaska	2000	198	428	0.38	314	USGS unpublished data
Current Total			**18,297**		**14,661**	
Previous SAR Total			15,090		12,774	

Minimum Population Estimate

The minimum population estimate (N_{MIN}) for this stock is calculated using Equation 1 from the Potential Biological Removal Guidelines (Wade and Angliss 1997): $N_{MIN} = N/\exp(0.842 \times [\ln(1+[CV(N)]^2)]^{½})$. The N_{MIN} for each survey area is presented in Table 1. The estimated N_{MIN} for the Southcentral Alaska stock is 14,661 sea otters.

Current Population Trend

All surveys analyzed for trends in abundance used methods described in Bodkin and Udevitz (1999), including use of a survey-specific correction factor to account for undetected animals, with the exception of the survey in the North Gulf of Alaska. Aerial surveys in Kachemak Bay in 2002, 2007, and 2008, indicated that the population is increasing, with an estimated annual rate of increase between 2002 and 2008 of 26% per year (USGS unpublished data, USFWS unpublished data). This rate slightly exceeds the estimated maximum productivity rates (R_{MAX}) for the species (see below). Immigration from other areas (Cook Inlet, Kenai Fjords) may have contributed to the observed increase in sea otter numbers in Kachemak Bay.

Aerial surveys in Kenai Fjords National Park in 2002, 2007, and 2010, had relatively high standard errors, but indicated overall that the population is stable and may be increasing (Coletti *et al.* 2011). Annual aerial surveys of sea otter abundance in western Prince William Sound from 1993 to 2009 (except for 2001 and 2006) identified a significant increase in abundance between 2001 and 2009 at this scale, with an average annual rate of increase from 1993 to 2009 of 2.6% (Bodkin *et al.* 2011). This trend is interpreted as strong evidence of a trajectory toward recovery of sea otter populations in Prince William Sound affected by the 1989 *Exxon Valdez* oil spill (Bodkin *et al.* 2011). Our best assessment is that the overall trend in abundance for this stock appears to be increasing at this time.

MAXIMUM NET PRODUCTIVITY RATE

Estes (1990) estimated a population growth rate of 17 to 20% per year for four northern sea otter populations expanding into unoccupied habitat. Although maximum productivity rates (R_{MAX}) have not been measured throughout much of the sea otter's range in Alaska, in the absence of more detailed information, the rate of 20% calculated by Estes (1990) is considered the best available estimate of R_{MAX}. There is insufficient information available to estimate the current net productivity rate for this population stock.

POTENTIAL BIOLOGICAL REMOVAL

Under the Marine Mammal Protection Act (MMPA), the potential biological removal (PBR) is defined as *the maximum number of animals, not including natural mortalities, that may be removed from a marine mammal stock while allowing that stock to reach or maintain its optimal sustainable population.* Potential biological removal is the product of the minimum population estimate (N_{MIN}), one-half the maximum theoretical net productivity rate, and a recovery factor (F_R): PBR = N_{MIN} x 0.5 R_{MAX} x F_R. The recovery factor for this stock is 1.0 (Wade and Angliss 1997) as population levels have remained stable with a known human take. Thus, for the Southcentral stock of sea otters, PBR = 1,466 animals (14,661 x 0.5 (0.2) x 1.0).

ANNUAL HUMAN CAUSED MORTALITY

Fisheries Information

A complete list of fisheries and marine mammal interactions is published annually by the National Oceanic and Atmospheric Administration (NOAA) Fisheries, the most recent of which was published on August 29, 2013 (78 FR 53336). Numerous fisheries exist within the range of the Southcentral Alaska stock of northern sea otters. Two have been identified as interacting with this stock, the Prince William Sound drift gillnet fishery with an estimated 537 vessels and/or persons participating, and the Cook Inlet salmon set gillnet fishery, with an estimated 738 participants. Additional salmon drift gillnet fisheries occur in Cook Inlet, with 589 vessels; however, with the exception of Kachemak Bay, all of the fishing effort involving salmon drift and set gillnet fisheries in Cook Inlet occurs north of the range of sea otters from the Southcentral Alaska stock (Manly 2006). Additional salmon set gillnet fisheries occur in Prince William Sound (30 participants).

While much of the salmon set gillnet effort in Cook Inlet occurs north of the range of sea otters, interactions between sea otters and fisheries are reported from the Kachemak Bay region. In July 2009, five sea otters with slashed throats were found dead on a Seldovia beach. They were believed to have been killed after being captured in a set gillnet. In July 2011, a female and pup were successfully released from a set gillnet in the Homer area. Interactions with set gillnet gear also have been observed in the Kodiak and Prince William Sound areas within the ranges of the Southwest and Southcentral Alaska stocks. Available information suggests that fisheries using other types of gear, including trawl, longline, and purse seine, appear to be less likely to have interactions with northern sea otters due to either the areas where such fisheries operate, or the specific gear used, or both.

Although commercial fisheries in Alaska have observer programs that monitor and report injury and mortality of marine mammals incidental to their operations, a reliable estimate of the levels of commercial fisheries incidental mortality and serious injury relative to the Southcentral sea otter stock cannot be made because observer coverage is not sufficient and data are not collected consistently over time. No incidents of sea otter incidental take have been observed in trawl, longline, or pot groundfish fisheries in southcentral Alaska from 1989 to 2010 (NOAA unpublished data). Sea otters are known to interact with pot fisheries in California, however, and it is possible that observer effort for pot fisheries in Alaska has been too low to detect sea otter bycatch (Hatfield *et al.* 2011). In addition to the fisheries listed above, observers monitored the Cook Inlet set gillnet and drift gillnet fisheries from 1999 to 2000 (Manly 2006). The observer coverage during both years was approximately 2 to 5%. No mortalities or injuries of sea otters were reported by fisheries observers for the Cook Inlet set gillnet and drift gillnet fisheries for this period. On several occasions, sea otters were observed within 10 meters (approximately 33 ft) of gillnet gear, but did not become entangled. No other fisheries operating in the region of the Southcentral Alaska stock were monitored by observer programs from 1992 through 2010. Prior to the implementation of the NOAA Fisheries observer program, studies were conducted on sea otter interactions with the drift net fisheries in western Prince William Sound from 1988 to 1990, and no mortalities were observed (Wynne 1990, Wynne *et al.* 1991).

An additional source of information on the number of sea otters killed or injured incidental to commercial fishery operations in Alaska is found in fisher self-reports required of vessel owners by NOAA Fisheries. In 1990, fisher self-report records show one mortality and four injuries due to gear interaction, and three injuries due to deterrence in the Prince William Sound drift gillnet fishery. Self-reports were not available for 1994 and 1995. Credle *et al.* (1994) considered fisher self-reports to be a minimum estimate of incidental take as these data are most likely negatively biased.

In summary, between 2006 and 2010, there were five records of incidental take of sea otters by commercial fisheries within the range of the Southcentral stock, and, therefore, the estimated mean annual mortality and serious injury reported for the 5-year period from 2006 to 2010 is one. Observer coverage for fisheries within the range of the Southcentral stock of sea otters has been absent in some fisheries and low in others, particularly with respect to the set and drift gillnet fisheries that are recognized as interacting with this stock, and current estimates of sea otter bycatch are not available. Self-reporting is not sufficiently reliable to replace observer effort. Additionally, assessment of injury and mortality in sea otters that interact with fisheries is difficult. Information is, therefore, insufficient to determine whether or not the total fishery mortality and serious injury for the Southcentral Alaska stock of the northern sea otter is insignificant and is approaching a zero mortality and serious injury rate.

Oil Spills

Activities associated with exploration, development, and transport of oil and gas resources can adversely impact sea otters and nearshore coastal ecosystems in Alaska. Sea otters rely on air trapped in their fur for warmth and buoyancy. Contamination with oil drastically reduces the insulative value of the pelage, and consequently, sea otters are among the marine mammals most likely to be detrimentally affected by contact with oil. It is believed that sea otters can survive low levels of oil contamination (<10% of body surface), but that greater levels (>25%) will lead to death (Costa and Kooyman 1981, Siniff *et al.* 1982). Vulnerability of sea otters to oiling was demonstrated by the 1989 *Exxon Valdez* oil spill in Prince William Sound. Total estimates of mortality for the Prince William Sound area vary from 750 (range 600 to 1,000; Garshelis 1997) to 2,650 otters (range 500 to 5,000; Garrot *et al.* 1993). Statewide, it is estimated that 3,905 sea otters (range 1,904 to 11,257) died in Alaska as a result of the spill (DeGange *et al.*1994). At present, although abundance of sea otters in some oiled areas of Prince William Sound remains below pre-spill estimates, evidence from ongoing studies suggests that sea otters numbers are increasing, a trend interpreted as evidence of a trajectory toward recovery of spill-affected sea otter populations in western Prince William Sound (Bodkin *et al.* 2002, Stephensen *et al.* 2001, Bodkin *et al.* 2011, Monson *et al.* 2011).

Within the range of the Southcentral Alaska sea otter stock, oil and gas development and production occurs only in Cook Inlet. As of 2011, 16 offshore oil platforms operated in Cook Inlet, and two more are slated to begin operations in 2012. A Federal lease sale in Cook Inlet may be held in 2012 to 2017, if industry interest is sufficient. Tankering of North Slope crude oil occurs regularly through the waters of Prince William Sound with no major oil spills since the *Exxon Valdez*. While the catastrophic release of oil has the potential to take large numbers of sea otters, there is no evidence that other effects (such as disturbance) associated with routine oil and gas development and transport have had a direct impact on the Southcentral Alaska sea otter stock.

Information on oil spills compiled by the Alaska Department of Environmental Conservation from 2006 to 2010 indicates that an average of four spills of crude oil occurred each year in the marine environment within the range of the Southcentral Alaska stock of sea otters. Crude oil spills ranged in size from less than 4 liters to 760 liters (approximately 1 gallon to 200 gallons), with a mean size of about 41.8 liters (approximately 11 gallons). In addition to spills directly associated with the development, production, and transport of crude oil, each year numerous spills of non-crude oil products in the marine environment occur from ships and shore facilities throughout Southcentral Alaska. During the same time period and area, there was an average of about 62 spills of non-crude oil per year, ranging in size from less than 4 to 24,320 liters (approximately 1 to 6,400 gallons). The majority of the non-crude oil spills were small, with a mean size of about 380 liters (100 gallons) and a median size of 4 liters (approximately one gallon). There is no indication that these small-scale spills have an impact on the Southcentral Alaska stock of northern sea otters.

Subsistence/Native Harvest Information

The MMPA exempts Alaska Natives from the prohibition on take of marine mammals, provided such taking is not wasteful and is done for subsistence use or for creating and selling authentic handicrafts or clothing. According to the U.S. Fish and Wildlife Service's (Service) Law Enforcement records from 2006 to 2010, individuals were prosecuted for unlawful possession, transport, or sale of 14 sea otter hides or skulls taken within the range of the Southcentral Alaska stock. Data for subsistence harvest of sea otters in southcentral Alaska are collected by a mandatory Marking, Tagging and Reporting Program administered by the Service since 1988. Figure 2 provides a summary of subsistence harvest information for the Southcentral stock from 1989 to 2010. The mean reported annual subsistence take during the past five complete calendar years (2006 to 2010) was 293 animals. Reported age composition during this period was 93% adults, 6% subadults, and 1% pups. Sex composition during the past five years was 72% males, 23% females, and 5% of unknown sex. The majority of the harvest over the past five years has occurred in northern and eastern Prince William Sound.

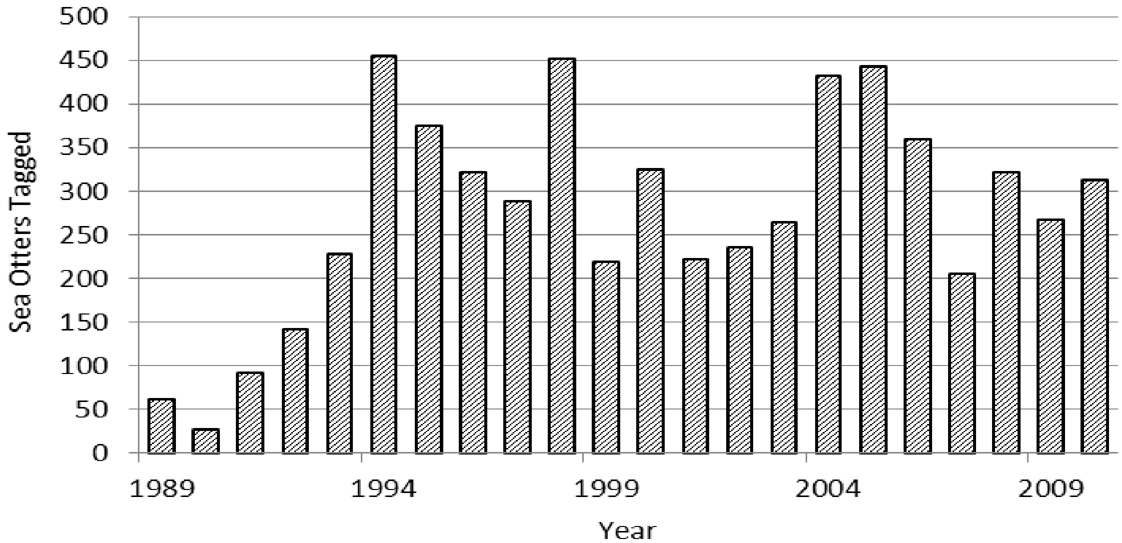

Figure 2. Reported subsistence harvest of northern sea otters from the Southcentral Alaska stock, 1989 to 2010.

Research and Public Display

During 2006 to 2010, four orphaned sea otter pups from the Southcentral Alaska stock were captured, rehabilitated, and placed for public display. During the same time period, 142 sea otters were captured and released for scientific research in Prince William Sound. There were no reported injuries and/or mortalities related to these activities.

Other Factors

In August 2006, the Working Group on Marine Mammal Unusual Mortality Events reviewed information provided by the Service and declared that a dramatic increase in sea otter strandings since 2002 constituted an Unusual Mortality Event (UME) in accordance with Section 404 of the MMPA. The disease complex that typifies this UME is caused by a *Streptococcus infantarius* infection and has been observed over a broad geographic range in Alaska, with the majority of cases identified from Kachemak Bay in the Southcentral Alaska stock. The dramatic increase of sea otter strandings in Kachemak Bay is now thought to be due to a rapidly increasing otter population in the bay combined with more community effort to report strandings. Testing and analysis are still being conducted to pinpoint the cause of this leading source of mortality. However, it is thought that the *Streptococcus infantarius* infection may be the result of immunosuppression due to an emerging virus in the Alaska population. At this time it is unclear what impact this has had, or will have, on the population.

Since 2002, the Service has undertaken a health and disease study of northern sea otters from all three Alaskan stocks. On average, the Service conducts about 100 necropsies a year on sea otter carcasses to determine cause of death, disease incidence, and status of general health parameters. Boat strike is a recurring cause of death across all three stocks. However, it has been determined in most of these cases that although trauma was the ultimate cause of death, there was a contributing factor, such as disease or biotoxin exposure, which incapacitated the animal and made it more vulnerable to boat strike.

STATUS OF STOCK

The known level of direct human-caused mortality within the Southcentral Alaska stock does not exceed the PBR level, and the Southcentral Alaska stock is neither listed as "depleted" under the MMPA nor listed as "threatened" or "endangered" under the U. S. Endangered Species Act of 1973, as amended. The known level of direct human-caused mortality is 293 otters per year. It would require an annual rate of fisheries-associated mortality and serious injury of over 1,170 otters per year for the total amount of direct human-caused mortality to exceed PBR for this stock. Despite uncertainties regarding fisheries mortality and serious injury, we believe that it is unlikely this level of take is occurring at present. Therefore, the Southcentral Alaska stock of the northern sea otter is classified as non-strategic. In addition, although the Service does not currently know the OSP for this stock, based on the known population level and our estimate of growth and considering the known level of human-caused mortality, we have determined that this stock is increasing and that human-caused mortality and serious injury is not likely to cause the stock to be reduced or to decrease its growth rate. Therefore, we would not expect the current level of human-caused mortality and serious injury to cause this stock to be reduced below its plausible OSP.

NORTHERN SEA OTTER (*Enhydra lutris kenyoni*):

Southwest Alaska Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Sea otters occur in nearshore coastal waters of the U.S. along the North Pacific Rim from the Aleutian Islands to California. The species is most commonly observed within the 40-meter (approximately 12.2 feet) depth contour because the animals require frequent access to benthic foraging habitat in subtidal and intertidal zones (Reidman and Estes 1990). Sea otters are not migratory and generally do not disperse over long distances, although movements of tens of kilometers (tens of miles) are common (Garshelis and Garshelis 1984). Annual home range sizes of adult sea otters are relatively small, with male territories ranging from 4 to 11 square kilometers (km^2) (approximately 10.5 to 28.5 square miles [mi^2]) and adult female home ranges from a few to 24 km^2 (approximately 62 mi^2) (Garshelis and Garshelis 1984; Ralls *et al*. 1988; Jameson 1989). Due to their benthic foraging, sea otter distribution is largely limited by their ability to dive to the sea floor (Bodkin *et al.* 2004).

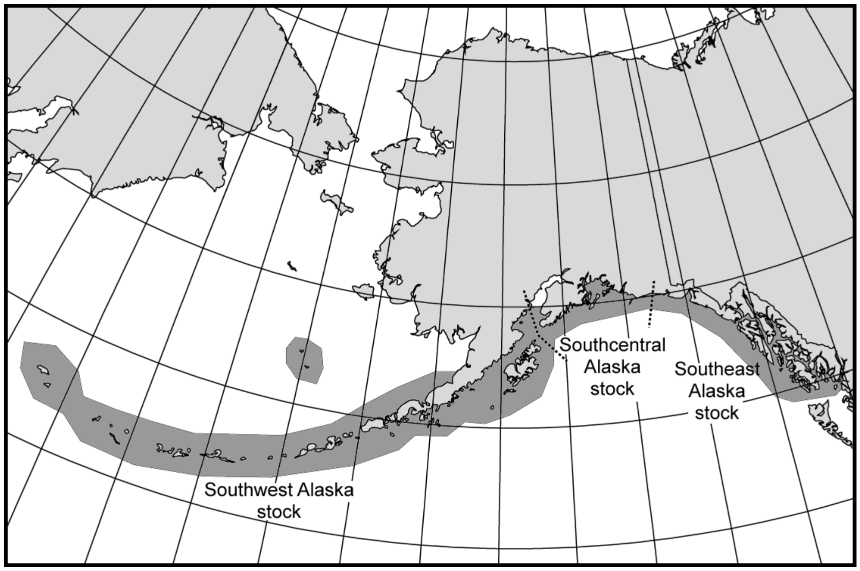

Figure 1. Approximate distribution and stock boundaries of northern sea otters in Alaska waters (shaded area).

The spatial scale at which sea otter populations are managed remains an important, although largely unexplored issue (Bodkin and Ballachey 2010) deserving further study. Bodkin and Ballachey (2010) used models of sea otter mortality to show that range-wide reductions and extirpations during the commercial fur trade of the 18th and 19th centuries occurred not simply because of excessive harvest, but because the harvest was not allocated proportional to the abundance and distribution of sea otters. This process of serial depletion was facilitated by the relatively sedentary nature of sea otters. To reduce the risk of overexploitation, sea otters must be managed on a spatial scale compatible with their well-known behavioral and reproductive biology (Bodkin and Monson 2002), incorporating traits such as home range and movements. These proposed scales for management are much smaller than the currently recognized stocks.

Gorbics and Bodkin (2001) applied the phylogeographic approach of Dizon *et al.* (1992) and used the best available data at the time to identify three sea otter stocks in Alaska: Southeast, Southcentral, and Southwest. The ranges of these stocks are defined as follows: (1) Southeast

Alaska stock extends from Dixon Entrance to Cape Yakataga; (2) Southcentral Alaska stock extends from Cape Yakataga to Cook Inlet including Prince William Sound, the Kenai Peninsula coast, and Kachemak Bay; and (3) Southwest Alaska stock includes the Alaska Peninsula and Bristol Bay coasts, and the Aleutian, Barren, Kodiak, and Pribilof Islands (Figure 1). This stock assessment report is focused on the Southwest stock of sea otters in Alaska.

POPULATION SIZE

Historically, sea otters occurred across the North Pacific Rim, ranging from Hokkaido, Japan, through the Kuril Islands, the Kamchatka Peninsula, the Commander Islands, the Aleutian Islands, peninsular and south coastal Alaska, and south to Baja California, Mexico (Kenyon 1969). In the early 1700s, the worldwide population was estimated to be between 150,000 (Kenyon 1969) and 300,000 individuals (Johnson 1982). Prior to large-scale commercial exploitation, indigenous peoples of the North Pacific hunted sea otters. Although it appears that harvests may have periodically led to local reductions of sea otters (Simenstad *et al.* 1978), the species remained abundant throughout its range until the mid-1700s. Following the arrival in Alaska of Russian explorers in 1741, extensive commercial harvest of sea otters over the next 150 years resulted in the near extirpation of the species. When sea otters were afforded protection by the International Fur Seal Treaty in 1911, probably fewer than 2,000 animals remained in thirteen remnant colonies (Kenyon 1969). Population recovery began following legal protection. As part of efforts to re-establish sea otters in portions of their historical range, otters from Amchitka Island and Prince William Sound were translocated to other areas in the

1960s and 1970s, including to southeast Alaska (Jameson *et al.* 1982). Sea otters have since recolonized much of their historical range in Alaska.

The most recent abundance estimates for survey areas within the Southwest Alaska stock are presented in Table 1. The estimate for the Katmai area has been added since the previous stock assessment report. Aerial surveys along the shorelines of the Aleutian Islands in April 2000 resulted in a count of 2,442 sea otters in the nearshore waters (Doroff *et al.* 2003). Comparison of aerial and skiff survey counts at six islands in 2000 was used to calculate a correction factor of 3.58 for this aerial survey, which resulted in an adjusted population estimate of 8,742 sea otters (CV= 0.22; Doroff *et al.* 2003).

In May 2000, a survey of offshore areas along the north Alaska Peninsula from Unimak Island to Cape Seniavin produced an abundance estimate of 4,728 sea otters (CV= 0.33; Burn and Doroff 2005). A similar survey of offshore areas along the south Alaska Peninsula from False Pass to Pavlov Bay conducted in summer 2001 resulted in a population estimate of 1,005 sea otters (CV= 0.81; Burn and Doroff 2005). Although a correction factor to account for sightability was not calculated during this survey, Evans *et al.* (1997) used a similar twin-engine aircraft flying at the same altitude and air speed to calculate a correction factor of 2.38 (CV = 0.09). Using this correction factor produced adjusted estimates of 11,253 (CV = 0.34) and 2,392 (CV = 0.82) for the north and south Alaska Peninsula offshore areas, respectively.

Table 1. Population estimates for the Southwest Alaska stock of northern sea otters. The previous stock assessment report (SAR) total is from 2008.

Survey Area	Year	Unadjusted Estimate	Adjusted Estimate	CV	N_{min}	Reference
Aleutian Islands	2000	2,442	8,742	0.22	7,309	Doroff *et al*. (2003)
North Alaska Peninsula	2000	4,728	11,253	0.34	8,535	Burn and Doroff (2005)
South Alaska Peninsula - Offshore	2001	1,005	2,392	0.82	1,311	Burn and Doroff (2005)
South Alaska Peninsula - Shoreline	2001	2,651	6,309	0.09	5,865	Burn and Doroff (2005)
South Alaska Peninsula - Islands	2001	402	957	0.09	889	Burn and Doroff (2005)
Unimak Island	2001	42	100	0.09	93	USFWS unpublished data
Kodiak Archipelago	2004		11,005	0.19	9,361	USFWS unpublished data
Katmai	2008		7,095	0.13	6,362	Coletti *et al*. (2009)
Kamishak Bay	2002		6,918	0.32	5,340	Bodkin *et al*. (2003)
Current Total			**54,771**		**45,064**	
Previous SAR Total			47,676		38,703	

In 2001, aerial surveys along the shoreline of the south Alaska Peninsula from Seal Cape to Cape Douglas recorded 2,651 sea otters (Burn and Doroff 2005). Additional aerial surveys of the south Alaska Peninsula island groups (Sanak, Caton, and Deer Islands, and the Shumagin and Pavlov Island groups) and a survey of Unimak Island, recorded 402 otters for the south Alaska Peninsula island groups and 42 animals for Unimak Island. Applying the same correction factor of 2.38 from Evans *et al.* (1997) produced adjusted estimates of 6,309 (CV = 0.09), 957 (CV = 0.09) and 100 (CV = 0.09) for the south Alaska Peninsula shoreline, south Alaska Peninsula islands, and Unimak Island, respectively.

An aerial survey of the Kodiak Archipelago conducted in 2004 resulted in an estimate of 11,005 sea otters (CV = 0.19; USFWS unpublished data). The methods used in this survey follow those of Bodkin and Udevitz (1999), which include the calculation of a survey-specific correction factor for animals undetected by observers. An aerial survey of Katmai National Park in 2009, also using the Bodkin-Udevitz method, resulted in an estimate of 7,095 sea otters (CV = 0.13; Coletti *et al.* 2009). Finally, an aerial survey of Kamishak Bay and western Cook Inlet conducted in June 2002 resulted in an estimate of 6,918 sea otters (CV = 0.32; Bodkin *et al.* 2003). This survey also used the methods of Bodkin and Udevitz (1999).

Combining the adjusted estimates for these areas, as summarized in Table 1, results in a total estimate of 54,771 sea otters for the Southwest Alaska stock. This estimated population size for the Southwest Alaska stock is slightly higher than in the 2008 stock assessment report due to the addition of an estimate for Katmai, which was surveyed in 2009 for the first time.

Minimum Population Estimate

The minimum population estimate (N_{MIN}) for this stock is calculated using Equation 1 from the Potential Biological Removal Guidelines (Wade and Angliss 1997): $N_{MIN} = N/\exp(0.842 \times [\ln(1+[CV(N)]^2)]^{½})$. The N_{MIN} for each survey area is presented in Table 1. The estimated N_{MIN} for the entire Southwest Alaska stock is 45,064 sea otters.

Current Population Trend

In spring 2000, the U.S. Fish and Wildlife Service (Service) repeated an aerial survey that had previously been conducted in 1992 and observed widespread declines throughout the Aleutian Islands, with the greatest decreases occurring in the central Aleutians. The uncorrected count for the area was 2,442 animals, indicating that sea otter populations had declined 70% since 1992 (Doroff *et al.* 2003). Burn *et al.* (2003) estimated that the sea otter population in the Aleutians in 2000 may have been reduced to less than 10% of the carrying capacity for the area. With the exception of the Kodiak Archipelago, which was surveyed in 2004, there have been no new large-scale abundance surveys for sea otters in southwest Alaska since the stock assessment report of August 2002.

On-going efforts to monitor trends in abundance include repeated skiff surveys at selected islands (index sites) in the Aleutian Islands. A Bayesian state-space trend analysis (Clark and Bjornstad 2004) developed using all available data compiled from skiff surveys around five islands in the western Aleutian Islands from 1993 to 2003 indicated that the population trends during this time period were strongly negative, with an average rate of decline of approximately 20% per year (USFWS 2013b, USGS unpublished data). Population trends changed during the period 2003 to 2011, with an average growth rate of approximately 0. Some variation in trends was evident but the trends were consistent among islands. These results suggest that population trends have stabilized in the western Aleutian Islands over the last 5 to 8 years, although there is still no evidence of recovery (USFWS 2013a, USFWS 2013b, USGS unpublished data).

Unlike in the Aleutian Islands and along the western Alaska Peninsula, sea otters in other areas within the range of the Southwest stock do not appear to have undergone a population decline over the past 20 years. Sea otter numbers in the Kodiak Archipelago, the Alaska Peninsula coast from Castle Cape to Cape Douglas, and Kamishak Bay in lower western Cook Inlet are stable and may be increasing (Coletti *et al.* 2009, Estes *et al*. 2010, USFWS 2013a, USGS unpublished data).

The estimated population size for the Southwest Alaska stock is slightly higher than in the previous stock assessment report due to the addition of Katmai, which was surveyed in 2009 for the first time. However, the overall sea otter population size in southwest Alaska has declined by more than 50% since the mid-1980s, and there is no evidence of recovery. Although current numbers are well below historical levels, the overall population trend for the Southwest Alaska stock is believed to have stabilized.

MAXIMUM NET PRODUCTIVITY RATE

Estes (1990) estimated a population growth rate of 17 to 20% per year for four northern sea otter populations expanding into unoccupied habitat. Although maximum productivity rates (R_{MAX}) have not been measured throughout much of the sea otter's range in Alaska, in the absence of more detailed information, the rate of 20% calculated by Estes (1990) is considered the best available estimate of R_{MAX}. There is insufficient information available to estimate the current net productivity rate for this population stock.

POTENTIAL BIOLOGICAL REMOVAL

Under the Marine Mammal Protection Act (MMPA), the potential biological removal (PBR) is defined as *the maximum number of animals, not including natural mortalities, that may* *be removed from a marine mammal stock while allowing that stock to reach or maintain its optimal sustainable population.* The potential biological removal is the product of the minimum population estimate (N_{MIN}), one-half the maximum theoretical net productivity rate, and a recovery factor (F_R): PBR = N_{MIN} x 0.5 R_{MAX} x F_R. In August 2005, sea otters in southwest Alaska were listed as a threatened distinct population segment (DPS) under the Endangered Species Act of 1973, as amended (70 FR 46366; August 9, 2005) (ESA). Although Wade and Angliss (1997) provide a default recovery factor of 0.5 as a guideline for threatened species, a lower value may be considered appropriate in the case of a declining population. Therefore, for the Southwest Alaska stock, which has experienced a decline, we are taking a more conservative approach and have set the recovery factor at the default value for an endangered species (0.1). The calculated PBR for this stock is 450 sea otters per year (45,064 x 0.5 (0.2) x 0.1).

ANNUAL HUMAN CAUSED MORTALITY

Fisheries Information

A complete list of fisheries and marine mammal interactions is published annually by the National Oceanic and Atmospheric Administration (NOAA) Fisheries, the most recent of which was published on August 29, 2013 (78 FR 53336). Numerous fisheries exist within the range of the Southwest Alaska stock of northern sea otters, with the only one identified as interacting with this stock being the Kodiak salmon set gillnet fishery, with an estimated 188 vessels and/or persons participating. Additional salmon set gillnet fisheries occur in Bristol Bay (982 participants) and the Alaska Peninsula/Aleutian Islands (114 participants). Although no interactions with salmon drift gillnets have been identified for this stock, interactions have been observed in Prince William Sound with the Southcentral Alaska stock. Salmon drift gillnet fisheries occur in Bristol Bay (1,863 vessels) and the Alaska Peninsula/Aleutian Islands (162 vessels). Although both salmon set and drift gillnet fisheries occur in Cook Inlet, most of the fishing effort for these gillnet fisheries occurs north of the range of sea otters from the Southwest Alaska stock. Available information suggests that fisheries using other types of gear, including trawl, longline, and purse seine, appear to be less likely to have interactions with northern sea otters due to either the areas where such fisheries operate, or the specific gear used, or both.

Although commercial fisheries in Alaska have observer programs that monitor and report injury and mortality of marine mammals incidental to their operations, a reliable estimate of the levels of commercial fisheries incidental mortality and serious injury relative to the Southwest sea otter stock cannot be made because observer coverage is not sufficient and data are not collected consistently over time. Observer data were summarized from 1989 to 2010 (Perez 2003, Perez 2006, Perez 2007, NOAA unpublished data) for Bering Sea, Aleutian Islands, and Gulf of Alaska trawl, longline, and pot groundfish fisheries. During this period, no sea otters were taken in any trawl or longline fisheries. In 1992, a total of eight sea otters were observed caught in the Pacific cod pot fishery in the Aleutian Islands. Observer records indicate that those takes occurred in nearshore waters that had been closed to fishing. This explains why no additional take of sea otters was observed in legal pot fisheries, which took place in other areas, through 2010 (Perez 2006, Perez 2007, NOAA unpublished data). Sea otters are known to interact with pot fisheries in California, and it is possible that observer effort for pot fisheries in Alaska has been too low to detect sea otter bycatch (Hatfield *et al.* 2011).

The NOAA Fisheries conducted a marine mammal observer program for the Kodiak salmon set gillnet fishery during the 2002 and 2005 fishing seasons. This fishery has a seasonal component, occurring only during the summer months. In 2002, four entanglement events were observed in this fishery (Manly *et al.* 2003). Two of these events required intervention to untangle the otter from the net, and the other two were able to escape by themselves. In none of these instances was there any sign of external injuries. The sea otter by-catch in this fishery was estimated at 62 otters during the 2002 fishing season. Although no serious injuries or mortalities were observed in this small sample size of observed entanglements, it is reasonable to assume that some of these otters may have suffered injury as a result of entanglement in set gillnet fisheries. In fact, there was one self-report of an otter killed during the 2002 fishing season. Results from the 2005 Kodiak salmon set gillnet fishery indicate entanglement of one otter that subsequently released itself from the net, although it was not clear if this was a sea otter or river otter (Manly 2007). Assuming that this animal was a sea otter, the total by-catch in this fishery would be estimated at 28 animals during the 2005 season. Based on these results, it would appear that although entanglement of sea otters does occur in this fishery, the rate of mortality or serious injury is low.

An additional source of information on the number of sea otters killed or injured incidental to commercial fishery operations in Alaska are fisher self-reports required of vessel owners by NOAA Fisheries. In 1997, fisher self-reports indicated one sea otter caught in the Bering Sea and Aleutian Island groundfish trawl fishery; however, it is unclear if the animal was alive when caught. Credle *et al.* (1994) considered fisher self-reports to be a minimum estimate of incidental take as these data are most likely negatively biased. Observer coverage for fisheries within the range of the Southwest stock of sea otters has been absent in some fisheries and low in others, particularly with respect to the set and drift gillnet fisheries that are recognized as interacting with this stock, and current estimates of sea otter bycatch are not available. Self-reporting is not sufficiently reliable to replace observer effort. Additionally, assessment of injury and mortality in sea otters that interact with fisheries is difficult. Information is, therefore, insufficient to determine whether or not the total fishery mortality and serious injury for the Southwest Alaska stock of the northern sea otter is insignificant and is approaching a zero mortality and serious injury rate.

Oil Spills

Activities associated with exploration, development, and transport of oil and gas resources can adversely impact sea otters and nearshore coastal ecosystems in Alaska. Sea otters rely on air trapped in their fur for warmth and buoyancy. Contamination with oil drastically reduces the insulative value of the pelage, and consequently sea otters are among the marine mammals most likely to be detrimentally affected by contact with oil. It is believed that sea otters can survive low levels of oil contamination (<10% of body surface), but that greater levels (>25%) will lead to death (Costa and Kooyman 1981, Siniff *et al.* 1982). Vulnerability of sea otters to oiling was demonstrated by the 1989 *Exxon Valdez* oil spill in Prince William Sound. Estimates of mortality for the Prince William Sound area vary from 750 otters (range 600 to 1,000; Garshelis 1997) to 2,650 otters (range 500 to 5,000; Garrott *et al.* 1993). Statewide, 3,905 sea otters (range 1,904 to 11,257) were estimated to have died in Alaska as a result of the spill (DeGange *et al.* 1994). At present, although abundance of sea otters in some oiled areas of Prince William Sound remains below pre-spill estimates, evidence from ongoing studies suggests that sea otters numbers in this area are increasing, a trend interpreted as strong evidence of a trajectory toward recovery of spill-affected sea otter populations in western Prince William Sound (Bodkin *et al.* 2002, Stephensen *et al.* 2001, Bodkin *et al.* 2011).

Within the range of the Southwest Alaska sea otter stock, oil and gas development and production occurs only in Cook Inlet. As of 2011, 16 offshore oil platforms operated in Cook Inlet, and two more are slated to begin operations in 2012. A Federal lease sale in lower Cook Inlet is planned for the fall of 2013. Although the amount of oil transported in southwest Alaska is relatively small, the *Exxon Valdez* oil spill demonstrated that spilled oil can travel long distances and take large numbers of sea otters far from the point of initial release. The grounding in 2004 of the freighter *Selendang Ayu* on Unalaska Island, within the range of this stock, released 1,219,800 liters (approximately 321,000 gallons) of non-crude oil and caused at least two sea otter mortalities (USFWS unpublished data). While the catastrophic release of oil has the potential to take large numbers of sea otters, there is no evidence that other effects (such as disturbance) associated with routine oil and gas development and transport have had a direct impact on the Southwest Alaska sea otter stock.

Information on oil spills compiled by the Alaska Department of Environmental Conservation from 2006 to 2010 indicates that there were no reported spills of crude oil in southwest Alaska during that time period. In addition to spills that may occur in association with the development, production, and transport of crude oil, each year numerous spills of non-crude oil products in the marine environment occur from ships and shore facilities throughout southwest Alaska. During that same time period, an average of 64 non-crude oil spills occurred each year, ranging in size from less than 4 to 551,000 liters (approximately1 to 145,000 gallons).

The majority of these spills were small, with a mean size of about 3,500 liters (approximately 921 gallons) and a median size of 15 liters (approximately 2 gallons). There is no indication that these small-scale spills have an impact on the Southwest Alaska stock of northern sea otters.

Subsistence/Native Harvest Information

The MMPA exempts Alaska Natives from the prohibition on take of marine mammals, provided such taking is not wasteful and is done for subsistence use or for creating and selling authentic handicrafts or clothing. In addition, section 10(e) of the ESA allows for take of listed species for primarily subsistence purposes under certain circumstances. According to the Service's Law Enforcement records, there were no prosecutions from 2006 to 2010 for unlawful take, possession, transport, or sale of sea otters or sea otter hides taken within the range of the Southwest Alaska stock. Data for subsistence harvest of sea otters in southwest Alaska are collected by a mandatory Marking, Tagging and Reporting Program administered by the Service since 1988. Figure 2 provides a summary of harvest information for the Southwest stock from 1989 through 2010. The mean reported annual subsistence take during the past five complete calendar years (2006-2010) was 76 animals. Reported age composition during this period was 84% adults, 12% subadults, 1% pups, and 3% unknown. Sex composition during the past five years was 77% males, 19% females, and 4% unknown. The majority of this harvest (83%) comes from the Kodiak Archipelago; areas within the stock that show signs of continued population declines have little to no record of subsistence harvest.

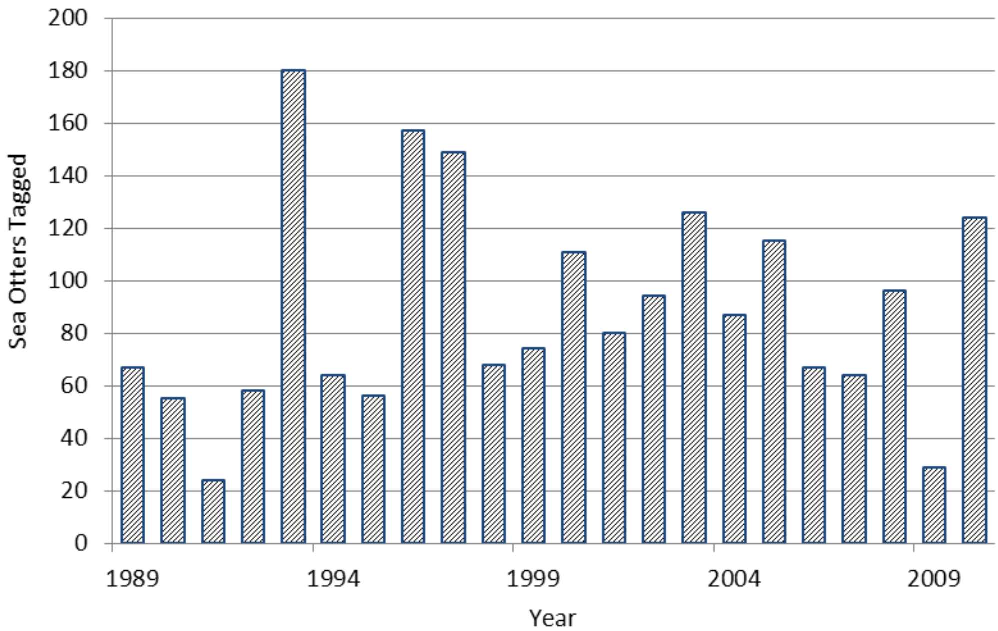

Figure 2. Reported subsistence harvest of northern sea otters from the Southwest Alaska stock, 1989-2010.

Research and Public Display

During 2006 to 2010, one orphaned sea otter pup from the Southwest Alaska stock was captured, rehabilitated, and placed for public display. During this period, a total of 65 otters were live-captured from this stock and released for research purposes. The captures occurred in the vicinities of Kukak Bay (Katmai National Park and Preserve coast), Unga Island (Shumagin Island group), and Dolgoi Island (Pavlov Island group). There were no reported injuries and/or mortalities related to these activities.

Other Factors

Each year, several thousand commercial vessels of varying sizes traverse the North Pacific Great Circle Route between North America and Asia, carrying a variety of cargoes. Vessels generally pass through the Aleutian Islands twice, through Unimak Pass to the east and near Buldir Island to the west. A risk assessment for the area concluded that while a majority of the vessel traffic along the Great Circle Route passes through the region without making any port calls, accidents involving these vessels have the potential to significantly and adversely impact coastal and marine ecosystems, economies, and human activities in the region (Aleutian Islands Risk Assessment Project Management Team 2011). Previous vessel accidents in the Aleutian Islands have resulted in loss of cargo, oil spills, and loss of life. The remoteness, limited infrastructure, and severe weather of the region often limit the potential to mitigate or respond to incidents. Overall, both the total number of accidents and the total risk of a bunker oil spill in the region are predicted to increase (Aleutian Islands Risk Assessment Project Management Team 2011).

Since 2002 the Service has undertaken a health and disease study of northern sea otters from all three Alaskan stocks. On average, the Service conducts about 100 necropsies a year on sea otter carcasses to determine cause of death, disease incidence and status of general health parameters. Boat strike is a recurring cause of death across all three stocks. However, it has been determined in most of these cases that although trauma was the ultimate cause of death, there was a contributing factor, such as disease or biotoxin exposure, which incapacitated the animal and made it more vulnerable to boat strike.

In August 2006, the Working Group on Marine Mammal Unusual Mortality Events reviewed information provided by the Service, and declared that a dramatic increase in sea otter strandings since 2002 constituted an Unusual Mortality Event (UME) in accordance with section 404 of the MMPA. The disease that typifies this UME is caused by a *Streptococcus infantarius* infection and has been observed over a broad geographic range in Alaska, including a few cases from southwest Alaska; however, the majority of cases have come from Kachemak Bay in the Southcentral Alaska stock. It is not clear if the observed stranding pattern is representative of overall sea otter mortality, or an artifact of having a well-developed stranding network in the Kachemak Bay area. The Service will continue to work with NOAA Fisheries and the Alaska Sea Life Center to develop the infrastructure for a State-wide marine mammal stranding network in Alaska.

STATUS OF STOCK

On August 9, 2005, the Southwest Alaska DPS of the northern sea otter was listed as "threatened" under the ESA, and it is, therefore, classified as a strategic stock under the MMPA.

Guidelines for Preparing Stock Assessment Reports Pursuant to Section 117 of the Marine Mammal Protection Act

1. General Guidelines

Introduction

Section 117 of the Marine Mammal Protection Act (MMPA) requires that the National Marine Fisheries Service (NMFS) and the U.S. Fish and Wildlife Service (FWS) develop Stock Assessment Reports (Reports) for all marine mammal stocks in waters under U.S. jurisdiction (U.S. waters). These Reports are to be based upon the best scientific information available. Reports are not required for stocks that have a remote likelihood of occurring regularly in U.S. waters (e.g., stocks for which only the margins of the range extend into U.S. waters or that enter U.S. waters only during anomalous current or temperature shifts).

The MMPA requires Reports to include, among other things, information on how stocks were identified, a calculation of Potential Biological Removal (PBR), and an assessment of whether incidental fishery takes are "insignificant and approaching zero mortality and serious injury rate," as well as other information relevant to assessing stocks. These reports are to be reviewed annually for "strategic stocks" and stocks for which significant new information is available, and at least once every three years for all other stocks. This document provides guidance for how these topics are to be addressed in the Reports.

The MMPA provides some general guidance for developing the Reports. More detailed guidelines were developed at a PBR workshop in June 1994 and were used in writing the original draft Reports. The draft guidelines and initial draft Reports were subjected to public review and comment in August 1994. Final guidelines and Reports were completed in 1995 (Barlow et al. 1995). In 1996, representatives of NMFS, FWS, regional Scientific Review Groups, and the Marine Mammal Commission reviewed the guidelines and proposed minor changes, which after public review and comment, were made final in 1997 (Wade and Angliss 1997). The guidelines were officially updated again in 2005, following a similar revision process beginning with workshop in September 2003 (NMFS 2005). In February 2011, NMFS again convened representatives of the review groups and agencies to review and, as appropriate, recommend revisions to the guidelines. Those recommended revisions (Moore and Merrick 2011) were made available for public review and comment, and are finalized here.

It is anticipated that the guidelines themselves will be reviewed and changed based on additional scientific research and on experience gained in their application. In this regard, FWS and NMFS will meet periodically to review and revise, as needed, the guidelines. When the agencies recommend revisions to the guidelines, these revisions will be made available for public review and comment prior to acceptance. Furthermore, the guidelines in this document do not have to be followed rigidly; however, any departure from these guidelines must be discussed fully within any affected Report.

The intent of these guidelines is to: (1) provide a uniform framework for the consistent application of the amended MMPA throughout the country; (2) ensure that PBR is calculated in a manner that ensures meeting the goals of the MMPA; (3) provide guidelines for evaluating whether fishery takes are insignificant and approaching a zero mortality and serious injury rate; and (4) make the Federal government's approach clear and open to the public. Where the guidelines provided here are not incorporated into a particular Report, justification for the departure will be provided within the Report. Similarly, the Reports will explain when deviations are made from specific recommendations from the Scientific Review Groups.

The FWS and NMFS interpret the primary intent of the 1994 MMPA amendments and the PBR guidelines developed pursuant to the Act as a mechanism to respond to the uncertainty associated with assessing and reducing marine mammal mortality from incidental fisheries takes. Accordingly, this mechanism is increasingly conservative under increasing degrees of uncertainty. The MMPA requires the calculation of PBR for all stocks, including those that are considered endangered or threatened under the Endangered Species Act (ESA) and those that are managed under other authorities, such as the International Whaling Commission. However, in some cases allowable takes under these other authorities may be less than the PBR calculated under the MMPA owing to the different degrees of "risk" associated with, and the treatment of, uncertainty under each authority. Where there is inconsistency between the MMPA and ESA regarding the take of listed marine mammals, the more restrictive mortality requirement takes precedence. Nonetheless, PBR must still be calculated for these stocks, where possible, and discussed in the text of the Reports. As directed in the MMPA, the PBR is calculated as "...the maximum number of animals, not including natural mortalities, that may be removed from a marine mammal stock while allowing that stock to reach or maintain its optimum sustainable population." Therefore, a PBR is an upper limit to removals that does not imply that the entire amount should be taken.

Section 117 requires PBR, human-caused mortality, and classification as to whether a stock is "strategic" or "non-strategic" to be included in the Reports for all stocks of marine mammals in U.S. waters. However, it should be noted that the co-management, between the Federal government and Alaska Native Organizations, of removals of marine mammals for subsistence purposes between the Federal government and Alaska Native organizations is specifically addressed in Section 119. In response to Section 119, NMFS and FWS have entered into cooperative agreements with Alaska Native Organizations to conserve marine mammals and provide co-management of subsistence use by Alaska Natives. FWS and NMFS believe that it is appropriate to develop management programs for stocks subject to subsistence harvests through the co-management process provided that commercial fisheries takes are not significant and that the process includes a sound research and management program to identify and address uncertainties concerning the status of these stocks. Calculations of PBR and classification as to whether a stock is strategic will be determined from the analysis of scientific and other relevant information discussed during the co-management process.

In the sections of the Reports on Stock Definition and Geographic Range, elements of the PBR formula, Population Trend, and Annual Human-caused Mortality and Serious Injury, authors are to provide a brief description of key uncertainties in each element and evaluate the effects of these uncertainties associated with parameters in these sections. In cases where more lengthy discussions of uncertainty are necessary, they should be published separately (e.g., as NOAA Technical Memorandum) and referenced in the SAR.

Definition of "Stock"

"Population stock" is the fundamental unit of legally-mandated conservation. The MMPA defines population stock as "a group of marine mammals of the same species or smaller taxa in a common spatial arrangement, that interbreed when mature." To fully interpret this definition, it is necessary to consider the objectives of the MMPA. Section 2 (Findings and Declaration of Policy) of the MMPA states that "...species and population stocks of marine mammals...should not be permitted to diminish beyond the point at which they cease to be a significant functioning element in the ecosystem of which they are a part, and, consistent with this major objective, they should not be permitted to diminish below their optimum sustainable population." Further, it states "...the primary objective of their management should be to maintain the health and stability of the marine ecosystem. Whenever consistent with this primary objective, it should be the goal to obtain an optimum sustainable population keeping in mind the carrying capacity of the habitat." Therefore, stocks must be identified in a manner that is consistent with these goals. For the purposes of management under the MMPA, a stock is recognized as being a management unit that identifies a demographically independent biological population. It is recognized that in practice, our ability to detect stocks may fall short of this ideal because of a lack of information, or for other reasons.

Many types of information can be used to identify stocks of a species (e.g., distribution and movements, population trends, morphology, life history, genetics, acoustic call types, contaminants and natural isotopes, parasites, and oceanographic habitat). Different population responses (e.g., different trends in abundance) between geographic regions are also an indicator of stock structure, as populations with different trends are not strongly linked demographically. When different types of evidence are available to identify stock structure, the Report must discuss inferences made from the different types of evidence and how these inferences were integrated to identify the stock.

Evidence of morphological or genetic differences in animals from different geographic regions indicates that these populations are demographically independent. Demographic independence means that the population dynamics of the affected group is more a consequence of births and deaths within the group (internal dynamics) rather than immigration or emigration (external dynamics). Thus, the exchange of individuals between population stocks is not great enough to prevent the depletion of one of the populations as a result of increased mortality or lower birth rates.

Failure to detect genetic or morphological differences, however, does not necessarily mean that populations are not demographically independent. Dispersal rates, though sufficiently high to homogenize morphological or genetic differences detectable between putative populations, may still be insufficient to deliver enough recruits from an unexploited population (source) to an adjacent exploited population (sink) so that the latter remains a functioning element of its ecosystem. Insufficient dispersal between populations where one bears the brunt of exploitation coupled with their inappropriate pooling for management could easily result in failure to meet MMPA objectives. For example, it is common to have human-caused mortality restricted to a portion of a species' range. Such concentrated mortality (if of a large magnitude) could lead to population fragmentation, a reduction in range, or even the loss of undetected populations, and would only be mitigated by high immigration rates from adjacent areas.

Therefore, careful consideration needs to be given to how stocks are identified. In particular, where mortality is greater than a PBR calculated from the abundance just within the oceanographic region where the human-caused mortality occurs, serious consideration should be given to identifying an appropriate management unit in this region. In the absence of adequate information on stock structure and fisheries mortality, a species' range within an ocean should be divided into stocks that represent defensible management units. Examples of such management units include distinct oceanographic regions, semi-isolated habitat areas, and areas of higher density of the species that are separated by relatively lower density areas. Such areas have often been found to represent true biological stocks where sufficient information is available. In cases where there are large geographic areas from which data on stock structure of marine mammals are lacking, stock structure from other parts of the species' range may be used to draw inferences as to the likely geographic size of stocks. There is no intent to identify stocks that are clearly too small to represent demographically independent biological populations, but it is noted that for some species genetic and other biological information has confirmed the likely existence of stocks of relatively small spatial scale, such as within Puget Sound, WA, the Gulf of Maine, or Cook Inlet, AK.

Each Report will state in the Stock Definition and Geographic Range section whether it is plausible the stock contains multiple demographically independent populations that should be separate stocks, along with a brief rationale. If additional structure is plausible and human-caused mortality or serious injury is concentrated within a portion of the range of the stock, the Report should identify the portion of the range in which the mortality or serious injury occurs. In addition, a description of any additional key uncertainties concerning the stock definition should be provided, along with an evaluation of the potential effects of these uncertainties on the stock definition.

In transboundary situations where a stock's range spans international boundaries or the boundary of the U.S. Exclusive Economic Zone (EEZ), the best approach is to establish an international management agreement for the species and to evaluate all sources of human-caused mortality and serious injury (U.S. and non-U.S.) relative to the PBR for the entire stock range. In the interim, if a transboundary stock is migratory and it is reasonable to do so, the fraction of time the stock spends in U.S. waters should be noted, and the PBR for U.S. fisheries should be apportioned from the total PBR based on this fraction. For non-migratory transboundary stocks (e.g., stocks with broad pelagic distributions that extend into international waters), if there are estimates of mortality and serious injury from U.S. and other sources throughout the stock's range, then PBR calculations should be based upon a range-wide abundance estimate for the stock whenever possible. In general, abundance or density estimates from one area should not be extrapolated to unsurveyed areas to estimate range-wide abundance (and PBR). But, informed interpolation (e.g., based on habitat associations) may be used to fill gaps in survey coverage and estimate abundance and PBR over broader areas as appropriate and supported by existing data.[1] If estimates of mortality or abundance from outside the U.S. EEZ cannot be determined, PBR calculations should be based on abundance within the EEZ and compared to mortality within the EEZ.

Prospective Stocks

When information becomes available that appears to justify a different stock structure or stock boundaries, it may be desirable to include the new structure or boundaries as "prospective stocks" within the existing Report. The descriptions of prospective stocks would include a description of the evidence for the new stocks, calculations of the prospective PBR for each new stock, and estimates of human-caused mortality and serious injury, by source. The notice of availability of draft Reports with prospective stocks would include a request for public comment and additional scientific information specifically addressing the prospective stock structure. Prospective stocks would be expected to become separate stocks in a timely manner unless additional evidence was produced to contradict the prospective stock structure. Summary information for prospective stocks should be included in the standard table in the Reports that summarizes the minimum population estimate, the maximum net productivity rate, etc. for each stock.

PBR Elements

The 1994 amendments to the MMPA mandate that, as part of the Reports, PBR must be calculated for each marine mammal stock in U.S. waters. The PBR is defined as "the maximum number of animals, not including natural mortality, that may be removed from a marine mammal stock while allowing that stock to reach or maintain its optimum sustainable population." In addition, the MMPA states that PBR is calculated as the product of three elements: the minimum population estimate (N_{min}); half the maximum net productivity rate (0.5 R_{max}); and a recovery factor (F_r). The guidelines for defining and applying each of these three elements are described below. Further specific guidance on the calculation of PBR is provided in part 2 (Technical Details) of this document. The Report should provide a description of any key uncertainties in the elements of the PBR equation and evaluate the effects of these uncertainties on the estimate.

An underlying assumption in the application of the PBR equation is that marine mammal stocks exhibit certain population dynamics. Specifically, it is assumed that a depleted stock will naturally grow toward OSP and that some surplus growth may be removed while still allowing recovery. There are unusual situations, however, where the formula Congress added to the MMPA to calculate PBR (N_{min}*0.5R_{max}*F_r) results in a number that is not consistent with the narrative definition of PBR (the maximum number of animals, not including natural mortality, that may be removed from a marine mammal stock while allowing that stock to reach or maintain

[1] "Informed interpolation" specifically refers to the use of a model-based method for interpolating density between transect lines, such as habitat-based density modeling and other forms of spatial modeling.

its OSP). That is, there are situations where a stock is below its OSP and is declining or stable, yet human-caused mortality is a not a major factor in the population's trend. Thus, for unknown reasons, the stock's population dynamics do not conform to the underlying model for calculating PBR. In such unusual situations, the PBR calculations should be qualified in the Report in the PBR section.

Minimum Population Estimate (N_{min})

N_{min} is defined in the MMPA amendments as an estimate of the number of animals in a stock that:

> "(A) is based on the best available scientific information on abundance, incorporating the precision and variability associated with such information; and,
>
> "(B) provides reasonable assurance that the stock size is equal to or greater than the estimate."

Consistent with these MMPA definitions, N_{min} should be calculated such that a stock of unknown status would achieve and be maintained within OSP with 95% probability. Population simulations have demonstrated (Wade 1994) that this goal can be achieved by defining N_{min} as the 20th percentile of a log-normal distribution based on an estimate of the number of animals in a stock (which is equivalent to the lower limit of a 60% 2-tailed confidence interval):

$$N_{min} = N/\exp(0.842 * (\ln(1+CV(N)^2))^{½})$$

where N is the abundance estimate and CV(N) is the coefficient of variation of the abundance estimate. If abundance estimates are believed to be biased, appropriate correction factors should be applied to obtain unbiased estimates of N. In such cases, the coefficient of variation for N should include uncertainty in the estimation of the correction factor. In cases where a direct count is available, such as for many pinniped stocks, this direct count could alternatively be used as the estimate of N_{min}. Other approaches could also be used to estimate N_{min} if they provide the same level of assurance that the stock size is equal to or greater than that estimate.

Clearly, the most recent abundance estimate becomes a less accurate population descriptor with time. When abundance estimates become many years old, at some point estimates will no longer meet the requirement that they provide reasonable assurance that the stock size is presently greater than or equal to that estimate. Therefore, unless compelling evidence indicates that a stock has not declined since the last census, the N_{min} estimate of the stock should be considered unknown if 8 years have transpired since the last abundance survey. Eight years was chosen, in part, because a population that declines at 10% per year from carrying capacity would be reduced to less than 50% of its original abundance after 8 years. A 10% decline per year over at least 8 years represents the greatest decline observed for a stock of marine mammals in U.S. waters. If N_{min} is unknown, then PBR cannot be determined, but this is not equivalent to considering PBR equal to zero. If there is known or suspected human-caused mortality of the stock, decisions about whether such stocks should be declared strategic or not should be made on a case-by-case basis. Stocks for which N_{min} becomes unknown should not move from "strategic" to "not-strategic", or v.v., solely because of an inability to estimate N_{min}.

Population Trend

The Reports will describe information on current population trend. The Report should also provide a description of any key uncertainties concerning the population trend, and evaluate the effects of these uncertainties on the trend.

Maximum Rate of Increase (R_{max})

One-half R_{max} is defined in the MMPA as "one-half of the maximum theoretical or estimated "net productivity rate of the stock at a small population size," where the term "net productivity rate" means "the annual per capita rate of increase in a stock resulting from additions due to reproduction, less losses due to natural mortality." Default values should be used for R_{max} in the absence of stock-specific measured values. To be consistent with a risk-averse approach, these default values should be near the lower range of measured or theoretical values (or 0.12 for pinnipeds and sea otters and 0.04 for cetaceans and manatees). Substitution of other values for these defaults should be made with caution, and only when reliable stock-specific information is available on R_{max} (e.g., estimates published in peer-reviewed articles or accepted by review groups such as the MMPA Scientific Review Groups or the Scientific Committee of the International Whaling Commission).

Details on rounding and precision, and on averaging more than one estimate of abundance to calculate N_{min}, can be found in part 2 (Technical Details) of this document.

Recovery Factor (F_r)

The MMPA defines the recovery factor, F_r, as being between 0.1 and 1.0. The intent of Congress in adding F_r to the definition of PBR was to ensure the recovery of populations to their OSP levels, and to ensure that the time necessary for populations listed as endangered, threatened, and/or depleted to recover was not significantly increased. The use of F_r less than 1.0 allocates a proportion of expected net production towards population growth and compensates for uncertainties that might prevent population recovery, such as biases in the estimation of N_{min} and R_{max} or errors in the determination of stock structure. Population simulation studies (Barlow et al. 1995, Wade 1998) demonstrate that the default F_r for stocks of endangered species should be 0.1, and that the default F_r for depleted and/or threatened stocks and stocks of unknown status should be 0.5.

The default status should be considered as "unknown." Stocks known to be within OSP (e.g., as determined from quantitative methods such as dynamic response or back-calculation), or stocks of unknown status that are known to be increasing, or stocks that are not known to be decreasing taken primarily by aboriginal subsistence hunters, could have higher F_r values, up to and including 1.0, provided there have not been recent increases in the levels of takes. Recovery factors for ESA-listed stocks can be changed from their default values, but only after careful consideration and where available scientific evidence confirms that the stock is not in imminent danger of extinction. Values other than the defaults for any stock should usually not be used without the approval of the regional Scientific Review Group, and scientific justification for the change should be provided in the Report.

The recovery factor can be adjusted to accommodate additional information and to allow for management discretion as appropriate and consistent with the goals of the MMPA. For example, if human-caused mortalities include more than 50% females, the recovery factor should be decreased to compensate for the greater impact of this mortality on the population (or increased if less than 50% female). Similarly, declining stocks, especially ones that are threatened or depleted, should be given lower recovery factors, the value of which should depend on the magnitude and duration of the decline. The recovery factor of 0.5 for threatened or depleted stocks or stocks of unknown status was determined based on the assumption that the coefficient of variation of the mortality estimate is equal to or less than 0.3. If the CV is greater than 0.3, the recovery factor should be decreased to: 0.48 for CVs of 0.3 to 0.6; 0.45 for CVs of 0.6 to 0.8; and 0.40 for CVs greater than 0.8.

Recovery factors could also be increased in some cases. If mortality estimates are known to be relatively unbiased because of high observer coverage, then it may be appropriate to increase the recovery factor to reflect the greater certainty in the estimates. Thus, in an instance where the observer coverage was 100% and the observed fishery was responsible for virtually all fishery mortality on a particular stock, the recovery factor for a stock of unknown status might be increased from 0.5 (reflecting less concern about bias in mortality, but continued concern about biases in other PBR parameters and errors in determining stock structure). Recovery factors of 1.0 for stocks of unknown status should be reserved for cases where there is assurance that N_{min}, R_{max}, and the estimates of mortality and serious injury are unbiased and where the stock structure is unequivocal.

Annual Human-caused Mortality and Serious Injury

A summary of all human-caused mortality and serious injury should be provided in each Report as the first paragraph under “Annual human-caused mortality and serious injury.” This summary should include information on all mortality and serious injury (e.g., U.S. commercial fishing, other fishery mortality from recreational gear and foreign fleets, strandings, vessel strikes, power plant entrainment, shooting, scientific research, after-action reports from otherwise authorized activities, etc.).

The Reports should contain a complete description of what is known about current human-caused mortality and serious injury. Information about incidental fisheries mortality should be provided, including sources such as observer programs, logbooks, fishermen’s reports, strandings, and other sources, where appropriate. It is expected that this section of the Reports will include all pertinent information that is subsequently used to categorize fisheries under Section 118. Therefore, any additional information that is anticipated to be used to categorize a fishery should be provided here.

If mortality and serious injury estimates are available for more than one year, a decision will have to be made about how many years of data should be used to estimate annual mortality. There is an obvious trade-off between using the most relevant information (the most recent data) versus using more information (pooling across a number of years) to increase precision and reduce small-sample bias. It is inappropriate to state specific guidance directing which years of data should be used, because the case-specific choice depends upon the quality and quantity of data. Accordingly, mortality estimates could be averaged over as many years as necessary to achieve statistically unbiased estimation with a CV of less than or equal to 0.3. Generally, estimates include the most recent five years for which data have been analyzed, as this accounts for inter-annual variability. However, information more than five years old can be used if it is the most appropriate information available in a particular case.

In some cases it may not be appropriate to average over as many as five years even if the CV of an estimate is greater than 0.3. For example, if within the last five years the fishery has changed (e.g., fishing effort or the mortality rate per unit of fishing effort has changed), it would be more appropriate to use only the most recent relevant data to most accurately reflect the current level of annual mortality. When mortality is averaged over years, an un-weighted average should be used, because true mortality rates vary from year-to-year. When data are insufficient to overcome small-sample bias of mortality estimates for purposes of comparing the estimates to PBR (see Technical Details), a statement acknowledging this elevated potential for small-sample bias should accompany mortality estimates in the Reports.

In some cases, mortality and serious injury occur in areas where more than one stock of marine mammals occurs. When biological information (e.g., photo-identification, genetics, morphology) is sufficient to identify the stock from which a dead or seriously injured animal came, then the mortality or serious injury should be associated only with that stock. When one or more deaths or serious injuries cannot be assigned directly to a stock, then those deaths or serious injuries may be partitioned among stocks within the appropriate geographic area, provided there is sufficient information to support such partitioning (e.g., based on the relative abundances of stocks within the area). When the mortality and serious injury estimate is partitioned among overlapping stocks, the Reports will contain a discussion of the potential for over- or under-estimating stock-specific mortality and serious injury. In cases where mortality and serious injuries cannot be assigned directly to a stock and available information is not sufficient to support partitioning those deaths and serious injuries among stocks, the total unassigned mortality and serious injuries should be assigned to each stock within the appropriate geographic area. When deaths and serious injuries are assigned to each overlapping stock in this manner, the Reports will contain a discussion of the potential for over-estimating stock-specific mortality and serious injury.

A summary of mortality and serious injury incidental to U.S. commercial fisheries should be presented in a table, providing the name of the fishery and, for each appropriate year, observed mortality and serious injury, estimated extrapolated mortality and serious injury and associated CV, and percent observer coverage in that year, with the last column providing the average annual mortality and serious injury estimate for that fishery. Information on non-serious injuries should also be provided, either in the table or the text.[2] Because U.S. commercial fisheries and foreign fisheries within the U.S. EEZ are subject to regulation under MMPA Section 118, mortality and serious injury from such fisheries should be clearly separated from other fishery-related mortality (e.g., mortality incidental to recreational fishing or foreign fishing beyond the U.S. EEZ) in the Reports.

There is a general view that marine mammal mortality information from logbook or fishermen's report data can only be considered as a minimum estimate of mortality, although exceptions may occur. Logbook or fishermen's report information can be used to determine whether the minimum mortality is greater than the PBR (or greater than 10% of the PBR), but it should not be used to determine whether the mortality is less than the PBR (or 10% of the PBR). Logbook data for fishermen's reports should not be used as the sole justification for determining that a particular stock is not strategic or that its mortality and serious injury rate is insignificant and approaching zero.

For fisheries without observer programs, information about incidental mortality and serious injury from logbooks, fishermen's self-reports, strandings, and other sources should be included where appropriate. When these other sources of data are used, particularly as a significant component of the measure of annual human-caused mortality, the following language should be added to the Report: "It is important to stress that this mortality estimate results from an actual count of verified human-caused deaths and serious injuries and should be considered a minimum." Such information should be presented in brackets to distinguish it from estimates of total mortality and serious injury in the fishery. If such information is not included in the table, but reports such as fishermen's self-reports are available, those reports should be described in the text and any concern with the quality of that report should be noted. Fishermen's self-reports of mortality or injuries should not be included if the fishery was observed and incidental mortality and serious injury was estimated based on observer records and associated coverage. Mortality and serious injury by those fisheries not regulated under MMPA Section 118 (i.e., incidental to foreign fisheries or recreational fisheries), should be distinguished from mortality and serious injury incidental to fisheries subject to Section 118. Further guidance on averaging human-caused mortality across years and across different sources of mortality can be found in the Technical Details section of these guidelines.

Because many stocks are subject to human caused mortality or serious injury that is unmonitored or not fully quantified, authors of the Reports should add a sub-section of the Human-Caused Mortality and Serious Injury section to include a summary of the most prevalent potential sources of human-caused mortality or serious injury that are not quantified (e.g., fisheries that have never

[2] In 2012, NMFS implemented a policy to distinguish serious from non-serious injuries (NOAA 2012). This policy and associated procedural directive detail the process by which NMFS evaluates injuries, documents that rationale, and reviews determinations.

been observed, or have not been observed recently, and ship strikes). If there are no major known sources of unquantifiable human-caused mortality or serious injury, this should be explicitly stated. Finally, a description of any additional key uncertainties concerning human-caused mortality or serious injury should be provided, along with an evaluation of the potential effects of these uncertainties on the mortality estimates.

Mortality Rates

Section 118 of the 1994 MMPA Amendments reaffirmed the goal set forth in the Act when it was enacted in 1972 that the take of marine mammals in commercial fisheries is to be reduced to insignificant levels approaching zero mortality and serious injury rate, and further requires that this goal be met within seven years of enactment of the 1994 Amendments (April 30, 2001). This fisheries-specific goal is referred to as the "zero mortality rate goal" (ZMRG). The Reports are not the vehicle for publishing determinations as to whether a specific fishery has achieved the ZMRG. A review of progress towards the ZMRG for all fisheries was submitted to Congress in August 2004.

However, Section 117 of the amended MMPA requires that Reports include descriptions of fisheries that interact with (i.e., kill or seriously injure) marine mammals, and these descriptions must contain "an analysis stating whether such level is insignificant and is approaching a zero mortality and serious injury rate." As a working definition for the Reports, this analysis should be based on whether the total mortality for a stock in all commercial fisheries with which it interacts is less than 10% of the calculated PBR for that stock. The following wording is recommended (typically in the "Status of Stock" section of the Report):

"The total fishery mortality and serious injury for this stock is (or is not) less than 10% of the calculated PBR and, therefore, can (or cannot) be considered to be insignificant and approaching a zero mortality and serious injury rate."

Status of Stocks

This section of the Reports should present a summary of four types of "status" of the stock: (1) current legal designation under the MMPA and ESA, (2) status relative to OSP (within OSP, below OSP, or unknown), (3) designation of strategic or non-strategic, and (4) a summary of trends in abundance and mortality. Based upon descriptions of levels of uncertainties from the Report sections on Stock Definition and Geographic Range, Elements of the PBR Formula, Population Trend, and Annual Human-Caused Mortality and Serious Injury, authors should evaluate and describe any consequences of these uncertainties on the assessment of the stock's status.

Stocks that have evidence suggesting at least a 50% decline, either based on previous abundance estimates or historical abundance estimated by back-calculation, should be noted in the Status of Stocks section as likely to be below OSP. The choice of 50% does not mean that the lower bound of a stock's OSP range is at 50% of historical numbers, but rather that a population below this level would be below OSP with high probability. However, without further analysis and completions of requirements laid out in Section 115, determination of stock status with regard to whether or not it is depleted (or, by extension, strategic based on depleted status) cannot be made. Similarly, a stock that has increased back to levels pre-dating the known decline may be within OSP; however, additional analyses may determine a population is within OSP prior to reaching historical levels.

Section 3(19) of the MMPA defines the term "strategic stock" as a marine mammal stock: (A) for which the level of direct human-caused mortality exceeds the potential biological removal level; (B) based on the best available scientific information, is declining and is likely to be listed as a threatened species under the Endangered Species Act of 1973 [16U.S.C. 1531 et seq.] within the foreseeable future; or (C) which is listed as a threatened species or endangered species under the ESA or is designated as depleted under the MMPA.

The MMPA requires a determination of a stock's status as being either strategic or non-strategic and does not include a category of unknown. If abundance or human-related mortality levels are truly unknown (or if the fishery-related mortality level is only available from self-reported data), some judgment will be required to make this determination. If the human-caused mortality is believed to be small relative to the stock size based on the best scientific judgment, the stock could be considered as non-strategic. If human-caused mortality is likely to be significant relative to stock size (e.g., greater than the annual production increment) the stock could be considered as strategic. Likewise, trend monitoring can help inform the process of determining strategic status.

The MMPA requires for strategic stocks a consideration of other factors that may be causing a decline or impeding recovery of the stock, including effects on marine mammal habitat and prey. In practice, interpretation of "other factors" may include lethal or non-lethal factors other than effects on habitat and prey. Therefore, such issues should be summarized in the Status of Stock section for all strategic stocks. If substantial issues regarding the habitat of the stock are important, a separate section titled "Habitat Issues" should be used. If data exist that indicate a problem, they should be summarized and included in the Report. If there are no known habitat issues or other factors causing a decline or impeding recovery, this should be stated in the Status of Stock section.

2. Technical Details

In this section, technical details are given for making appropriate calculations of PBR and mortality. The first section provides details on precision and rounding issues. The second section provides details for combining more than one abundance estimate for calculating N_{min}. The third section contains details for calculating the estimate of annual human caused mortality and its associated variance.

Precision and Rounding

The following rules on precision and rounding should be applied when calculating PBR and other values:

(a) N (the abundance estimate), CV(N), R_{max}, and F_r should be reported in the Report to whatever precision is thought appropriate by the authors and involved scientists, so long as what is reported is exactly what the PBR calculation is based on.
(b) PBR should be calculated from the values for (a) to full precision, and not be calculated from an intermediary rounded off N_{min}. However, N_{min} should be reported as a rounded integer.
(c) PBR and mortality should be reported with one decimal place if they are below 10. Otherwise, PBR and mortality should be reported as a rounded integer.
(d) If PBR and mortality round to the same integer, the Report will report both values to the precision necessary to determine which is larger. This would also be done if 10% of PBR and mortality round to the same integer.

Computation of Average Abundance and its Variance

When estimates of abundance are available for more than one year or from more than one source in the same year, it may be appropriate to combine those estimates into an average abundance for the time period in question. It was agreed that a weighted mean was probably the most appropriate average to use, where the weights are equal to the inverse of the associated variance:

Error!

where:

$$w_i = \frac{1/var(a_i)}{\sum_{j=1}^{n} 1/var(a_j)} \quad .$$

The variance of a weighted mean of several abundance estimates is calculated as:

$$var(a) = w_1^2 var(a_1) + w_2^2 var(a_2) + ... w_2^2 var(a_n) = \sum_{i=1}^{n} w_i^2 var(a_i) \ .$$

Finally, the variance is parameterized as a CV in the provided equation for calculating N_{min}. The CV is calculated as:

$$CV(a) = \frac{\sqrt{var(a)}}{a}$$

Computation of Average Human-Caused Mortality and its Variance

When estimates of human-caused mortality and serious injury (called here "mortality") are available for more than one year and/or from more than one source, such as a fishery, it is necessary to calculate an estimate of the mean annual mortality along with its associated variance (or CV). The following section provides guidelines for doing this. For convenience, the section refers to averaging the incidental bycatch of fisheries, but the guidelines apply equally well to estimates of human-caused mortality from other sources.

<u>Calculating the overall mean annual bycatch</u>

First, it was agreed that it was most appropriate for the bycatch estimates from a fishery to be averaged UN-WEIGHTED across years, as the true bycatch might be different in each year, and thus is not stationary. This is just the simple average of the available estimates of bycatch. If estimates are available from more than one fishery, a mean annual bycatch from each fishery should be calculated first, and then the annual mean from each fishery should be summed to calculate an overall estimate of the mean annual bycatch.

<u>Calculating the coefficient of variation (CV) of the mean annual bycatch of a single fishery</u>

There are two potential methods for calculating the CV or variance of the mean annual bycatch of a single fishery. Method 1 involves using standard statistical formulas for combining the variances of the individual yearly bycatch estimates (assuming they are available). Method 2 involves estimating the variance empirically from the 2-5 years of point estimates of bycatch, which is done by calculating the standard deviation of the 2-5 mortality estimates and dividing it by the square root of *n*, where *n* is the number of years available. Both methods are valid. However, two points favor Method 1.

First, because the true bycatch might be different in each year, and thus is not stationary, estimating the variance using Method 2 above could over-estimate the true variance of the estimates of bycatch, and this positive bias would be related to how much the bycatch truly varied from year to year independent of observation error.

Second, Method 1 is likely to give a more precise estimate of the variance because it has more degrees of freedom. Using Method 2 involves estimating the variance from a sample size of just 2-5, and ignores the information that is known about the precision of each individual estimate.

Obviously, Method 2 is the only method that can be used if there are no estimates of the variance of the bycatch estimates available. Method 1 is the recommended method if the estimates of bycatch in each year do have an estimated variance (or CV).

<u>Method 1</u>
Table 1 outlines the computations needed for estimates of average bycatch mortality by *f* fisheries operating over *n* years. Table 2 gives an example computation for *f*=3 fisheries operating over a horizon of *n*=3 years and all of the estimates are non-zero. Most variance estimators will provide an estimate of 0 for the variance when the estimated mortality is zero; however, the true variance is non-zero. In this case, a more realistic estimate of the variance can be developed by averaging the variances for those years which have a positive variance. The variance computations in Table 1 are simply modified by dividing by the square of the number of years with a non-zero variance. The computation of the average is unaffected with the zero included in the average (Table 3). In certain circumstances a fishery may have been operating but was not monitored for mortality. Missing estimates should be dropped both from the calculation of the average and the variance (Table 4).

<u>Method 2</u>
In Method 2 the only change is in how the variance is calculated for the estimate of average bycatch mortality for each fishery over *n* years. In Method 2 the variance of the average bycatch is estimated empirically from the several point estimates of bycatch available from different years. This is done by calculating the variance of those estimates and dividing it by *n*, where *n* is the number of years used in calculating the average:

$$var(m_{i.}) = \frac{\sum_{j=1}^{n} \frac{(m_{ij}-m_{i.})^2}{n-1}}{n} \quad .$$

The above formula would thus be substituted for the formula for $var(m_{1.})$ presented in Table 1. The second step of combining variances across fisheries is identical to Method 1.

Table 1. Computation table for average mortality for *n* years with *f* fisheries. The mortality estimate for fishery *I* during year *j* is m_{ij} and the corresponding variance estimate is v_{ij}. The estimated total mortality for year *j* is $m_{.j}$, the sum of mortality estimates for each fishery and the variance is $v_{.j}$, the sum of the variances. The average mortality for fishery *I* is $m_{I.}$ and its variance is $vi_{.}$, which is the sum of the variances for each year within the fishery divided by the number of years (*n*) squared.

Fishery	Year 1	Year 2 ...	Year *n*	Average
1	m_{11} var(m_{11})	m_{12} var(m_{12})	m_{1n} var(m_{1n})	$m_{1.} = \sum_{j=1}^{n} m_{1j}/n \quad var(m_{1.}) = \sum_{j=1}^{n} var(m_{1j})/n^2$
2 . .	m_{21} var(m_{21})	m_{22} var(m_{22})	m_{2n} var(m_{2n})	$m_{2.} = \sum_{j=1}^{n} m_{2j}/n \quad var(m_{2.}) = \sum_{j=1}^{n} var(m_{2j})/n^2$
f	m_{f1} var(m_{f1})	m_{f2} var(m_{f2})	m_{fn} var(m_{fn})	$m_{f.} = \sum_{j=1}^{n} m_{fj}/n \quad var(m_{f.}) = \sum_{j=1}^{n} var(m_{fj})/n^2$
Total				$m_{..} = \sum_{i=1}^{f} m_{i.} \quad var(m_{..}) = \sum_{i=1}^{f} var(m_{i.})$

Guidelines for minimum observer sample size requirements
(Avoiding small-sample bias when PBR is small)

Table 6. Recommended data levels to attain approximately unbiased estimation of average annual fisheries-related mortality and serious injury, relative to PBR (i.e., if true annual bycatch = PBR) (from Moore and Merrick 2011). “Approximately unbiased” implies median absolute bias < 25%. The top table recommends minimum observer coverage (annual average), given a certain PBR and level of data pooling (years of information combined). The bottom table recommends minimum levels of data pooling, given a certain PBR and observer coverage. If true bycatch = PBR and sampling effort is below the recommended levels, *median* bias is always negative (i.e., true bycatch > estimate), but the combination of *very* limited sampling (≤5% coverage, ≤ 5 yrs data pooling) and *very* low bycatch (e.g., 1/yr) generates bimodal estimation bias, whereby bycatch is always either underestimated (if no bycatch is observed) or overestimated (if ≥ 1 bycatch event is observed).

	Observer program length (years)								
PBR	1	2	3	4	5	6	7	8	9
1	80%	40%	30%	30%	20%	15%	15%	10%	10%
2	40%	20%	15%	10%	10%	7.5%	7.5%	5%	5%

3. Descriptions of U.S. Commercial Fisheries

Fisheries table in each stock assessment report

Sample incidental fisheries mortality table to be included in Reports. Each fishery noted as interacting with a stock should be included in the table, even if little information is available. Information on the number of incidental injuries and which injuries should be considered serious should be provided in either the table or the text, if appropriate. See discussion in 5.2 of Wade and Angliss (1997).

Table 7. Summary of incidental serious injury and mortality (SI/M) of stock ___ due to commercial fisheries from 1990 through 1994 and calculation of the mean annual SI/M rate. Mean annual SI/M in brackets represents a minimum estimate from logbooks or MMPA reports.

*Note -- numbers indicated with an asterisk are optional -- different preferences have been expressed in different regions.

Fishery Name [1]	Years	Data Type	Range of Observer Coverage	Observed SI/M (in given yrs.)	Estimated SI/M (in given yrs.)	Mean Annual SI/M
groundfish trawl fishery 1	90-94	obs data	53-74%	13, 13, 15, 4, 9	13, 19, 21, 6, 11	14 (0.32)
groundfish trawl fishery 2	90-94	obs data	33-55%	2, 0, 0, 1, 1	4, 0, 0, 3, 3	2 (0.24)
longline fishery 1	90-94	obs data	23-55%	1, 0, 0, 1, 0	2, 0, 0, 4, 1	1.4 (0.15)
drift gillnet fishery 1	90-91	obs data	4-5%	0, 2	0, 29	14.5 (0.42)
Observer program total						31.9 (0.xx)
set gillnet fishery 1	90-93	log book	n/a	0, 1, 1, 1	n/a	[≥.75]*

longline fishery 2	94	mmap reports	n/a	1	n/a	[≥ 1]*
Minimum total annual mortality						≥ 34.2*

[1]The name should be consistent with fishery names in the List of Fisheries.

General information about a fishery (not stock-specific)

Information to provide

As discussed at the GAMMS workshop, information on U.S. commercial fisheries should be included either within each Report, as an appendix, or as a companion document. Information on U.S. commercial fisheries was collected during the preparation of the Environmental Assessment for the proposed regulations implementing Section 118 (NMFS, 1994). The following information, which was provided for each fishery whenever possible, has direct relevance to managing incidental serious injuries and mortalities of marine mammals:

Fishery name: A description of those fisheries that are classified in Category I or II in the LOF, and those fisheries in Category III that have experienced incidental mortality and serious injury of marine mammals should be provided. The Category of the fishery in the List of Fisheries should be specified in the text.

Number of permit holders: NMFS is required by the MMPA to provide the number of permit holders in each fishery included in the List of Fisheries. Information on the number of permit holders in federal fisheries can often be found in recent amendments to Fishery Management Plans. Information on fisheries that occur within state waters but are managed via an interstate commission may be found in interstate fishery management plans. Information on state fisheries that are managed by individual states can typically be found by contacting the state office responsible for licensing commercial fishing vessels.

Number of active permit holders: Because not all licensed commercial fishers participate actively in each fishery, the number of active permit holders may be different than the number of actual permit holders in a fishery. This is particularly true for fisheries that operate in state waters.

Total effort: Provide an estimate of the total fishing effort, in the number of hours fished, for each fishery. This information is typically available only for fisheries that are both federally managed and observed.

Geographic range: Provide a description of the geographic range of the fishery. The description of the geographic range of the fishery should include any major seasonal changes in the distribution of the fishing effort.

Seasons: Describe the seasons during which the fishery operates.

Gear type: Describe the gear type used in the fishery as specifically as possible. Include mesh size, soak duration, trawl type, depth of water typically fished, etc. if the information is available.

Regulations: Indicate whether the fishery is managed through regulations issued by the federal government, interstate fishery commissions, individual states, or treaty.

Management type: Indicate what types of fishery management techniques are used to manage the fishery. Some examples include limited entry, seasonal closures, and gear restrictions.

Comments: Include any additional relevant information on the fishery.

4. Additional Recommendations of the GAMMS III Workshop

The following recommendations were made by the participants of the GAMMS III Workshop:

(1) In order to provide the kind of information that is required to answer the question "is it plausible that there are multiple demographically independent population stocks (DIPS) within this stock?" (in the revised Definition of Stock section), it is recommended that a national workshop be held to review and summarize information that is relevant to population structure. The workshop should include participation from Headquarters and all Centers and Regions, at a minimum. It is unlikely that the workshop could feasibly review all stocks in all areas. Therefore, a list of priority stocks for consideration should be established prior to the workshop. This might efficiently be done by a Steering Committee with stocks to be reviewed proposed from each region. Stocks should be selected to cover a broad range of geographic and taxonomic diversity (e.g., it might be appropriate to review at least one stock each of phocids, otariids, large whales, delphinids, phocoenids, and ziphiids in each region (if presently recognized). Priority should be given to stocks that are geographically large, span multiple bioregions, or potentially experience substantial human-caused mortality in a portion of their range. It would also be appropriate to examine areas of U.S. waters where stocks have not previously been defined (e.g., Guam, Caribbean). The information to be reviewed should include (at least) all information used for defining stocks as recommended in the Guidelines. This includes distribution and movements, acoustic call types, population trends, morphological differences, differences in life history, genetic differences, contaminants and natural isotope loads, parasite differences, and oceanographic habitat differences (such as marine bioregions). It should be emphasized that the purpose of the workshop is to review and summarize relevant information. As possible and appropriate, the workshop will propose revisions to stock structure. A major objective will be to review the information for these stocks in a manner to provide a template for how to complete review of all stocks in each region.

(2) To recognize that the population dynamics of some stocks (such as Cook Inlet beluga and Hawaiian monk seal) may not conform with the underlying assumptions on which the PBR calculation is based (relevant "PBR elements" section of the guidelines), it was recommended that the next administration MMPA reauthorization bill include the explicit option for setting R_{max} (or F_r) to zero in appropriate cases.

(3) A list of regional and F/PR points-of-contact should be created, in order to implement recommendations of Topics 5 and 9 of the GAMMS III workshop pertaining to the timely annual transmission of information on non-serious injury, serious injury, and or death reported under LOAs and IHAs from F/PR to Regional Offices and Science Centers (including to Report authors).

5. Overview of changes from the 2005 Guidelines

The following additions have been made:

- In the stock assessment report (SAR) sections of the Reports on Stock Definition and Geographic Range, elements of the PBR formula, Population Trend, and Annual Human-caused Mortality and Serious Injury, authors are to provide a description of key uncertainties in each element and evaluate their effects;
- Acoustic call type was added as a type of information that can be used to identify stocks;
- Each SAR will state in the Stock Definition and Geographic Range section whether it is plausible the stock contains multiple demographically independent populations that should be separate stocks, along with a brief rationale;
- Informed interpolation may be used to fill gaps in survey coverage;
- A summary of all human-caused mortality should be included in SARs;
- Text regarding avoiding small sample bias was added;
- For mixed stocks, apportion takes among stocks where possible; otherwise, apply take to each stock in area;
- Direction regarding reporting of mortality and serious injury;
- Stocks that have evidence suggesting at least a 50% decline should be noted in the Status of Stocks section as likely to be below their optimum sustainable population level;
- Trend modeling may be used to determine stock status;
- "Other factors" leading to decline or impeding recovery should be considered, including non-lethal factors;
- Added guidelines for minimum observer sample size requirements; and
- Added section on population trends

The following deletions have been made:

- Removed "undetermined" PBR for unusual cases such as Hawaiian monk seal; instead, calculate PBR if possible and qualify in the report;
- Removed statement that default stock status should be strategic; and
- Removed "sources of information on U.S. commercial fisheries" section

The following changes to text/guidance have been made:

- "Demographic isolation" was changed to "demographic independence" and "reproductive isolation" was changed to "reproductive independence";
- Updated the reference section; and
- Replaced the recommendations from the GAMMS II workshop with recommendations from GAMMS III workshop

ABSTRACT

Shore based surveys of northbound eastern North Pacific gray whale calves were conducted between March and June from the Piedras Blancas Light Station on the central California coast each year from 1994-2016. Estimates of the total number of northbound calves displayed a high degree of inter-annual variability, ranging from 254 calves in 2010 to 1528 calves in 2004. Calf production has been particularly high during the past 5 years (2012-2016) with a total of >6,500 calves estimated during this period, including four of the highest years of calf production (>1,000 calves per year) since our calf counts began in 1994. The 2016 estimate of calf production (1,351) is about 5% of the reported total abundance (26,960) for the eastern North Pacific population. A trend in median migration dates was observed, indicating that the midpoint of the migration is now occurring about a week later than it did in the mid-1990s. The 23-year data set described herein serves as an excellent foundation upon which to examine the inter-play between changing environmental conditions and gray whale population dynamics.

INTRODUCTION

The majority of Eastern North Pacific gray whales *(Eschrichtius robustus)* annually migrate southward from summer feeding grounds in the Pacific Arctic to wintering areas off Baja California, Mexico (Rice and Wolman 1971, Perryman and Lynn 2002). Both the southward and northward migration is segregated, to a large extent, by age, sex and reproductive condition. During the northward migration, females with their calves of the year are the last to depart the Baja wintering areas. These mother-calf pairs are observed on the migration route between March and May and typically arrive to the summer feeding grounds between May and June.

Shore-based counts of northbound gray whale calves have been conducted off central California each spring from 1994 to 2016. This report presents an overview of results from this 23-year time series of estimates of gray whale calf production.

METHODS

Shore-based counts of northbound gray whale calves have been conducted from the Piedras Blancas Light Station (north of San Simeon, California) each spring from 1994 to 2016. Data collection methods and analytical techniques have remained consistent each year and follow those reported elsewhere (see Perryman *et al*. 2002, 2011). Briefly, counts were conducted by four observers, with two on effort at any one time, rotating through the following schedule: (a) 90-min on effort as the offshore search area observer, (b) 90-min on effort as the inshore search area observer, (c) 3-hr off effort. Weather permitting, this work was carried out for 12 hours per day; 6 days per week in 1994-2003 and 2005 and 5 days per week in 2004 and 2006-2016. Primary search effort was carried out with unaided eye but 7x50 and 25x150 binoculars were also used when needed.

Based on night/day migration rate data derived from thermal sensors (1994-1996) and aerial surveys (1994-1995) to determine offshore distribution (Perryman *et al*. 2002), we assumed that: (1) the number of gray whale calves passing the survey site far enough offshore to be undetectable by visual observers was negligible, and (2) day and night passage rates were equivalent. We also assumed that detection probabilities were the same across acceptable sighting conditions (see Reilly *et al*. 1983; Reilly 1992). To correct for imperfect probability of detection of calves by the visual observers, we corrected the observer estimates of northbound calves by the average detection probability estimates from seven consecutive years (1994-2000) of replicate counts (mean = 0.889; SE = 0.06375).

Each day of survey effort was divided into four 3-hr periods and passage rates during these periods were calculated from the observed counts multiplied by the inverse of the detection function. To correct for periods when observers were not on watch (e.g. poor weather, night time, days off), we embedded the estimators in a finite population model that was stratified by week to account for varying passage rates (Cochran 1977). A Taylor series expansion (Seber 1982) was used to calculate the variance of the estimates.

RESULTS

Estimates of the total number of northbound calves showed a high degree of inter-annual variability, ranging from 254 calves in 2010 to 1528 calves in 2004 (Table 1). Calf production has been particularly high during the past 5 years (2012-2016) with a total of >6,500 calves estimated during this period, including four of the highest years of calf production (>1,000 calves per year) since our calf counts began in 1994 (Fig. 1). The 2016 estimate of calf production (1,351) is about 5% of the reported total abundance (26,960; Durban et al. SC/67a) for the eastern North Pacific population in 2016.

A trend in median migration dates was observed in the time series, indicating that the midpoint of the migration is now occurring about a week later than it did in the mid-1990s. The slope of the migration timing is significant ($F = 6.030$, $p = 0.023$) if the outlier from 1999, the first year of an unusual mortality event for the eastern North Pacific population, is deleted from the data set (Fig. 2).

DISCUSSION

During the 23-year time series reported here, estimates of gray whale calves displayed a high degree of inter-annual variability. Based on data from 1994 to 2000, Perryman *et al*. (2002) suggested that the reliance of female gray whales on stored fat resources during pregnancy combined with sea ice regulated access to food during the beginning of a feeding season may impact their ability to carry existing pregnancies to term. When these calf estimates were examined in the context of environmental data from the northern Bering Sea, a relationship was found between the timing of seasonal ice melt and estimates of northbound gray whale calves counted the following spring. In heavy ice years, when ice extends far to the south, the temporary lack of access to foraging areas appears to have a negative impact on calf production.

The particularly high calf production observed during the past 5 years (2012-2016), including four years of the highest calf production recorded (>1,000 calves per year) since our counts began in 1994 suggests that gray whales have been experiencing a period of favorable feeding conditions in the Arctic, possibly related due to the combination of expanding ice-free habitat (Moore 2016), increased primary production (Arrigo and Dijken 2015) and increased flow of nutrient-rich waters through the Bering Strait (Woodgate *et al*. 2012). This hypothesis is further supported by the recent (2014/2015 and 2015/2016) increase in abundance of the eastern North Pacific gray whale population (Durban et al. SC/67a)

The trend in median migration dates reported here, indicating that the midpoint of the migration is now occurring about a week later than it did in the mid-1990s, is analogous to the finding of a one week delay in annual mean sighting dates of southbound whales migrating past Granite Canyon, California (Rugh *et al*. 2001). While the impacts of climate change in the Arctic environment are far from being understood, this change in migratory timing of gray whales may reflect a response to shifting habitat parameters on the summer feeding grounds. In the short term, changes in the Arctic environment may represent "boom time" for baleen whales as suggested by Moore (2016).

ACKNOWLEDGEMENTS

Our shore-based surveys of gray whales conducted from the Piedras Blancas Light Station would not be possible without the support and hospitality provided by U.S. Department of Interior, Bureau of Land Management. We are particularly indebted to the support provided by John Bogacki, Jim Boucher and Ryan Cooper. A long list of talented field biologists contributed to this study but the contribution of Richard Rowlett, Susan Chivers and Morgan Lynn stand out as exceptional. The support of NOAA Fisheries and the International Whaling Commission has been a critical component of this research.

Annex R
A Full Description of the Standard BALEEN II Model and Some Variants Thereof

A.E. Punt

Division of Marine Research, CSIRO Marine Laboratories, GPO Box 1538, Hobart, Tas 7001, Australia

ABSTRACT

A full mathematical description of the BALEEN II population dynamics model is provided. The specifications required for alternative parameterisations of this model and to initiate projections when the population is not at its pre-exploitation equilibrium are also listed. Some new insights into the implications of different definitions for the yield curve are provided.

INTRODUCTION

The Hitter-Fitter package (de la Mare, 1989; Punt and Butterworth, 1991; de la Mare and Cooke, 1992; Punt, 1996) has been used in the assessments of a number of whale stocks (e.g. IWC, 1991a; b; Butterworth and Punt, 1992a). The BALEEN II population dynamics model underlying this package is age- and sex-structured, and can take age-specific recruitment and maturation ogives into account. Both maximum likelihood (e.g. Butterworth and Punt, 1992a) and Bayesian estimators (e.g. Givens *et al.*, 1993; 1995) have been used to estimate the parameters of this population model.

This paper provides a full description of the BALEEN II population dynamics model[1]. It also describes the implementation details of a subset of the various possible parameterisations of the model (primarily those related to the assessment of the Bering-Chukchi-Beaufort (B-C-B) Seas stock of bowhead whales), provides full specifications for the case in which the population projection does not start at pre-exploitation equilibrium, lists the specifications of the output from the model, and contrasts a variety of ways of defining *MSYL* and *MSYR* in terms of population components other than that from which harvests are removed (i.e. other than the 'recruited'[2] component of the population as modelled).

THE BALEEN II POPULATION DYNAMICS MODEL

Basic dynamics

BALEEN II is age- and sex-structured, and considers animals as being either 'recruited' or 'unrecruited'. It assumes that all whaling takes place at the start of the year, and that all animals are 'recruited' (and have reached the age at first parturition) by age $x - 1$. The dynamics of the population are assumed to be governed by the equations:

$$N^s_{t+1,a} = \begin{cases} 0.5\,\alpha^s_0\,P^{\mathrm{M,f}}_{t+1}\,f_{t+1} & \text{if } a = 0 \\ N^s_{t,a-1}(1-F^s_{\mathrm{r},t,a-1})S^s_{a-1} \\ \quad + U^s_{t,a-1}(1-F^s_{\mathrm{u},t})\,S^s_{a-1}\,\delta^s_a & \text{if } 1 \le a \le x-1 \\ N^s_{t,x}(1-F^s_{\mathrm{r},t,x})S^s_x \\ \quad + N^s_{t,x-1}(1-F^s_{\mathrm{r},t,x-1})S^s_{x-1} & \text{if } a = x \end{cases} \tag{1}$$

$$U^s_{t+1,a} = \begin{cases} 0.5(1-\alpha^s_0)P^{\mathrm{M,f}}_{t+1}\,f_{t+1} & \text{if } a = 0 \\ U^s_{t,a-1}(1-F^s_{\mathrm{u},t})\,S^s_{a-1}(1-\delta^s_a) & \text{if } 1 \le a \le x-2 \end{cases} \tag{2}$$

where

$N^s_{t,a}$ is the number of 'recruited' animals of age a and sex s (m/f) at the start of year t,

$U^s_{t,a}$ is the number of 'unrecruited' animals of age a and sex s at the start of year t,

δ^s_a is the proportion of 'unrecruited' animals of sex s and age a-1 which recruit at age a,

S^s_a is the annual survival rate of animals of sex s and age a, and is equal to $\exp(-M^s_a)$

where M^s_a is the instantaneous rate of natural mortality on animals of sex s and age a,

$F^s_{\mathrm{r},t,a}$ is the exploitation rate on 'recruited' animals of sex s and age a during year t,

$F^s_{\mathrm{u},t}$ is the exploitation rate (uniform over age) on 'unrecruited' animals of sex s during year t,

α^s_a is the proportion of animals of sex s and age a which would be 'recruited' if the population were at pre-exploitation equilibrium,

$P^{\mathrm{M,f}}_t$ is the number of females that have reached the age at first parturition by the start of year t,

f_t is pregnancy rate (number of calves per 'mature' female) during year t (note that Equations (1) and (2) assume an equal male : female sex ratio at birth), and

x is the maximum (lumped) age-class.

Note that in the interests of generalisation, f_t is defined as in Punt (1996), which differs from convention in some earlier papers (de la Mare, 1989; Punt and Butterworth, 1991; de la

[1] W.K. de la Mare wrote the core code for BALEEN II for the Hitter-Fitter package.

[2] 'Recruited' and 'unrecruited' are placed in quotes because there are cases in which some of the catch is taken from the 'unrecruited' component of the population because the catch exceeds the size of the 'recruited' component of the population.

Mare and Cooke, 1992) in that it applies to both sexes born rather than to females only. Note also that the convention of referring to $P_t^{M,f}$ as the 'mature' female component of the population is used here, although it actually refers to animals no younger than their true age-at-maturity plus the gestation period, which is assumed to be one year. The survival rate S is assumed to depend on sex and age but to be independent of time. Punt (1996) provides a description of an extension to the BALEEN II model that allows for the possibility of density-dependent natural mortality and Punt and Butterworth (1996) include assessments of the B-C-B bowhead stock under the assumption that density-dependence impacts natural mortality rather than fecundity.

The possibility that age 0 animals (calves) are 'recruited' is allowed. However, for most applications (including the assessment of the B-C-B bowhead stock), the value of α_0^s is set equal to zero[3]. The values of $U_{t,x-1}^s$ and $U_{t,x}^s$ are not defined by Equation (2) because it is assumed that all animals of ages x-1 and x are 'recruited' (i.e. $\alpha_{x-1}^s = \alpha_x^s = 1$).

Density dependence

Density dependence on fecundity can be modelled by writing the pregnancy rate, f_t, as follows:

$$f_t = \max\left(f_{eq}\left[1+A\left\{1-\left(P_t^D / K_t^D\right)^z\right\}\right],0\right) \qquad (3)$$

where f_{eq} is the pregnancy rate at the pre-exploitation equilibrium, $f(0)$[4]:

$$f(F) = 2\left\{\sum_{a=\text{mat}_{\min}}^{x} \beta_a\left[\tilde{N}_a^f(F)+\tilde{U}_a^f(F)\right]\right\}^{-1} \qquad (4)$$

A is the resilience parameter:

$$A = \frac{f_{\max} - f_{eq}}{f_{eq}} \qquad (5)$$

$f_{\max}$ is the maximum (theoretical) pregnancy rate,

z is the degree of compensation,

P_t^D is the size, at the start of year t, of the component of the population to which density dependence is functionally related (either total (1+) population size, P_t^{1+}, 'recruited' population size[5], $P_b^{E'}$, or the number of females that have reached the age at first parturition $P_t^{M,f}$:

$$P_t^{1+} = \sum_s \sum_{a=1}^{x}\left(N_{t,a}^s + U_{t,a}^s\right) \qquad (6a)$$

$$P_t^E = \sum_s \sum_{a=1}^{x} N_{t,a}^s \qquad (6b)$$

$$P_t^{M,s} = \sum_{a=\text{mat}_{\min}}^{x} \beta_a (N_{t,a}^s + U_{t,a}^s) \qquad (6c)$$

$\text{mat}_{\min}$ is the lowest age that a female can reach first parturition (constrained to be at least 2),

β_a is the fraction of females of age a which have reached the age at first parturition,

K_t^D is the pre-exploitation equilibrium size (carrying capacity) at the start of year t of the component of the population to which density dependence is functionally related,

$\tilde{N}_a^s(F)$ is the number of animals of sex s and age a that are 'recruited' when the exploitation rate is fixed at F, expressed as a fraction of the number of calves of the same sex s (see Appendix 1), and

$\tilde{U}_a^s(F)$ is the number of animals of sex s and age a that are 'unrecruited' when the exploitation rate is fixed at F, expressed as a fraction of the number of calves of the same sex s.

Note that although these equations are written formally as if only the pregnancy rate component of 'fecundity' as defined here is density-dependent, exactly the same equations follow if some or all of this dependence occurs in the infant survival rate. Note that the dependence of K^D on t allows for the possibility that carrying capacity has varied over time. Butterworth *et al.* (1990) examine the implications of changes in carrying capacity for the assessment of the Eastern North Pacific gray whale.

Catches

BALEEN II allows for two series of sex-specific catches. One series of catches is taken uniformly from the 'recruited' component of the population while the other series is taken uniformly from the component of the population that is both 'recruited' and 'mature', which is termed 'mature-recruited' below. The equations which define $F_{r,t,a}^s$ and $F_{u,t}^s$ depend upon which of four cases applies. Of the four cases, Case 1 represents the normal situation; Cases 2 - 4 cover situations in which the catch in a given year exceeds the size of the component of the population from which it is assumed to be taken.

Case 1 - The total catch is less than the total number of 'recruited' animals and the 'mature-recruited' catch is less than the number of 'mature' animals (after the catch of 'recruited' animals is removed) (i.e. $C_t^{E,s} + C_t^{M,s} < P_t^{E,s}$ and $C_t^{M,s} < P_t^{M,s}(1 - C_t^{E,s}/P_t^{E,s})$). For this case, the catch can be taken as desired:

$$F_{r,t,a}^s = C_t^{E,s} / P_t^{E,s} + \beta_a C_t^{M,s} / P_t^{M,s}$$

$$F_{u,t}^s = 0 \qquad (7a)$$

where

$C_t^{E,s}$ is the total catch of animals of sex s during year t taken uniformly from the 'recruited' component of the population,

$C_t^{M,S}$ is the total catch of animals of sex s during year t taken uniformly from the 'mature-recruited' component of the population[6], and

$P_t^{E,s}$ is the total number of 'recruited' animals of sex s at the start of year t:

$$P_t^{E,s} = \sum_{a=0}^{x} N_{t,a}^s \qquad (8)$$

To understand Equation (7a) further, consider the sum over all age-classes of the product of the number of recruited animals and the exploitation rate:

[3] The current Baleen II software actually prohibits age 0 animals from being 'recruited'.

[4] The pregnancy rate at the pre-exploitation equilibrium can be considered to be the equilibrium pregnancy rate when the exploitation rate, F, is fixed at zero.

[5] The contribution of 'recruited' animals of age 0 to Equation (6b) is ignored to avoid the need for solving a non-linear equation for the number of births.

[6] The calculation of the exploitation rate assumes that all 'mature' animals are 'recruited'.

$$\sum_{a=0}^{x} F^s_{r,t,a} N^s_{t,a} = \sum_{a=0}^{x} (C^{E,s}_t / P^{E,s}_t + \beta_a C^{M,s}_t / P^{M,s}_t) N^s_{t,a} =$$

$$\frac{C^{E,s}_t}{P^{E,s}_t} \sum_{a=0}^{x} N^s_{t,a} + \frac{C^{M,s}_t}{P^{M,s}_t} \sum_{a=0}^{x} \beta_a N^s_{t,a} = C^{E,s}_t + C^{M,s}_t$$

Case 2 - The total catch is less than the total number of 'recruited' animals but the 'mature-recruited' catch is greater than the number of 'mature' animals (after the catch of 'recruited' animals is removed) (i.e. $C^{E,s}_t + C^{M,s}_t < P^{E,s}_t$ and $C^{M,s}_t > P^{M,s}_t(1 - C^{E,s}_t/P^{E,s}_t)$). For this case, the total catch is assumed to be removed uniformly from the 'recruited' component of the population:

$$F^s_{r,t,a} = (C^{E,s}_t + C^{M,s}_t) / P^{E,s}_t$$
$$F^s_{u,t} = 0 \qquad (7b)$$

Case 3 - The total catch is greater than the total number of 'recruited' animals but is less than the total (0+) population size (i.e. $C^{E,s}_t + C^{M,s}_t > P^{E,s}_t$ and $C^{E,s}_t + C^{M,s}_t < P^{T,s}_t$). For this case, the 'recruited' component is extirpated and the difference between the total catch and the size of 'recruited' component of the population is removed with uniform selectivity from the 'unrecruited' component of the population:

$$F^s_{r,t,a} = 1$$
$$F^s_{u,t} = (C^{E,s}_t + C^{M,s}_t - P^{E,s}_t) / (P^{T,s}_t - P^{E,s}_t) \qquad (7c)$$

where $P^{T,s}_t$ is the size of the total (0+) component of the population for sex s:

$$P^{T,s}_t = \sum_{a=0}^{x} (N^s_{t,a} + U^s_{t,a}) \qquad (9)$$

Case 4 - The total catch is greater than the total (0+) population size (i.e. $C^{E,s}_t + C^{M,s}_t > P^{T,s}_t$). For this case, the entire population (both 'recruited' and 'unrecruited' components) is extirpated:

$$F^s_{r,t,a} = 1$$
$$F^s_{u,t} = 1 \qquad (7d)$$

These equations are based on the assumption that the harvest occurs in a pulse at the start of the year (before natural mortality). It would be straightforward to generalise Equation (7) to allow the harvest to occur at any time during the year.

Recruitment and maturity

The fraction of 'unrecruited' animals of sex s and age a which 'recruit' at age a+1, α^s_{a+1}, is given by:

$$\alpha^s_{a+1} = \begin{cases} (\alpha^s_{a+1} - \alpha^s_a)/(1-\alpha^s_a) & \text{if } \alpha^s_a < 1 \\ 1 & \text{if } \alpha^s_a = 1 \end{cases} \qquad (10)$$

where α^s_a is the proportion of animals of sex s and age a which would be 'recruited' if the population were at pre-exploitation equilibrium:

$$\alpha^s_a = \begin{cases} 0 & \text{if } a < \text{rec}_{\min} \\ \left[1+\exp\{-(a-r^s_{50})/\sigma^s_r\}\right]^{-1} & \text{if rec}_{\min} \le a \le x-2 \\ 1 & \text{if } a \ge x-1 \end{cases} \qquad (11)$$

r^s_{50} is the age at 50% recruitment for animals of sex s,

σ^s_r is the parameter which determines the width of the recruitment ogive for animals of sex s[7], and

$\text{rec}_{\min}$ is the lowest age at which an animal may be 'recruited'.

The component of the population which may reproduce in a given year is the females that have reached the age at first parturition; this is the age at sexual maturity plus the gestation period (taken in BALEEN II to be one year). The proportion of females of age a which have reached the age at first parturition is given by:

$$\beta_a = \begin{cases} 0 & \text{if } a < \text{mat}_{\min} \\ \left[1+\exp\{-(a-p_{50})/\sigma_p\}\right]^{-1} & \text{if mat}_{\min} \le a \le x-2 \\ 1 & \text{if } a \ge x-1 \end{cases} \qquad (12)$$

where p_{50} is the age at 50% maturity plus one year, and σ_p is the parameter which determines the width of the maturation ogive.

Initial conditions

The population is assumed either to be at pre-exploitation equilibrium or to have a stable age-structure at the start of the projection period (year $t_{\rm INIT}$). For the former case, a value for $K^E_{t_{INIT}}$, the pre-exploitation equilibrium size of the 'recruited' component of the population at the start of year $t_{\rm INIT}$, is used to calculate the numbers at each age[8]:

$$U^s_{t_{INIT},a} = K^E_{t_{INIT}} \tilde{U}^s_a(0) / \sum_{s'} \sum_{a'=0}^{x} \tilde{N}^{s'}_{a'}(0)$$
$$N^s_{t_{INIT},a} = K^E_{t_{INIT}} \tilde{N}^s_a(0) / \sum_{s'} \sum_{a'=0}^{x} \tilde{N}^{s'}_{a'}(0) \qquad (13)$$

For the case in which the population is assumed to have a stable age structure (corresponding to uniform harvesting on the 0+ population[9]) at the start of year t_{INIT}, the numbers at each age are given by:

$$U^s_{t_{INIT},a} = N^E_{t_{INIT}} \tilde{U}^s_a(F_{INIT}) / \sum_{s'} \sum_{a'=0}^{x} \tilde{N}^{s'}_{a'}(F_{INIT})$$
$$N^s_{t_{INIT},a} = N^E_{t_{INIT}} \tilde{N}^s_a(F_{INIT}) / \sum_{s'} \sum_{a'=0}^{x} \tilde{N}^{s'}_{a'}(F_{INIT}) \qquad (14)$$

where $N^E_{t_{INIT}}$ is the size of the 'recruited' component of the population at the start of year t_{INIT}.

The value of F_{INIT} is selected numerically so that:

$$N^E_{t_{INIT}} = 0.5 N_0(F_{INIT}) \sum_{s} \sum_{a=0}^{x} \tilde{N}^s_a(F_{INIT}) \; ^{10} \qquad (15)$$

where $N_0(F_{INIT})$ is the number of calves (of both sexes) at the start of the year when $F = F_{INIT}$ (Appendix 2 for a derivation):

$$N_0(F_{INIT}) = \left(1 - \frac{1}{A}\left[\frac{f(F_{INIT})}{f_{\rm eq}} - 1\right]\right)^{1/z} \frac{K^D_{t_{INIT}}}{\tilde{P}^D(F_{INIT})} \qquad (16)$$

$\tilde{P}^D(F)$ is the size of the component of the population to which density dependence is functionally related as a function of F (either the total (1+) population size, the 'recruited'

[7] BALEEN II allows for the possibility that recruitment (and maturity) are knife-edged functions of age (i.e. $\sigma^s_r \to 0 (\sigma_p \to 0)$).

[8] Equation (13) is based on $K^E_{t_{INIT}}$ rather than, say, the pre-exploitation equilibrium size of the total population because $K^E_{t_{INIT}}$ is the parameter which for which a value is specified/estimated in the Hitter-Fitter package.

[9] The stable age-structure applies to the 0+ component of the population because F_{INIT} should be considered to be an increase rate rather than an exploitation rate.

[10] The 0.5 is needed to correct for the equations in Appendix 1 being defined in terms of one animal of each sex at birth.

population size, or the number of females that have reached the age at first parturition), expressed as a fraction of the number of calves (of both sexes).

The value for K^D_{tINIT} needed to apply Equation (16) is computed straightforwardly from K^E_{tINIT}. This calculation does not involve the values for the parameters that determine the extent of density dependence (*A* and *z*).

Determination of the resilience and degree of compensation parameters

The values of the parameters *A* and *z* are obtained by assigning values to the quantities *MSYL* and *MSYR*, and then solving the set of equations relating these quantities to *z* and *A*. *MSYL* and *MSYR* may be chosen to refer either to the 'recruited' component of the population, that component which has reached the age at first parturition (the 'mature' component), or the 1+ population with uniform selectivity harvesting. Sex-structure is ignored when calculating the resilience and degree of compensation from *MSYR* and *MSYL*. The recruitment ogive and the age-specific natural mortality rates for females are thus assumed to apply to both sexes for the purposes of this calculation. In reality, male and female recruitment ogives will not always be identical which will lead to some error in evaluating *A* and *z* (and hence *MSY*).

The (normalised) sustainable yield as a function of the exploitation rate, *C*(*F*), is given by:

$$C(F) = F\,P(F) = F\,B(F)\,\tilde{P}(F) \qquad (17)$$

where *P*(*F*) is the equilibrium number of 'recruited' animals when the exploitation rate is fixed at *F* (either the number of animals defined by the female recruitment ogive, the number which have reached the age at first parturition, or the number of age 1+ animals),

B(*F*) is the normalised number of births when the exploitation rate is fixed at *F*, and

$\tilde{P}(F)$ is the number of 'recruited' animals per birth when the exploitation rate is fixed at *F*.

The normalisation is provided by dividing by the number of births at pre-exploitation equilibrium.

For *MSY*:

$$\left.\frac{dC}{dF}\right|_{F=F_{MSY}} = \left.\frac{d\{F\,B(F)\tilde{P}(F)\}}{dF}\right|_{F=F_{MSY}} = 0 \qquad (18)$$

i.e.:

$$P(F_{MSY}) + F_{MSY}\left\{ B(F_{MSY})\left.\frac{d\tilde{P}(F)}{dF}\right|_{F=F_{MSY}} + \tilde{P}(F_{MSY})\left.\frac{dB(F)}{dF}\right|_{F=F_{MSY}} \right\} = 0 \qquad (19)$$

The values for the resilience and degree of compensation parameters are obtained by solving Equation (19) given a value for *MSYR* (= F_{MSY} - see Equation (17)) subject to the constraint that *MSYL* is equal to a pre-specified value.

Now, the population component (*H*) chosen for defining *MSYL* will not necessarily be the same as that to which density dependence is functionally related (*D*). For the calculations that follow, the value of $MSYL^D = P^D(F_{MSY})/K^D$ is required. This is obtained from the formula (Punt and Butterworth, 1991):

$$MSYL^D = \left[MSYL^H\,\tilde{K}^H\,\tilde{P}^D(F_{MSY})\right] / \left[\tilde{P}^H(F_{MSY})\,\tilde{K}^D\right] \qquad (20)$$

where $\tilde{K}$ is defined as $\tilde{P}(0)$ for the relevant component of the population.

The left-hand side of Equation (19) can be simplified to a form that does not involve the parameter (see Appendix 3):

$$1 + F_{MSY}\left(\frac{1}{\tilde{P}(F_{MSY})}\left.\frac{d\tilde{P}(F)}{dF}\right|_{F=F_{MSY}} - \frac{1}{\tilde{P}^D(F_{MSY})}\left.\frac{d\tilde{P}^D(F)}{dF}\right|_{F=F_{MSY}} - \frac{1}{z}\frac{(MSYL^D)^{-z}-1}{f(F_{MSY})-f_{eq}}\left.\frac{df(F)}{dF}\right|_{F=F_{MSY}} \right) \qquad (21)$$

where the required derivatives are determined by taking finite differences. The value of *z* is determined by solving Equation (21).

To calculate *MSYR* ($=F_{MSY}$) and *MSYL* for alternative harvesting patterns (e.g. uniform selectivity harvesting of the 1+ component of the population) than that used when calculating *A* and *z*, Equation (21) is solved for F_{MSY} where the alternative harvesting pattern is used to calculate the vectors $\tilde{U}^f$ and $\tilde{N}^f$ and hence the functions $\tilde{P}(F)$, $\tilde{P}^D(F)$ and *f*(*P*). The value of *MSYL* is then calculated using an appropriate modification of Equation (20).

OUPUT STATISTICS

Population components

BALEEN II stores time-trajectories of the following population components:

(a) Total (1+) population size, P_t^{1+}.
(b) Total (0+) population size, P_t^T.
(c) Total 'mature' population size, $P_t^{M,f} + P_t^{M,m}$.
(d) 'Mature' female population size, $P_t^{M,f}$.
(e) Total 'recruited' population size, $P_t^{E,f} + P_t^{E,m}$.
(f) 'Recruited' male population size, $P_t^{E,m}$.
(g) 'Recruited' female population size, $P_t^{E,f}$.
(h) Calves, $P_t^{M,f} f_t$.

These model outputs can be used to calculate a variety of output statistics, e.g., the depletion in any year, trends in population size over various years, the maximum (realised) pregnancy rate over the projection period, and the fraction of the total (0+) population size in a given year consisting of, for example, calves.

Replacement yield

The replacement yield for year *t* is defined as the catch, at the start of year *t*, which will leave the size of the 'recruited' component of the population the same at the start of year *t*+1 as at the start of year *t*:

$$RY_t = \frac{P_t^E}{\sum_s \sum_{a=0}^{x} S_a^s N_{t,a}^s}\left[\sum_s\left(N_{t,0}^s + \sum_{a=0}^{x-2} S_a^s U_{t,a}^s \delta_{a+1}^s\right) + \sum_s \sum_{a=0}^{x} S_a^s N_{t,a}^s - P_t^E\right] \qquad (22)$$

The term in square parenthesis is almost[11] the difference between the size of the 'recruited' component at the start of year *t* and the size of this component at the end of year *t* in

[11] Almost, because the $N_{t,0}^s$ term should be replaced by $N_{t+1,0}^s$ - this is not needed here because the computation of *RY* assumes that population is in steady state and that the harvest will be equal to the replacement yield so that $N_{t+1,0}^s = N_{t,0}^s$. Note that for most applications, calves are not recruited so this complication does not arise.

the absence of harvesting (i.e. accounts for the impact of recruitment and natural mortality). The first term accounts for the fact that the catch is assumed to occur in a pulse at the start of the year, and is equal to $1/S$ if survival is assumed to be independent of age for all 'recruited' animals.

Productivity

The productivity of the resource can be assessed through *MSYR* and *MSYL* (defined in terms of harvesting of the 'recruited', total (1+) or 'mature' components of the population). The maximum sustainable yield, *MSY*, can be calculated as *MSYR.MSYL.K* where *K* is the pre-exploitation size of that component of the population in terms of which *MSYR* and *MSYL* are defined. Other measures of productivity are the maximum theoretical pregnancy rate, $f_{\max}$, and the maximum steady rate of increase, $\lambda_{\max}$. The latter is the positive real root of the equation:

$$1 = f_{\max}\left[\sum_{a=\mathrm{mat}_{\min}}^{x-1} \frac{\beta_a}{\lambda_{\max}^{a+1}} \prod_{a'=0}^{a-1} S^{\mathrm{f}}_{a'} + \frac{\beta_x \prod_{a'=0}^{x-1} S^{\mathrm{f}}_{a'}}{\lambda_{\max}^{x}(\lambda_{\max} - S^{\mathrm{f}}_{x})}\right] \qquad (23)$$

Equations (1) and (2) of Breiwick *et al.* (1984) can be shown to be special cases of Equation (23).

ALTERNATIVE PARAMETERISATIONS

The most common method for parameterising the BALEEN II model involves providing specifications for the following.

(a) The historical catches.
(b) Natural mortality for each combination of sex and age.
(c) The parameters of the recruitment ogive.
(d) The parameters of the maturity ogive.
(e) The pre-exploitation equilibrium size of the 'recruited' component of the population at the start of year, t_{INIT}, $K^E_{t_{INIT}}$.
(f) The size of the 'recruited' component of the population at the start of year, t_{INIT}, $N^E_{t_{INIT}}$, if it is assumed that the population was not at its pre-exploitation equilibrium size at the start of year t_{INIT}.
(g) *MSYR*, *MSYL* and the components to which these quantities apply.
(h) The component to which density dependence is functionally related.

However, alternative paramerisations are possible. The following three sections outline three alternatives that may be appropriate for an assessment of the B-C-B bowhead stock.

'Forwards' vs. 'Backwards'

The 'backwards' parameterisation of the BALEEN II model is based on the 'Hitting-with-fixed-MSYR' option of the Hitter-Fitter package. It involves specifying the size of some component of the population in some given year, N_{targ}, and selecting the value of $N^E_{t_{INIT}}$ (or $K^E_{t_{INIT}}$ if it is assumed that the population was at its pre-exploitation equilibrium level at the start of year t_{INIT}) so that if the population is projected from year t_{INIT} to the current year, the projected size of that component of the population in the specified year is equal to N_{targ}. Brent's method (Press *et al.*, 1988) is used to solve the non-linear equation relating N_{targ} to $N^E_{t_{INIT}}$. Note that for some choices of N_{targ} (e.g. $N_{\mathrm{targ}} >> K$) there is no solution to this non-linear equation while for some choices for *MSYR*, there may be multiple solutions (Butterworth and Punt, 1995).

Using the maximum theoretical pregnancy rate

Equation (5) shows that the maximum theoretical pregnancy rate, $f_{\max}$, is closely related to the resilience parameter *A*. Therefore, instead of specifying a value for *MSYR* it is possible to specify a value for $f_{\max}$ instead. Within BALEEN II, this involves solving the non-linear equation $f_{\max} = f_{\max}(MSYR, MSYL)$, i.e. *MSYR* is chosen so that the implied value for $f_{\max}$ is equal to the specified value.

Another possible use for introducing the parameter $f_{\max}$ is to eliminate the juvenile natural mortality rate, M_J. M_J may apply solely to calves (e.g. Wade, 1996). However, for the B-C-B bowhead case, M_J has been assumed to apply from age 0 to a transition age (Givens *et al.*, 1995; IWC, 1995). Given values for *MSYR*, *MSYL* and $f_{\max}$, it is possible, using the following algorithm, to solve for *A*, *z* and M_J.

(a) Guess a value for M_J.
(b) Calculate $\tilde{U}(0)$, $\tilde{N}(0)$, $\tilde{U}(F_{MSY})$ and $\tilde{N}(F_{MSY})$.
(c) Calculate f_{eq} using Equation (4).
(d) Calculate *A* and *z* from *MSYL* and *MSYR* as described above.
(e) Calculate $f_{\max}$ using Equation (5).
(f) Compare this value of $f_{\max}$ with the input value and repeat steps (a) - (f) until convergence is achieved.

When solving for M_J, it is common to impose biologically sensible bounds such as that M_J is greater than the natural mortality rate for adults. Punt and Butterworth (1997) note that it is possible to use this approach to eliminate any of the other 'biological' parameters (age-at-maturity, adult natural mortality rate, etc.), but it seems most sensible to eliminate M_J because direct information about this parameter is seldom (if ever) available.

Using the maximum increase rate

The parameter $\lambda_{\max}$ can be used to replace *MSYR*[12]. For the case in which $f_{\max}$ is also used to specify M_J, the calculation procedure is as follows:

(a) Solve Equation (23) for M_J given $f_{\max}$, $\lambda_{\max}$ and the remaining biological parameters.
(b) Calculate $\tilde{U}(0)$ and $\tilde{N}(0)$, and hence f_{eq} (see Equation (4)).
(c) Guess a value for F_{MSY}.
(d) Calculate $\tilde{U}(F_{MSY})$ and $\tilde{N}(F_{MSY})$.
(e) Calculate *A* and *z* from *MSYL* and *MSYR* ($=F_{MSY}$) as described above.
(f) Calculate $f_{\max}$ using Equation (5).
(g) Compare this value of $f_{\max}$ with the input value and repeat steps (c) - (g) until convergence is achieved.

IMPLICATIONS FOR DEFINING *MSYR* AND *MSYL* IN TERMS OF OTHER POPULATION COMPONENTS

There has been considerable debate in the Scientific Committee regarding the appropriate component to which the assumption $MSYL = 0.6$ should be assumed to apply (e.g. Butterworth and Punt, 1992b; Cooke and de la Mare, 1994; IWC, 1994; 1998). To examine this issue further, yield curves have been produced for representative choices for the biological parameters for the East Greenland-Iceland fin

[12] In principle, $\lambda_{\max}$ can replace $f_{\max}$ but this option is ignored here.

whales and the B-C-B bowhead whales (see Table 1)[13]. Fig. 1(a) show plots of sustainable yield against 'mature' female and total (1+) depletion for the B-C-B bowhead stock when harvesting is assumed to be uniform on the 'mature' component of the population, $MSYL_{mat} = 0.6$ and $MSYR_{mat} = 3/5/7\%$. Fig. 1(b) shows the same quantities except that harvesting is assumed to be uniform on the 1+ component of the population (the values for the parameters A and z for Fig. 1(b) are computed using the specifications for Fig. 1(a)). Fig. 2 shows the same quantities as Fig. 1 except that A and z are computed for the case $MSYL_{1+} = 0.6$. Fig. 3 shows the same quantities as Fig. 1, except that the results pertain to the East Greenland-Iceland fin whales.

The most notable feature of Fig. 1(a) is that, for some choices for *MSYR*, if *MSYL* is defined in terms of the 'mature' component of the population, the size of the 1+ component at *MSYL* can be above *K*. This occurs because the stock-recruitment relationship exhibits strong super-compensation (i.e. the number of births drops as the population approaches carrying capacity – Holt, 1985; Butterworth and Best, 1990; Fig. 4) and so that the age-structure of the population at *MSY* is markedly skewed towards animals younger than the age at first parturition. The same qualitative result (quantitatively less marked) occurs if harvesting occurs on 1+ component of the population (Fig. 1b) or if the biological parameters for the East Greenland - Iceland fin whales are assumed instead (Fig. 3). The difference between the depletion of the 'mature' and 1+ components at *MSYL* is also reduced if density dependence is assumed to be functionally related to the 1+ rather than the 'mature' component of the population. As expected, defining *MSYL* in terms of the 1+ component of the population leads to *MSYL* for the 'mature' component of the population occurring at sizes well below 0.6 (Fig. 2). The

[13] For simplicity, density dependence is assumed to act on the mature female component of the population in all of the calculations of this section.

Table 1

Values for the biological and technological parameters for the East Greenland-Iceland stock of fin whales and the Bering-Chukchi-Beaufort Seas stock of bowhead whales used as inputs for the BALEEN II computations for Figures 1-4.

Parameter	East Greenland-Iceland fin whales[1]	Bering-Chukchi-Beaufort Seas bowhead whales[2]
Natural mortality (yr^{-1})	0.04 for all ages	0.04 (a=0,...,4); 0.02 (a=5+)
Age at 50% recruitment (males) (yr)	5	1
Age at 95% recruitment (males) (yr)	7	1
Age at 50% recruitment (females) (yr)	4	1
Age at 95% recruitment (females) (yr)	5	1
Age at 50% maturity[3] (yr)	8.5	20
Age at 95% maturity[3] (yr)	9.5	20

[1] Source: Butterworth and Punt (1992a).
[2] The adult natural mortality rate and the ages defining the parturition ('maturity') ogive are chosen to lie close to the medians of priors selected by IWC (1995).
[3] The corresponding age at first parturition is taken to be one year older than this.

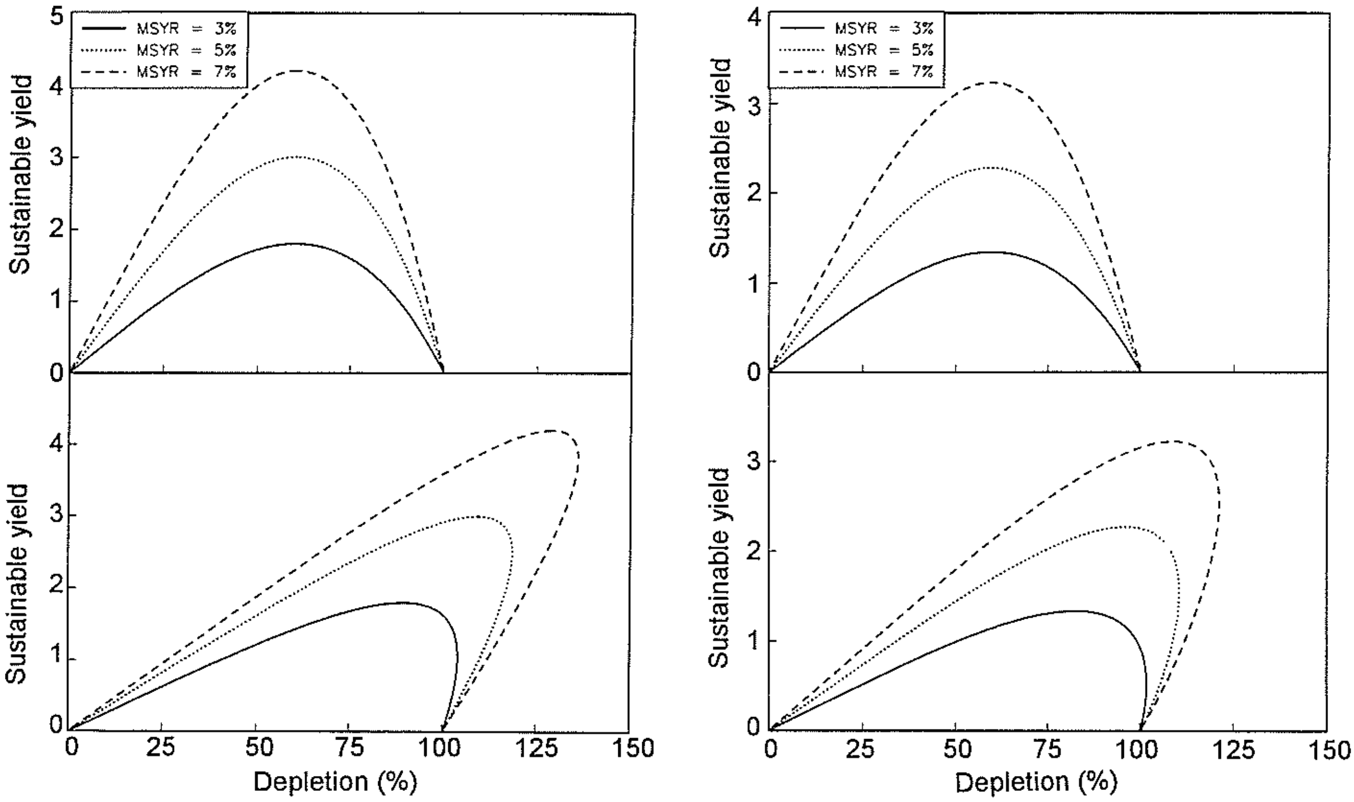

Fig. 1. Yield curves for the Bering-Chukchi-Beaufort Seas stock of bowhead whales. Each plot shows results for $MYSR_{mat}$ = 3%, 5%, and 7%. The upper panels show yield expressed as a function of the depletion of the 'mature' female component of the population, while the lower panels show yield expressed as a function of the depletion of the 1+ component of the population. Results are shown in (a) for harvesting of the 'mature' component of the population and in (b) for harvesting of the 1+ component of the population. The results in this figure pertain to $MSYL_{mat} = 0.6$ and density dependence acting on the 'mature' female component of the population.

results in Figs 1-3 therefore show that the relationship between $MSYL_{1+}$ and $MSYL_{mat}$ does not depend strongly on the exploitation pattern assumed when calculating *MSY*.

The implications of Figs 1-3 need to be taken into consideration when output statistics are defined for assessments (e.g. if *MSYL* for the B-C-B bowhead stock is defined to be 0.6 in terms of the total (1+) component of the population, the 'target level' for the 'mature' component of the population may be 0.4 or less) and performance statistics for simulation trials.

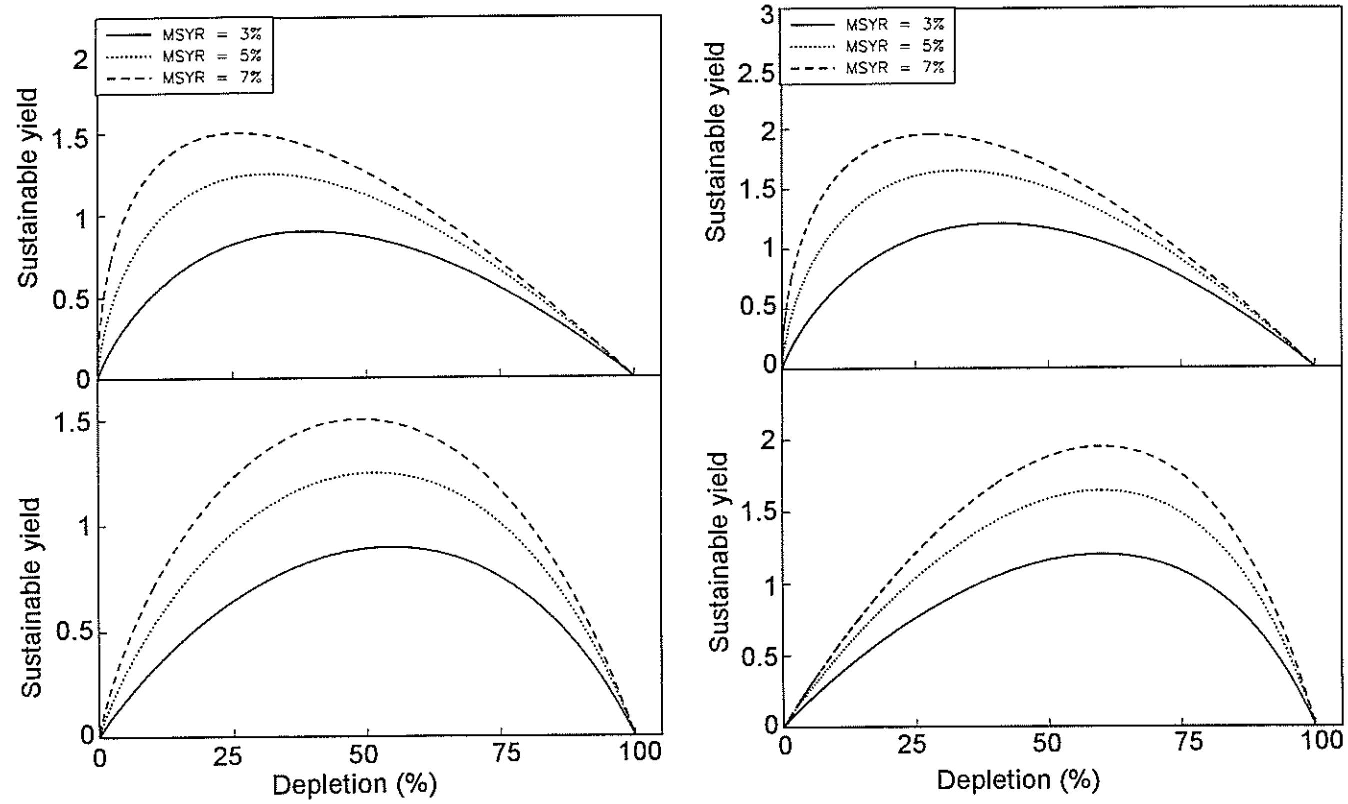

Fig. 2. As for Fig. 1 except that $MSYL_{1+}=0.6$.

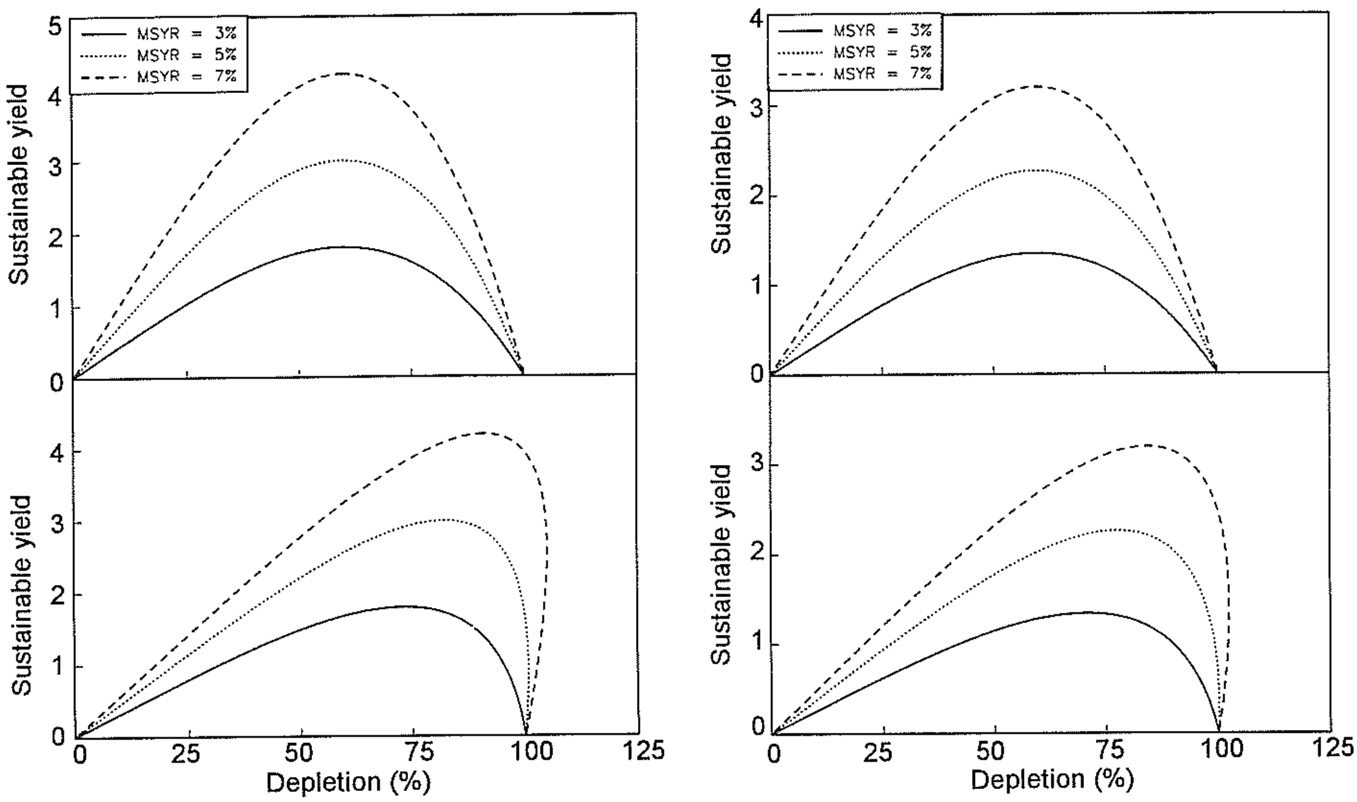

Fig. 3. As for Fig. 1 except that results are shown for the East Greenland-Iceland fin whale stock.

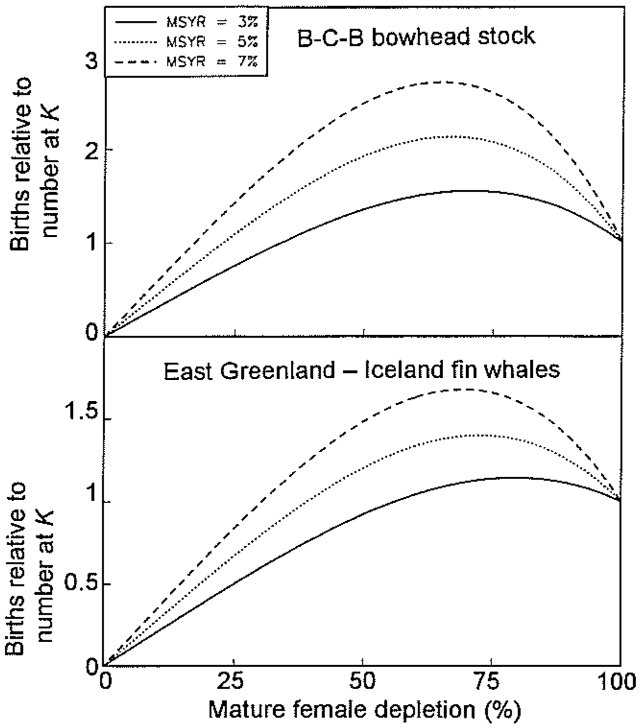

Fig. 4. Stock recruitment relationships for the Bering-Chukchi-Beaufort Seas stock of bowhead whales and the East Greenland-Iceland fin whale stock. Results in this figure pertain to $MSYL_{mat} = 0.6$ and density dependence acts on the 'mature' female component of the population. The number of births is shown relative to the number when the resource is at its pre-exploitation equilibrium level.

ACKNOWLEDGEMENTS

Cherry Allison (IWC Secretariat), Jeff Breiwick (NMML, NMFS), Doug Butterworth (Dept. of Mathematics and Applied Mathematics, University of Cape Town) and Geof Givens (Dept. of Statistics, Colorado State University) are thanked for their comments on an early draft of this paper.

Appendix 1

EQUILIBRIUM AGE-STRUCTURES

(A) Harvesting of the 'recruited' component of the population

$$\tilde{U}_a^s(F) = \begin{cases} 1-\alpha_0^s & \text{if } a=0 \\ S_{a-1}^s \tilde{U}_{a-1}^s(F)(1-\delta_a^s) & \text{otherwise} \end{cases} \quad \text{(A1.1a)}$$

$$\tilde{N}_a^s(F) = \begin{cases} \alpha_0^s & \text{if } a=0 \\ S_{a-1}^s (\tilde{N}_{a-1}^s(F)(1-F) + \tilde{U}_{a-1}^s(F)\delta_a^s) & \text{if } 1 \le a < x \\ S_{x-1}^s \tilde{N}_{x-1}^s(F)(1-F)/(1-S_x^s(1-F)) & \text{if } a = x \end{cases} \quad \text{(A1.1b)}$$

(B) Harvesting of the 1+ component of the population

$$\tilde{U}_a^s(F) = \begin{cases} 1-\alpha_0^s & \text{if } a=0 \\ S_0^s(1-\alpha_0^s)(1-\delta_1^s) & \text{if } a=1 \\ S_{a-1}^s(1-F)\tilde{U}_{a-1}^s(F)(1-\delta_a^s) & \text{otherwise} \end{cases} \quad \text{(A1.2a)}$$

$$\tilde{N}_a^s(F) = \begin{cases} \alpha_0^s & \text{if } a=0 \\ S_0^s(\alpha_0^s + (1-\alpha_0^s)\delta_1^s) & \text{if } a=1 \\ S_{a-1}^s(1-F)(\tilde{N}_{a-1}^s(F) + \tilde{U}_{a-1}^s(F)\delta_a^s) & \text{if } 2 \le a < x \\ S_{x-1}^s(1-F)\tilde{N}_{x-1}^s(F)/(1-S_x^s(1-F)) & \text{if } a = x \end{cases} \quad \text{(A1.2b)}$$

(C) Harvesting of the 'mature' component of the population

$$\tilde{U}_a^s(F) = \begin{cases} 1-\alpha_0^s & \text{if } a=0 \\ S_{a-1}^s(1-F\beta_{a-1})\tilde{U}_{a-1}^s(F)(1-\delta_a^s) & \text{otherwise} \end{cases} \quad \text{(A1.3a)}$$

$$\tilde{N}_a^s(F) = \begin{cases} \alpha_0^s & \text{if } a=0 \\ S_{a-1}^s(1-F\beta_{a-1})(\tilde{N}_{a-1}^s(F) + \tilde{U}_{a-1}^s(F)\delta_a^s) & \text{if } 1 \le a < x \\ S_{x-1}^s(1-F\beta_{a-1})\tilde{N}_{x-1}^s(F)/(1-S_x^s(1-F)) & \text{if } a = x \end{cases} \quad \text{(A1.3b)}$$

Appendix 2

THE DERIVATION OF EQUATION (16)

The equation defining fecundity as a function of density is given by:

$$f(F) = f_{eq}[1 + A\{1-(P^D(F)/K^D)^z\}] \quad \text{(A2.1)}$$

Substituting $N_0(F)\tilde{P}^D(F)$ for $P^D(F)$ gives:

$$f(F) = f_{eq}[1 + A\{1-(N_0(F)\tilde{P}^D(F)/K^D)^z\}] \quad \text{(A2.2)}$$

Solving Equation (A2.2) for leads to Equation (16)

Appendix 3

THE DERIVATION OF EQUATION (21)

The equation defining *MSY* is:

$$P(F_{MSY}) + F_{MSY}\left\{B(F_{MSY})\frac{d\tilde{P}(F)}{dF}\bigg|_{F=F_{MSY}} + \tilde{P}(F_{MSY})\frac{dB(F)}{dF}\bigg|_{F=F_{MSY}}\right\} = 0 \quad \text{(A3.1)}$$

Dividing Equation (A3.1) by gives:

$$1 + F_{MSY}\left\{\frac{1}{\tilde{P}(F_{MSY})}\frac{d\tilde{P}(F)}{dF}\bigg|_{F=F_{MSY}} + \frac{1}{B(F_{MSY})}\frac{dB(F)}{dF}\bigg|_{F=F_{MSY}}\right\} = 0 \quad \text{(A3.2)}$$

Now, differentiating $P^D(F) = B(F)\tilde{P}^D(F)$ with respect to F gives:

$$\frac{dP^D(F)}{dF} = B(F)\frac{d\tilde{P}^D(F)}{dF} + \tilde{P}^D(F)\frac{dB(F)}{dF}$$

Therefore:

$$\frac{dB(F)}{dF} = \frac{1}{\tilde{P}^D(F)}\frac{dP^D(F)}{dF} - \frac{B(F)}{\tilde{P}^D(F)}\frac{d\tilde{P}^D(F)}{dF} \qquad \text{(A3.3)}$$

Now, $f(F) = f_{eq}[1 + A\{1-(P^D(F)/K^D)^z\}]$

$$\text{i.e.} \quad \frac{df(F)}{dF} = \frac{-f_{eq}Az}{K^D}\left[P^D(F)/K^D\right]^{z-1}\frac{dP^D(F)}{dF} \qquad \text{(A3.4)}$$

Solving Equation (A3.4) for $\frac{dP^D(F)}{dF}$ then gives:

$$\frac{dP^D(F)}{dF} = \frac{-K^D}{f_{eq}Az}\left[P^D(F)/K^D\right]^{1-z}\frac{df(F)}{dF} \qquad \text{(A3.5)}$$

Substituting Equation (A3.5) into equation (A3.3) then gives:

$$\frac{dB(F)}{dF} = -\frac{B(F)}{\tilde{P}^D(F)}\frac{d\tilde{P}^D(F)}{dF} - \frac{1}{\tilde{P}^D(F)}\frac{K^D}{f_{eq}Az}\left[P^D(F)/K^D\right]^{1-z}\frac{df(F)}{dF} \qquad \text{(A3.6)}$$

Now, $MSYL^D = P^D(F_{MSY})/K^D = B(F_{MSY})\tilde{P}^D(F_{MSY})/K^D$ (A3.7a)

or $K^D = B(F_{MSY})\tilde{P}^D(F_{MSY})/MSYL^D$ (A3.7b)

Evaluating Equation (A3.6) at $F = F_{MSY}$, substituting Equation (A3.7) into the resulting equation, dividing by $B(F_{MSY})$, and then simplifying gives:

$$\frac{1}{B(F_{MSY})}\frac{dB(F)}{dF}\bigg|_{F=F_{MSY}} = -\frac{1}{\tilde{P}^D(F_{MSY})}\frac{d\tilde{P}^D(F)}{dF}\bigg|_{F=F_{MSY}} - \frac{(MSYL^D)^{-z}}{f_{eq}Az}\frac{df(F)}{dF}\bigg|_{F=F_{MSY}} \qquad \text{(A3.8)}$$

Now, from Equation (3), A is related to z and $MSYR^D$ according to the formula:

$$A = \frac{f(F_{MSY})/f_{eq} - 1}{1-(MSYL^D)^z} \qquad \text{(A3.9)}$$

Thus, substituting Equation (A3.9) into Equation (A3.8) and simplifying gives:

$$\frac{1}{B(F_{MSY})}\frac{dB(F)}{dF}\bigg|_{F=F_{MSY}} = -\frac{1}{\tilde{P}^D(F_{MSY})}\frac{d\tilde{P}^D(F)}{dF}\bigg|_{F=F_{MSY}} - \frac{1}{z}\frac{(MSYL^D)^{-z}-1}{f(F_{MSY})-f_{eq}}\frac{df(F)}{dF}\bigg|_{F=F_{MSY}} \qquad \text{(A3.10)}$$

Substituting Equation (A3.10) into Equation (A3.2) gives Equation (21) of the main text.

ABSTRACT
A sex- and age-structured population dynamics model which can represent the stock hypotheses developed during the April 2014 rangewide review of population structure and status of North Pacific gray whales is outlined. The model allows for multiple stocks, each of which can have sub-stocks, multiple feeding and wintering grounds, as well as migratory corridors. Animals can move between sub-stocks in a pulse or diffusively. The values for the parameters of the model can be estimated by fitting it to data on trends in relative and absolute abundance, in addition to mixing proportions based on telemetry and mark-resight data. The model is generic, but the specifications in this document include choices made when an operating model was developed to evaluate alternative *SLA*s for the Pacific Coast Feeding Group (PCFG) for the eastern north Pacific gray whales. An example application of the model is provided.

INTRODUCTION
The workshop on the rangewide review of the population structure and status of North Pacific gray whales (IWC, 2014) developed several conceptual models for gray whales in the North Pacific. These hypotheses differed in terms of the number of stocks and how those stocks are divided into sub-stocks and how they are distributed across the North Pacific. The Workshop recommended that a framework based on an age- and sex-structured population dynamics model be developed to explore whether the conceptual models are consistent with the available data and whether the existing data are sufficient to enable most of the parameters of the model to be estimated.

This paper provides the mathematical specifications for a strawman sex- and age-structured model, outlines how this model could be used to implement one of the conceptual models developed by IWC (2014) [Fig. 1], and provides some preliminary results.

MODEL STRUCTURE
The model distinguishes 'stocks' and 'sub-stocks'. Stocks are demographically and genetically independent whereas sub-stocks are linked through dispersal of individuals[1], though perhaps at very low rates for some combinations of sub-stocks.

Each stock / sub-stock is found in a set of sub-areas, each of which may have catches (commercial, aboriginal or incidental), proportions of stocks / sub-stocks mixing[2] in those sub-areas, and indices of relative or absolute abundance. Catches may be specified to sets of months during the year if the various sub-stocks are not equally vulnerable to catches throughout the year.

[1] The term 'dispersal' is used here in the sense of 'effective dispersal', and refers to permanent movement of individuals among stocks. Such individuals become part of the population to which they move and contribute to future reproduction.

[2] Mixing is defined here as two stocks which overlap at some time on the feeding groups, but do not interbreed.

Basic Population Dynamics

The population dynamics are based on the standard age-structured model used by the IWC Scientific Committee and which has formed the basis for the evaluation of *SLA*s for the Eastern North Pacific gray whales, i.e.:

$$
\begin{aligned}
N_{t+1,0}^{m/f,i,j} &= 0.5B_{t+1}^{i,j} && a = 0 \\
N_{t+1,a}^{m/f,i,j} &= ((N_{t,a-1}^{m/f,i,j} - C_{t,a-1}^{m/f,i,j})\,S_{a-1} + I_{t,a-1}^{m/f,i,j})\tilde{S}_t^{i,j} && 1 \le a \le x-1 \\
N_{t+1,x}^{m/f,i,j} &= ((N_{t,x}^{m/f,i,j} - C_{t,x}^{m/f,i,j})S_x + (N_{t,x-1}^{m/f,i,j} - C_{t,x-1}^{m/f,i,j})\,S_{x-1} + I_{t,x}^{m/f,i,j} + I_{t,x-1}^{m/f,i,j})\,\tilde{S}_t^{i,j} && a = x
\end{aligned}
\quad (1.1)
$$

where $N_{t,a}^{m/f,i,f}$ is the number of males / females of age *a* in sub-stock *j* of stock *i* at the start of year *t*; $C_{t,a}^{m/f,i,f}$ is the catch of males / females of age *a* in sub-stock *j* of stock *i* during year *t* (whaling is assumed to take place in a pulse at the start of each year); S_a is the annual survival rate of animals of age *a* in the absence of catastrophic mortality events (assumed to be the same for males and females):

$$S_a = \begin{cases} S_0 & \text{if } a = 0 \\ S_{1+} & \text{if } 1 < a \end{cases} \quad (1.2)$$

S_0 is the calf survival rate for animals; S_{1+} is the survival rate for animals aged 1 and older; $\tilde{S}_t^{i,j}$ is the amount of catastrophic mortality (represented in the form of a survival rate) for sub-stock *j* of stock *i* during year *t* (catastrophic events are assumed to occur at the end of the year after mortality due to whaling and non-catastrophic natural causes and dispersal; in general $\tilde{S}_t^{i,j}$ =1, i.e. there is no catastrophic mortality); $B_{t+1}^{i,j}$ is the number of births to sub-stock *j* of stock *i* during year *t*; $I_{t,a}^{s,m/f}$ is the net dispersal of female/male animals of age *a* into sub-stock *j* of stock *i* during year *t*; and *x* is the maximum (lumped) age-class (all animals in this and the *x*-1 class are assumed to be recruited and to have reached the age of first parturition). *x* is taken to be 15[3].

Births and density-dependence

Density-dependence is assumed to be a function of numbers of animals ages 1 and older by feeding ground relative to the carrying capacity by feeding ground. The density-dependence component of sub-stock *j* of stock *i* is the sum of the density-dependence components by feeding group weighted by the proportion of animals from sub-stock *j* of stock *i* which are found on each feeding ground, i.e.:

$$F(i,j,t) = \sum_A \left(X^{A,i,j} (N_t^{1+,A} / K^{1+,A})^z \right) / \sum_A X^{A,i,j} \quad (2.1)$$

where z is the degree of compensation; N_t^{1+A} is the number of 1+ animals on feeding ground *A* at the start of year *t*:

$$N_t^{1+,A} = \sum_i \sum_j X^{A,i,j} \sum_{a=1}^{x} (N_{t,a}^{m,i,j} + N_{t,a}^{f,i,j}) \quad (2.2)$$

K_t^{1+A} is the carrying capacity for feeding ground *A*:

[3] The results would be identical to those reported here if x was set to the maximum of the age-at-recruitment and the age-at-maturity.

$$K^{1+,A} = \sum_i \sum_j X^{A,i,j} \sum_{a=1}^{x} (N_{-\infty,a}^{m,i,j} + N_{-\infty,a}^{f,i,j}) \tag{2.3}$$

$X^{A,i,j}$ is the proportion of animals of sub-stock *j* of stock *i* which is in feeding ground *A*.[4]

The number of births at the start of year *t* for sub-stock *j* of stock *i*, $B_t^{i,j}$, is given by:

$$B_t^{i,j} = b_t^{i,j}\, N_t^{f,i,j} \tag{2.4}$$

where $N_t^{f,i}$ is the number of mature females in sub-stock *j* of stock *i* at the start of year *t*:

$$N_t^{f,i,j} = \sum_{a=a_m}^{x} N_{t,a}^{f} \tag{2.5}$$

a_m is the age-at-maturity (the convention of referring to the mature population is used here, although this actually refers to animals that have reached the age of first parturition); $b_t^{i,j}$ is the probability of birth/calf survival for mature females:

$$b_t^{i,j} = \max(0, b_K\{1 + A^{i,j}(1 - F(I, j, t))\}) \tag{2.6}$$

b_K is the average number of live births per year per mature female at carrying capacity; and
$A^{i,j}$ is the resilience parameter for substock *j* of stock *i*.

Immigration (dispersal)
The numbers dispersing into sub-stock *j* of stock *i*, include contributions from pulse migration as well as diffusive dispersal:

$$\begin{aligned} I_{t,a}^{s,j,i} = & \sum_k \delta^{k,j,i} \tilde{N}_{t,a}^{s,i,k} - \sum_k \delta^{j,k,i} \tilde{N}_{t,a}^{s,i,j} + \\ & \sum_{k \neq j} \Omega_y^{k,j,i} \frac{\tilde{N}_{t,a}^{s,i,k}}{\sum_{a=1}^{x} (\tilde{N}_{t,a}^{m,i,k} + \tilde{N}_{t,a}^{f,i,k})} - \sum_{k \neq j} \Omega_y^{j,k,i} \frac{\tilde{N}_{t,a}^{s,i,j}}{\sum_{a=1}^{x} (\tilde{N}_{t,a}^{m,i,j} + \tilde{N}_{t,a}^{f,i,j})} - \end{aligned} \tag{3.1}$$

where $\delta^{k,j,i}$ is the rate of dispersal from sub-stock *k* to sub-stock *j* of stock *i*; $\Omega_y^{k,j,i}$ is the number of animals which disperse in year *y* from sub-stock *k* to sub-stock *j* of stock *i* in a pulse; and $\tilde{N}_{t,a}^{s,i,k} = (N_{t,a}^{s,i,k} - C_{t,a}^{s,i,k})\, S_a$.

Anthropogenic~~gonetic~~ removals
The catch by stock / sub-stock is generally determined by apportioning the catches by fleet[5], taking account of mixing (i.e. exposure to harvesting) matrices, according to:

$$C_{t,a}^{m/f,i,j} = \sum_k C_t^{m/f,k} \frac{\alpha_a^k X^{A_k,i,j} N_{t,a}^{m/f,i,j}}{\sum_{i,j,a} \alpha_a^k X^{A_k,i,j} N_{t,a}^{m/f,i,j}} \tag{4.1}$$

---

[4] It is usually the case that $\sum X^{A,i,j} = 1$. However, for the gray whales, this is not necessarily the case because catches can take place in the various sub-areas at different times. What is then important is the relative values of the $X^{A,i,j}$ among stocks and sub-stocks for a given feeding ground.

[5] A fleet is the combination of a fishery sector (commercial / aboriginal) and the sub-area in which the catch is taken.

where $C_t^{m/f,k}$ is the catch of males/females caught by fleet *k* during year *t*; A_k is the sub-area in which fleet *k* operates; and α_a^k is the relative vulnerability of animals of age *a* to harvest to the fleets which operate in sub-area *k*.

The incidental catches by sub-area are computed using the equation:

$$C_y^{\mathrm{I},A} = \begin{cases} \{1-\frac{0.5}{69}[1999-y]\}\bar{C}^{I.A} & \text{if } y \le 1999 \\ \bar{C}^{I,A} N_y^{1+,A} / N_{1999}^{1+,A} & \text{otherwise} \end{cases} \tag{4.2}$$

where $C_y^{\mathrm{I}/s,A}$ is the incidental catch of animals of sex *s* in sub-area *A* during year *y*; and $\bar{C}^{I.A}$ is the mean catch in sub-area *A* (see Table 1). The incidental catches are allocated to stock using the formula:

$$C_{t,a}^{I,m/f,i,j} = \sum_A C_t^{I,A} \frac{\tilde{\alpha}_a X^{A,i,j} N_{t,a}^{m/f,i,j}}{\sum_{i,j,a} \tilde{\alpha}_a X^{A,i,j} N_{t,a}^{m/f,i,j}} \tag{4.3}$$

where the selectivity pattern for incidental catches $\tilde{\alpha}_a$ is 1 for all ages (Weller *et al.*, 2008).

Initializing the parameter vector

The numbers at age in the pristine population are given by:

$$\begin{aligned} N_{-\infty,a}^{m/f,i,j} &= 0.5\, N_{-\infty,0}^{i,j} \prod_{a'=0}^{a-1} S_{a'} && \text{if } a < x \\ N_{-\infty,x}^{m/f,i,j} &= 0.5\, N_{-\infty,0}^{i,j} \prod_{a'=0}^{x-1} S_{a'} / (1-S_x) && \text{if } a = x \end{aligned} \tag{5.1}$$

The value for $N_{-\infty,0}^{i,j}$ is determined from the value for the pre-exploitation size of the 1+ component of sub-stock *j* of stock *i* using the equation:

$$N_{-\infty,0}^{m,i,j} = K^{1+,i,j} / \left(\sum_{a=1}^{x-1} \left(\prod_{a'=0}^{a-1} S_{a'} \right) + \frac{1}{1-S_x} \prod_{a'=0}^{x-1} S_{a'} \right) \tag{5.2}$$

where $K^{1+,i,j}$ is the carrying capacity (in terms of the 1+ population size size) for sub-stock *j* of stock *i*:

$$K_t^{1+,i,j} = \sum_{a=1}^{x} (N_{-\infty,a}^{m,i,j} + N_{-\infty,a}^{f,i,j}) \tag{5.3}$$

$N_{-\infty,a}^{m/f,i,j}$ is the number of animals of age *a* that would be in sub-stock *j* of stock *i* in the pristine population.

The model is based on the assumption that the age-structure at the start of year τ is stable rather than that the population was at its pre-exploitation equilibrium size at some much earlier year. The determination of the age-structure at the start of year τ involves specifying the effective 'rate of increase', γ, that applies to each age-class. There are two components contributing to γ, one relating to the overall population rate of increase (γ^+) and the other to the exploitation rate. Under the assumption of knife-edge recruitment to the fishery at age a_r, only the γ^+ component (assumed to be zero following Punt and Butterworth [2002]) applies to ages

a of a_r or less. The number of animals of age a at the start of year τ relative to the number of calves at that time, $N^*_{\tau,a}$, is therefore given by the equation:

$$N^*_{\tau,a} = \begin{cases} 1 & \text{if } a = 0 \\ N^*_{\tau,a-1}\, S_{a-1} & \text{if } a \le a_r \\ N^*_{\tau,a-1}\, S_{a-1}(1-\gamma) & \text{if } a_r < a < x \\ N^*_{\tau,x-1}\, S_{x-1}(1-\gamma)/(1-S_x(1-\gamma)) & \text{if } a = x \end{cases} \tag{5.4}$$

where B_τ is the number of calves in year τ and is derived directly from equations 2.1 and 2.6.

$$B_\tau = \left(1 - \left[1/(N^f_\tau b_K) - 1\right]/A\right)^{1/z} \frac{K^{1+}}{N^{1+,*}_\tau} \tag{5.5}$$

The effective rate of increase, γ, is selected so that if the population dynamics model is projected from year τ to a year Ψ, the size of the 1+ component of the population in a reference year Ψ equals a value, P_Ψ.

Likelihood function
Under the assumption that the estimates of abundance for a sub-area are log-normally distributed, the negative of the logarithm of the likelihood function is given by:

$$-\ell nL = \ell n\sqrt{\text{Det}[V]} + 0.5\sum_k (\ell\,\text{n}\,\underline{N}^{A,obs} - \ell\,\text{n}\,\underline{N}^A)[V^{-1}](\ell\,\text{n}\,\underline{N}^{A,obs} - \ell\,\text{n}\,\underline{N}^A)^T \tag{6.1}$$

where $N^{A,\text{obs}}_t$ is survey estimate of abundance for sub-area A during year t; and V is the sum of the variance-covariance matrix for the abundance estimates plus an additional variance term (assumed to be independent of year).

The data on the proportion of each stock in each sub-area is modelled under the assumption that the proportions are normally distributed, i.e.:

$$-\ell nL = \sum_i \sum_A \sum_t \tfrac{1}{2(\tau^{i,A}_t)^2}(p^{i,A}_t - p^{i,A,\text{obs}}_t)^2 \tag{6.2}$$

where $p^{i,A}_t$ is the model-estimate of the proportion of the animals in sub-area A which are from stock i; $p^{i,A,\text{obs}}_t$ is the observed proportion of animals in in sub-area A which are from stock I; and $\tau^{i,A}_t$ is the standard error of $p^{i,A,\text{obs}}_t$.

Quantification of uncertainty
Uncertainty can be quantified in various ways. For the purposes of the analyses of this report, the uncertainty of the model predictions for a scenario (choices for the stock structure hypothesis, MSYR, etc.) is quantified by bootstrapping. This involved generating pseudo abundance estimates from distributions with means given by the actual data and variance-covariance matrix V (with the values for the additional variance parameters set to those obtained by fitting the model to the actual estimates of abundance).

EXAMPLE APPLICATION
Stocks and spatial structure
The example application is based on the conceptual model of gray whales outlined in Fig. 1. There are two stocks ('Asian' and 'Eastern') for the example application, with the 'eastern' stock divided into three sub-stocks ('Sakhalin', 'North' and 'PCFG'). There are eight feeding

grounds (‘West of Kamchatka’, ‘Sakhalin’, ‘Kamchatka-East’, ‘Northern Bering Sea / South Chukchi’, ‘North Chukchi’, ‘Gulf of Alaska’, and ‘PCFG’), there are three migration corridors (Japan, Korea and California), and there are two wintering grounds (Asia and Mexico). The feeding grounds, migration corridors, and wintering grounds are the sub-areas for the model.

For this hypothesis, the ‘Northern Bering Sea / South Chukchi’ and ‘North Chukchi’ feeding grounds are combined into a single feeding ground (sub-area), denoted the ‘North’ feeding ground, while the Japanese and Korean migration corridors are also merged into a single ‘Japan/Korea/China’ migration corridor. Two of the feeding grounds ‘PCFG’ and ‘California’ are divided seasonally [Jun-Dec; Jan – May] because of differences in rates of incidental catch, combined with differences of the relative vulnerability of the various stocks and sub-stocks at this time. There are two fleets in the ‘North’ feeding ground to allow for historical commercial and aboriginal catches. An extra sub-area (Calif-3) is added to the model to enable it to be fitted to the estimates of absolute abundance under the assumption that all animals passing through California are subject to being counted with equal probability.

Parameterization

Catastrophic mortality is assumed to be zero (i.e., $\tilde{S}_t^{i,j}$ =1) except for the North sub-stock for 1999 and 2000 when it is assumed to be equal to the parameter $\tilde{S}$ (IWC, 2013). This assumption reflects the large number of dead gray whales observed stranded along the coasts of Oregon and Washington during 1999 and 2000 relative to the number stranded there in other years with data (Brownell *et al.*, 2007; Gulland *et al.*, 2005). The catastrophic mortality in 1999 and 2000 is assumed to have only impacted the North sub-stock because the abundance estimates for the PCFG and Sakhalin sub-stocks increased when the catastrophic mortality occurred, in contrast to those for the North sub-stock which declined substantially. Immigration occurs only between the North sub-stock and the PCFG sub-stock, and only animals aged 1+ immigrate. Allowance is also made for a pulse dispersal of 20 animals from the North sub-stock to the PCFG sub-stock in each of the years 1999 and 2000 (IWC, 2013).

The parameters of the population dynamics model are the carrying capacities of each stock, the proportion which each stock is at the start of the first year considered in the model (τ=1930), the intrinsic rate of growth of each stock, the survival rates for the North sub-stock in 1999 and 2000 (assumed to be the same), the dispersal rate between the North and PCFG sub-stocks, the relative vulnerability of PCFG as compared to other ~~whales~~sub-stocks in Southeast Alaska, the PCFG area in Dec-May (the migratory period)[6], and in California, and the additional variance parameters for each time-series of abundance estimates. There are in total 17 estimable parameters.

The value for the degree of compensation parameter is set to 2.39 (which corresponds approximately to MSYL occurring at 60% of carrying capacity) and MSYR is assumed to be 3.5%. For ease of parameterization, the numbers of animals dispersing from the ‘north’ and PCFG sub-stocks to the ‘Sakhalin’ sub-stock is assumed to be zero.

Two scenarios regarding the proportion of Sakhalin animals found in the Japan/Korea/China area are considered (0.2 and 0.1).

Data utilized

Table 3 (available as a spreadsheet) lists the historical catch data by sex, year, and area based on IWC (2011, 2013), Bradford (2003) and input from members of the Steering Group. Table 4 lists the abundance estimates for the Sakhalin, California and PCFG feeding grounds. The

[6] All PCFG sub-area catches during June-November are assumed to be from the PCFG sub-stock. See table 2 for the catch mixing matrices.

1998 estimate for the PCFG feeding ground is considered to be biased and is consequently ignored. Table 5 summarizes the mixing proportion data on which the analyses are based.

RESULTS AND DISCUSSION

Results of preliminary analyses

Figures 2 and 3 show the fits of the model to the abundance estimates. The model is able to capture the trends in abundance adequately when the mixing proportion of Sakhalin animals in the Japan/Korea/China migration corridor is assumed to be 0.2 (Fig. 3), but the fit to the abundance estimates for the PCFG feeding ground are misspecified when this mixing proportion is 0.1. The extent of additional variation (expressed as standard errors of logs) obtained by fitting the operating model to the actual data (the base model) is 0.054/0.052 (Sakhalin series), 0.088/0.081 (Southern California series), and < 0.02 (PCFG series) for the two choices for the mixing rates of Sakhalin animals in the Japan/Korea/China area. The model predicted proportions in the Japan/Korea/China area are 0.55 and 0.44 (0.2 mixing proportion for Sakhalin whales in the Japan/Korea/China area) and 0.68 and 0.31 (0.1 mixing proportion for Sakhalin whales in the Japan/Korea/China area) for observed proportions of 1 and 0 Sakhalin animals. The base model predictions of the proportion of PCFG whales in southeast Alaska, the PCFG sub-area (Dec-May), and California (June-Nov, Dec-May) is 0.57, 0.30, 0.27, and 0.19 respectively (0.2 mixing proportion) and 0.55, 0.27, 0.25 and 0.15 respectively (0.1 mixing proportion). These values match the data used for conditioning (0.57, 0.36, 0.30 and 0.09) adequately give the assumed standard deviation of 0.1 (Table 5).

The time-trajectories of abundance by stock are sometimes sensitive to the value of the mixing proportion of Sakhalin whales in the Japan-Korea area (Figs 4 and 5). Specifically, the Asian stock is a higher fraction of its initial size if the probability of the Sahkalin sub-stock being in Japan / Korea is 0.2. However, the fits to the Sakhalin abundance series is clearly mis-specified. This mis-specification can be addressed by increasing the MSY rate from 3.5%, but in the interests of simplicity, the results of this paper are based on a common MSY rate across stocks.

The stocks are estimated to be well below their (current) carrying capacities when the mixing proportion for Sakhalin whales in the Japan/Korea/China area is 0.2, with the Asian and Sakhalin stocks approximately 10% of their carrying capacities and the North and PCFG sub-stocks approximately half of theirs (Fig. 5). Note that the model does not have direct information on carrying capacity for the Sakhalin and North sub-stocks because neither of the associated abundance time-series provide strong evidence for a reduction in growth rate over time. The abundance data for the PCFG sub-area is stable. However, the model (which includes dispersal from the North to PCFG sub-stocks) suggests an increasing trend. In principle, model runs could be conducted in which the carrying capacity of the PCFG stock is set to approximately 200 1+ animals.

In contrast to the outcomes from the model in which the mixing proportion for Sakhalin whales in the Japan/Korea/China area is 0.2, setting the mixing rate to 0.1 leads to unrealistic estimates of the trend in abundance in the PCFG feeding ground. This may be due to convergence to a local minimum of the objective and hence requires further investigation.

Next steps

Several of the data inputs are preliminary. Specifically, it is necessary to finalize the catch series, update the survey estimates of abundance to include the variance covariance matrices for the abundance estimates for the Sakhalin feeding ground and the recent surveys off California. The mixing proportions should be updated to reflect ~~telemetry~~ photo-identification data and other catches of known stock animals off Asia. The underlying data on mixing should be reanalysed to provide appropriate values for standard errors.

Once the data have been finalized, allowance should be made for uncertainty regarding the mixing proportions when constructing the bootstrap data sets, and the model applied to all of the stock structure hypotheses. Finally, scenarios should be developed to examine the impact of anthropogenic impacts of gray whales across their range.

ACKNOWLEDGEMENTS

This work was funded by the IWC. The document was been updated substantially thanks to input from the Steering Group, and especially Amanda Bradford and Jonathan Scordino.

Abstract

Management strategy evaluation (MSE) involves using simulation to compare the relative effectiveness for achieving management objectives of different combinations of data collection schemes, methods of analysis and subsequent processes leading to management actions. MSE can be used to identify a 'best' management strategy among a set of candidate strategies, or to determine how well an existing strategy performs. The ability of MSE to facilitate fisheries management achieving its aims depends on how well uncertainty is represented, and how effectively the results of simulations are summarized and presented to the decision-makers. Key challenges for effective use of MSE therefore include characterizing objectives and uncertainty, assigning plausibility ranks to the trials considered, and working with decision-makers to interpret and implement the results of the MSE. This paper explores how MSEs are conducted and characterizes current 'best practice' guidelines, while also indicating whether and how these best practices were applied to two case-studies: the Bering–Chukchi–Beaufort Seas bowhead whales (*Balaena mysticetus*; Balaenidae) and the northern subpopulation of Pacific sardine (*Sardinops sagax caerulea;* Clupeidae).

Introduction

Management strategies (also referred to as management procedures; Butterworth 2007, 2008a,b) are combinations of data collection schemes, the specific analyses applied to those data and the harvest control rules used to determine management actions based on the results of those analyses. Management strategy evaluation (MSE),[1] the evaluation of management strategies using simulation, is widely considered to be the most appropriate way to evaluate the trade-offs achieved by alternative management strategies and to assess the consequences of uncertainty for achieving management goals. Butterworth *et al.* (2010a) list three primary uses for MSE:

1. development of the management strategy for a particular fishery;
2. evaluation of generic management strategies; and
3. identification of management strategies that will not work and should therefore be eliminated from further consideration.

One specific use for MSE, particularly in the United States where the forms of the harvest control rules for federal fisheries management are constrained by the Magnusson–Stevens Act (MSA), is to quantify the impacts of uncertainty associated with management strategies adopted at present, and to identify the 'realizable' performance which can be achieved given the quality of the data available and the types of uncertainties which are inherent in the system being managed.

Butterworth (2007) contrasts MSE with the traditional approach to providing management advice, which involves conducting a 'best assessment' of the resource, evaluating uncertainty using confidence intervals and sensitivity tests, and providing a recommendation for a management action based on applying some harvest control rule or by conducting constant catch or constant fishing mortality projections. That paper explains how MSE overcomes many of the concerns with the traditional approach, including that the full range of uncertainty can be taken into account and that decision-makers consider longer term trade-offs among the management objectives, instead of focusing on short-term considerations only.

For the purposes of this paper, a MSE must address the fact that the data and models on which management strategies are based are subject to uncertainty. Consequently, analyses in which fishing mortality can be set and implemented exactly (e.g. Punt and Butterworth 1991) are not considered to be MSEs, even though such analyses may be useful in terms of understanding the dynamical properties of exploited ecosystems.

Management strategy evaluation has been used extensively to understand the expected behaviour of management strategies, but is increasingly being implemented to select management strategies for implementation in actual fisheries. The earliest use of MSE for such selection occurred in South Africa, where the control rules used to set total allowable catches (TACs) for the anchovy *Engraulis encrasicolus*, Engraulidae, and later the sardine *Sardinops sagax*, Clupeidae, fisheries were selected using what has since become known as MSE (Bergh and Butterworth 1987; Geromont *et al.* 1999; De Oliveira and Butterworth 2004). MSE has also been used in South Africa to select management strategies for the Cape hake *Merluccius paradoxus* and *M. capensis*, Merlucciidae (Rademeyer *et al.* 2008), rock lobster *Jasus lalandii* and *Palinurus gilchristi*, Palinuridae (Johnston and Butterworth 2005; Johnston *et al.* 2008) and most recently horse mackerel, *Trachurus trachurus capensis*, Carangidae (Furman and Butterworth 2012) fisheries. The use of management strategies that have been tested using simulation has been routine for the major fisheries in South Africa for some 20 years.

Management strategy evaluation has been used extensively by the International Whaling Commission (IWC) since the late 1980s to select management strategies to calculate potential catch limits for commercial whaling and determine actual strike limits for aboriginal subsistence whaling

[1]A term introduced into the fisheries lexicon by Smith (1994). To the extent possible, the nomenclature for MSE outlined by Rademeyer *et al.* (2007) is followed throughout.

(Punt and Donovan 2007). The use of MSE accelerated internationally following a 1998 ICES Symposium on Confronting Uncertainty in the Evaluation and Implementation of Fisheries-Management Systems, which included several papers illustrating the methods underlying MSE and then current applications (Butterworth and Punt 1999; Cooke 1999; Smith *et al.* 1999).

Management strategy evaluation has been used by the Commission for the Conservation of Southern Bluefin Tuna (CCSBT) to select a management strategy for southern bluefin tuna *Thunnus maccoyii*, Scombridae (Kurota *et al.* 2010; Anonymous 2011). The Potential Biological Removals method, used to determine upper limits on anthropogenic removals of marine mammals in the USA, was also developed using MSE (Wade 1998). Similarly, MSE was used to evaluate a by-catch management control rule for seabirds (Tuck 2011). Outside of South Africa and the IWC, MSE has been applied most extensively in Australia where it has been used to compare and select management strategies for the Southern and Eastern Scalefish and Shark Fishery, SESSF (Punt *et al.* 2002; Wayte and Klaer 2010; Little *et al.* 2011), the Queensland spanner crab *Ranina ranina*, Raninidae fishery (Dichmont and Brown 2010), the Northern Prawn Fishery (Dichmont *et al.* 2008, 2013), the fishery for southern rock lobster *Jasus edwardsii*, Palinuridae off South Australia (Punt *et al.* 2012a) and the Tasmanian abalone fishery (Haddon and Helidoniotis 2013). The management strategies used to recommend catch limits for southern rock lobster off New Zealand have also been selected using MSE (Starr *et al.* 1997; Breen and Kim 2006).

Management strategy evaluation has been applied extensively to European fisheries to explore the performance of management strategies theoretically (Kell *et al.* 2005a,b, 2006), but few applications have resulted in strategies being formally implemented. The International Council for the Exploration of the Seas (ICES) provides a list of 18 management plans for North East Atlantic stocks that have been evaluated using MSE approaches since 2008 (ICES 2013). As an advisory body to the governments of ICES member countries and the European Commission, ICES bases its advice on these management plans if advice recipients have agreed that they can be used as a basis for that advice and provided the MSEs have shown them to fulfil ICES' precautionary criteria (ICES 2012). If this does not apply, ICES reverts to its own MSY framework, and if there is no basis for giving MSY-related advice, takes account of precautionary considerations (ICES 2012). The European Commission has its own advisory body, the Scientific, Technical and Economic Committee for Fisheries (STECF, established to advise on matters pertaining to the conservation and management of living aquatic resources) that performs impact assessments of proposed management plans, and may make use of MSEs for this purpose (STECF 2011a).

In North America, MSE has been applied to evaluate management strategies for the fishery for the northern subpopulation of Pacific sardine *Sardinops sagax caerulea*, Clupeidae, and the control rule used for this fishery from 1998 until 2012 was based on a MSE (PFMC 1998), as was the 2014 revision to this control rule (Hurtado-Ferro and Punt 2014). A revision to the management strategy adopted became necessary when the estimated relationship between recruitment success and environmental factors changed given new information. MSE has also been used to establish a management strategy for sablefish *Anoplopoma fimbria*, Anoplopomatidae off British Columbia (Cox and Kronlund 2008), for West Greenland halibut *Reinhardtius hippoglossoides*, Pleuronectidae (Butterworth and Rademeyer 2010; NAFO 2010) and for pollock *Pollachius virens*, Gadidae off eastern Canada (Rademeyer and Butterworth 2011).

Management strategy evaluation has recently been used to evaluate alternate management strategies for Tristan rock lobster (*Jasus tristani*) for three of the islands that form the Tristan da Cunha group of islands (Johnston and Butterworth 2013, 2014; Butterworth and Johnston 2014).

The focus for most previous MSEs has been single-species systems. However, MSE has also been used to evaluate management strategies to achieve multispecies or ecosystem objectives (Sainsbury *et al.* 2000; Fulton *et al.* 2007; Dichmont *et al.* 2008, 2013; Plagányi *et al.* 2013).

Management strategy evaluation is at the interface between science and policy. While it would be desirable to keep science and policy separate, there is a link. Decision-makers need to identify the desirable outcomes that any management strategy adopted should aim to achieve, while scientific analyses (the MSE) can inform the decision-makers on the feasible ranges of trade-offs. A well-structured MSE will utilize the links between policy and science, but ensure that a 'wall of science' remains whereby decision-makers do not decide scientific issues and scientists do not make policy decisions (Field *et al.* 2006).

While MSE is widely acknowledged to be the most appropriate way to compare management strategies, and the basic approach has been summarized in many publications, actual uses can differ markedly with regard to the likelihood that the resulting management strategy actually provides the best trade-off amongst the management objectives and is robust to uncertainty. Furthermore, it is well recognized that poorly conducted MSEs are likely to be less useful for management purposes than using the traditional best assessment approach coupled to essentially *ad hoc* advice (Rochet and Rice 2009; Butterworth *et al.* 2010b; Kraak *et al.* 2011). This paper therefore outlines the process of conducting MSEs and identifies a set of 'best practice' guidelines (Table 1). These proposed best practices for MSEs should assist in facilitating that MSEs are conducted in the most appropriate manner so that the resulting management strategies are best able to achieve their goals. The focus of the paper is on single-species applications of MSE, although applications that consider multispecies and ecosystem aspects are also considered. The extent to which these guidelines have been followed in practice is illustrated for two case-studies: the management strategy for the northern subpopulation of Pacific sardine and that for bowhead whales, *Balaena mysticetus* Balaenidae, in the Bering Sea, Chukchi Sea and Beaufort Sea.

MSE – the basics

The basic steps that need to be followed when conducting a MSE (Fig. 1) are as follows:

1. identification of the management objectives in concept and representation of these using quantitative performance statistics;
2. identification of a broad range of uncertainties (related to biology, the environment, the fishery and the management system) to which the management strategy should be robust;
3. development of a set of models (often referred to as 'operating models') which provide a mathematical representation of the system to be managed; an operating model must represent the biological components of the system to be managed, the fishery which operates on the modelled population, how data are collected from the managed system and how they relate to the modelled population (including the effect of measurement 'noise'); in addition, an implementation model is required that reflects how management regulations are applied in practice; note that more than a single operating model is nearly always required because of the need to cover the range of the ever-present uncertainties, which include the imprecision of the values of parameters estimated from fits to data, as well as structural uncertainties such as how many reproductively separate stocks of a species are present in the region considered;
4. selection of the parameters of the operating model(s) and quantifying parameter uncertainty (ideally by fitting or 'conditioning' the operating model(s) to data from the actual system under consideration);
5. identification of candidate management strategies which could realistically be implemented for the system;
6. simulation of the application of each management strategy for each operating model; and
7. summary and interpretation of the performance statistics; this may lead to refinement of the relative weighting of the management objectives as the simulation process develops and continues to provide more refined results to inform the quantitative trade-offs among competing goals.

The feedback loop between the management strategy and the operating model(s) is a fundamental aspect of MSE and is the particular feature, which distinguishes it from simple risk assessment where the implications of unchanging management regulations (e.g. constant TAC) are evaluated by use of projections. Simple risk assessment overestimates risk through failing to take account of management reactions to the information provided by future data.

Management strategy evaluation is not the same as conducting projections from a stock assessment, although a stock assessment may form the basis for the operating model(s) which are core to a MSE. Specifically, MSE takes feedback control into account, that is it takes account of the collection and use of future data on the status of the managed system. In addition, stock assessments usually involve selecting a single model structure and estimating the parameters of the model.

Table 1 Summary of the best practice guidelines.

Selection of objectives and performance metrics

- Involve decision-makers and stakeholders (e.g. using workshops) throughout the process to ensure the performance statistics capture the management objectives and are understandable.
- At a minimum, report statistics related to average catches, variation in catches and the impact on stock size.

Selection of uncertainties

- Consider a range of uncertainties, which is sufficiently broad that new information collected after the management strategy is implemented should generally reduce rather than increase this range.
- Include trials for each potential source of uncertainty (unless there is clear evidence that the source does not apply) and for the factors considered in Table 3.
- Consider the need for spatial structure, multiple stocks, predator-prey interactions and environmental drivers on system dynamics; modelling the last by imposing trends on the parameters of the operating model is often sufficient to understand its implications.
- Include predation effects using minimum realistic models and examine the potential for technical interactions amongst major fished species, especially in multispecies fisheries.
- Divide the trials into 'reference' and 'robustness' sets.
- Use Bayesian posterior distributions to capture the parameter uncertainty for each trial if possible.

Identification of candidate management strategies

- This should be the primary responsibility of the stakeholders/decision–makers, but with guidance from the analysts given the limitations of the management strategy evaluation (MSE). Care needs to be taken that the management strategy can be implemented in practice.
- Evaluate the entire management strategy. In cases in which the management strategy is complex, this may be impossible computationally, in which case a simplification of the assessment method is needed – the nature of the simplification should be based on simulation analyses.

Simulation of the application of the management strategy

- Check that operating model and management strategy are consistent with reality; projections into the future should generate quantities, such as past assessment errors and levels of variability in biomass and recruitment, on the same scales as those estimated to have occurred in the past.
- Conduct tests of the software, for example using 'perfect' data before conducting actual analyses.
- Base recommendations for management actions in management strategies only on data which would (with near certainty) actually be available.
- Document any assumptions regarding parameters assumed known when applying the management strategy.

Presentation of results and selection of a management strategy

- Develop a process, so that the decision-makers understand the results of the MSE and the range of trade-offs which are available to them.
- Use effective graphical summaries which are developed collaboratively with the stakeholders.
- Identify whether there are 'performance standards' which must be satisfied to eliminate some possible management strategies immediately and hence simplify the final decision process.
- Select a method for assigning a plausibility rank to each trial and take these ranks into account when making a final selection among candidate management strategies.

Other

- Include 'Exceptional Circumstances' provisions which specify the situations under which a management strategy's recommendations may be over-ridden.
- Include a schedule for when formal reviews of the implemented management strategy will take place.

Although an aim of a stock assessment is to quantify uncertainty, it is rarely possible to capture all the key sources of uncertainty within the confines of a stock assessment, in particular 'outcome uncertainty' (see below), and to carry uncertainty forward fully into the provision of management advice. MSE can also be used when it is not possible to apply standard methods of stock assessment, as is common in data-poor situations.

Although not the focus of the present paper, Marasco *et al.* (2007) observe that the results from a MSE may be used not only to choose amongst the candidate management strategies, but also to identify future research and monitoring goals. In addition, the results of a MSE can be used to evaluate how well existing monitoring and data analysis methods are able to reflect the true status of the system with reasonable accuracy (see e.g. Ful-

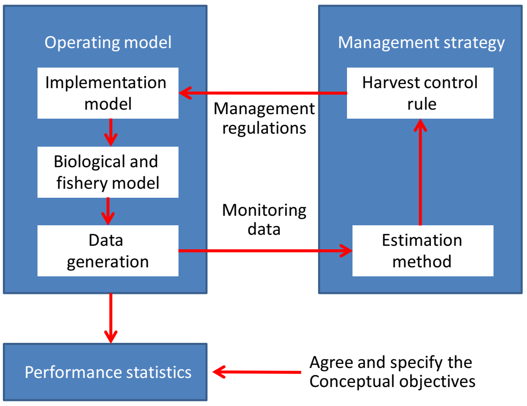

Figure 1 Conceptual overview of the management strategy evaluation modelling process.

ton *et al.* 2004; for an evaluation of ecosystem indicators). Marasco *et al.* (2007) also emphasize the need to continue to monitor the system following the implementation of a management strategy. Consistent with practice in, for example, the IWC and South Africa (Butterworth 2007; Punt and Donovan 2007), they stress the need to review and revise the MSE periodically, as consolidated outcomes from future monitoring and research become available.

Overview of the case-studies

Bering–Chukchi–Beaufort Seas bowhead whales

Bowhead whales in the Bering, Chukchi and Beaufort Seas are considered to be a single stock, separate from the stocks in the Okhotsk Sea, the Davis Strait and Hudson Bay, and off Spitsbergen. This stock, often referred to as the Bering–Chukchi–Beaufort (or BCB) Seas stock of bowhead whales, has been subject to hunting by aboriginal peoples off Alaska (USA) and Russia for centuries. In common with other stocks of bowhead whales, it was severely depleted by commercial whaling, which occurred between 1848 and 1914 in the case of the BCB stock. Commercial whaling on the BCB bowhead stock ceased once whaling there became economically non-viable, but aboriginal whaling continues at low levels.

Management of bowhead whales is challenging because individuals can live beyond 100 years (George *et al.* 1999). In addition, the location of the population and the fishery makes monitoring difficult (it involves ice platform sighting surveys of bowhead whales as they migrate through leads which open as the ice thaws). The aboriginal hunt of bowhead whales off Alaska and Russia is managed under the IWC. Management for aboriginal whaling is based on strike limits, which are the number of strikes of whales permitted within a season. Management advice is based on the number of strikes rather than numbers of whales landed because of the need to account for mortality when animals are struck but subsequently not landed ('lost').

Each country wishing to take whales for aboriginal subsistence purposes must provide the IWC with a 'Need Statement' which documents the number of annual strikes needed to satisfy the requirements of aboriginal peoples in terms of nutrition and culture. Management advice in the context of the BCB bowhead whales relates to whether the need requested can be satisfied without impacting the ability to achieve conservation-related management goals; this contrasts with commercial whaling, where the aim is to maximize the catch subject to the same constraint. The development of a management strategy for aboriginal subsistence whaling, and in particular for the BCB bowhead whales, commenced in 1995 after a management strategy for commercial whaling was adopted in 1994 (IWC 1994). A 'Strike Limit Algorithm' (SLA) was later adopted as the management strategy for the BCB bowhead whales in 2003 (IWC 2003). Prior to the use of the SLA, evaluation of whether the need requested was consistent with the IWC's conservation-related objective involved comparing the proposed need in terms of strikes with an estimate of a lower percentile (usually the lower 5th percentile) of a distribution for the replacement yield (the number of animals removed from the population each year which will keep the population at its current level; Givens *et al.* 1995).

The development of the SLA involved the IWC identifying management objectives for aboriginal subsistence whaling, obtaining a 'need envelope' from hunters and their scientific representatives (the range of possible maximum need levels by year over the next 100 years), developing operating models tailored to the dynamics of the BCB bowhead whale population, and simulating the application of candidate SLAs (equivalent to management strategies). The operating models for the BCB bowheads were case-specific, rather than generic as was the case for commercial whaling, because this was considered likely to lead to an improved ability to satisfy the management goals and because there are only a few aboriginal whaling fisheries. The development process was competitive, with several sets of 'developers' 'competing' to best satisfy the management goals. However, as it happened, the final selected SLA was none of these individual SLAs, but rather an average of the best two.

Northern subpopulation of Pacific sardine

The northern subpopulation of Pacific sardine is harvested off Mexico, the USA (including Alaska) and Canada. The population dynamics of Pacific sardine, in common with those of many small pelagic fish species, are characterized by large changes in abundance, driven primarily by environmental conditions. The long-term nature of these fluctuations has been confirmed for Pacific sardine using samples of fish scales from sediment cores in the Santa Barbara basin (Soutar and Isaacs 1969, 1974; Baumgartner *et al.* 1992). Sardine populations in the Santa Barbara basin are estimated to have peaked at intervals of approximately sixty years. The biomass and catch of Pacific sardine increased rapidly during the 1930s until the mid-1940s, and declined thereafter. The decline was likely due to a combination of environmental conditions leading to poor recruitments and very high fishing mortality rates.

The biomass of Pacific sardine began to rebuild during the 1980s, and by 1991 a directed fishery was re-established. The Pacific sardine fishery was managed by the State of California until 2000 when management authority was transferred to the Pacific Fishery Management Council (PFMC; Hill *et al.* 2011). Harvest Guidelines for Pacific sardine between 1998 and 2012 were set using a harvest control rule of the form (PFMC 1998):

$$\text{HG} = (\text{BIOMASS} - \text{CUT-OFF}) * \text{FRACTION} * \text{DISTRIBUTION}$$

where: HG (Harvest Guideline) is the allowable catch for each management year; BIOMASS is the estimate of the biomass of Pacific sardine aged 1 and older obtained from an age-structured stock assessment model; CUT-OFF is 150 000 mt and is the escapement threshold below which fishing is prohibited; FRACTION is a temperature-dependent exploitation fraction which ranges from 5 to 15%; and DISTRIBUTION is the average proportion of the coastwide biomass in USA waters, estimated at 0.87. In addition, there is a maximum allowable catch regardless of biomass such that HG ≤ MAXCAT, where MAXCAT is 200 000 mt. The purpose of CUT-OFF is to protect the stock when biomass is low. The purpose of FRACTION is to specify how much of the stock is available to the fishery when BIOMASS exceeds CUT-OFF. The DISTRIBUTION term recognizes that the stock ranges beyond USA waters and is therefore subject to foreign fisheries. In PFMC (1998), FRACTION was determined on the basis of a 3-year running average of the temperature at Scripps Pier, La Jolla, USA.

The overarching management plan for all coastal pelagic species (CPS) managed by the PFMC was modified in 2011 to be consistent with the 2006 reauthorization of the MSA. This involved formally introducing how the overfishing limit (OFL, the annual catch amount consistent with an estimate of the annual fishing mortality that corresponds to maximum sustainable yield) is calculated, as well as the acceptable biological catch (ABC, a harvest limit set below the OFL that incorporates a buffer against overfishing to take account of scientific uncertainty).

The specifications of the harvest control rule adopted in 1998 were determined using simulations in which the population dynamics were represented by a production model where productivity was related to an environmental variable (PFMC 1998). Results of assessments conducted after 1998 were analysed during a workshop in February 2013 (PFMC 2013) which suggested that the temperature at Scripps Pier no longer exhibited the same trends as most other measures of temperature for the offshore waters to the west of North America (McClatchie *et al.* 2010). Rather, the relationship between recruitment, spawning biomass and temperature was strongest when temperature was based on sea surface temperature obtained from CalCOFI samples (PFMC 2013).

The results from the February 2013 workshop formed the basis for developing a set of operating models for the northern subpopulation of Pacific sardine, as well as an initial set of candidate management strategies (PFMC 2013). The process of selecting the operating models and the candidate management strategies was iterative, involving presentations by the analysts to the PFMC as well as its Scientific and Statistical Committee, Coastal

Pelagic Species Advisory Panel and Coastal Pelagic Species Management Team. The PFMC took advice from these advisory bodies as well as from members of the public, including industry and environmental non-governmental organizations (ENGOs), and then directed the analysts. Hurtado-Ferro and Punt (2014) summarize the most recent MSE results, along with the specifications for the operating models and candidate management strategies.

Best practices for MSE

Establishing objectives and performance statistics

One of the main strengths of MSE is that the decision-makers clarify their objectives. Objectives for fisheries management can be categorized as either 'conceptual' ('strategic') or 'operational' ('tactical'). Conceptual objectives are generic, high-level policy goals. For example, the conceptual objectives for CPS off the USA west coast (i) promote efficiency and profitability in the fishery, including stability of the catch; (ii) achieve 'Optimum Yield' (OY); (iii) encourage cooperative international and interstate management of CPS; (iv) accommodate existing fishery sectors; (v) avoid discards; (vi) provide adequate forage for dependent species; (vii) prevent overfishing; (viii) acquire biological information and develop a long-term research programme; (ix) foster effective monitoring and enforcement; (x) use resources spent on management of CPS efficiently; and (xi) minimize gear conflicts (PFMC 2011). These goals are largely self-consistent, but this need not always be the case. For example, the conceptual objectives for aboriginal subsistence whaling (i) ensure that risks of extinction are not seriously increased by whaling; (ii) enable native people to hunt whales at levels appropriate to their cultural and nutritional requirements (i.e. satisfy their 'need'); and (iii) move populations towards and then maintain them at healthy levels. Objective (ii) may be in conflict with objectives (i) and (iii) for some populations.

To be included in a MSE, the conceptual objectives need to be converted into operational objectives (expressed in terms of the values of performance measures or performance statistics). This usually involves translating each conceptual objective into one or more operational objective(s) and performance statistic(s). For example, the conceptual objective of 'avoid overfishing' could be represented operationally as 'the annual probability that the stock drops below 20% of the unfished level should not exceed 5%'. However, some conceptual objectives may link to multiple operational objectives. For example, the conceptual objective 'achieve OY' could be quantified by the operational objectives 'maximize catch in biomass', 'minimize the interannual variation in catch' and 'maximize the economic rent to the fishing industry', amongst others.

The operating model(s) should be developed so that performance statistics can be calculated. For example, when there are explicit ecosystem and economic objectives, the operating model(s) may need to include a fleet dynamics model (Ulrich *et al.* 2007) or models of how fishing impacts ecosystem components other than the target species (Schweder *et al.* 1998), as well as related performance statistics.

It is inevitable that some of the objectives will be in conflict to some extent, and one aim of MSE is to highlight trade-offs among the objectives as quantified using performance statistics. For example, increased monitoring efforts may allow higher catches for the same level of risk (see Fig. 2), but the increased monitoring will come at a financial cost. The more common trade-offs are between risk to the resource and benefits to the fishery, and between average catch and variation in catch (the less variability in catch permitted, the lower the average catch needs to be able to accommodate catch reductions needed at times the resource might be at a low abundance). It is critical to ensure that the decision-makers are aware of these trade-offs. One way to achieve this is to use a utility function which balances the various factors in providing a single number. However, efforts to base MSEs on utility functions have generally been unsuccessful because decision-makers (and stakeholder groups) wish to see how well each candidate management strategy achieves each objective and how they trade off.

The difficulties associated with conflicting objectives become more challenging when management strategies are developed for fisheries which target multiple species, or when there are multiple stakeholder groups which fish using different gears or may have markedly different objectives (e.g. commercial and recreational sectors within a fishery). This is because what is seen as the 'optimal' state of the system will differ among stakeholders. Few management strategies that have been

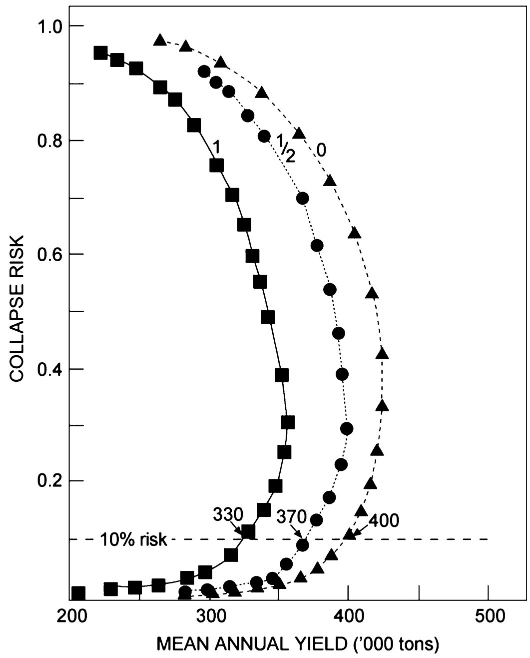

Figure 2 Relationship between risk and reward for South African anchovy ('collapse' is defined here as the spawning biomass falling below 10% of its average unexploited level, and risk reports the probability of that happening at least once during a 20-year period). Each line indicates a different level of survey precision (1: current precision; ½: double the survey effort; 0: perfect information; reproduced from Bergh and Butterworth 1987).

implemented have addressed the issue of between-species trade-offs. One notable exception is the South African fishery for anchovy and sardine. Here, there is a trade-off between anchovy and sardine catches because of an unavoidable by-catch of juvenile sardine with anchovy, which decreases the TAC possible for the more valuable adult sardine. This multiple species allocation problem was addressed over one period by allowing each company with rights to each of the two species to choose its preferred trade-off. First, the TACs that would follow under each company's desired trade-off were calculated; next quotas were allocated to that company which were computed by multiplying the TACs related to its trade-off by the proportional right to the combined (sardine and anchovy) fishery as a whole that it had been awarded; finally, the TACs themselves were calculated by summing the quotas awarded to each company for each species (De Oliveira 2003; Butterworth *et al.* 2012).

Best practice in terms of specifying objectives, particularly operational objectives, is through the use of inclusive workshops (Cox and Kronlund 2008; Mapstone *et al.* 2008; PFMC 2013). Workshop participants need to be representative of the decision-makers and other stakeholders, and efforts should be made to ensure that the decision-makers are fully aware of which decisions are theirs (weighting objectives, and selecting management strategies to be tested) and which decisions are primarily technical. Progress in such workshops may be facilitated by providing draft specifications that can be criticized, expanded upon or rejected outright.

The statistics used to evaluate the performance of alternative candidate management strategies should be chosen, so that they are easy for decision-makers and stakeholders to interpret (Francis and Shotton 1997; Peterman 2004). Butterworth and Punt (1999) comment that standard deviations or coefficients of variation of catch limits are difficult for many stakeholders to understand. Experience suggests that stakeholders find it much easier to relate to statistics such as the fraction of years in which the catch is less than some desirable level. Care should be taken to avoid having too many performance statistics. While it may seem desirable to have, for example, a number of performance statistics to quantify catch variation (IWC 1992), the final decision process is made considerably easier if the number of performance statistics is small, so that they can easily be summarized graphically. In any case, experience suggests that such catch variation statistics are often highly correlated with each other.

It is common to include performance statistics such as the probability of dropping below some threshold level [such as the minimum stock size threshold (MSST) defined in the USA MSA, or 20% of the estimated unfished biomass, B_0]. However, while dropping below MSST has implications in the USA (leading to the requirement for a rebuilding plan), the use of a metric such as the probability of dropping below a fixed fraction of B_0 can be criticized both because any such level is somewhat arbitrary, and because there is seldom evidence for threshold or depensatory effects. Nevertheless, in relation to answering questions of direct interest to decision-makers, such policy-related performance statistics may need to be included in the set reported. ICES (2013) notes that there are three ways to define the probability of dropping below a threshold: (i) the average probability (over simulations and years) of being below the threshold; (ii) the probability (over simulations) of dropping below the threshold at least once during each projection; and (iii) the maximum annual probability (over simulations) of being below the threshold over the projection period. Other ways to summarize these probabilities exist, including, for example, the probability in a given year. de Moor *et al.* (2011) comment that the probability of dropping below a threshold depends on the extent of process error, and define a performance statistic that evaluates risk in terms of the extent to which this probability increases with fishing, relative to its value in the absence of fishing.

A complicating factor with performance statistics that pertain to population size relative to B_0 or the MSY level is how these are to be defined in a changing environment and when there is time-varying predation (A'mar *et al.* 2009a,b, 2010). Usually, this problem has been resolved by replacing carrying capacity in these statistics by the population size which would have occurred had there been no catches (IWC 2003). However, for multispecies operating models, this can lead to counter-intuitive results where the unfished level is actually lower than the fished population size (Mori and Butterworth 2006).

Although most operational objectives relate to the fishery and the conservation of the species on which it depends, increasingly these objectives include ones pertaining to ecosystem impacts of fishing (Dichmont *et al.* 2008) and economic objectives (Dichmont *et al.* 2008; Anderson *et al.* 2010). Performance statistics can also relate to the management system itself. For example, in a MSE to evaluate management strategies for overfished USA west coast groundfish stocks, Punt and Ralston (2007) considered performance statistics such as when rebuilding was estimated to have occurred compared to how long this had been anticipated to take when the rebuilding plan was developed, and how often a rebuilding plan failed. This was because these were issues of interest to the decision-makers, which also related to the confidence stakeholders and the public have in the management system.

In the context of BCB bowheads, the conceptual objectives were selected by the IWC (i.e. the Commissioners). The operational objectives (and related performance statistics) were selected by the Scientific Committee of the IWC to reflect the intent of the conceptual objectives. These included statistics related to (i) the proportion of the nutritional and cultural need requested by aboriginal communities which could be satisfied, (ii) the delay in rebuilding to the population size corresponding to MSY caused by the mortality permitted and (iii) measures of the variation in the number of strikes permitted. No performance statistics specifically related to extinction risk were considered because none of the management strategies explored led to an appreciable risk of extinction – indeed the probability of extinction was zero for all management strategies and (plausible) simulations. The performance statistics related to the delay in rebuilding were hard to interpret, so that the final conservation-related statistics were based on simpler concepts such as the lowest ratio of population size to carrying capacity and the ratio of population size to carrying capacity after 100 years of simulated management.

The performance statistics for the Pacific sardine MSE were initially proposed during a workshop with stakeholders (PFMC 2013); these statistics were then refined based on input from the PFMC and its advisory bodies. The final set of performance statistics included conventional statistics related, for example, to average catches and variation in catches. However, the performance statistics also included quantities such as the proportion of times that the fishery was closed or its catch was <50 000 t, the average number of consecutive years the fishery was predicted to be closed, and the proportion of years that the biomass of animals aged 1 and older was <400 000 t. The last statistic was a proxy for indications of whether the biomass is sufficiently low that predators may be impacted.

Selection of uncertainties to consider and selection of operating model parameter values

Ideally, the range of uncertainties considered in a MSE should be sufficiently broad that new information collected after the management strategy is implemented should reduce rather than increase the range (Punt and Donovan 2007; IWC 2012a). However, in practice, it is seldom the case that it is possible to come close to incorporating all the pertinent uncertainties fully for any given situation, and choices are needed as to which uncertainties are the most consequential and reflect more plausible alternative hypotheses. Several attempts (Francis and Shotton 1997; Haddon 2011a) have been made to characterize sources of uncertainty. For the purposes of this paper, five sources of uncertainty are distinguished.

1. Process uncertainty: variation (usually assumed to be random, though sometimes incorporating autocorrelation) in parameters often considered fixed in stock assessments such as natural mortality, future recruitment about a stock–recruitment relationship and selectivity.
2. Parameter uncertainty: many operating models are fit to the data available, but the values estimated for the parameters of those operating models (e.g. fishery selectivity-at-age, the parameters of the stock–recruitment relationship and historical deviations in recruitment about the stock–recruitment relationship) are subject to error.
3. Model uncertainty: the form of relationships within an operating model will always be subject to uncertainty. The simplest type of model uncertainty involves, for example, whether the stock–recruitment relationship is Beverton–Holt or Ricker, whether a fixed value for a model parameter is correct, or whether fishery selectivity is asymptotic or dome-shaped. However, there are other more complicated types of model structure uncertainty such as how many stocks are present in the area modelled, the error structure of the data used for assessment purposes, the impact of future climate change on biological relationships such as the stock–recruitment function, and ecosystem impacts on biological and fishery processes.
4. Errors when conducting assessments, which inform the catch control rule that is being evaluated using the MSE: management advice for any system is based on uncertain data. Consequently, the data that inform catch control rules need to be generated in a manner which is as realistic as possible. Uncertainty arises when the model used for conducting assessments and providing management advice differs from the operating model, or the data are too noisy to estimate all key parameters reliably.
5. Outcome (or 'implementation') uncertainty: the impact of fishers and other players in the management system on the performance of management strategies has long been recognized (Rosenberg and Brault 1993; Rosenberg and Restrepo 1994). The most obvious form of this type of uncertainty is when catches are not the same as the TACs – typically more is taken or the decision-makers do not implement the TACs suggested by the management strategy. However, there are many other sources of outcome uncertainty, such as that associated with catch limits set for recreational fisheries and regulating discards. In some cases, this source of uncertainty has been found to dominate all the others (Dichmont *et al.* 2008; Fulton *et al.* 2011a).

In general, the evaluation of management strategies proceeds by first identifying the set of factors which are perceived to contribute the most to the uncertainty for the case in question. There will usually be factors for each of the five sources of uncertainty listed above. For example, factors could be 'the extent to which carrying capacity changes into the future', or 'the variation in realized catches about those intended'. Each factor will have a number of levels: for example, different rates of change in carrying capacity or variations in realized catch about the intended catch. Trials would then be constructed by selecting a level for each factor and thereby represent the range of uncertainty about a hypothesis to be considered in the evaluation. Best practice for a specific case involves explicitly addressing each of these uncertainties, or at least indicating how the uncertainties reflected were selected. Minimally, a MSE should consider (i) process uncertainty, in particular, variation in recruitment about the stock–recruitment relationship; (ii) parameter uncertainty relating to (a) productivity and (b) the overall size of the resource; and (iii) observation error in the data used when applying the management strategy. Which uncertainty is most important will be case-specific. For example, process uncertainty is unlikely to be very important for the management of large whale populations, whereas this uncertainty could be very consequential for a short-lived species such as Pacific sardine; the uncertainty factors considered in the MSEs for the two case-studies unsurprisingly differed markedly (Table 2).

Best practice is to divide MSE trials into a 'reference' (or 'base case') set of trials and a 'robustness' set of trials (Rademeyer *et al.* 2007). The reference trials are considered to reflect the most plausible hypotheses (see below for further comments on assigning plausibility to trials) and hence form the primary basis for identifying the 'best' management strategy, while the robustness trials are used to determine whether the management strategy behaves as intended in scenarios that are fairly unlikely, even though they are still plausible. While it is clearly desirable to conduct trials for all combinations for the levels for each factor (Kurota *et al.* 2010), this is often computationally impossible except when the management strategies being evaluated are fairly simple (Carruthers *et al.* 2014), and even then, conducting a MSE could be very computer-intensive depending on how many trials are run. Although partial factorial designs can be used to address this difficulty (Schweder *et al.* 1998), it is more common to select 'base' levels for each factor (in some cases multiple 'base levels'), and then to develop trials which involve varying each 'base' level in turn, perhaps also adding a few trials in which multiple factors are changed from their 'base' levels.

Table 2 Factors related to uncertainties considered in the simulation trials developed to test the management strategies for the Bering–Chukchi–Beaufort (BCB) Seas bowhead whales and the northern subpopulation of Pacific sardine.

BCB bowhead whales	Pacific sardine
Population dynamics	
• Inherent productivity	Extent of variation in recruitment
• Shape of the production function	Time-varying natural mortality
• Process error in calving rate	Time-varying productivity[1]
• Time trends in carrying capacity	Changes in selectivity spatially
• Time trends in productivity	Time-varying selectivity
• Occasional catastrophic mortality or recruitment events	Time-varying weight-at-age
• Time lags in the density dependence function	
• Alternative stock structure hypotheses[2]	
Data related	
• Survey frequency	Extent of auto-correlation in biomass estimates
• Average bias of survey estimates	Extent of variation in biomass estimates
• Trends in bias of survey estimates	Biomass estimates non-linearly related to true abundance
• Survey CV	
• Bias in reported catches	
Implementation related	
• Survey conducted to maximize strike limits	Only the USA follows the control rules

1All trials allowed for some variation in productivity due to environmental effects, but the manner in which productivity was related to the environment was varied in these trials.
2Conducted during the 2007 *Implementation Review* (International Whaling Commission 2008a,b, 2009, 2014).

Kraak *et al.* (2011) assert that the choice of sources of uncertainty included in MSE simulations often is quite arbitrary, and the uncertainties chosen do not necessarily reflect the key sources of uncertainty. They note that some MSEs conducted in Europe ignore spatial structure and whether egg production rather than spawning biomass drives recruitment. If these were indeed key uncertainties for the resources concerned, the scientists conducting those MSEs would clearly have been in error in ignoring them.

Best practice would involve trials based on at least a standard set of factors (Cooke 1999), so that the simulations extend over the set of uncertainties found to have had a large impact on the performance of management strategies for other systems (a list is given in Table 3). Most early operating models considered a single stock, ignored climate drivers of recruitment, growth and natural mortality, and treated the area being managed as a single homogeneous region. Each of these limitations can be overcome, particularly given the availability of sufficient computing resources. For example, although Butterworth and Punt (1999) commented that there were very few operating models which accounted for spatial structure when they conducted their review in 1998, subsequently Punt *et al.* (2005), IWC (2008a,b, 2009, 2014), Punt and Hobday (2009) and Carruthers *et al.* (2011) have all developed operating models which can, to some extent, account for spatial structure.

Climate and environmental variation is increasingly recognized as factors which often need to be included when evaluating management strategies. Two basic approaches have been adopted. The first is to include these factors in end-to-end models which represent entire ecosystems from physical processes to high trophic levels and fisheries, such as Atlantis (Fulton *et al.* 2011b) and Ecopath-with-Ecosim (Gaichas *et al.* 2012). The second is to relate environmental change to values of parameters empirically (Punt *et al.* 2014). Under the latter approach, environmental change can be

Table 3 List of factors, whose uncertainty commonly has a large impact on management strategy performance, which should be considered for inclusion in any management strategy evaluation.

Productivity • Form and parameters of the stock–recruitment relationship. • Presence of depensation. • Extent of variation and correlations in recruitment about the stock–recruitment relationship. • Occasional catastrophic mortality or recruitment events.	*Data-related issues* • CVs and effective samples sizes of data. • Changes in the relationship between catchability and abundance. • Changes in survey bias (fishery-independent data). • Survey and sampling frequency. • Ageing error. • Historical catch inaccuracy (bias).
Non-stationarity • Changes in the stock–recruitment relationship. • Time-varying natural mortality (potentially a multispecies operating model). • Time-varying carrying capacity (regime shift; linked to environmental variables or multispecies effects). • Time-varying growth and selectivity. *Other factors* • Spatial and stock structure. • Technical interactions. • Time-varying selectivity, movement and growth. • Initial stock size (unless it is estimated reliably when conditioning the operating model).	*Outcome (Implementation) uncertainty* • Decision-makers adjust or ignore management advice. • Realized catches differ from total allowable catches due to mis-reporting, black market catches, discards, etc.

modelled by linking environmental variables to the parameters that determine the dynamics of the population represented in the operating model (A'mar *et al.* 2009a; Ianelli *et al.* 2011; Punt 2011), or regime shift changes in parameters can be modelled (A'mar *et al.* 2009b; Wayte 2011; Szuwalski and Punt 2013). Most studies in which biological parameters are driven by environmental effects are conducted in circumstances where the relationships between the environment and the population dynamics are largely unknown (Hurtado-Ferro and Punt 2014). Most previous MSEs have allowed only one parameter of the operating model to exhibit time trends. However, it is possible to force a number of operating model parameters to do so. For example, Kell and Fromentin (2010) explored the performance of a VPA-based management strategy where both recruitment and migration varied as a function of the environment, while Punt *et al.* (2013) investigated the robustness of a management strategy for rock lobsters off Victoria, Australia, to time trends in natural mortality, catchability and growth.

Ecosystem effects, in particular biological and technological interactions, can be addressed within the context of end-to-end models such as Atlantis and Ecosim. However, most current investigations of the impacts of ecosystem effects on the performance of management strategies have been based on models of intermediate complexity for ecosystems (MICE; Punt and Butterworth 1995; Schweder *et al.* 1998; Plagányi 2007; A'mar *et al.* 2010; Howell *et al.* 2013), primarily because it is possible to parameterize these types of models by fitting them to monitoring data, although this renders the conclusions case-specific (Plagányi *et al.* 2014).

Technical interactions are probably easier to include in operating models given that there are usually direct data on catches and by-catches by fleet. Such interactions have been included in the MSEs conducted by De Oliveira and Butterworth (2004) for South African sardine and anchovy, by Dichmont *et al.* (2006a) for two prawn species off northern Australia, by Punt *et al.* (2005) for two shark species of southern Australia and by Kraak *et al.* (2008) for the flatfish complex in the North Sea. Dichmont *et al.* (2006a) and Kraak *et al.* (2008) model effort allocation based on economic incentives that lead to technical interactions among species.

How realistically the data are generated will directly impact the performance of any assessment method, and therefore also of any management strategies which depend on the results of the assessment. For example, most simulation studies generate age/length composition data from the survey or fishery catch in a way that matches the distributions assumed when fitting the assessment model (Bence *et al.* 1993; Sampson and Yin 1998; Radomski *et al.* 2005). However, this means that even very small sample sizes can appear to be extremely informative. In contrast, the residual patterns for actual stock assessments are often suggestive of both overdispersion and model misspecification. It is important to ensure that a number of plausible relationships between indices and true abundance are considered when assessments rely on fishery-dependent index data.

Best practice for parameter uncertainty for a given model structure is to sample parameters values from a Bayesian posterior distribution, or less ideally to use bootstrap samples or to sample parameter vectors from the asymptotic variance–covariance matrix for the parameters. Constructing Bayesian posterior distributions or developing bootstrap distributions for parameters can, however, be very intensive computationally.

Although the ideal is to evaluate management strategies using a trial structure which has been developed for a given stock or system, this may be impossible to achieve for data-poor situations. Nevertheless, it remains important to evaluate management strategies for data-poor situations, especially when the management strategies use proxies for measures of biomass; consequently, extensive testing of management strategies for data-poor situations has been undertaken, particularly in Australia (Haddon 2011b; Little *et al.* 2011; Plagányi *et al.* 2013, in press) and New Zealand (Bentley and Stokes 2009a,b). In these cases, there is a value in developing management strategies which can be applied generically. Naturally, generic management strategies would not be expected to perform as well as a management strategy that has been developed for a specific case (Butterworth and Punt 1999). When an evaluation of generic management strategies is to be undertaken, it is necessary to ensure that a broad range of species life histories are explored, along with a broad range of hypotheses regarding the quality of past and future data, and the state of the stock when the management strategy is first applied (Wiedenmann *et al.* 2013; Carruthers *et al.* 2014; Geromont and Butterworth in press-a). The values for the operating model parameters in this case would be selected based on generic considerations, and values for species which are characteristic of those to which the management strategy is to be applied.

Finally, it would be naive to believe that it is possible to identify all key uncertainties correctly, and it should not come as a surprise that some potential uncertainties not taken into account during the development of a management strategy turn out to be consequential. Kolody *et al.* (2008) drew attention to a key uncertainty (underestimation of historical catches) that was not initially considered during the development of a management strategy for southern bluefin tuna (*T. maccoyii*). They also questioned whether analyses of historical data, for example, as part of the process of conditioning the operating model(s) to data will capture the full extent of uncertainties. This problem should not imply that it is not worthwhile to conduct a MSE, but rather emphasizes that the earlier view that management strategies can be developed to run on 'autopilot' for a large number of years is likely flawed. Thus, the value of management strategies including 'Exceptional Circumstances' provisions and conducting regular *Implementation Reviews* (see final section) is high and justified, even if it entails additional work. Butterworth (2008a) emphasizes that the operating models considered in MSE analyses should remain 'broadly comparable' with the data. In practice, this means that use of, for example, strict model selection criteria to weight trials should be considered very carefully; in particular, use of, for example, AIC-weighting or the analytic hierarchy process (Merritt and Quinn 2000) should only be considered when there is confidence that the likelihood function is reliable (which is often not the case because the data inputs are not completely independent, as is usually assumed). Best practice in cases when the data used to parameterize the operating model are in conflict, for example when the various indices of abundance exhibit different trends, is to develop alternative operating models which represent each data set (Butterworth and Geromont 2001).

Identification of candidate management strategies which could realistically be considered for implementation

Ultimately, the management strategy chosen should reflect the policies developed by the decision-makers. Management strategies can be divided roughly into those that are model-based and those that are empirical, although some management strategies could be considered to be a mixture of the two types of strategies (Starr *et al.* 1997). Broadly, model-based management strategies usually involve two stages (see below), although some management strategies such as the IWC's Revised Management Procedure (IWC 1994) integrate the two stages to the point that it is impossible to distinguish them. For southern bluefin tuna, the model-based part of the management strategy is in effect a biologically plausible smoother of the two abundance indices used, with the actual harvest control rule having more in common with empirical harvest control rules than the more traditional model-based versions (Anonymous 2011).

The first stage in a model-based management strategy involves applying a stock assessment method (which may be much simpler than the methods used to develop the operating models that provide the basis for the MSE simulation testing process), and the second involves taking the results from that stock assessment model as the input for a harvest control rule. Several jurisdictions, including the USA and Australia, apply complex model-based management strategies, at least for their 'data rich' stocks. Despite the process being very intensive computationally, these types of management strategies have been evaluated using simulation (Dichmont *et al.* 2006b; A'mar *et al.* 2008, 2009a,b, 2010; Anonymous 2011; Fay *et al.* 2011; Punt *et al.* 2013). Model-based management strategies tend to lead to lower variation in terms of, for example, TACs than empirical approaches that do not constrain the estimated dynamics using population models (Butterworth and Punt 1999; Anonymous 2011), although this effect may be alleviated by imposing constraints on the extent of interannual change permitted in catch limits (see below).

In contrast to model-based management strategies, empirical management strategies do not utilize a population model to estimate biomass, fishing mortality or related quantities for use in harvest control rules. Rather, they set regulations such as TACs directly from monitoring data, usually after some data summary methods have been applied (e.g. CPUE standardization for catch and effort data). For example, the empirical harvest control rule used to recommend annual catch limits for the South African sardine involves setting catch limits as a constant proportion of the resource abundance estimated from the most recent hydro-acoustic survey. This rule is then subject to a number of constraints, or meta-rules, such as a maximum TAC and a maximum amount by which the TAC can decrease interannually. By removing this latter constraint during years of high TACs, the rule was designed to be flexible enough to allow the industry to take advantage of the occasional 'booms' that are a feature of this highly variable resource, without increasing the risk of the resource dropping to an undesirably low level (de Moor *et al.* 2011).

Rademeyer *et al.* (2007) remark that empirical management strategies are easier to test and are often easier to explain to decision-makers, but have the disadvantage that there might not be a clear basis for determining the target at which the resource will eventually equilibrate (Little *et al.* 2011). Examples of management strategies implemented which are empirical are those for hake, rock lobster, horse mackerel, anchovy and sardine off South Africa, for rock lobsters off South Australia and Tristan da Cunha, for West Greenland halibut and for pollock off eastern Canada. Most empirical management strategies base management decisions on trends in an index of abundance. However, there is a move towards 'target'-based rules, where TAC changes depend on the difference between the most recent level and the target for some abundance-related index (Little *et al.* 2011; Rademeyer and Butterworth 2011; Geromont and Butterworth in press-b), because the resultant catch limits tend to show less variability without impacting performance on other statistics such as average catch and risk to the resource. An example of an empirical 'target'-based rule is that used to recommend annual catch limits for the South African south coast rock lobster: the annual TAC is adjusted up or down from that recommended for the previous year according to whether the most recent measure of standardized CPUE is above or below a target value, with the extent of TAC adjustment proportional to the magnitude of the difference between the recent CPUE and the target value (Johnston *et al.* 2014). Management strategies can also be based on changes in metrics defined from age and size compositions (Butterworth *et al.* 2010b; Wayte and Klaer 2010; Fay *et al.* 2011).

Many management strategies impose constraints on how much catch limits can vary from 1 year to the next. For example, the management strategies for Australia's SESSF include 10 and 50% rules, which state that no change in TAC up or down will be larger than 50% of the current TAC; similarly, if a predicted change is <10% of the current TAC, then no change is made. In South Africa, both the hake and rock lobster management strategies include maximum TAC changes of either 5 or 10%, although these are over-ridden if appreciable declines in abundance become evident from the indices monitoring resource abundance. These minimum change rules have the advantage of smoothing out what might be noise from the management strategy output arising from noise in its data inputs.

Most of the management strategies considered in MSEs have been based on the conventional data used for stock assessments (e.g. catches, indices of abundance, age/length composition information). However, it is possible to develop management strategies, particularly for data-poor situations, using non-conventional data. For example, McGilliard *et al.* (2010) and Babcock and MacCall (2011) developed management strategies that use the ratio of the density inside and outside of marine protected areas to adjust limits on catch and effort in fished areas. Wilson *et al.* (2010) extended these approaches to use data on the proportion of old fish in the population. Christensen (1997) defined (and evaluated) a management strategy in which limits on effort are a function of the economic rent from the fishery, while Pomarede *et al.* (2010) evaluated one based on estimates of total mortality. The management control in most management strategies changes based on the data collected (feedback strategies), although some management strategies for data-poor situations are effectively non-feedback, setting management controls based, for example, on historical catch only. The performance of non-feedback strategies is, however, generally poor (Carruthers *et al.* 2014).

While the candidate management strategies which could be adopted should be identified by the decision-makers (or their advisers), best practice for MSE is also to evaluate additional management strategies to better understand the behaviour of the strategies identified by the stakeholders and decision-makers. In particular, it is a valuable exercise to apply variants of a management strategy in which the state of the stock is known exactly by the management strategy because this provides an upper limit to the 'value of information'. In addition, having results for 'reference' strategies, such as the strategy which maximizes average catch, can be useful for determining whether or not differences in performance statistics among management strategies are meaningful.

Most management strategies involve changes in the values of traditional management instruments such as catch limits, the total amount of effort or the length of the fishing season. However, MSE can also be used to evaluate novel management strategies such as that of Kai and Shirakihara (2005) that involves changing the size of a closed area based on the results of monitoring data.

It is essential that the management strategies being tested or compared are fully specified and can be implemented both for the operating models and in reality. Best practice is to simulate the management strategy exactly as it would be applied in reality, and this is commonly done when the management strategy is empirical (De Oliveira and Butterworth 2004; Little *et al.* 2011; Punt *et al.* 2012a; Carruthers *et al.* 2014), or the assessment method is not very demanding computationally (Kell and Fromentin 2009). It is becoming easier to evaluate complex management strategies given the increased availability of, for example, distributed computing including cloud computing. However, simulating very complicated management strategies such as those that involve fitting a statistical catch-at-age model can still require considerable computation (e.g. a single set of 100 simulations of 45 years to evaluate the actual management strategy for Gulf of Alaska walleye pollock took over 3 weeks on a fast desktop computer) and run the risk that fully automated fitting procedures may not find the global minimum that would be detected in the comprehensive searches typical of 'best assessment' approaches. Consequently, it is common to approximate application of a management strategy, for example by assuming that the estimates of biomass are log-normally distributed about the true biomass, perhaps with autocorrelated errors (DiNardo and Wetherall 1999; Hilborn *et al.* 2002; Anderson *et al.* 2010; Punt *et al.* 2012b).

However, ICES (2013) comments that it is generally not sufficient to simply add random noise to quantities derived from the operating model, and express concern that only 4 of the 18 MSEs which they reviewed had simulation tested the actual assessment. Failing to simulate application of the actual assessment method allows a broader set of hypotheses to be explored quickly, but the risk is that the actual error distribution associated with assessments does not match that assumed, and hence the values of the performance statistics are incorrect. In the extreme, the resultant relative ranking of management strategies may become incorrect. The justification for using an approximation to a management strategy may be examined by running a few simulations for the actual management strategy and the approximation, and comparing the results to ascertain whether the approximation is adequate. For example, ICES (2008) compared a 'full' and 'shortcut' MSE and found that the ranking of the performance of the harvest control rules evaluated changed when conducting a shortcut MSE compared to a full MSE (i.e. the best performing harvest control rule was different for the two evaluations).

The management strategy adopted for the BCB bowhead whales is based on averaging the strike limits from two SLAs (IWC 2003): (i) an empirical relationship between the strike limit and estimates of carrying capacity, the replacement yield predicted for the year for which a strike limit is needed, and the current stock size (Johnston and Butterworth 2000; Givens 2003); and (ii) a control rule based on the concept of adaptive Kalman filtering (a combination of Kalman filtering and Bayesian methodology; Dereksdóttir and Magnússon 2003). Both SLAs included ways to restrict interannual variation in strike limits, a factor considered very important during the selection process for a SLA. In particular, the component SLAs included a 'snap to need' feature which sets the strike limit equal to the need if the strike limit indicated by the algorithm is very close to the need.

The management strategy used for Pacific sardine is based on a set of control rules (Fig. 3) that are applied to an estimate of age 1+ biomass from a stock assessment model. The value for the FRACTION parameter may depend on the value of an environmental variable. The MSE for Pacific sardine (Hurtado-Ferro and Punt 2014) did not simulate application of the actual stock assessment process, but instead generated estimates of biomass directly from the operating model. Nevertheless, the extent of the errors

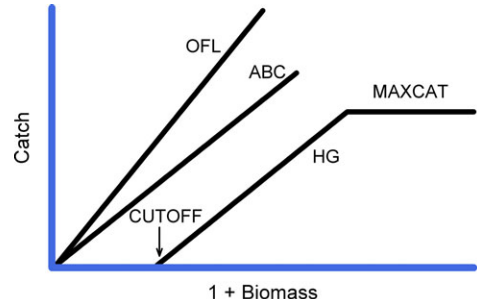

Figure 3 Harvest control rules applied to the northern subpopulation of Pacific sardine. The OFL is the overfishing level, which is based on the fishing mortality corresponding to maximum sustainable yield. The ABC is the acceptable biological catch, computed as the overfishing limit (OFL) reduced to account for scientific uncertainty. CUT-OFF determines the 1+ biomass at which the harvest guideline (HG) is zero, and MAXCAT is the maximum catch possible under the control rule.

associated with the biomass estimates for Pacific sardine was selected using a simulation evaluation of the actual stock assessment method (Hurtado-Ferro *et al.* 2014) in an attempt to ensure realism.

Simulation of application of each management strategy for each operating model

The actual process of linking the data generation phase of the operating model with the management strategy is generally straightforward, even if the process of conducting the simulations and summarizing the results can be very time-consuming. The difficult issues with MSE at this stage are primarily related to software development. There are several ways to minimize the chances of errors due to software coding, and use of these methods is best practice for MSE.

1. Base the operating model(s) and the management strategy on software that has been developed for broad application and has been tested extensively, such as Stock Synthesis (Methot and Wetzel 2013; Anderson *et al.* 2014; Maunder 2014), or use tools specifically developed to evaluate management strategies (Kell *et al.* 2007; Hillary 2009). However, in many instances, it is necessary to develop software for a specific case given the nature of the management strategy being evaluated and the hypotheses considered plausible – capturing the full range of uncertainty and of potentially

appropriate candidate management strategies should take priority over using available software.

2. Conduct simulations in which the system dynamics are deterministic, the operating model matches the estimation component of the management strategy, and the data are generated without error. In this situation, it should be possible for an analyst to heuristically predict the state of the system in the future fairly accurately (e.g. the stock should equilibrate at B_{MSY} if a strategy is based on a target fishing mortality of F_{MSY}, while if a strategy has a target level based on CPUE the stock should equilibrate at this level unless there are response-delay factors that induce oscillations) and compare this with where the MSE predicts the system will be. This provides a basic test to ensure that the coding of the operating model and of the management strategy is correct.
3. Conduct simulations in which the system dynamics are deterministic, the assessment model underlying the management strategy (if required) matches the operating model, and the data are generated with random error. Again, this provides a case where it is relatively straightforward to predict the results of the analyses.

The second and third of these steps also provide a way to eliminate poor management strategies from further consideration; it is virtually certain that a management strategy will not perform adequately in complex trials if it performs poorly when the data are not subject to error or there is no process error in the system.

The number of simulations for each trial (10 000 in the case of Pacific sardine and 100 in the case of the BCB bowheads) should be selected to ensure that the percentiles of the distributions on which performance statistics are based can be calculated with the precision required for the decisions to follow. The number to achieve a particular precision for probability-based statistics can be calculated taking into account that the simulations are independent (ICES 2013), and probability measures based on counts are therefore binomially distributed. Note that a very (perhaps prohibitively) large number of simulations may be needed if the decision-makers wish to draw conclusions based on very precise estimates of the lower fifth or first percentile of the distribution for some output from the operating model(s).

The number of years for which the operating model is projected will depend on the life history of the species under consideration. The number should be chosen, so that it is possible that the management strategy can impact the dynamics of the system and should cover 1–2 generations at minimum to allow for transients arising from response delays linked, for example, to the age at maturity. For example, the number of years for short-lived species such as sardine can be quite low while this number will be much higher for species such as bowhead whales.

It is essential, and hence best practice, that the management strategy bases recommendations for management actions only on data which would actually be available, and any assumptions regarding parameters assumed known when applying the management strategy need to be clearly documented (e.g. that natural mortality is assumed to be known exactly). One way to achieve this goal is to have separate segments of software for the operating model and for the management strategy, and to pass information (and management recommendations) between the operating model and management strategy using input and output files or their software equivalent.

The same set of random numbers should be used for all simulations for each trial, so that differences between candidate management strategies reflect the differences between the strategies themselves and not the consequences of different sets of observation and process errors.

Most management strategies assume that the data needed to apply them are always available (e.g. surveys are conducted at the expected frequency). However, this assumption might not be met in practice (e.g. a survey may not take place because of mechanical problems), and Butterworth (2008b) highlights that a management strategy should ideally also include specifications for how to provide management advice in circumstances in which anticipated data are not available. A related aspect is that the management strategy should ideally reward the provision of extra data and penalize the reverse situation. For example, the IWC's Revised Management Procedure reduces whale fishery catch limits to zero if new survey estimates do not become available within a specified time period (IWC 2012b).

Presentation of results and selection of a management strategy

Ultimately, the selection of a management strategy is not a scientific enterprise, but involves addressing trade-offs. This task lies primarily within the purview of decision-makers and policy. In principle, the selection of a management strategy could be automatic if a utility function was selected, which reflects the desired trade-offs amongst the objectives, and probabilities could be assigned to each alternative operating model configuration. However, this is rarely possible, and the authors know of no examples where a management strategy which has actually been implemented was selected this way.

There are almost always trade-offs among the management objectives. Consequently, it is desirable to provide results for a number of candidate strategies. Evaluation by the decision-makers of the trade-offs amongst the management objectives achieved by each candidate strategy may lead to a better understanding of what is possible, and even to changes to the relative ranking of management objectives. However, the results of management strategy simulations can be extensive and complicated, and the entire MSE process may be difficult for non-experts to comprehend. In South Africa, the details of the assumptions and sources of uncertainty were communicated, but statistics such as probability distributions were found hard to interpret (Cochrane *et al.* 1998). A better understanding of some of the trade-offs, particularly that between catch and catch variation, can be achieved by 'real-time gaming' of the MSE, which involves the decision-makers managing simulated populations where they are provided with the data which would actually be available on an annual basis. Walters (1994) provides an overview of the use of gaming to compare management options, including some best practices. Gaming has been used successfully in the South African fisheries (Butterworth *et al.* 1993). However, many MSE analyses are very computationally intensive, making real-time gaming impractical.

Stakeholders need to be involved in the decision process. However, more than that, they also need to be integrated within the entire MSE development process, including problem formulation, and even perhaps selecting the assumptions on which projections are based. This is, however, seldom easy and can be very time-consuming. Pastoors *et al.* (2007) describe an instance where stakeholders evaluated a MSE based on the extent to which hindcasts of the operating model could reproduce the observed dynamics of how TACs were set and whether the trends in stocks and catches proceeded 'logically'. Their advice was to present results relative to reference levels rather than in absolute terms, so as to reduce some of the concerns which stakeholders expressed.

As emphasized by Rademeyer *et al.* (2007), the basis for selecting a management strategy has to be clear to all stakeholders and should be made as simple as can be justified. Although much of the literature has focused on trade-offs among the objectives, some systems have fixed constraints. For example, the USA MSA effectively prohibits fishing mortality exceeding F_{MSY} for long periods, while adoption of a management strategy that would lead to high probabilities of decline of BCB bowhead whales would be considered unacceptable. Miller and Shelton (2010) identify an approach to selecting a management strategy based on 'satisficing', in which there are certain minimum standards for any candidate strategy, and only those candidates who satisfy these standards can be considered for possible adoption. Care should be taken not to require management strategies to meet performance statistic targets defined in terms of extreme tail probabilities, for example implementing a standard such as 'the probability of overfishing on an annual basis should not exceed 0.1%', because such probabilities are likely to be very poorly determined (Rochet and Rice 2009; Kraak *et al.* 2011). In cases in which the decision-makers require high certainty about a particular outcome, it is imperative that the analysts convey the likely level of precision possible from a MSE and that the major strength of a MSE lies in comparing the relative performance of alternative management strategies.

The first step in the process of selecting a management strategy should be explaining all of the options to the decision-makers, and placing the management strategies evaluated in the context of current management arrangements (Dowling *et al.* 2008). The value of effective graphical summaries cannot be over-emphasized. Some simple rules for constructing graphical summaries of results (see Figs 4 and 5 for examples) are to define 'best' performance for all operational objectives to be a high value for the associated performance statistics, and not to display too many performance statistics or management strategies on a single plot (contrast Figs 4 and 5 in this regard).

Perhaps most importantly, graphical approaches to summarizing performance statistics should be selected in collaboration with the decision-makers who need to understand and use them. For example, the axes in Fig. 5 were defined to report on the major areas of concern for stakeholders. 34 performance measures were identified by fishers, processors and local community, as well as given legislated fisheries and conservation objectives to across social, economic and ecological aspects (Fulton *et al.* 2014). For transparency, all of these measures were reported on, but it was not until the outcomes were aggregated and summarized around the major topic areas (using Fig 5 and other similar plots) that the relative performance and trade-offs between the objectives were clear. The axes represent natural groupings of the performance measures, but also highlight key concerns of the various stakeholders. Note that the industry and management efficiency axes used inverted performance scores, so that a larger score reflected better performance for all axes.

A key step in selecting a management strategy is dealing with the fact that not all of the trials reflect equally plausible hypotheses. This is partially addressed by assigning some trials to a reference set and the remaining trials to a robustness set (see above). However, other approaches are possible. For example, the IWC has adopted a set of guidelines for interpreting the results of trials to evaluate management strategies for commercial whaling. Specifically, trials are assigned to one of three categories ('high plausibility', 'medium plausibility' or 'low plausibility') by the Scientific Committee of the IWC (2012a). The required conservation performance of acceptable management strategies, expressed in terms of the values for performance statistics, is pre-specified for each

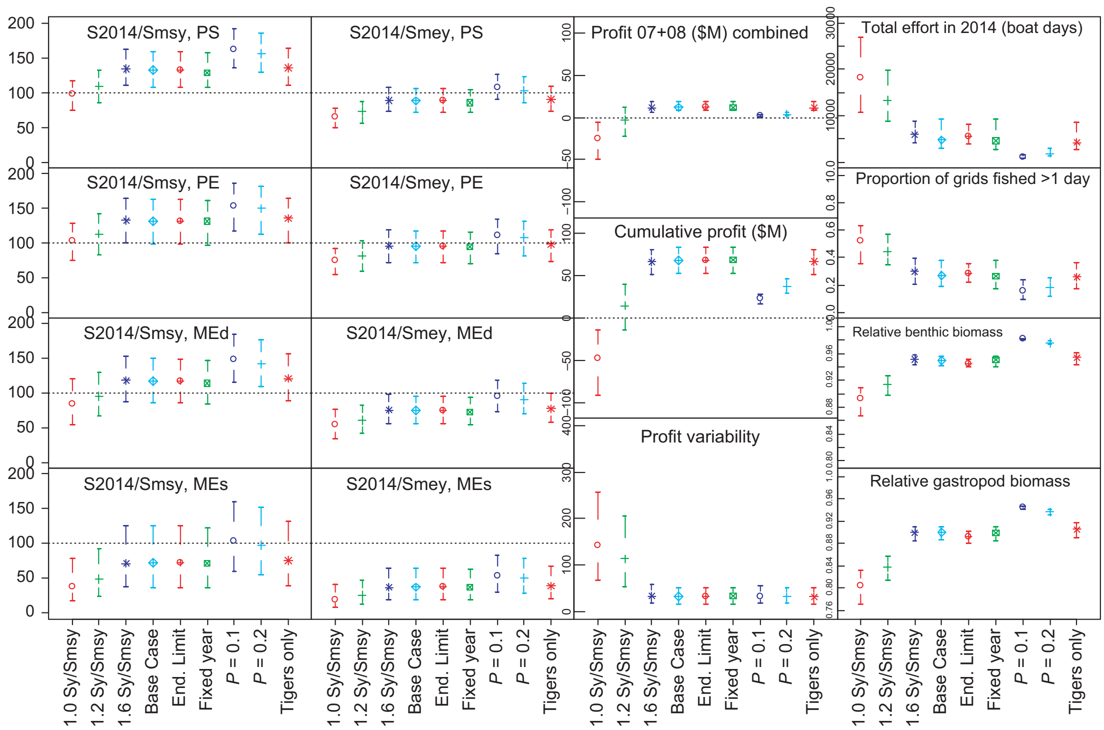

Figure 4 Biological, economic and ecosystem performance measures for a variety of management strategies for Australia's Northern Prawn Fishery (reproduced from Dichmont *et al.* 2008). The symbols indicate distribution medians, and the bars cover 95% of the simulation distributions. The performance statistics relate to spawning biomass relative to that at which MSY and maximum economic yield are achieved for four species (first two columns) and profit and its variability (third column). The right-most column shows the total effort in 2014, the proportion of grids fished for more than 1 day in 2014, the total benthic biomass relative to unfished levels, and the biomass of gastropods in 2014 relative to unfished levels. The management strategies differ in terms of the target biomass, the extent of precaution, and whether assessments for only two of the species form the basis for changes to effort limits.

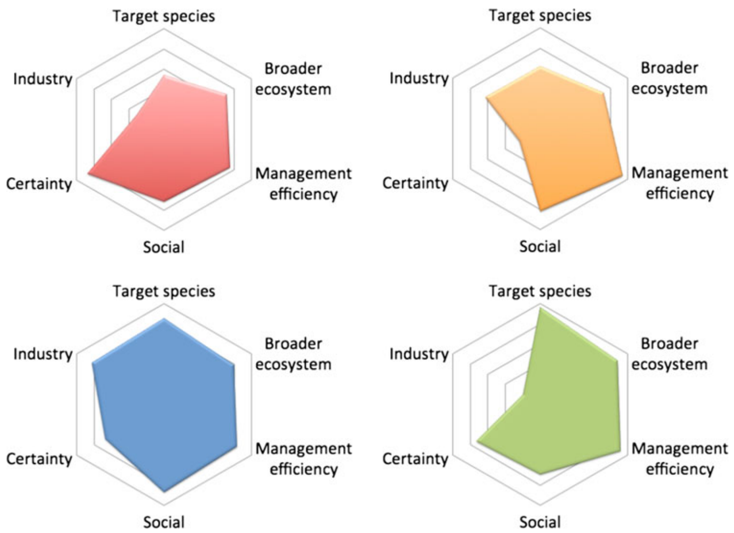

Figure 5 Example of plots which qualitatively compare four management strategies across six general areas of mean performance for a large multisector, multispecies fishery in southeastern Australia (E. Fulton, CSIRO, personal communication). A better result for a performance statistic is indicated by a vertex which is further from the centre of each hexagon.

category, which essentially (though not entirely – see IWC 2012a, for details) automates the process of selecting a 'best' management strategy. The assignment of plausibility for a trial is based on assigning a plausibility ranking to the level for each factor on which the trial is based ('high', 'medium', 'low' or 'no agreement'), with levels for which there is no agreement being treated as 'medium'. The ranking of a trial reflects the lowest rank assigned to each level of the factors on which it is based (thus to be categorized as a 'high' plausibility trial, the levels of all the factors included in the trial need to be considered to be of 'high' plausibility). Any trials considered to be 'low' plausibility are assigned a 'low' rank and ignored. This approach has been applied to select management strategies for the western North Pacific minke whales (IWC 2014), the western North Pacific Bryde's whales (IWC 2010) and the North Atlantic fin whales (IWC 2009).

In an effort to provide an improvement to simply selecting plausibility ranks based on expert judgement, Butterworth *et al.* (1996) proposed four sets of criteria with which plausibility ranks might be assessed:

1. how strong is the basis for the hypothesis in the data for the species or region under consideration?
2. how strong is the basis for the hypothesis in the data for a similar species or another region?
3. how strong is the basis for the hypothesis for any species? and
4. how strong or appropriate is the theoretical basis for the hypothesis?

Although this approach was presented to the Scientific Committee of the IWC, it was never adopted, and in general weights are almost always assigned based on expert judgement.

An alternative approach to addressing plausibility in selecting a management strategy is to assign weights to each trial and to compute integrated values for the performance statistics. However, this involves selection of quantitative weights upon which it is likely to be even more difficult to reach agreement than on assigning trials to categories of plausibility. Moreover, integrated performance statistics may obscure low plausibility trials for which performance is very poor (Rademeyer *et al.* 2007). Those authors also comment that stakeholders may benefit from being shown results of individual catch and population trajectories, as these tend to give a better impression of variation than statistics such as CVs and variances, which may be difficult for some stakeholders to understand.

Assignment of quantitative weights for plausibility becomes necessary if decision-makers wish to draw conclusions based on some percentile of the distribution of a performance statistic and the MSE is being conducted over a reference set of operating models. This was the case in the CCSBT, where the use of this set, rather than working only with a single reference case operation model, rendered consensus much more easily achieved in the Scientific Committee. Subsequently, the Commission requested its Scientific Committee to report results for reaching a target recovery level of 20% of the estimate unfished abundance by 2035 with 70% probability [see final agreed management strategy specifications reflected in CCSBT (2011)]. To provide such results, integration across the reference set became necessary.

While providing percentile results for a single operating model is a relatively objective process, as the statistical basis to take account of the associated stochastic effects is well established, extending to a reference set creates some difficulties. This is because the results will depend on the choice of which models are included in the set and how they are weighted, which is much less straightforward. Given that balance (between more optimistic and more pessimistic scenarios) is usually seen as a desired feature of a reference set of operating models, estimates of the medians of performance statistics would be expected to remain relatively robust and reliable. However, care should be taken in the interpretation of high and low percentiles of distributions for a reference set, as these will not be as firmly established as in the case of a single reference case operating model.

In the BCB bowhead case, the Chair of the group tasked with developing and testing alternative SLAs briefed the IWC as well as representatives of the hunting communities. In particular, as a key objective of the SLA was to satisfy the nutritional and cultural needs of aboriginal communities rather than to maximize catch, an important input to the analyses was the ‘Need Envelope’. This function was obtained through discussion with the hunters and their scientific representatives, and formed the basis for specifying performance statistics such as the fraction of total need over 100 years which could be satisfied.

In contrast to the bowhead case-study, the MSE for Pacific sardine was developed in the context of a USA Regional Fishery Management Council process. This allows for input by stakeholders, state and federal analysts, and the public during the development of management decisions. The structure of the MSE was initially developed during a workshop (PFMC 2013) which included biologists familiar with Pacific sardine and its relationship with the environment, modellers (including assessment biologists and ecosystem modellers), representatives of the advisory bodies of the PFMC, and stakeholders (conservation and industry). The MSE structure was then subjected to peer review through the PFMC’s Scientific and Statistical Committee on several occasions. Input from stakeholder groups included interpretation of the results of the simulations in the context of the objectives which each such group considered most important (Parrish 2014).

Did the case-studies follow ‘best practice’?

The two case-studies highlighted in this paper followed best practice to different extents. Both case-studies involved stakeholders and decision-makers at various points in the development and selection process, and included default performance statistics. The range of uncertainties was wider in the bowhead case-study, and there are some uncertainties which are likely important for Pacific sardine which were not explored (such as that the USA fishery operates at some times on the southern as well as the northern subpopulation). Such omissions were due to limited time being made available to conduct the MSE. In actual development and implementation, limited time frames are common and constitute a constraint on achieving best practice.

Neither of the case-studies explicitly considered predator-prey interactions as these were not seen as likely to have large impacts; the sardine case-study did however explore environmental impacts on recruitment, and both case-studies accounted for spatial structure to some extent. The bowhead case-study represented parameter uncertainty by sampling parameter vectors from a posterior distribution, whereas the sardine case-study explored this uncertainty through sensitivity testing.

The candidate management strategies for Pacific sardine were selected by the stakeholders and the decision-makers, whereas these were identified by the competing teams of ‘developers’ in the bowhead case. In contrast to the bowhead SLA, the actual management strategy for sardine was not simulated exactly because it was not the assessment itself (which is based on a statistical catch-at-age analysis) that was simulated. Rather, this assessment was approximated by true biomass from the operating model plus autocorrelated log-normal error. However, an attempt was made to assess the likely level of assessment error.

Both case-studies applied standard programming techniques to attempt to ensure that the code implementing the operating model(s) and management strategies was correct, but only in the sardine case were deterministic analyses undertaken. The code implementing the operating models for the bowhead case was developed by a member of the staff of the IWC and independently checked by one of us (AEP). Neither case-study conducted a thorough comparison of whether the operating model and management strategy produced results of projections consistent with reality through, for example, comparing variability in assessment outcomes with historical results, although some checks were carried out for sardine. Neither of the management strategies adopted included 'Exceptional Circumstances' provisions, although *Implementation Reviews* are mandated and have been conducted for the bowheads. The SLA for the BCB bowheads was subject to an *Implementation Review* in 2007 (IWC 2008a,b, 2009, 2014) and 2013 (IWC 2013). The 2007 *Implementation Review* focused on the possibility that the BCB stock may actually consist of two stocks as well as that different age and sex classes migrate differently. However, it did not lead to a change to the SLA developed for the BCB stock because the performance of this SLA was not markedly impacted by the multi-stock scenarios examined.

Both case-studies relied on graphical and tabular summaries, and both involved trying to educate the decision-makers on how to interpret the results from the MSE. Performance standards were adopted for interpreting the results of the trials for bowheads (IWC 2003), but the comparison of alternatives for Pacific sardine was based primarily on finding an acceptable trade-off among the performance statistics. The trials for the bowhead case were divided into 'reference' and 'robustness' trials, with most focus during selection given to the 'reference' set.

In summary, the application of MSE for bowheads followed the proposed best practice guidelines to the largest extent possible, while that for sardine took several short cuts, owing primarily to the need to complete the analyses in time for management decision-making.

Final comments

Management strategy evaluation arose from the desires to deal more systematically with the issue of uncertainties and to identify management strategies that are adaptive given the collection of new data. Although the benefits of active adaptive management strategies, that is management strategies which select management actions to increase 'contrast' and hence improve the information content of the available data, have long been known (Walters 1986), few jurisdictions have been able or willing to implement such strategies (Sainsbury *et al.* 1997 being a noteworthy exception, although in that case the 'experimental unit' was primarily a foreign fishery off Australia's northwest shelf). Consequently, MSE has in practice generally involved evaluation of passive adaptive management options, that is learning about the system dynamics through ongoing monitoring but without attempting to deliberately manipulate the system to learn more about it, although the strategy developed for the mid-water fishery for horse mackerel in South Africa is an exception to this (Furman and Butterworth 2012).

Management strategy evaluation has been applied most widely in relation to fisheries and cetacean conservation and management. However, it has also been applied to explore the performance of ballast-water management options (Dunstan and Bax 2008), and recently there have been calls for MSE to be applied to terrestrial systems, including in the development of conservation plans for threatened species (Milner-Gulland *et al.* 2010; Bunnefeld *et al.* 2011; Moore *et al.* 2013). Most fisheries applications have focused on single-species cases. However, MSE can be applied to identify management strategies to achieve ecosystem and multiuse objectives. The applications in this area remain few, in particular because of the computational requirements associated with fitting and projecting models such as Atlantis. However, one would expect that the number of these applications will increase rapidly as computational constraints become less of an issue.

Management strategy evaluation has generally been used to evaluate management strategies in terms of their ability to satisfy management goals, either generically or for a specific situation, with a view to possible formal adoption and implementation. However, an additional key reason for conducting a MSE is to identify when management strategies are likely to fail, and either to identify new data collection schemes to detect when failure might occur or to revise an existing management strategy appropriately. Finally, evaluation of the management strategies on which a fishery is based is part of several eco-certification systems, including that of the Marine Stewardship Council (MSC). In the case of Tristan da Cunha rock lobster, the MSE was conducted specifically to satisfy one of the performance indicators for MSC certification.

Smith *et al.* (1999) outline the roles for the various participants in the MSE development process, including those of decision-makers, industry, conservation agencies and groups, fishery scientists and MSE analysts. As noted above, the involvement of as many of these groups as possible enhances the likelihood that the results of the MSE will be considered credible and hence the strategy actually implemented throughout the period for which it is intended to apply. Although inclusion of stakeholders in the development of management strategies is emphasized by Smith *et al.* (1999) and in many other publications, the actual number of MSEs for which there is direct evidence that stakeholders were involved throughout the entire process is rare. ICES (2013) outlines the roles of stakeholders (and decision-makers) in the MSE process as it is typically applied in Europe. The MSE developed for Australia's SESSF was guided by a steering committee of stakeholders from all sectors of the fishing industry, an ENGO, decision-makers and representatives of two key funding agencies (Smith *et al.* 2007). In South Africa, the process is taken forward in the species-specific scientific working groups of the Fisheries Branch of the Government Department responsible; these groups include observers from both industry and ENGOs who participate actively.

The establishment of a management strategy is a critical part of effective management. However, it is only one part. There still needs to be a formal process for reviewing the appropriateness of a management strategy given information collected following adoption. In Europe, apart from performing impact assessments of proposed management plans, the European Commission's advisory body, STECF, also evaluates the performance of existing management plans in relation to their original objectives (STECF 2011b; Kraak *et al.* 2013). In South Africa, reviews of management strategies are planned for every 4 years, while reviews of the CCSBT management strategy are planned for every 9 years, with the latter commonly adjusting TACs only every 3 years (Butterworth 2008b). The IWC has established a formal process for the regular (usually 5-year) review of the basis for specific management strategies, termed *Implementation Reviews* (IWC 2012a, 2013; Punt and Donovan 2007).

A management strategy is tested for the set of hypotheses considered plausible when it was first developed. However, subsequent research could indicate that those hypotheses did not include the entire plausible range. Consequently, rules have been developed (IWC 2013) for when it is necessary to temporarily stop applying the management strategy and rely on *ad hoc* adjustments to management regulations or to initiate an *Implementation Review* before one is due. The management strategies for South African fish stocks include some formal 'Exceptional Circumstances' provisions (Butterworth 2008b), as do those for southern bluefin tuna, west Greenland halibut and east Canadian pollock, but most other management strategies do not. 'Exceptional Circumstances' are generally defined to apply when the future data fall outside of the range indicated for the projections considered in the MSE. The inclusion of such provisions should be considered a standard component of best practice.

We have identified 'best practices' for conducting MSE (Table 1). The 'best practices' should be followed as closely as possible, particularly when the intent is to use the MSE to develop a management strategy for a particular fishery. However, as we illustrate for the two case-studies, a MSE can be useful even if not all of the best practices are followed strictly. This is particularly the case when the aim of the MSE is to evaluate generic management strategies rather than to propose a management strategy for implementation to a specific stock. Most critical perhaps is that the primary aim of a MSE is to identify which uncertainties are most important in terms of achieving management objectives. What is the minimum that can be done for the process still to be considered as a MSE? We would propose this to be that a MSE *considers* all sources of influential uncertainty, even if they are not all represented in the operating models, *considers* all the management objectives, even if they cannot all be reflected in the operating models, and minimally allows for uncertainty in the information on which management advice is based.

Finally, the practice of MSE continues to develop, and so, just as management strategies should be adapted under changing circumstances, MSE best practice is expected to continue to become further articulated as more experience is gained.

Developing management procedures that are robust to uncertainty: lessons from the International Whaling Commission

André E. Punt and Greg P. Donovan

Punt, A. E. and Donovan, G. P. 2007. Developing management procedures that are robust to uncertainty: lessons from the International Whaling Commission. – ICES Journal of Marine Science, 64: 603–612.

Traditionally, fisheries management advice has been based on stock assessments that considered merely the "best" set of assumptions while uncertainty arising only from observation and process error was quantified, if considered at all. Unfortunately, uncertainty attributable to lack of understanding of the true underlying system and to ineffective implementation may dominate the sources of error that must be accounted for if management is to be successful. The management procedure approach is advocated as the appropriate way to develop management advice for renewable resources. This approach, pioneered by the International Whaling Commission (IWC) Scientific Committee, takes politically agreed management objectives and incorporates all scientific aspects of management including data collection and analysis, development of robust harvest control laws or effort regulations, and monitoring. A primary feature is that uncertainty (including that arising from sources conventionally ignored) is taken into account explicitly through population simulations for a variety of scenarios. The nature of the management procedures developed for commercial and aboriginal subsistence whaling and the processes by which they have been developed is highlighted. We also identify lessons that have been learned from two decades of IWC experience and suggest how these can be applied to other fishery situations.

Keywords: baleen whales, error, management procedure, monitoring, stock assessment, uncertainty.

Introduction

Management of renewable marine resources to the satisfaction of all is difficult, even if managers are provided with exact information on the status and likely future trends of the resources being exploited, because it is necessary to balance various, often conflicting, "resource orientated" and "user-orientated" management objectives (Hall and Donovan, 2002). Additionally, different sources of uncertainty complicate attempts to manage the resources. The sources of uncertainty can be classified broadly (Francis and Shotton, 1997) as: (i) observation error (arising from sampling and monitoring of resources); (ii) model structure error (arising from lack of knowledge of population dynamics processes); (iii) process error (arising from seemingly unpredictable natural variability in population parameters affecting abundance, particularly recruitment); and (iv) implementation error (arising from problems in enforcement of measures taken).

Management decisions are often based on scientific assessments of stock status and the predicted consequences of alternative management actions. Although the need for scientific advice when managing renewable resources is now widely accepted, one of the earliest examples of this requirement enshrined in an international convention is the International Convention for the Regulation of Whaling (IWC, 2005a), signed in 1946, which states that amendments to its regulations shall be "based on scientific findings" (Donovan, 1992). National legislation may also include such exhortations (Anon., 1996).

Historically, stock assessments have been based on only the "best" set of assumptions, irrespective of how good they may be. Scientific uncertainty, if considered at all, quantified only the uncertainty arising from observation and process error. In addition, assessments usually attempted to relate then current stock status to what now are termed "biological reference points". These can be catch-, biomass-, or fishing-mortality-based. Although catch-based reference points are now generally regarded as insufficiently precautionary (Larkin, 1977), the use of biomass- and fishing-mortality-based reference points remains widespread. For example, the Pacific Fishery Management Council (PFMC) defines a stock as overfished (and in need of a formal rebuilding plan) when stock biomass drops below 25% of the average value in an unfished state, and overfishing to be occurring when the rate of fishing mortality (F) exceeds F_{MSY} (F at which the maximum sustainable yield is achieved).

Reference points alone are not sufficient to provide a scientific basis for making management decisions, so harvest control rules (HCRs; see Figure 1 for an example) that use reference points are commonly applied. Unfortunately, although the use of HCRs

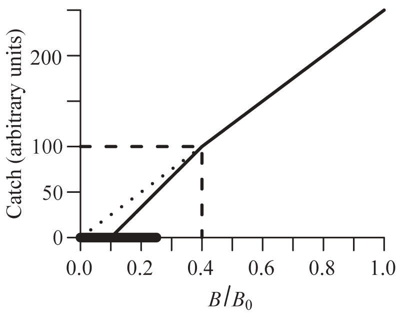

Figure 1. The harvest control rule (solid curve) used by the Pacific Fishery Management Council for stocks not designated as overfished (the solid bar indicates the range of stock sizes corresponding to being in an overfished state). Catch is reduced faster than linearly if a stock is assessed to be below the target biomass of 40% of the averaged unfished biomass ($0.4B_0$). Catch limits are not necessarily set to zero if a stock is depleted below $0.1B_0$; rather, a rebuilding plan is mandated to be developed for stocks depleted below $0.25B_0$.

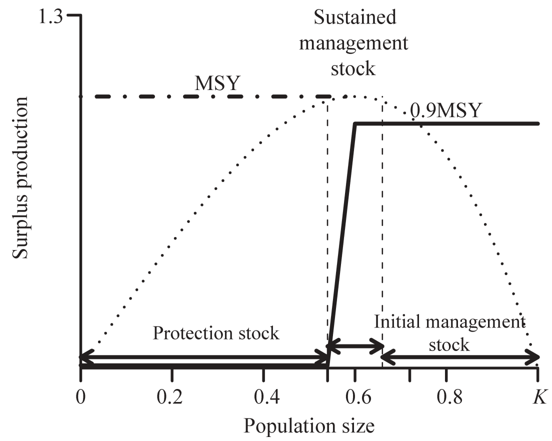

Figure 2. The catch control law for the NMP (solid lines) for the case in which MSYL is assumed to be $0.6K$.

provides a means of specifying scientific management advice in a more objective manner, uncertainty traditionally has not been explicitly accounted for in their application. The HCR in Figure 1 is fully specified when augmented with specifications related to how to conduct assessments and rebuilding analyses (Anon., 2005). The parameters required include the stock biomass in an unfished state (B_0), the current stock biomass ($B_{current}$), and F_{MSY}. Estimates of B_0 and $B_{current}$ are usually obtained by applying statistical catch-at-age analysis (e.g. Methot, 2006), and proxies for F_{MSY} are available, based on the relationship between spawning-biomass-per-recruit and F (Ralston, 2002). In 2005, this HCR could be applied to just 22 of the 80 species in the PFMC Groundfish Fishery Management Plan, i.e. insufficient information was available for all others. A further problem is that this HCR does not explicitly include a way to deal with uncertainty. Although scientists conducting assessments are encouraged to provide assessment scenarios that "bracket" uncertainty (Anon., 2006), there has been little consistency to date in how uncertainty has been bracketed for west coast groundfish, nor is there a formal way to use information from multiple alternative assessments when making management decisions.

Unfortunately, there is no guarantee that the management goals for a fishery will be satisfied even if (i) the HCR is fully-specified; (ii) data are available that, in principle, allow it to be applied; and (iii) some attempt is made to quantify uncertainty (Kirkwood, 1996). The only way to determine the effectiveness of a management process is to test it fully, using the simulation modelling approach pioneered by the Scientific Committee (SC) of the International Whaling Commission (IWC) when developing the Revised Management Procedure (RMP).

The IWC began using an HCR to provide formal management advice for commercial whaling in 1974, when it adopted what was termed the "New Management Procedure" (NMP; Figure 2). Problems with the NMP led to the development and adoption by the IWC of the "management procedure approach" (for a detailed account, see Hammond and Donovan, in press). Under this approach, management advice is based on a fully specified set of rules that have been tested in simulations of a wide variety of scenarios that specifically take uncertainty into account. The full procedure includes specifications for the data to be collected and how those data are to be used to provide management advice, in a manner that incorporates a feedback mechanism. Increasingly, there are examples of this approach being applied elsewhere (Kell *et al.*, 2006; Punt, 2006).

The problems with the NMP and the process of its replacement by the management procedure approach provide valuable lessons for other renewable resources. We review these problems (identifying the lessons learned), the process by which management procedures are evaluated by the SC, and how uncertainty is treated to ensure that the resulting management recommendations are sufficiently robust.

The New Management Procedure

The NMP was developed by Australian scientists as one response to calls for a moratorium on commercial whaling made at the United Nations conference on the environment and development, held in Stockholm in 1972 (Donovan, 1992, 1995). Although implicitly rather than explicitly expressed at the time, its two objectives were subsequently defined (IWC, 1981) as: (i) to ensure that the risks of extinction to individual stocks are not seriously increased by exploitation; and (ii) to maintain the status of whale stocks so as to make possible the highest continuing yield so far as the environment permits.

The conceptual basis for the NMP was the relationship between surplus production and population depletion (Allen, 1980). This relationship was assumed to be governed by a Pella–Tomlinson (1969) function, where the MSY level (MSYL) (the population size at which MSY is achieved) for whales was conventionally assumed to be 60% of the carrying capacity, K (Figure 2). Based on this, the NMP requires populations to be classified as either:

(i) Protection stocks–stocks depleted <0.9MSYL (the "protection level");

(ii) Sustained management stocks–stocks >0.9MSYL, but <1.2MSYL (a stock might also be classified in this category if it had been stable for "a considerable period" under a regime of constant catches);

(iii) Initial management stocks–stocks >1.2MSYL.

In addition, catch limits were constrained not to exceed the lower of 5% of the initial stock size and 0.9MSY.

The NMP was revolutionary for its time because it: (i) included a relatively high protection level (0.9MSYL, or 54% of the estimated unexploited level) at which catch limits were set to zero – although originally primarily justified for catch maximization rather than risk prevention (Butterworth and Best, 1994), many current management procedures still fail to include the concept of a protection level, or if they do, set the protection level considerably lower than 0.9MSYL; (ii) imposed a maximum catch limit that was less than the MSY estimate; (iii) aimed (even if implicitly) to leave stocks above (rather than at) MSYL; and (iv) appeared to take the decision-making process away from the politicians and to leave it with the scientists by "mechanizing" the provision of advice on catch limits.

Although seemingly well specified, the NMP definition is formally inconsistent because the constraint that catches cannot exceed 0.9MSY means that stocks will not be reduced to MSYL (de la Mare, 1986). In practice, however, this was one of the ways in which the NMP attempted to account for uncertainty by recognizing that determining whether a stock was at MSYL was difficult. A more serious problem was the lack of any formal (and agreed) basis to determine management units and to estimate the parameters needed to apply the NMP for each management unit, e.g. mortality, reproductive rates, and MSYL, with the required level of precision (Donovan, 1992). Although it is difficult to simulate the NMP decision-making process, de la Mare (1986) and IWC (1992a) evaluated the performance of one possible implementation using simulations and found it to behave poorly.

One consequence of these problems was that the SC was frequently unable to agree on catch limits when using the NMP. This was one of a complex set of reasons that the IWC introduced a moratorium on commercial whaling in 1982 to take effect in 1986 (e.g. Donovan, 1995). For example, in 1984, three species in four areas were considered in detail: sperm whales (*Physeter macrocephalus*) in the western North Pacific; Antarctic minke whales (*Balaenoptera bonaerensis*) in the southern hemisphere; common minke whales (*B. acutorostrata*) in the North Atlantic; and common minke whales in the North Pacific (IWC, 1985). However, the SC (i) was unable to provide estimates of initial and current population size for sperm whales in which it had confidence, and consequently did not provide advice on catch limits; (ii) was unable to agree on a classification for southern hemisphere minke whales (at that time, believed to have increased to above the initial carrying capacity in response to an expected surplus of krill resulting from the depletion of other large baleen whales, which made it impossible to be classified according to the NMP specifications), or on catch limits; (iii) could not classify either of the two stocks of minke whales in the northeastern Atlantic subject to commercial whaling (although ranges for catch limits were recommended despite dissenting views); and (iv) was able to classify only one of the two stocks of common minke whales in the North Pacific.

The Revised Management Procedure

Conceptual basis

The introduction of the moratorium led to the process of developing the RMP over a 6-y period (Hammond and Donovan, in press), which was finalized in 1994 with a written specification. The experience gained made it possible to develop a list of the steps needed to define and evaluate management procedures. Since then, these have been described extensively elsewhere (Kirkwood, 1996; Cooke, 1999; Sainsbury *et al.*, 2000; Donovan and Hammond, 2004; Kell *et al.*, 2006; Punt, 2006), but are summarized briefly here:

(i) qualitative specification and prioritization of the management objectives, as derived from legislation, legal decisions, and international standards and agreements;

(ii) quantification of the qualitative management objectives in the form of performance measures;

(iii) development and parameterization of a set of "operating models" that represent different plausible alternatives to the dynamics of the "true" resource and fishery being managed;

(iv) identification of candidate management procedures, including monitoring strategies;

(v) simulation of the future use of each candidate management procedure, involving for each time-step during the projection period: (a) generation of assessment data; (b) determination of the management action (i.e. assessment and application of some HCR); and (c) evaluation of the biological implications of the management action by removing the catch from the population as represented in the operating model;

(vi) summary of the performance of the candidate management procedures in terms of values for the performance measures; and

(vii) selection of the management procedure that best meets the specified objectives.

Most management procedures developed to date have focused on management using catch limits (e.g. Butterworth and Bergh, 1993; Geromont *et al.*, 1999; Punt and Smith, 1999), although some have been based on effort controls and forms of spatial management (e.g. Dichmont *et al.*, 2005). The major difference between these two types pertains to how management decisions are imposed (i.e. implementation error). For example, the performance of management systems based on catch limits can be affected by "highgrading" and "quota busting", while those based on effort regulations can be affected by "effort creep" and uncertainty in the relationship between fishing effort and fishing mortality. Key to the success of any evaluation of a management system based on a management procedure is the selection of the most important uncertainties to be reflected in the alternative operating models. These uncertainties should capture the major (but nevertheless plausible) factors that may affect the ability of each management procedure to satisfy the prescribed objectives.

Development

The development process of the RMP involved a series of workshops and discussion sessions during annual meetings of the SC. The initial focus was on developing a generic method for calculating safe catch limits that could be applied to any baleen whale population on its feeding grounds given perfect knowledge of stock structure (referred to as the "Catch Limit Algorithm", CLA). The CLA lies at the core of the RMP, which also includes

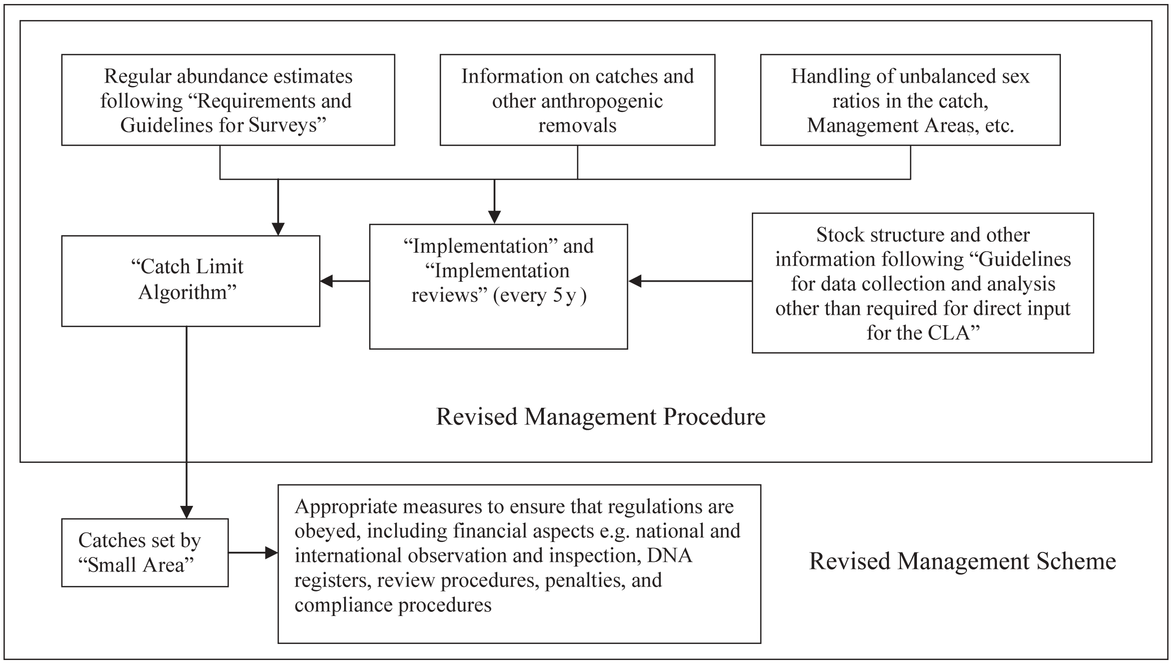

Figure 3. Schematic diagram of the management-procedure approach for commercial whaling (after Hammond and Donovan, in press) demonstrating the relationship between the CLA, the RMP, and the RMS.

rules on other scientific aspects of management, including multi-stock rules, and data and analysis requirements (Figure 3). Focus then shifted to developing ways of handling situations in which stock structure was uncertain. The approach chosen was to allow selection between a number of "variants". These variants are based on first setting catch limits for spatial/spatio-temporal strata that are small enough to ensure that whales of different stocks taken within each stratum will be taken in proportion to the abundances of those stocks (to avoid unintentionally taking whales out of proportion with their abundance in the area surveyed; IWC, 1999). Once these "Small Areas" have been determined, there are several ways (variants) in which catch limits may be combined to give a total limit for a wider area, depending, *inter alia*, on the available data for a particular species/region. Therefore, although the RMP is largely generic, it has case-specific aspects, because the choice between these multi-stock variants depends on further simulations (see the section "Implementation process" below).

The five CLAs developed by scientists from Australia, UK, South Africa, Iceland, and Japan initially differed quite markedly, e.g. in terms of the desired trade-off between risk and reward, whether population models were fitted to data on relative as well as absolute abundance indices, and whether relative abundance (catch per unit effort, cpue) data were used at all (Donovan, 1989; Hammond and Donovan, in press). However, the approaches converged over time. For example, it was rapidly agreed that there was little point in using cpue data because of disagreements regarding their reliability (IWC, 1989), and that future management procedures should be based on survey estimates of absolute abundance only.

This general approach of different teams developing candidate procedures has also been followed during the development phase of an Aboriginal Subsistence Whaling Management Procedure (AWMP), which eventually led to the adoption of "Strike Limit Algorithms" (SLAs) for the Bering–Chukchi–Beaufort Seas stock of bowhead whales (IWC, 2003a) and the eastern North Pacific stock of gray whales (IWC, 2005b). In the AWMP case, SLA development was pursued somewhat more cooperatively than had been the case for the RMP.

Discussion

Generic vs. case-specific approaches

An important difference between the AWMP and RMP is that the former followed a case-specific rather than a generic approach, the main reasons being that only a small number of aboriginal subsistence operations have been identified by the IWC and that it is unlikely that more will be accepted. In contrast, the number of potential commercial operations is substantially larger (in principle, all populations of all species of baleen whales could be subject to harvest), so that some standardization seemed desirable for reasons of efficiency. Furthermore, the management objectives for subsistence whaling differ from those for commercial whaling (e.g. rather than maximizing yield, the aim is to satisfy a pre-specified "need" in perpetuity, provided that certain conservation performance measures are met). Finally, aboriginal subsistence fisheries differ considerably in terms of the nature of the operations, the data available for assessment, and knowledge of stock structure. The adoption of a case-specific approach for data-rich operations (such as the bowhead and gray whale fisheries) accelerated the development of SLAs that met the management objectives. Had a generic management procedure robust to short time-series of abundance estimates and stock structure uncertainty been developed, the ability to satisfy subsistence needs for the data-rich aboriginal fisheries might well have been compromised.

The generic and the case-specific approaches have both advantages and disadvantages. For example, the amount of data available for individual species in finfish and invertebrate fisheries around the world ranges from extensive to almost nil, which would plead for case-specific approaches, because almost inevitably, generic procedures would have to be very conservative to achieve reasonable conservation performance in all cases. However, developing case-specific management procedures for all (or even the major) exploited stocks would be an immense undertaking that might be made lighter by first developing more generally applicable generic approaches. At the least, there may be value in developing generic management procedures that can be applied while case-specific procedures are being developed.

Implementation process

The RMP is considered final and has been adopted, but has not been used to set catch limits because the commercial whaling moratorium is still in place and no requests for advice on catch limits have been issued by the IWC. Before recommending that the RMP be applied to a species in a "region" (generally part of an ocean basin), simulation trials must be developed and run to capture the uncertainties deemed to be the most important for that stock complex/region. This process, referred to as an "Implementation" (in the IWC context, meaning that the SC notifies the Commission that it could produce information on catch limits if asked to do so), focuses primarily on uncertainties about stock structure, in particular temporal and spatial variation in the mixing of stocks in areas where whaling is to take place.

Many "Implementation Simulation Trials" (ISTs) may be required for specific cases if there are many alternative hypotheses related to stock structure, mixing, and other uncertainties such as the impact of bycatch of whales in fisheries. The process of designing, running, and interpreting ISTs can be onerous. For example, it took 12 y to complete the Implementation for western North Pacific minke whales (66 ISTs; IWC, 2003b). The reasons for this were that whaling occurs during migration (rather than on the feeding grounds, the situation for which the RMP had originally been designed) and that, because of the complex stock structure, new research conducted during the Implementation process led to a need to revise the hypotheses on which trials were based. The time required led to considerable frustration in the SC, and even to questions whether the RMP could be Implemented at all. Consequently, a rigorous set of requirements and guidelines was developed on how Implementations are to be conducted, so that the process could be completed within 2 y (Donovan and Hammond, 2004; IWC, 2005c). The guidelines also identify the information needed before an Implementation can commence (Figure 4). This information includes hypotheses about possible stock structure, specification of likely future removals (by both whaling and other anthropogenic causes), hypotheses about the size and spatial distribution of historical catches, and the abundance and migration data that will be used in the trials. The hypotheses identified during this "Pre-Implementation Assessment" should be sufficiently broad to prevent potential new information from leading to new hypotheses (but rather narrow or remove hypotheses). The guidelines also impose a temporal restriction on data that can be used. Data collected after a specified date can be used only when Implementations are reviewed.

The Implementation process focuses on developing ISTs to reflect plausible hypotheses and on assigning weights to each, based on perceived plausibility. The plausibility issue is one of the most difficult aspects to resolve and was a particular problem in the case of the western North Pacific common minke whale. Interpretation of the IST results (i.e. whether a particular variant performs adequately in terms of conservation objectives) is facilitated by a pre-specified set of rules. The first full application of the guidelines specified by IWC (2005c), from the Pre-Implementation Assessment through Implementation, is for western North Pacific Bryde's whales, and is scheduled for completion in 2007. North Atlantic fin whales have just completed the Pre-Implementation Assessment stage (IWC, 2007). The process used to develop and select management procedures is clearly far more formal at the IWC than that used to develop most fisheries management procedures. However, we believe that a process such as that adopted by the IWC would lead to a more rapid (and perhaps better documented) development and selection process.

Implementation Reviews

Although the simulation trials are based on 100-y projection periods (selected because of the slow dynamics of whales), the RMP and the AWMP include the requirement that "Implementation Reviews" be conducted every 5 y (IWC, 1999). North Atlantic common minke whales have already been through one review (IWC, 2004a). The aim of such reviews is to check that research conducted since the original Implementation does not reveal that hypotheses used in previous ISTs were not sufficiently broad to encompass reality or are no longer considered plausible. Basic changes to the RMP (as opposed to, for example, stock structure hypotheses in ISTs) are expected to arise rarely, and stringent conditions have been set on how proposed changes are reviewed (IWC, 1994, 2007).

Management procedures that have been implemented for finfish and invertebrate fisheries are generally revised irregularly (Punt, 2006), outside a formal structure and without formal requirements. An exception to this is the process established in South Africa (MCM, 2006).

Transparency

The taking of cetacean species for aboriginal and (particularly) commercial purposes remains a politically sensitive issue. Although the SC does not address issues regarding the politico-ethical acceptability of whaling (see Donovan, 1992), it is important that the process of developing and evaluating management procedures is wholly transparent. Transparency has been facilitated by having the chair of the group responsible for developing management procedures being considered both objective and independent (i.e. neither having expressed pro- or anti-whaling views nor being involved in developing one of the competing candidate management procedures). Transparency has also been achieved by having the computing manager at the IWC Secretariat responsible for coding (and testing) the operating models specified by the SC, validating the code for the CLA and SLAs, and conducting all calculations when recommendations on catch or strike limits are made. In contrast, such a clear separation of tasks is rarely the case for fisheries management. The development of a management procedure for southern bluefin tuna appears to be an exception (CCSBT, 2005a, 2005b).

Data collection and availability

The IWC has set standards for data collection. Specifically, a set of guidelines has been adopted for how surveys are to be conducted if the results are to be used in the RMP (IWC, 2005d). These guidelines also specify that catch limits will be reduced linearly to zero

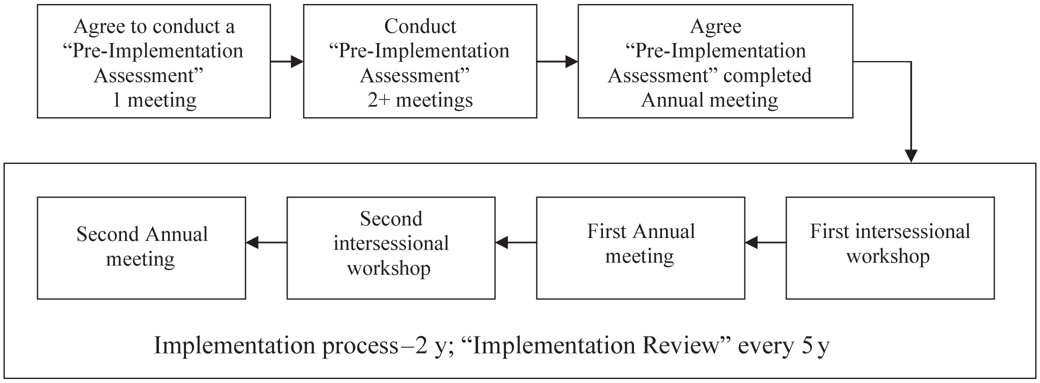

Figure 4. Conceptual overview of the procedure adopted by the IWC to facilitate implementation of the RMP (see IWC, 2005c).

over a period of 9–13 y after the last survey of an area (IWC, 1999). A data availability agreement (IWC, 2004a) specifies that all data used in the Implementation process must be freely available to members of the SC, although formal safeguards apply (e.g. with respect to publication rights). To date, no management procedure for a fish or invertebrate species has adopted such data collection standards or rules if the data required to apply the management procedure are not forthcoming.

Uncertainty factors considered

The uncertainties captured in simulation trials cover a number of factors. In general, the trials that capture uncertainty are divided into those considered most likely (the base-case or "evaluation" trials) and those considered less plausible, but for which performance should be adequate ("robustness" trials). The factors considered during the development of the CLA (Table 1) focused on those aspects considered most likely to affect performance. As expected, the factor having the greatest impact was the productivity of the resource. Therefore, the CLA was developed to perform adequately in the face of few data (only one estimate of absolute abundance when first applied) for stocks with perceived low productivity (an MSY that is only 1% of the number of mature animals at MSYL). Consequently, the resource is greatly underutilized when in fact productivity is higher. Other factors such as survey bias and temporal change in biological parameters also affected performance. Trials also included changes in carrying capacity and episodic events.

The uncertainties considered in developing SLAs for the Bering–Chukchi–Beaufort Seas stock of bowhead whales and the eastern North Pacific stock of gray whales (IWC, 2003b) were similar to those in Table 1, except that the impacts of demographic stochasticity, time-dependence in survey bias, and changes over time in the rate of natural mortality were also explored.

Stock structure

The multi-stock trials developed for specific Implementations have been much more complex than the single-stock trials used for developing the CLA and for the case-specific SLAs. For example, the trials developed for western North Pacific minke whales considered four major stock-structure assumptions based on an operating model that included 13 areas and a monthly time-step. The hypotheses underlying those assumptions were developed primarily from interpretations of genetic and length frequency data. The discussions of their relative plausibility were particularly fraught and led to the development of the guidelines referred to above (Donovan and Hammond, 2004; IWC, 2005e).

In fact, the major difference between the way management procedures have been evaluated for cetaceans and for fish and invertebrates is the focus on uncertainty in relation to stock structure. IWC (1992b, 1993, 1994) showed that a management procedure that performs adequately when stock structure is known can perform poorly when this is not the case. Specifically, conservation performance is poor when two stocks are assessed and managed as a unit, but catches are only taken (unintentionally) from one stock (Hall and Donovan, 2002). The lack of robustness to this type of uncertainty was the reason for the development of the multi-stock

Table 1. Factors and levels considered in the trials used to select the CLA (after IWC, 1992a). Underlined values denote those used to evaluate the candidate procedures, whereas the others were used to examine robustness.

Factor	Levels
Productivity	MSY rates of 1%; 4%; 7%; varying from 1% to 4%
Initial depletion, P_0	0.05, 0.3, 0.6, 0.99
Survey bias	0.5, 1, 1.5
Period of protection prior to management	Yes, No
Catches in error	No, half the true values
Age-at-maturity	7, 10
Episodic events	No, 50% of the population dies if an episodic event occurs at some specified frequency
MSYL	0.4*K*, 0.6*K*, 0.8*K*
Carrying capacity	Constant, increasing linearly over time, declining linearly over time
Survey intensity	Every fifth year, every tenth year

rules discussed above, and explains the need to conduct case-specific trials for any new Implementation of the RMP. An important new area of research being undertaken by the SC is the development of an individual-based simulation framework to investigate the performance of methods for analysing genetic data that may be used to inform stock-structure discussions in a management context (IWC, 2004b).

In reviewing how management procedures have been evaluated, Butterworth and Punt (1999) noted little progress in evaluating the impacts of spatial and stock structure on the performance of management procedures outside the IWC. More progress has been made on this front since then for shark populations off southern Australia (Punt *et al.*, 2005), groundfish species off southern Australia (Punt *et al.*, 2002), prawns off northern Australia (Dichmont *et al.*, 2005), and rock lobster off southern New Zealand (Bentley *et al.*, 2003). Plagányi *et al.* (2007) note that spatial structure will be considered when the management procedures for rock lobster, hake, sardine, and anchovy off South Africa are next revised.

Multispecies interactions

Interactions among species occur through bycatch, predation, or competition. Increasingly, such interactions are being explicitly included in operating models (Punt, 1993; Schweder *et al.*, 1998; Punt *et al.*, 2002; De Oliveira and Butterworth, 2004; Dichmont *et al.*, 2005; Plagányi and Butterworth, 2006). However, most focus has been on technical (i.e. bycatch) rather than biological (predation/competition) interactions. Adding biological interactions makes an operating model much more complicated, and requires more data to specify its parameters. The IWC has not attempted to build multispecies operating models, but rather has chosen to examine the impact of temporal changes in biological parameters that might be affected by biological interactions (such as carrying capacity, productivity, and natural mortality). Although it remains to be confirmed whether the implications of complicated biological interactions on the performance of management procedures can be captured adequately by varying parameter values of single-species operating models, the difficulties of predictive multispecies modelling approaches are well known, both in terms of assumptions and data requirements (e.g. IWC, 2004c).

Other features

The management procedures for commercial and aboriginal subsistence whaling share some common features, although their underlying objectives differ.

(i) The estimation methods that underlie the management procedures incorporate Bayesian aspects, by being based either on a conventional Bayesian assessment (Dereksdóttir and Magnússon, 2003, 2005), a Bayesian assessment that downweights the data to prevent large changes in stock status caused by noisy data (IWC, 1999), or on maximum-likelihood techniques with a penalty on deviations in parameter estimates from prior values (Johnston and Butterworth, 2004). The use of such methods is not related to philosophy, but rather to ensure that the parameters on which catch limits are based are set to conservative default values in the absence of informative data.

(ii) The RMP and Dereksdóttir–Magnússon SLAs account for parameter uncertainty by setting the catch limit based on a percentile of a posterior distribution <0.5. Consequently, increased uncertainty leads to lower catch limits.

(iii) The data used represent only a restricted subset of all data sources. For example, data on absolute abundance from surveys or (age-, sex-, and size-compositions of) catches, on relative abundance (e.g. from analyses of cpue data), and on fecundity rates exist for many whale stocks. However, only data on absolute abundance are used for setting catch limits, because other data sources can be subject to considerable uncertainty in interpretation. Hence, use of such data can lead to poorer performance than when they are ignored when the assumptions on which their use is predicated are wrong (e.g. that cpue is linearly proportional to abundance). Of course, ignoring additional data sources when they do provide useful information on status and trends may lead to some loss of yield (on average) for the same perceived risk to the resource. Although not used in the CLA, these data are used as part of the Implementation Review process to ensure that the parameter space of the uncertainty tested is still applicable.

(iv) All management procedures adopted involve fitting population dynamics models to data, because early work during RMP development suggested that model-based management procedures lead to less interannual variation in catch limits (IWC, 1992a). In contrast, many management procedures used in fisheries are based on changing catch limits in a direct relationship with the extent of changes in directly measurable quantities, such as cpue or survey estimates of abundance (De Oliveira and Butterworth, 2004; Breen *et al.*, 2006). One reason for this is that these more "empirical" approaches can be explained more easily to stakeholder groups. Although the need for simplicity is acknowledged by the IWC, stakeholder groups at the IWC generally have scientific advisors well versed in management procedures and their evaluation. In addition, particularly with respect to the AWMP development process, there has been a consistent effort to explain all stages of the process to the users and to consult with them on practical issues or design features (use of block quotas rather than annual quotas, carry-over provisions where catch limits are not reached in a particular year, etc.) (Donovan, 2006).

Given the recent adoption by the IWC of a formal structure to implement the RMP for a specific species and region and, in particular, the idea that there should be pre-specified standards of performance before the SC can recommend an Implementation, recognition of the value of research in reducing key uncertainties that lead to poor performance has increased. Specifically, IWC (2005c) allows for the use of a "research-conditional" option (Donovan and Hammond, 2004). Under strict conditions, this allows for temporary use of a variant that does not satisfy the pre-specified conservation performance standards, if this use is accompanied by an SC-approved research programme that should be able to determine whether or not the hypotheses on which performance is poor are indeed plausible. If the research fails to show within a specified time frame that the hypotheses are implausible, catch limits will be reduced to account for any catches above those that would have been set had a more conservative RMP variant been adopted that was robust to these hypotheses being true or not.

Available expertise and resources

The lack of people trained in the area of stock assessment and fisheries management is well recognized (Mace *et al.*, 2001). Unfortunately, the construction of alternative operating models that capture the key uncertainties requires considerable modelling experience. Consequently, efforts to develop appropriate management procedures are limited in many parts of the world more by an absence of suitable people than by financial resources. The lack of sufficient qualified personnel is one reason that the SC is reticent to conduct more than two Implementations at a time (IWC, 2005e), and why the Implementation process for North Atlantic fin whales will be delayed until after 2007 (both the western North Pacific Bryde's whale Implementation and a major bowhead whale Implementation Review are scheduled for completion in 2007).

Conclusions and lessons learned

The long development process of the management procedure approach within the SC of the IWC has been both painful and sometimes exhilarating. Nevertheless, the approach may well represent one of the most important recent advances in the management of renewable resources. The degree of rigour employed, particularly the explicit manner with which inevitable scientific uncertainty is dealt, is perhaps a by-product of the controversy surrounding whaling. In many respects, the framework is the first to have been specified for applying the precautionary principle to the management of renewable resources in a quantifiable manner (Garcia, 2000). Ironically though, the approach pioneered by the SC is not being used yet to manage commercial whaling, but is being applied to manage aboriginal subsistence fisheries as well as some commercial finfish and invertebrate fisheries (Hammond and Donovan, in press). In our opinion, the approach, despite the manifold difficulties that have been and will be encountered, represents the way forward to manage natural resources properly. The primary lessons learned may be summarized as follows.

(i) Management procedures should incorporate a degree of Bayesian philosophy; specifically the parameter values on which catch limits (or other regulations) are based should default to conservative values (e.g. a percentile <0.5 of their posterior distributions) until available data indicate otherwise. As a rule, if the point estimates of the parameters on which some management measure is based are identical for two stocks, the management measure taken should be less restrictive for the stock for which the information available is more precise. Including this feature in a management procedure encourages additional data collection.

(ii) Major gains may be made by having more than one team, each with a broad range of expertise, participating in the development process. Ensuring that the developers span a range of disciplines (biological, mathematical, and statistical) is likely to enhance the chances of the development of a management procedure that better satisfies the management objectives. Also, interaction among developers from different backgrounds, whether in a combative or collaborative environment, leads to innovative solutions. Close collaboration with representatives of all stakeholders and communication of the process to them will allow appropriate specification and quantification of the management objectives as well as the development of a procedure that is practical and carries a broad degree of support among users.

(iii) Management procedures should clearly specify their requirements for data and analysis, and include specific rules to handle situations in which the data needed to apply the management procedure are not available.

(iv) The time and effort required to develop sound management procedures should not be underestimated.

(v) Most non-IWC applications focus on the impact of observation and process error. However, structural error is likely to have a greater impact on performance, specifically with respect to spatial and stock structure.

(vi) A formal and well-specified process for evaluation is needed, particularly if the implementation is likely to be highly contentious. Of particular importance are a formal process for assigning weights to alternative simulation trials, a set of rules to determine when performance is considered adequate, and a "temporal science barrier"–a time limit after which new information will not be permitted to change how simulation trials are developed and performance is evaluated.

Acknowledgements

Funding for this work was provided to AEP by NMFS Grant NA04NMF4550330. We thank the many members of the RMP and AWMP groups within the IWC Scientific Committee who have contributed to what is, in our opinion, the major advance in management science in the past two decades. We dedicate this paper to two friends and colleagues who have recently died, Kjartan Magnússon and Geoff Kirkwood. Their contributions to the development of the RMP and AWMP processes were immense. Doug Butterworth (UCT) and the guest editor are thanked for useful comments on an earlier version of this manuscript.

The National Oceanic and Atmospheric Administration (NOAA), organized in 1970, has evolved into an agency that establishes national policies and manages and conserves our oceanic, coastal, and atmospheric resources. An organizational element within NOAA, the Office of Fisheries, is responsible for fisheries policy and the direction of the National Marine Fisheries Service (NMFS).

In addition to its formal publications, the NMFS uses the NOAA Technical Memorandum series to issue informal scientific and technical publications when complete formal review and editorial processing are not appropriate or feasible. Documents within this series, however, reflect sound professional work and may be referenced in the formal scientific and technical literature.

NOAA Technical Memorandum NMFS
This TM series is used for documentation and timely communication of preliminary results, interim reports, or special purpose information. The TMs have not received complete formal review, editorial control, or detailed editing.

Summary

A single population stock of gray whales referred to as the eastern North Pacific (ENP) stock is presently recognized in U.S. waters (Carretta *et al.* 2013). A small group of gray whales, known as the Pacific Coast Feeding Group, or PCFG spends the summer and autumn along the Pacific coast of North America, where they overlap with the Makah Tribe's Usual and Accustomed (U&A) fishing grounds off the coast of Washington. In 2005, the Makah requested that NOAA/NMFS waive the MMPA take moratorium and adopt regulations that would authorize the tribe to hunt ENP gray whales within their U&A. As part of its review of this proposed hunt, NMFS continues to evaluate information relevant to ENP stock structure and status, including the population dynamics of the PCFG. Assessing whether the PCFG is currently at Optimum Sustainable Population (OSP) (i.e., not depleted) was the objective of the analysis described in this report[1]. The assessment is based on modifications to an existing population dynamics model used by the International Whaling Commission (IWC) to conduct projections of gray whale abundance. The model is deterministic, age- and sex-structured, and consists of two groups (the 'north' group and the PCFG), which are assumed to be separate for purposes of the analysis, but with possible immigration between them. Parameter estimation is based on Bayesian methods. Thirteen variants of the model were run (models A – M); these differed with respect to how priors were specified and the number of parameters estimated. Ultimately it was not possible to draw a definitive conclusion as to whether the PCFG is within OSP. Across all 13 model variants, the estimated probability of the PCFG being above its Maximum Net Productivity Level (*MNPL*) and hence within OSP ranged from ≈ 0.35 on the low end (models F and G) to 0.83 (model M) and 0.88 (model K) on the high end. In the latter two models (K and M), bycatch mortality[2] was fixed at zero, which is not realistic. For the remaining 11 models, the probability was ≤ 0.70, which is fairly equivocal. This stems from the PCFG abundance time series being largely uninformative regarding population rate parameters since it is relatively flat (no information about growth rate or density-dependence), apart from the short period of growth explained by an atypical pulse immigration event. Given the limited available information, the apparent stability of the PCFG population size for the past decade has several possible explanations. One explanation is that the population is at or near its carrying capacity and thus above *MNPL* and within OSP. However, it is also possible, given different potential rates of intrinsic population growth, that the PCFG area could support more whales and that current numbers are regulated by a combination of bycatch mortality and emigration that offsets immigration and internal production (recruitment of calves born to known PCFG females). Obtaining better empirical estimates of bycatch mortality, net annual immigration rates, and reducing prior uncertainty in Maximum Sustainable Yield Rate (*MSYR)* and *MNPL* could potentially improve inference about the likelihood of the PCFG being within OSP.

---

[1] This is a continuation of work first considered during the gray whale stock identification workshop described in Weller *et al*. (2013).

[2] "Bycatch mortality" refers to human-caused fisheries-related mortality (e.g., from entanglement in gear) as summarized in U.S. marine mammal stock assessment reports (e.g., Carretta *et al*. 2013).

Introduction

The National Marine Fisheries Service (NMFS) recognizes a single population stock of gray whales (*Eschrichtius robustus*) within U.S. waters, termed the Eastern North Pacific (ENP) stock (Carretta *et al.* 2013). This stock ranges from wintering areas in Baja California, Mexico, to summer/autumn feeding areas in the Bering, Beaufort, and Chukchi Seas. A relatively small number (100s) of these whales, referred to as the Pacific Coast Feeding Group (PCFG), spend the summer/autumn along the Pacific coast of North America, between Kodiak Island, Alaska, and northern California (Calambokidis *et al*. 2012). In 2010, the International Whaling Commission (IWC) Standing Working Group on Aboriginal Whaling Management Procedure noted that different names had been used to refer to gray whales feeding along the Pacific coast, and agreed to standardize the terminology referring to animals that spend the summer and autumn feeding in coastal waters of the Pacific coast of North America from California to southeast Alaska as the PCFG (IWC 2011). This definition was further refined for purposes of abundance estimation, limiting the geographic range to the area from northern California to northern British Columbia (from 41°N to 52°N), limiting the temporal range to the period from June 1 to November 30, and counting only those whales seen in more than one year within this geographic and temporal range (IWC 2012) for abundance estimation purposes. The IWC adopted this definition, but noted that "not all whales seen within the PCFG area at this time will be PCFG whales and some PCFG whales will be found outside of the PCFG area at various times during the year." (IWC 2012).

The range of the PCFG overlaps with the Makah Tribe's Usual and Accustomed (U&A) fishing grounds off the coast of Washington. In 2005, the Makah requested that NOAA/NMFS waive the U.S. Marine Mammal Protection Act (MMPA) take moratorium and adopt regulations that would authorize the tribe to hunt ENP gray whales within their U&A. As part of its review of this proposed hunt, NMFS continues to evaluate information relevant to ENP stock structure and status, including the population dynamics of the PCFG. This paper evaluates whether the PCFG is likely to be within its Optimum Sustainable Population level, or OSP. Under the MMPA, OSP means, "with respect to any population stock, the number of animals which will result in the maximum productivity of the population or the species, keeping in mind the carrying capacity of the habitat and the health of the ecosystem of which they form a constituent element." Federal regulations implementing the MMPA describe OSP as a population size within a range that is at or above the level where the population's maximum net productivity occurs (termed the Maximum Net Productivity Level, or MNPL).[3] Populations below OSP are considered 'depleted' under the MMPA. Assessing whether the PCFG is currently within OSP (not depleted) was the objective of the analysis described in this report.

---

[3] Regulations implementing the MMPA at 50 CFR 216.3 state that "Optimum sustainable population is a population size which falls within a range from the population level of a given species or stock which is the largest supportable within the ecosystem to the population level that results in maximum net productivity. Maximum net productivity is the greatest net annual increment in population numbers or biomass resulting from additions to the population due to reproduction and/or growth less losses due to natural mortality."

Methods

Population Model

The assessment of ENP gray whales is based on a population dynamics model with two groups, a 'north' group and the PCFG. These two groups are assumed to be separate for purposes of the analysis, but with possible immigration between them. The model considers four strata (north of 52^0N, south of 41^0N, PCFG area December – May, and PCFG area June – November) because the relative vulnerability of the two groups to whaling and bycatch mortality differs among these strata.

The parameters of the model are estimated using Bayesian methods. Unlike IWC (2013), the analysis allows for uncertainty in the amount of 'pulse' immigration from the north group to the PCFG in 1999 and 2000, uncertainty in the annual level of immigration from the north group to the PCFG, and in $MSYL_{1+}$ [4] and $MSYR_{1+}$ [5] (the subscript 1+ refers to animals 1-year old and older). In contrast, IWC (2013) conducted analyses for pre-specified values for the level of 'pulse' immigration, the annual level of immigration, and $MSYL_{1+}$ and $MSYR_{1+}$. Note that the terms *MSYL* and *MSYR* reflect IWC terminology; within an MMPA context MSYL is the same as MNPL.

The underlying population dynamics model is deterministic, age- and sex-structured, and based on a two-stock version of the Baleen II model (Punt, 1999). Reference to 'stock' or 'population' below means either the north group or the PCFG, noting that usage of the term 'stock' with the model descriptions refers generically to a population unit and does not imply a formally recognized stock as defined under the MMPA.

Basic dynamics

Equation 1 provides the underlying 1+ dynamics.

$$
\begin{aligned}
R^{s,m/f}_{t+1,a+1} &= (R^{s,m/f}_{t,a} + I^{s,m/f}_{t,a} - C^{s,m/f}_{t,a})\,\tilde{S}^s_t\,S^s_a + U^{s,m/f}_{t,a}\,\tilde{S}^s_t\,S^s_a\,\delta_{a+1} && 0 \le a \le x-2 \\
R^{s,m/f}_{t+1,x} &= (R^{s,m/f}_{t,x} + I^{s,m/f}_{t,x} - C^{s,m/f}_{t,x})\,\tilde{S}^s_t\,S^s_x + (R^{s,m/f}_{t,x-1} + I^{s,m/f}_{t,x-1} - C^{s,m/f}_{t,x-1})\,\tilde{S}^s_t S^s_{x-1} && (1) \\
U^{s,m/f}_{t+1,a+1} &= U^{s,m/f}_{t,a}\,\tilde{S}^s_t\,S^s_a\,(1-\delta_{a+1}) && 0 \le a \le x-2
\end{aligned}
$$

where $R^{s,m/f}_{t,a}$ is the number of recruited males/females of age *a* in stock *s* at the start of year *t*; $U^{s,m/f}_{t,a}$ is the number of unrecruited males/females of age *a* in stock *s* at the start of year *t*; $C^{s,m/f}_{t,a}$ is the catch of males/females of age *a* from stock *s* during year *t* (whaling and bycatch mortality is assumed to take place in a pulse at the start of each year); δ_a is the fraction of unrecruited animals of age *a*-1 which recruit at age *a* (assumed to be independent of sex, time, and stock); S^s_a is the annual survival rate of animals of stock *s* and age *a* in the absence of catastrophic mortality events (assumed to be the same for males and females):

$$
S^s_a = \begin{cases} S^s_0 & \text{if } a = 0 \\ S^s_{1+} & \text{if } 1 < a \end{cases} \qquad (2)
$$

[4] MSYL (Maximum Sustainable Yield Level) is the population size relative to carrying capacity at which surplus production is maximized; this is the same as MNPL under the MMPA.

[5] MSYR is the ratio of MSY to the population size at which MSY is achieved.

S_0^s is the calf survival rate for animals of stock *s*; S_{1+}^s is the survival rate for animals aged 1 and older for animals of stock *s*; $\tilde{S}_t^s$ is the amount of catastrophic mortality (represented in the form of a survival rate) for stock *s* during year *t* (catastrophic events are assumed to occur at the start of the year before mortality due to whaling, bycatch and natural causes; in general $\tilde{S}_t^s=1$, i.e. there is no catastrophic mortality); $I_{t,a}^{s,m/f}$ is the net migration of female/male animals of age *a* into stock *s* during year *t*; and *x* is the maximum (lumped) age-class (all animals in this and the *x*-1 class are assumed to be recruited and to have reached the age of first parturition). *x* is taken to be 15 for these trials.

Catastrophic mortality is assumed to be zero (i.e., $\tilde{S}_t^s=1$) except for the north group in 1999 and 2000 when it is assumed to be equal to the parameter $\tilde{S}$ (Punt and Wade, 2012). This assumption reflects the large number of dead ENP gray whales observed stranded along the coasts of Oregon and Washington during 1999 and 2000 relative to annual numbers stranding there historically (Gulland *et al*. 2005; Brownell *et al*. 2007). The mortality event is assumed to have only impacted the north group because the abundance estimates for the PCFG increased when the mortality event occurred, in contrast to those for the north group which declined substantially.

Immigration only occurs from the north group to the PCFG, and only animals aged 1+ immigrate. The annual number of animals immigrating is $I_t=\bar{I}\,N_t^{\text{north},1+}/20000$ where $\bar{I}$ is the hypothesized recent average number of individuals recruiting into the PCFG and 20000 is the approximate 1+ population size for the north group during those years (i.e., recent $N_t^{\text{north},1+}/20000\approx 1$ (Laake *et al*. 2012) and thus recent $I_t=\bar{I}$). The annual number of immigrants by age and sex is given by:

$$I_{t,a}^{s,m/f}=I_t\,\frac{(R_{t,a}^{\text{north},m/f}+U_{t,a}^{\text{north},m/f})}{N_t^{\text{north},1+}} \tag{3}$$

Emigration from the PCFG is modelled by implementing an extra survival rate, $\tilde{\tilde{S}}$ after 1930 (immigration or emigration are ignored when carrying capacity and the parameters which determine the productivity of the population are calculated). Owing to the different sizes of the two groups, emigrants from the PCFG are assumed to die rather than join the north group. The value of $\tilde{\tilde{S}}$ is set so that at carrying capacity immigration and emigration are balanced, i.e.:

$$\frac{\bar{I}\,K_{1+}^{\text{north}}}{20000}=K_{0+}^{\text{PCFG}}(1-\tilde{\tilde{S}}) \tag{4}$$

Births

The number of births to stock *s* at the start of year *t*+1, B_{t+1}^s, is given by:

$$B_{t+1}^s=b_{t+1}^s\,N_{t+1}^{s,f} \tag{5}$$

where $N_t^{s,f}$ is the number of mature females in stock *s* at the start of year *t*:

$$N_t^{s,f} = \sum_{a=a_m}^{x} (R_{t,a}^{s,f} + U_{t,a}^{s,f}) \qquad (6)$$

a_m is the age-at-maturity (the convention of referring to the mature population is used here, although this actually refers to animals that have reached the age of first parturition); b_{t+1}^s is the probability of birth/calf survival for mature females:

$$b_{t+1}^s = b_{-\infty}^s \{1 + A^s (1 - (N_{t+1}^{s,1+} / K^{s,1+})^{z^s})\} \qquad (6)$$

$b_{-\infty}^s$ is the average number of live births per year per mature female in the pristine (pre-exploitation) population for stock *s*; A^s is the resilience parameter for stock *s* (A^s determines how much birth rate can increase from $b_{-\infty}^s$ when resources are not limiting); z^s is the degree of compensation for stock *s* (determines the population size – relative to carrying capacity – at which MNPL occurs); and $N_t^{s,1+}$ and $K^{s,1+}$ are defined according to the equations:

$$N_t^{s,1+} = \sum_{a=1}^{x} (R_{t,a}^{s,\mathrm{f}} + U_{t,a}^{s,\mathrm{f}} + R_{t,a}^{s,\mathrm{m}} + U_{t,a}^{s,\mathrm{m}}) \qquad K^{s,1+} = \sum_{a=1}^{x} (R_{-\infty,a}^{s,\mathrm{f}} + U_{-\infty,a}^{s,\mathrm{f}} + R_{-\infty,a}^{s,\mathrm{m}} + U_{-\infty,a}^{s,\mathrm{m}}) \qquad (7)$$

The number of female births, $B_t^{s,f}$, is computed from the total number of the births during year *t* according to the equation:

$$B_t^{s,f} = 0.5 B_t^s \qquad (8)$$

The numbers of recruited/unrecruited calves is given by:

$$\begin{aligned} R_t^{s,f} &= \pi_0 B_t^{s,f} & R_t^{s,m} &= \pi_0 (B_t^s - B_t^{s,f}) \\ U_t^{s,f} &= (1-\pi_0) B_t^{s,f} & U_t^{s,m} &= (1-\pi_0)(B_t^s - B_t^{s,f}) \end{aligned} \qquad (9)$$

π_0 is the proportion of animals of age 0 which are recruited ($\pi_0 = 0$ for the analyses of this report).

Catches

The historical ($t < 2010$) catches by stratum (north, south, PCFG December – May, and PCFG June – November) are taken to be equal to the reported catches (IWC 2011; Table 1). The historical catches are allocated to the north group or PCFG in fixed proportions as follows:

(1) North area catches: all north animals;
(2) PCFG area catches in December – May: PCFG animals with probability ϕ_{PCFG} (base-case value 0.3, as determined by the photo-ID data; Calambokidis *et al*. 2012);
(3) PCFG area catches in June – November: all PCFG animals; and
(4) South area catches: PCFG animals with probability ϕ_{south} (base-case value 0.01, as determined by relative abundance).

The bycatch estimates by stratum for the historical period are computed using the equation (IWC 2013):

$$C_y^{\mathrm{I}/s} = 0.5\begin{cases}\left\{1-\frac{0.5}{69}[1999-y]\right\}\bar{C}^I & \text{if } y \le 1999 \\ \bar{C}^I N_y^{1+} / \bar{N}^{1+} & \text{otherwise}\end{cases} \tag{10}$$

where $C_y^{\mathrm{I}/s}$ is the bycatch of animals of sex s during year y; $\bar{C}^I$ is the mean catch in the stratum (see Table 2); and $\bar{N}^{1+}$ is the mean 1+ abundance (in the stratum concerned from 2000-2009). The catches from the PCFG and the north group are then allocated to age and size using the formula:

$$C_{t,a}^{s,m} = C_t^{s,m} R_{y,a}^{s,m} / \sum_{a"} R_{y,a"}^{s,m}; \qquad C_{t,a}^{s,\mathrm{f}} = C_t^{s,\mathrm{f}} R_{y,a}^{s,\mathrm{f}} / \sum_{a"} R_{y,a"}^{s,\mathrm{f}}; \tag{11}$$

Recruitment

The proportion of animals of age a that would be recruited if the population was pristine is a knife-edged function of age at age 0, i.e.:

$$\pi_a = \begin{cases} 0 & \text{if} \quad a = 0 \\ 1 & \text{otherwise}\end{cases} \tag{12}$$

The (expected) number of unrecruited animals of age a that survive to age a+1 is $U_{t,a}^{s,m/f}\ S_a$. The fraction of these that then recruit is:

$$\delta_{a+1} = \begin{cases}[\pi_{a+1} - \pi_a]/[1-\pi_a] & \text{if } 0 \le \alpha_a < 1 \\ 1 & \text{otherwise}\end{cases} \tag{13}$$

Maturity

Maturity is assumed to be a knife-edged function of age at age a_{m}.

Initialising the population vector

The numbers at age in the pristine population are given by:

$$\begin{aligned} R_{-\infty,a}^{s,\mathrm{m/f}} &= 0.5 \quad N_{-\infty,0}^{s} \quad \pi_a \prod_{a'=0}^{a-1} S_{a'}^{s} && \text{if} \quad 0 \le a < x \\ U_{-\infty,a}^{s,\mathrm{m/f}} &= 0.5 \quad N_{-\infty,0}^{s} \quad (1-\pi_a) \prod_{a'=0}^{a-1} S_{a'}^{s} && \text{if} \quad 0 \le a < x \\ R_{-\infty,x}^{s,\mathrm{m/f}} &= 0.5 \quad N_{-\infty,0}^{s} \quad \prod_{a'=0}^{x-1} \frac{S_{a'}^{s}}{(1-S_x)} && \text{if} \quad a = x \end{aligned} \tag{14}$$

where $R_{-\infty,a}^{s,\mathrm{m/f}}$ is the number of animals of stock s of age a that would be recruited in the pristine population; $U_{-\infty,a}^{s,\mathrm{m/f}}$ is the number of animals of stock s of age a that would be unrecruited in the pristine population; and $N_{-\infty,0}^{s}$ is the total number of animals of stock s of age 0 in the pristine population.

The value for $N^s_{-\infty,0}$ is determined from the value for the pre-exploitation size of the 1+ component of the population using the equation:

$$N^s_{-\infty,0} = K^{s,1+} / \left(\sum_{a=1}^{x-1} \prod_{a'=1}^{a-1} S^s_a + \frac{1}{1-S_x} \prod_{a'=0}^{x-1} S^s_{a'} \right) \tag{15}$$

It is not possible to make a simple density-dependent population dynamics model consistent with the abundance estimates for ENP gray whales (Reilly 1981; 1984; Cooke 1986; Lankester and Beddington 1986; Butterworth *et al.* 2002). This is why recent assessments of this stock (e.g. Punt and Wade 2012) have been based on starting population projections from a more recent year (denoted as τ) than that in which the first recorded catch occurred. The analyses are therefore based on the assumption that the age-structure at the start of τ = 1930 is stable rather than that the populations were at their pre-exploitation equilibrium sizes at the start of some much earlier year. The choice of 1930 for the first year of the simulation is motivated by the fact that the key assessment results are not sensitive to a choice for this year from 1930-1968 (Punt and Butterworth 2002; Punt and Wade 2012). The determination of the age-structure at the start of 1930 involves specifying the effective 'rate of increase', γ, that applies to each age-class. There are two components contributing to γ, one relating to the overall population rate of increase (γ^+) and the other to the exploitation rate. Under the assumption of knife-edge recruitment to the fishery at age 1, only the γ^+ component (assumed to be zero following Punt and Butterworth 2002) applies to ages *a* of age 0. The number of animals of age *a* at the start of τ=1930 relative to the number of calves at that time, $N^{s,*}_{\tau,a}$, is therefore given by the equation:

$$N^{s,*}_{\tau,a} = \begin{cases} 1 & \text{if } a=0 \\ N^{s,*}_{\tau,0} S^s_0 & \text{if } a \le 1 \\ N^{s,*}_{\tau,a-1} S^s_{a-1} (1-\gamma^+) & \text{if } 1<a<x \\ N^{s,*}_{\tau,x-1} S^s_{x-1} (1-\gamma^+) / (1-S^s_x (1-\gamma^+)) & \text{if } a=x \end{cases} \tag{16}$$

where B^s_τ is the number of calves in year τ (=1930) and is derived directly from equations 5 and 6 (for further details see Punt [1999]):

$$B^s_\tau = \left(1 - \left[1/(N^{s,f}_\tau b^s_{-\infty}) - 1\right] / A^s\right)^{1/z^s} \frac{K^{s,1+}}{N^{s,1+*}_\tau} \tag{17}$$

The effective rate of increase, γ^s, is selected so that if the population dynamics model is projected from 1930 to 1968, the size of the 1+ component of the population (both groups) in 1968 equals a pre-specified value, P^s_{1968}.

z and A

A^s, z^s and S^s_0, are obtained by solving the system of equations that relate $MSYL^s_{1+}$, $MSYR^s_{1+}$, S^s_0, S_{1+}, $f_{\max}$, a_m, A^s and z^s, where $f_{\max}$ is the maximum theoretical pregnancy rate (Punt 1999).

Parameter estimation

The method for estimating the parameters of the model (i.e. selecting 5,000 sets of equally likely values for the parameters $a_{\rm m}$, S_0^s, S_{1+}, $\tilde{S}$, $K_{1+}^{\rm north}$, $K_{1+}^{\rm PCFG}$, $A^{\rm north}$, $A^{\rm PCFG}$, $z^{\rm north}$, and $z^{\rm PCFG}$) is based on a Bayesian assessment (Punt and Butterworth 2002; Wade 2002; Punt and Wade 2012). The algorithm for conducting the Bayesian assessment is as follows:

(a) Draw values for the parameters S_{1+}, $f_{\rm max}$, $a_{\rm m}$, $K_{1+}^{\rm north}$, $K_{1+}^{\rm PCFG}$, $P_{1968}^{\rm north}$, $P_{1968}^{\rm PCFG}$, $\tilde{S}$, $MSYR_{1+}^s$, $MSYL_{1+}^s$, $CV_{add}^{\rm north}$ (the additional variance for the estimates of 1+ abundance at Carmel, California in 1968), $CV_{add}^{\rm PCFG}$ (the additional variance for the estimates of 1+ abundance from northern California to Southeast Alaska in 1968 – had such a survey taken place) from the priors (see Table 3 for the reference priors).

(b) Solve the system of equations that relate $MSYR_{1+}^s$, $MSYL_{1+}^s$, S_0^s, S_{1+}, $f_{\rm max}$, $a_{\rm m}$, A^s and z^s to find values for S_0^s, A^s and z^s.

(c) Calculate the likelihood of the projection for each area, given by[6]:

$$-\ell{\rm n}L = 0.5\ell{\rm n}\,|\,\mathbf{V}+\Omega\,| + 0.5\sum_i\sum_j(\ell{\rm n}N_i^{\rm obs} - \ell{\rm n}\hat{P}_i^{1+})[(\mathbf{V}+\Omega)^{-1}]_{i,j}(\ell{\rm n}N_j^{\rm obs} - \ell{\rm n}\hat{P}_j^{1+}) \qquad (18)$$

where $N_i^{\rm obs}$ is the $i^{\rm th}$ estimate of abundance[7] (Tables 4a, 4b), $\hat{P}_i^{1+}$ is the model-estimate corresponding to $N_i^{\rm obs}$, $\mathbf{V}$ is the variance-covariance matrix for the abundance estimates, and Ω is a diagonal matrix with elements given by $E(CV_{add,t}^2)$:

$$E(CV_{add,t}^2) = CV_{add}^2\,\frac{0.1+0.013P^*/\hat{P}_t}{0.1+0.013P^*/\hat{P}_{1968}} \qquad (19)$$

(d) Steps (a) – (c) are repeated a large number (typically 1,000,000) of times.

(e) 5,000 sets of parameters vectors are selected randomly from those generated using steps (a) – (c), assigning a probability of selecting a particular vector proportional to its likelihood. The number of times steps (a) – (c) are repeated is chosen to ensure that most of the 5,000 parameter vectors are unique.

The expected value for the estimate of abundance of the north area is taken to the total 1+ abundance (north group and PCFG combined) while the abundance estimates for the PCFG area are assumed to pertain to the PCFG only.

Model Scenarios

Thirteen models were run (Table 5). These included a reference model (Table 3) and 12 variants. These models do not represent a comprehensive set of options, but were used to

[6] This formulation assumes that the observed data relate to the medians of sampling distributions for the data. Alternative assumptions (such as that the observed data relate to the means of the sampling distributions) will be inconsequential given the extent of uncertainty associated with the estimates of abundance.

[7] The shore-based abundance estimate for year *y*/*y*+1 is assumed to pertain to abundance at the start of year *y*+1.

explore how the model behaved under certain conditions (e.g., parameter constraints) with respect to providing inference about the probability of the PCFG being within OSP.

Results and Discussion

Ultimately it was not possible to draw a definitive conclusion as to whether the PCFG is within OSP. Across all 13 model variants, the estimated probability of the population being above *MSYL* (i.e., *MNPL*), and hence within OSP ranged from ≈ 0.35 on the low end (models F and G) to 0.83 (model M) and 0.88 (model K) on the high end (see Table 6). In the latter two models (K and M), bycatch mortality was fixed at zero, which is not realistic. For the remaining 11 models, the probability was ≤ 0.70, which is fairly equivocal.

The time series of PCFG abundance estimates indicates that a rapid phase of population growth occurred between 1998 and 2001 associated with a pulsed immigration event (≈ 25 – 30 immigrants per year from the north group to the PCFG), followed by no substantial trend in abundance since then (Figure 1). A key reason for the inability to draw definitive conclusions about OSP is because it is unclear whether the stability of the PCFG over the last decade is best explained by it being at or near carrying capacity or whether it has been regulated at a lower level by some other processes.

Unfortunately, the time-series of abundance estimates for the PCFG is largely uninformative regarding population growth rate since it is relatively flat (no information about growth rate or density-dependence) apart from the short period of growth explained by an atypical immigration event. Consequently, estimates for population growth at *MNPL*, the value of *MNPL* itself (as a fraction of K), carrying capacity, and hence the current population depletion level (percentage of carrying capacity) for the PCFG were influenced strongly by the prior distributions. For example, the upper prior limit for K for the PCFG was 500 for models A – D, and the posterior median estimates for K ranged from 265 – 293 with upper 95% estimates close to 500, whereas, the upper prior limit was 1000 for models E – M, and the posterior median estimates for K ranged up to 441 with upper 95% estimates close to 800 or higher for most of these models (Table 6). Thus, in all of these models, the right tail of the posterior distribution for K was truncated to some extent by the upper bound for the prior for K (Figure 2), implying non-trivial (and sometimes substantial) probability that carrying capacity could be as high as the specified upper bound (and thus substantial probability that current population size is below *MNPL*).

Constraining both *MSYR* and *MNPL* for the PCFG to equal those of the north group (thus drawing on north group data to estimate some PCFG growth parameters; models J through M) did not substantially improve inference. For models J and L, the probability of the PCFG being within OSP was 0.44 and 0.52, respectively (Table 6). Models K and M included the additional constraint of fixing annual bycatch at zero, and model M also assumed zero annual immigration. The posterior distribution for carrying capacity was reasonably unconstrained by the prior (Figure 2) and the carrying capacity estimates were ≤ 250 animals (Table 6) for these two models (and also for model I, where *MNPL* and bycatch, but not *MSYR*, were constrained). Even so, the estimated probability of the population being within OSP was not definitive in these cases (probability = 0.83 and 0.88), and the assumptions of zero bycatch (models I, K, M) or full population closure (model M) are not justified for the PCFG (Weller *et al*. 2013), so these models do not represent realistic scenarios anyway. However, the estimates for these models provided the insight that bycatch mortality and movement between the north group and PCFG makes it difficult to estimate other population parameters, given the nature of the time series of abundance estimates (since parameters were not estimated well for other models that did not include the same constraints). Specifically, the only way for the model to mimic population stability when the population is assumed to be closed to bycatch or emigration is for the population to be at or near K (when K is estimated to be small), but many possible levels of K can explain the data when the population is allowed to be open (with some population losses due to bycatch and emigration).

In summary, the apparent stability of the PCFG population size for the past decade has multiple possible explanations given the limited available information. One explanation is that the population is at or near its carrying capacity and thus above *MNPL* and within OSP. However, it is also possible that the PCFG area could support more whales and that current numbers are regulated by a combination of emigration and bycatch mortality that offsets immigration and internal production (recruitment of calves born to known PCFG females). The PCFG would be expected at most to grow at around 6% per year (if it were well below *MNPL* and had the same intrinsic growth potential as the north group; Punt and Wade [2012]). It would grow at a slower rate if it is close to *MNPL* or has a lower growth rate potential than the larger north group (e.g., feeding in a less productive environment). Considering its small population size (around 200 animals), the PCFG therefore has the potential to increase at most by approximately 12 animals per year from births minus deaths, and the increase could be much smaller (e.g., just several animals per year). The PCFG can additionally grow due to immigration from the larger north group, but as modeled, immigration is offset by emigration to an extent that depends on the estimated abundance levels of the two groups relative to their respective carrying capacities. For example, if both groups are currently at the same fraction of K, PCFG immigration and emigration would be estimated to be equal. As a result, small losses from emigration and bycatch are sufficient to offset population gains from birth and immigration, especially if the PCFG has a relatively low intrinsic growth rate compared to the north group (e.g., as in models E through I; see Table 6). Moreover, bycatch mortality estimates in the models are likely underestimates of true bycatch mortality (Weller *et al.* 2013). If higher bycatch mortality rates were included in the analyses, this would decrease the estimated likelihood of the PCFG being within OSP, but true bycatch mortality rates are unknown with no good way at present of being approximated (thus we used the same values as in IWC analyses; Table 2).

Obtaining better empirical estimates of bycatch mortality, net annual immigration rates, and reducing prior uncertainty in *MSYR* and *MNPL* could potentially improve inference about the likelihood of the PCFG being within OSP.

ABSTRACT

An age- and sex-structured population dynamics model is fitted using Bayesian methods to data on the catches and abundance estimates for the eastern North Pacific (ENP) stock of gray whales (*Eschrictius robustus*). The prior distributions used for these analyses incorporate revised estimates of abundance for ENP gray whales and account explicitly for the drop in abundance caused by the 1999-2000 mortality event. A series of analyses are conducted to evaluate the sensitivity of the results to different assumptions. The baseline analysis estimates the ENP gray whale population to be above the maximum net productivity level (MNPL), because the posterior mean for the ratio of 2009 abundance to MNPL, termed the optimal sustainable population ratio, is 1.29 (with a posterior median of 1.37 and a 90% probability interval of 0.68-1.51), indicating the population is estimated to be well above MNPL. The baseline analysis estimates a probability of 0.884 that the population is above its MNPL, which means there is a 0.884 probability that it is at its optimum sustainable population size as defined by the U.S. Marine Mammal Protection Act. These results are consistent across all the model runs. The baseline model also estimates the 2009 ENP gray whale population size (posterior mean of 21,911) to be at 85% of its carrying capacity (posterior mean of 25,808), and this is also consistent across all the model runs.

CONTENTS

INTRODUCTION

The eastern North Pacific (ENP) gray whale (*Eschrichtius robustus*) population has been hunted extensively by both commercial and aboriginal whalers. Indigenous peoples of both North America and Russia have hunted gray whales in some locations for centuries and possibly for 2,000 years or more (Krupnik 1984, O'Leary 1984). The winter breeding grounds of the ENP gray whale (lagoons and adjacent ocean areas in Baja California, Mexico) were discovered by Yankee whalers in the early 19th century, and two commercial whaling vessels first hunted gray whales (in Magdalena Bay) in the winter of 1845-46 (Henderson 1984). This began a period of intense hunting with large catches of ENP gray whales by Yankee whalers from 1846 until 1873 which decimated the population. Whaling ships and shore-based whalers continued to catch gray whales for the next two decades which drove the population to apparent commercial extinction by 1893. In the 20th century, modern commercial pelagic whaling of ENP gray whales began in 1910 and ended in 1946 when gray whales received full protection under the International Convention for the Regulation of Whaling (Reeves 1984). Aboriginal catches of ENP gray whales along the Chukotka Peninsula of Russia have continued since 1946 until the present. Gray whales were listed as endangered under the U.S. Endangered Species Act in 1973 and after increasing substantially in population size, they were removed from the endangered species list in 1994.

From 1846 to 1900 recorded commercial kills numbered nearly 9,000 gray whales, and it is roughly estimated that about 6,000 gray whales were killed by aboriginal hunters during this same period, for a total of more than 15,500 whales caught (Table 1). Since 1900, about 11,500 additional ENP gray whales have been killed by commercial and aboriginal whalers for a total since 1846 of more than 27,000 whales caught (Table 1). The magnitude of the catches, particularly for the period of high exploitation during the 1800s, gives some information on the likely pre-exploitation population size. For example, Jones et al. (1984) state that "most whaling historians and biologists believe the pre-exploitation stock size was between 15,000 and 24,000 animals".

ENP gray whales migrate along the west coast of North America, and the National Marine Fisheries Service (NMFS) has taken advantage of this nearshore migration pattern to conduct shore-based counts of the population in central California during December-February from 1967-68 to 2006-07. These survey data have been used to estimate the abundance of the ENP gray whale stock over the survey period (Reilly 1981; Buckland et al. 1993; Laake et al. 1994; Hobbs et al. 2004; Rugh et al. 2005, 2008a).

The resulting sequence of abundance estimates has also been used to estimate the population's growth rate (Buckland et al. 1993, Buckland and Breiwick 2002), as well as its status relative to the maximum net productivity level (MNPL)[1] and carrying capacity (*K*) (Reilly 1981, Lankester and Beddington 1986, Cooke 1986, Wade 2002, Punt and Butterworth 2002). However, attempts to model the gray whale population from 1846 until the present, accounting for the catch record, assuming that the stock was at its carrying capacity in 1846 (has and this has not changed) has run into difficulties because the catch history cannot be reconciled with a population that increased at the observed rate from 1967-68 to 1979-80 (Reilly 1981, Cooke 1986, Lankester and Beddington 1986). The explanation for this is simple; if one assumes a relatively low maximum growth rate, the ENP gray whales would not have been able to increase between 1967-68 and 1979-80 because of the catches during that time, and if one assumes a high maximum growth rate, the population would not be increasing then because it would have already returned to carrying capacity. Butterworth et al. (2002) investigated the inability to fit a standard population dynamics model to the data for the ENP gray whales extensively and concluded that the catch history and the observed rate of increase could be reconciled in one of three different ways, which were not mutually exclusive: a) a 2.5× increase in *K* between 1846 and 1988, b) a 1.7× increase or more in the commercial catch between 1846 and 1900, and c) a 3× increase or more in aboriginal catch levels prior to 1846 compared to what was previously assumed (Butterworth et al. 2002).

---

[1]The maximum net productivity level is described in the National Marine Fisheries Service's definition of "optimum sustainable population" (OSP) (50 CFR 216.3) as the abundance level that results in the greatest net annual increment in population numbers or biomass resulting from additions to the population due to reproduction and/or growth less losses due to natural mortality. Under the U.S. Marine Mammal Protection Act, populations above MNPL are considered to be at OSP; populations below MNPL can be designated as 'depleted' and are afforded a greater level of protection.

Given these difficulties, recent gray whale population assessments have been conducted by modeling the population since 1930 or later, rather than trying to model the population since 1846 (e.g., Punt and Butterworth 2002, Wade 2002). These analyses differed from the earlier assessments by not assuming the population size in 1846 was *K*. Instead, *K* is essentially estimated by the recent trend in abundance, where a growing population implies that *K* has likely not yet been reached, and a roughly stable population implies the population is at or near *K*. Based on abundance surveys through 1995-96, point estimates of *K* from these analyses ranged from 24,000 to 32,000, but these estimates were relatively imprecise because they had broad confidence intervals (Wade 2002, Punt and Butterworth 2002). In particular, the results did not exclude the possibility that *K* could be much larger than this range. However, these analyses did suggest that the population was likely close to *K* and at or above its MNPL. For example, Wade (2002) estimated a probability of 0.72 the population was above MNPL in 1996. Punt and Butterworth (2002) also conducted analyses projecting the population from the year 1600 under various assumptions that historic commercial and aboriginal catches were underestimated (as in Butterworth et al. (2002)). Those analyses resulted in point estimates of *K* that ranged between 15,000 and 19,000. In those analyses, it was estimated the population was at a very high fraction of *K* in 1996 and had a very high probability of being above MNPL.

Recently, Rugh et al. (2008b) evaluated the accuracy of various components of the shore-based survey method, with a focus on pod size estimation. They found that the correction factors that had been used to compensate for bias in pod size estimates were calculated differently for different sets of years. In particular, the correction factors estimated by Laake et al. (1994) were substantially larger than those estimated by Reilly (1981). Also, the estimates for the surveys prior to 1987 in the trend analysis were scaled based on the abundance estimate from 1987-88. This meant that the first 16 abundance estimates used one set of correction factors, and the more recent 7 abundance estimates used different (and larger) correction factors which would influence the estimated trend and population trajectory. In addition, there were other subtle differences in the analysis methods used for the sequence of abundance estimates. Thus, a re-evaluation of the analysis techniques and a reanalysis of the abundance estimates were warranted to apply a more uniform approach throughout the years. Laake et al. (2009) derived a better, more consistent, approach to abundance estimation, and incorporated it into an analysis to re-estimate abundance for all 23 shore-based surveys. These new revised abundance estimates led to this re-assessment of the ENP gray whale population.

Here, we re-assess the population of ENP gray whales by fitting an age- and sex-structured population model to these revised abundance estimates, using similar methods as those used by Wade (2002) and Punt and Butterworth (2002). Note also that we use recent abundance estimates from 1997-98, 2000-01, 2001-02, and 2006-07 that were not available in previous assessments. As in Punt and Butterworth (2002), we also perform sensitivity tests to various assumptions or modeling decisions.

These analyses also incorporate new information about the biology of the ENP gray whales developed in recent studies. In particular, it is now recognized that the population experienced an unusual mortality event in 1999 and 2000. An unusually high number of gray whales were stranded along the west coast of North America in those years (Moore et al. 2001, Gulland et al. 2005). Over 60% of the dead whales were adults, and more adults and subadults stranded in 1999 and 2000 relative to the years prior to the mortality event (1996-98), when calf strandings were more common. Many of the stranded whales were emaciated, and aerial photogrammetry documented that migrating gray whales were skinnier in girth in 1999 relative to previous years (Perryman and Lynn 2002, W. Perryman, Southwest Fisheries Science Center, SWFSC, pers. comm.). In addition, calf production in 1999 and 2000 was less than one third of that in the previous years (1996-98). In 2001 and 2002, strandings of gray whales along the coast decreased to levels that were below their pre-1999 level (Gulland et al. 2005), and average calf production in 2002-2004 returned to the level seen in pre-1999 years (Table 2). A Working Group on Marine Mammal Unusual Mortality Events (Gulland et al. 2005) concluded that the emaciated condition of many of the stranded whales supported the idea that starvation could have been a significant contributing factor to the higher number of strandings in 1999 and 2000. Perryman et al. (2002) found a significant positive correlation between an index of the amount of ice-free area in gray whale feeding areas in the Bering Sea and their estimates of calf production for the following spring for the years 1994 to 2000; the suggested mechanism is that longer periods of time in open water provides greater feeding opportunities for gray whales. Whether or not heavy ice cover was ultimately the mechanism that caused the 1999-2000 event, it is clear that ENP gray whales were substantially affected in those years; whales were on average skinnier, they had a lower survival rate (particularly of adults), and calf production was dramatically lower. Given that this event may have affected the status of the ENP gray whale population relative to *K*, we specified an additional model parameter ("catastrophic mortality") that allowed for lower survival in the years 1999 and 2000 to investigate this effect.

METHODS

Available Data

A variety of data sources are available to assess the status of the ENP stock of gray whales. These data sources are used when developing the prior distributions for the parameters of the population dynamics model, when pre-specifying the values for some of the parameters of this model, and when constructing the likelihood function. Table 1 lists the time series of removals. It should be noted that the catches for the years prior to 1930 are subject to considerable uncertainty, and evaluating these catches remains an active area of research. However, the uncertainty associated with these early catches is inconsequential for this report because the population projections do not start before 1930.

The key source of information on the abundance of the ENP gray whales is based on data collected from the southbound surveys that have been conducted since 1967-68 near Carmel, California (Laake et al. 2009; Table 2). Information on trends in calf numbers are also available from surveys of calves during the northbound migration (Perryman et al. 2002, W. Perryman, pers. comm., Table 2). The calf abundance data are not included in the baseline analyses, but are considered in one of the tests of sensitivity.

Analysis Methods

The Population Dynamics Model

The analyses use an age- and sex-structured population dynamics model which assumes that all whaling takes place at the start of the year, and that all animals are 'recruited' to the hunted population by age 5 (i.e., hunting only occurs on animals age 5 and older) (Punt 1999, Punt and Butterworth 2002). The dynamics of the population are assumed to be governed by the equations:

$$N^s_{t+1,a} = \begin{cases} 0.5 \ P^{\mathrm{M}}_{t+1} \ f_{t+1} & \text{if } a = 0 \\ N^s_{t,a-1}(1-F^s_{t,a-1})\, S_{a-1}\tilde{S}_y & \text{if } 1 \le a \le x-1 \\ N^s_{t,x}(1-F^s_{t,x})\, S_x\tilde{S}_y + N^s_{t,x-1}(1-F^s_{t,x-1})\, S_{x-1}\tilde{S}_y & \text{if } a = x \end{cases} \quad , \qquad (1)$$

where $N^s_{t,a}$ is the number of animals of age a and sex s (m / f) at the start of year t,

S_a is the annual survival rate of animals of age a in the absence of catastrophic mortality events (assumed to be the same for males and females),

$\tilde{S}_y$ is the amount of catastrophic mortality (represented in the form of a survival rate) during year y (catastrophic events are assumed to occur at the start of the year before mortality due to whaling and natural causes),

$F^s_{t,a}$ is the exploitation rate on animals of sex s and age a during year t,

P^{M}_t is the number of females that have reached the age at first parturition by the start of year t,

$$P^{\mathrm{M}}_t = \sum_{a=a_m+1}^{x} N^{\mathrm{f}}_{t,a} \quad , \qquad (2)$$

a_m is the age-of-maturity,

f_t is pregnancy rate (number of calves of both sexes per ‘mature’ female) during year t (note that Equation (1) assumes an equal male : female sex ratio at birth), and

x is the maximum age class, which for convenience is lumped across older age classes (i.e., individuals stay in this age class until they die).

Density dependence on fecundity can be modeled by writing the pregnancy rate, f_t, as follows:

$$f_t = \max\left(f_{eq}\left[1 + A\left\{1 - \left(\tilde{S}_{t-2}P^{1+}_{t-2} / K^{1+}\right)^z\right\}\right], 0\right) \quad , \qquad (3)$$

where f_{eq} is the pregnancy rate at the pre-exploitation equilibrium, $f(F=0)$[2]:

$$f(F) = 2\left\{ \sum_{a=a_m+1}^{x} \tilde{N}_a^{\mathrm{f}}(F) \right\}^{-1} \quad , \qquad (4)$$

A is the resilience parameter:

$$A = \frac{f_{\max} - f_{eq}}{f_{eq}} \quad , \qquad (5)$$

$f_{\max}$ is the maximum (theoretical) pregnancy rate,

z is the degree of compensation,

P_t^{1+} is number of animals aged 1 and older at the start of year *t*:

$$P_t^{1+} = \sum_s \sum_{a=1}^{x} N_{t,a}^s \quad , \qquad (6)$$

K^{1+} is the (current) pre-exploitation equilibrium size (carrying capacity) in terms of animals aged 1 and older,

$\tilde{N}_a^s(F)$ is the number of animals of sex *s* and age *a* when the exploitation rate is fixed at *F*, expressed as a fraction of the number of calves of the same sex *s* (see Appendix 1 of Punt (1999) for details).

Note that although these equations are written formally as if only the pregnancy rate component of 'fecundity' as defined here is density-dependent, exactly the same equations follow if some or all of this dependence occurs in the infant survival rate (Punt 1999). Catastrophic mortality is assumed to occur before density-dependence because many of the deaths in 1999 and 2000 occurred before mating was likely to have occurred. Note that non-catastrophic natural mortality does not appear in Equation 3 because it cancels out. The time-lag in Equation 3 is specified to

---

[2] The pregnancy rate at the pre-exploitation equilibrium can be considered to be the equilibrium pregnancy rate when the exploitation rate, *F*, is fixed at zero.

match the reproductive cycle of gray whales; mature female gray whales mate and become pregnant in early winter, have a gestation period of slightly longer than one year, and give birth at the start of the next year (on average in January) (Rice and Wolman 1971, Shelden et al. 2004). Their body condition at the end of the summer feeding season will help determine their probability of becoming pregnant the following winter and producing a calf a year later. Therefore, the density-dependent effect on calf production is assumed to be determined by the population size during the feeding season two time-steps prior (approximately 1.5 years earlier).

Following past assessments of the ENP stock of gray whales (e.g., Butterworth et al. 2002, Punt and Butterworth 2002, Punt et al. 2004), the catch (by sex) is assumed to be taken uniformly from the animals aged 5 and older, that is,

$$F_{t,a}^{s} = C_{t}^{s} / \sum_{a=5}^{x} N_{t,a}^{s} \quad . \tag{7}$$

The population is assumed to have had a stable age-structure at the start of the projection period (year t_{INIT}).

$$N_{t_{\text{INIT}},a}^{s} = N_{t_{\text{INIT}}}^{\text{Tot}} \tilde{N}_{a}^{s}(F_{\text{INIT}}) / \sum_{s'} \sum_{a'=0}^{x} \tilde{N}_{a'}^{s'}(F_{\text{INIT}}) \quad , \tag{8}$$

where $N_{t_{INIT}}^{\text{Tot}}$ is the size of the total (0+) component of the population at the start of year t_{INIT}. The value of F_{INIT} is selected numerically so that:

$$N_{t_{\text{INIT}}}^{\text{Tot}} = 0.5\, N_{0}(F_{\text{INIT}}) \sum_{s} \sum_{a=0}^{x} \tilde{N}_{a}^{s}(F_{\text{INIT}}) \quad , \tag{9}$$

where $N_{0}(F_{\text{INIT}})$ is the number of calves (of both sexes) at the start of the year when $F = F_{\text{INIT}}$:

$$N_{0}(F_{\text{INIT}}) = \left(1 - \frac{1}{A}\left[\frac{f(F_{\text{INIT}})}{f_{\text{eq}}} - 1\right]\right)^{1/z} \frac{K^{1+}}{\tilde{P}^{1+}(F_{\text{INIT}})} \quad , \tag{10}$$

$\tilde{P}^{1+}(F)$	is the size of the 1+ component of the population as a function of F, expressed as a fraction of the number of calves (of both sexes).

Parameter Estimation

Catastrophic mortality is assumed to be zero (i.e., $\tilde{S}_y = 1$) except for 1999 and 2000 when it is assumed to be equal to a parameter $\tilde{S}$. This assumption reflects the large number of dead ENP gray whales observed stranded along the coasts of Oregon and Washington during 1999 and 2000 relative to numbers stranding there annually historically (Gulland et al. 2005, Brownell et al. 2007).

The parameters of the population dynamics model are a_m; $\tilde{S}$; K^{1+}; the 1+ population size at the start of 1968, P^{1+}_{1968} [3]; $MSYL^{1+}$ (the maximum sustainable yield level for the 1+ population, which is the population size at which maximum sustainable yield (MSY) is achieved when hunting takes place uniformly on animals aged 1 and older); $MSYR^{1+}$ (the ratio of MSY to $MSYL^{1+}$); f_{max}; and the non-calf survival rate, S_{1+}. The analysis does not incorporate a prior distribution for the survival rate of calves (S_0) explicitly. Instead, following Wade (2002), an implicit prior distribution for this parameter is calculated from the priors for the five parameters a_m, f_{max}, S_{1+}, $MSYR^{1+}$ and $MSYL^{1+}$. For any specific draw from the prior distributions for these five parameters, the value for S_0 is selected so that the relationships imposed by the population model among the six parameters are satisfied. If the resulting value for S_0 is less than zero or greater than that of S_{1+}, the values for S_{1+}, a_m, f_{max}, $MSYR^{1+}$ and $MSYL^{1+}$ are drawn again[4]. Thus, the prior for S_0 is forced to conform to the intuitive notion that the survival rate of calves must be lower than that for older animals (and must be larger than zero) (Caughley 1966).

---

[3] The 1968 population size is taken to be a measure of initial abundance so that the analyses based on different starting years are comparable in terms of their prior specifications.

[4] The implications of different treatments of how to handle situations in which the calculated value for S_0 is outside of plausible bounds is examined by Brandon et al. (2007).

Under the assumption that the logarithms of the estimates of abundance based on the southbound surveys are normally distributed, the contribution of these estimates to the negative of the logarithm of the likelihood function (ignoring constants independent of the model parameters) is

$$-\ell nL = 0.5\ell n\,|\mathbf{V}+\Omega| + 0.5\sum_i \sum_j (\ell nN_i^{obs} - \ell n\hat{P}_i^{1+})[(\mathbf{V}+\Omega)^{-1}]_{i,j}(\ell nN_j^{obs} - \ell n\hat{P}_j^{1+}) \ , \qquad (11)$$

where N_i^{obs} is the i[th] estimate of abundance[5],

$\hat{P}_i$ is the model-estimate corresponding to N_i^{obs},

$\mathbf{V}$ is the variance-covariance matrix for the abundance estimates, and

Ω is a diagonal matrix with elements CV_{add}^2 (this matrix captures sources of uncertainty not captured elsewhere; termed "additional variance" in Wade (2002)).

A Bayesian approach is used to estimate the 'free' parameters of the model based on the prior distributions in Table 3 and the sampling/importance resampling (SIR) algorithm (Rubin 1988).

(a) Draw values for the parameters S_{1+}, a_m, f_{max}, MSYR^{1+}, MSYL^{1+}, K^{1+}, P_{1968}^{1+}, $\tilde{S}$, and CV_{add} from the priors in Table 3.
(b) Solve the system of equations that relate S_0, S_{1+}, a_m, f_{max}, MSYR^{1+}, MSYL^{1+}, A and z (Punt 1999, Eqs. 18-21) to find values for S_0, A, and z, and find the population size in year t_{INIT} and the population rate of increase in this year, so that, if the population is projected from year t_{INIT} to 1968, the total (1+) population size in 1968 equals the generated value for P_{1968}^{1+}.
(c) Compute the likelihood for the projection (see Equation 11).
(d) Repeat steps (a)-(c) a very large number (typically 5 million) of times.
(e) Select 5,000 parameter vectors randomly from those generated using steps (a)-(d), assigning a probability of selecting a particular vector proportional to its likelihood

[5] The abundance estimate for year *y*/*y*+1 is assumed to pertain to abundance at the start of year *y*+1.

The above formulation implies that the year for which a prior on abundance is specified (1968) is not necessarily the same as the first year of the population projection (t_{INIT} , baseline value 1930). Starting the population projection before the first year for which data on abundance are available allows most of the impact of any transient population dynamics caused by the assumption of a stable age-structure to be eliminated. Therefore, the model population should mimic the real population more closely by allowing the sex- and age-selectivity of the catches to correctly influence the sex- and age-distribution of the population once the trajectory reaches years where it is compared to the data (i.e., 1967-68 and beyond).

Output Statistics

The results are summarized by the posterior medians, means and 90% credibility intervals for $MSYR^{1+}$, $MSYL^{1+}$, S_{1+}, S_0, $\tilde{S}$, and K^{1+} and the following management-related quantities:

(a) P^{1+}_{2009} / K^{1+} – the *depletion level*, or the number of 1+ animals at the start of 2009, expressed as a percentage of that corresponding to the equilibrium level;

(b) $P^{1+}_{2009} / MSYL^{1+}$ - the *OSP ratio*, the number of 1+ animals at the start of 2009, expressed as a percentage of that at which *MSY* is achieved; and

(c) $\lambda_{\max}$ – the maximum rate of increase (given a stable age-structure and the assumption of no maximum age; Breiwick et al. 1984)

P^{1+}_{2009} / K^{1+} is termed the *depletion level* because it provides a measure of how depleted the population is relative to the carrying capacity ("*K*"), as the equilibrium level in a density-dependent model is equivalent to carrying capacity. $P^{1+}_{2009} / MSYL^{1+}$ is referred to as the *OSP ratio* because it provides a measure of whether the population is above MNPL ($MSYL^{1+}$ is essentially equivalent to MNPL) and therefore at OSP (e.g, Gerrodette and DeMaster 1990). Because the model is age-structured and includes human removals it is parameterized in terms of $MSYL^{1+}$. $MSYL^{0+}$, which is the population level at which MSY occurs when hunting takes place uniformly on animals aged 0 and older, is exactly equivalent to MNPL. The difference between $MSYL^{1+}$ and $MSYL^{0+}$ is small in a long-lived animal with a relatively slow population growth rate. In the case of the ENP gray whale assessment model, $MSYL^{1+}$ has been found to be nearly equivalent to MNPL (Punt, unpublished data), so we consider $MSYL^{1+}$ to be equivalent to MNPL here for the calculation of the output statistic *OSP ratio*. Populations at OSP will have a value of 1.0 or higher for *OSP ratio*. Note that $\lambda_{\max}$ can be equated to r_{max} (e.g., as in Wade (1998)) through the equation $r_{max} = \lambda_{\max} - 1.0$.

Sensitivity Tests

Our baseline assessment includes the baseline estimates of 1+ abundance (Table 2) and allows for a catastrophic mortality event in 1999-2000. The sensitivity of the results of the analyses is explored to:

(a) Vary the first year considered in the population projection (1940, 1950 and 1960);
(b) Replace the estimates of abundance for the southbound migration by the values used in the previous assessment (Table 2, "Unrevised estimates");
(c) Replace the abundance estimates with the "Lo" and "Hi" series (Table 2)[6];
(d) Ignore the catastrophic event in 1999-2000 (abbreviation "No event");
(e) Base the analysis on the generalized logistic equation (see Appendix for details) (abbreviation "Gen Logist")[7];
(f) Split the abundance series after 1987-88 (abbreviation "Split series"), where the first abundance series is treated as a relative index of abundance scaled to absolute abundance through a constant of proportionality, and the second series is treated as an absolute index of abundance; and
(g) Include the calf counts at Point Piedras Blancas, California (Perryman et al. 2002, Perryman, pers. comm.) in the analysis (abbreviation "With calf counts").

For the last sensitivity test, the contribution of the data on calf counts to the negative of the logarithm of the likelihood function (ignoring constants independent of the model parameters) is

[6] The sequence of gray whale abundance estimates depends in part on the estimates of observer detection probability that were measured with the double observer data. Assessment of matches amongst the pods detected by the observers depends on the weighting parameters for distance and time measurements (Laake et al. 2009). The weighting parameters used for the baseline abundance estimates were selected such that 95% of the observations of the same pod would be correctly matched. Sensitivity is explored to matching weighting parameters that gave a 98% and 90% (Table A2; Laake et al. 2009).
[7] The sensitivity test is provided because the generalized logistic model has been the basis for some previous management advice for this stock (e.g., Wade 2002).

based on the assumption that the calf counts are relative indices of the total number of calves and are subject to both modeled and unmodeled sources of uncertainty; that is,

$$-\ell n L = 0.5\sum_i \ell n(\sigma_i^2 + CV_{\text{add-2}}^2) + 0.5\sum_i \frac{(\ell n C_i^{\text{obs}} - \ell n(q(N_{i,0}^{\text{m}} + N_{i,0}^{\text{f}})))^2}{\sigma_i^2 + CV_{\text{add-2}}^2} \quad , \qquad (12)$$

where C_i^{obs} is the observed number of calves during year *i*,

q is the constant of proportionality between the calf counts and model estimates of the number of calves,

σ_i is the standard deviation of the logarithm of C_i^{obs}, and

$CV_{\text{add-2}}^2$ is the additional variance associated with the calf counts.

Prior Distributions

The prior distributions (Table 3) are generally based on those used in recent International Whaling Commission (IWC) assessments of ENP gray whales. The prior distributions for S_{1+}, K^{1+}, $\tilde{S}$, CV_{add}, $CV_{\text{add-2}}$, and $\ell n q$ were selected to be uniform over a sufficiently wide range so that there is effectively no posterior probability outside of that range.

The prior for the age-at-maturity differs from that used in previous assessments, Uniform[5,9], based on the review by Bradford et al. (unpublished manuscript)[8] who could find no basis for that range in the literature. They concluded that the most relevant data set for age-at-maturity was that of Rice and Wolman (1971), corrected by Rice (1990) for the underestimation of whale ages by one year in the original study, resulting in a median age of 9, and lower and upper bounds of 6 and 12. Bradford et al. (unpublished manuscript) note that the only observation of the age-at-first-reproduction (AFR) in ENP gray whales (a known whale observed with a calf for the first time) was 7 years for a whale first seen as a calf in a lagoon in Mexico. In the western Pacific population of gray whales, there have been observations of AFR of 7 and 11 years for the

[8] Bradford, A.L., D.W. Weller, A.R. Lang, A.M. Burdin, and R.L. Brownell, Jr. Unpublished manuscript. Comparing age at first reproduction information from western gray whale to age at sexual maturity estimates of eastern gray whales. School of Aquatic and Fishery Sciences, Box 355020, University of Washington, Seattle.

only two whales whose first calving has been documented to date (Bradford et al. unpublished manuscript). The prior for the maximum birth rate, $f_{max,}$ was set equal to the prior selected for recent assessments (Wade 2002, Punt and Butterworth 2002). This prior implies a minimum possible calving interval between 1.67 and 3.33 years.

The prior for the population size (in terms of animals aged 1 and older) in 1968 differs from that used in previous assessments. Rather than combining a uniform prior on 1968 population size with the abundance estimate for 1968 to create an informative prior for P_{1968}^{1+} as was the case in previous assessments, this assessment assumes a broad uniform prior for 1968 population size, and includes all of the estimates of abundance in the likelihood function. This is because the previous approach cannot be applied because all of the estimates of abundance are correlated (Laake et al. 2009).

The prior for MSYR is bounded below by the minimum possible value and above by a value which is above those supported by the data. This prior is broader than those considered in previous assessments because those assessments assigned a prior to MSYR when this parameter is expressed in terms of removals of mature animals only. The prior for $MSYL^{1+}$ has been assumed to be uniform from 0.4 to 0.8. The central value for this prior reflects the common assumption when conducting IWC assessments of whale stocks that maximum productivity occurs at about 60% of carrying capacity. The upper and lower bounds reflect values commonly used to bound MSYL for whale stocks (e.g., those used in the tests that evaluated the IWC's catch limit algorithm).

RESULTS

The baseline assessment estimates that ENP gray whales increased substantially from 1930 until 1999 when a substantial reduction in population size from close to carrying capacity (in terms of median parameter estimates) occurred (Fig. 1). This reduction was associated with an estimated decline in non-calf survival from 0.982 to 0.847 (posterior means, where $0.981 \times 0.863 = 0.847$) in each of 1999 and 2000. The population is estimated to have been increasing since 2000. The model fits the data well, although, as in previous IWC assessments, the analyses suggest that the coefficients of variation for the abundance estimates are underestimated (by 14% median estimate). The baseline assessment estimates that this stock is currently well above MSYL^{1+} (posterior mean for $P_{2009}^{1+} / MSYL^{1+}$ of 1.29) (Table 4). The probability that the stock is currently greater than MSYL^{1+} is 0.884.

The probability that the stock is currently above MSYL^{1+} is less for the baseline analysis and for the analysis in which the original abundance estimates are used ("Unrevised estimates" in Table 4) than in some earlier assessments. The reasons for this are explored using the analyses in which no allowance is made for survival having dropped in 1999-2000 ("No Event" and "Unrevised, No event" in Table 4, see also Fig. 2) because the previous assessments did not explicitly account for the mortality event. This comparison suggests that allowing for the possibility of a catastrophic mortality event in 1999-2000 has reduced the ability to constrain the upper bound for carrying capacity because the lower 5% limit for $P_{2009}^{1+} / MSYL^{1+}$ is notably higher for the analyses which ignore this event (Table 4). Bayes factors comparing the analyses which include a 1999-2000 catastrophic mortality event and those which do not provide support for estimating a parameter for the 1999-2000 event; for example, in the baseline analysis the ln(Bayes factor) value is 3.00 compared to the "No event" model, which is interpreted as strong but not definitive support (Kass and Raftery 1995) for including the catastrophic mortality parameter in the model.

The results are insensitive to changing the first year of the analysis (Table 4, Fig. 3). The key management-related results are also not sensitive to splitting the series in 1987-88, using the calf count estimates and using the "Lo" and "Hi" abundance estimates (Fig. 4). The results for the generalized logistic model are most comparable with the two "No event" analyses because no account is taken of a catastrophic mortality event in 1999-2000 when fitting the generalized logistic model (Appendix). While not entirely comparable, the qualitative conclusions from the generalized logistic model are identical to those from the age-structured model.

Figure 5 shows the posterior distributions for the parameters for the baseline analysis. These posteriors show that the data update the priors for MSYR^{1+} and MSYL^{1+} to a substantial extent. The posterior MSYL^{1+} emphasizes higher values for MSYL^{1+}, which is not unexpected given that the rate of increase for the ENP gray whales is assessed to have been high until just before this population (almost) reached its current carrying capacity. The posteriors for the age-at-maturity, maximum fecundity, and adult survival place greatest support on low, high, and high values, respectively. This is consistent with the fairly high growth rates and values for $MSYR^{1+}$. The posterior for the survival multiplier is also updated substantially, with both high (close to 1) and low values (below 0.7) assigned low posterior probability.

The maximum rate of increase, λ_{max}, is well-defined in all of the analyses. The posterior mean estimates of this quantity range from 1.057 to 1.068 and are fairly precisely determined (Table 4).

DISCUSSION

The sensitivity tests were designed to examine the effect of various assumptions on the assessment results and to examine the effect of changes in the methods that have occurred, particularly in the abundance estimation. Overall, the results are consistent across most of the sensitivity tests with some exceptions. In particular, the baseline model fit to the unrevised abundance estimates had relatively different results from the other analyses. Leaving aside that analysis for the moment, the posterior medians for the parameters of interest were relatively consistent. Across all the other analyses, posterior means for K^{1+} ranged from 21,146 to 27,716, for the *depletion level* ranged from 0.76 to 0.96, and for the *OSP ratio* ranged from 1.22 to 1.54. Therefore, as in previous assessments, the ENP gray whale population is estimated to be above $MSYL^{1+}$ and approaching or close to *K*. The estimates of *depletion level* and *OSP ratio* in Wade (2002) and in Punt and Butterworth (2002) are very similar to the results presented here, though the current estimates of *K* are lower. The results in Wade and Perryman (2002) and Brandon (2009), which were the only previous assessments to use abundance estimates from the 1997-98 and subsequent surveys, gave higher and more precise estimates for *depletion level* and *OSP ratio* than estimated here; however, in common with previous assessments, those results are superseded by this new assessment because it uses the revised abundance estimates of Laake et al. (2009).

The posterior means for the life history parameters were very consistent as well, with the posterior means for λ_{max} ranging from 1.057 to 1.068, non-calf survival ranging from 0.972 to 0.983, and calf survival ranging from 0.706 to 0.730. The parameter $MSYL^{1+}$ was updated to strongly emphasize higher values in the baseline analysis. As discussed above, $MSYL^{1+}$ is nearly equivalent to MNPL. There are theoretical arguments for why MNPL should be relatively higher in marine mammals than, say, marine fishes (Eberhardt and Siniff 1977, Fowler 1981, Taylor and DeMaster 1993), but, in general, there has not been empirical data of sufficient quantity and quality to estimate this parameter well in marine mammals (Goodman 1988, Ragen 1995, Gerrodette and DeMaster 1990). Empirical evidence that is available for large, long-lived mammals has shown convex nonlinear density-dependence in life history parameters such as age-specific birth and mortality rates (Fowler et al. 1980; Fowler 1987, 1994), which suggest MNPL > 0.5*K*. A relatively long time-series of abundance estimates has documented the recovery of harbor seal (*Phoca vitulina*) populations in Washington state, and Jeffries et al. (2003) estimated MNPL to be greater than 0.5*K* for these populations. In the ENP gray whale analysis here, values from 0.40 to 0.54 for $MSYL^{1+}$ have low probability in the posterior distribution (Fig. 5, Table 4) which is consistent with the conclusions of Taylor and Gerrodette (1993) that MNPL was likely to be greater than 0.5*K*. Thus, the posterior distribution for $MSYL^{1+}$ estimated here suggests that the ENP gray whale population experienced a decrease in population growth only when it was relatively close to K^{1+}.

The results did not vary much for a large number of the sensitivity tests, providing assurance that the assumptions made for the baseline analysis did not have a substantial influence on the results. Changing the initial year from which the model was projected had little effect on the results, which is similar to the results seen in Punt and Butterworth (2002) for initial years ranging from 1930 to 1968, as used here. The results for the 'Lo' and 'Hi' series of abundance estimates are very similar to the baseline results, suggesting that that those assumptions made in calculating the abundance estimates do not have a strong influence on the results of the assessment. Additionally, splitting the abundance time series in 1987-88 did not have a substantial effect. This is particularly reassuring, because some changes in the field methods happened at that time, notably the use of a second independent observer during that and subsequent surveys (Laake et al. 2009). The generalized logistic model provided similar results to the 'No-event' analysis, with some small differences. This was similar to results seen in Wade (2002), where the quantitative values for some parameters were somewhat different for the generalized logistic, although the qualitative results are nearly identical in this case. That the quantitative results differ between the generalized logistic and the baseline analyses is to be expected because the analysis based on the generalized logistic did not account for the dynamics of sex- and age-structure, and also ignored time-lags in the dynamics.

The baseline analysis fits the abundance data better than in the 'No-event' analysis because it includes the catastrophic mortality event in 1999-2000 (Figs. 1, 2). Furthermore, the Bayes factor confirms that there is strong, but not definitive, evidence supporting the use of a model including the catastrophic mortality. The model estimates that 15.3% of the non-calf population died in each of the years with catastrophic mortality, compared to about 2% in a normal year. In that 2-year period, the model estimates the population fell from being at 99% of K^{1+} in 1998 to 83% in 1999 and 71% in 2000, before increasing back up to 91% by 2009. In contrast, the 'No-event' analysis estimates the population had reached a level very close to K^{1+} by ~1995 and has remained there since, which clearly does not fit with the evidence regarding the biological effects on the population in 1999 and 2000. In the baseline analysis the estimate of the number of whales that died in 1999 and 2000 was 3,303 (90% interval 1,235-7,988) and 2,835 (90% interval 1,162-6,389), respectively, for a combined total for the two years of 6,138 (90% interval 2,398-14,377). In comparison, the 'No-event' analysis estimates that the number of whales that died in 1999 was 587, and in 2000 it was 447. Comparing the number of strandings (from Mexico to Alaska) reported in Gulland et al. (2005) in the years around the mortality event to these estimates of total deaths from the baseline model indicates that only 3.9-13.0% of all ENP gray whales that die in a given year end up stranding and being reported.

The baseline analysis is more conservative regarding status relative to K^{1+} than the 'No-event' analysis. On the other hand, it can be argued that the 'No-event' analysis provides a more accurate estimation of current average K^{1+}. In other words, the baseline analysis does a better job of modeling the actual time-course of the population by including the mortality event, but it might provide an overestimate of the average recent K^{1+} by essentially considering high abundance estimates to be near K^{1+}, but lower abundance estimates to be lower than K^{1+}. The different interpretations hinge on whether K^{1+} is viewed as relatively fixed, with the 1999-2000 mortality event considered to be unrelated to density-dependence (and therefore K^{1+}), or whether K^{1+} is viewed as something that can vary from year to year, with the 1999-2000 years viewed as an event when K^{1+} itself was low. As populations increase in density, the impact of density-independent factors on population dynamics probably become more pronounced (Durant et al.

2005, Wilcox and Eldred 2003). The actual carrying capacity of the environment, in terms of prey available for the ENP gray whale population, is likely to vary from year to year to a greater or lesser extent due to oceanographic conditions affecting primarily benthic production. In terms of the model, the parameter K^{1+} that is being estimated is interpreted as the average carrying capacity in recent years. In the baseline analysis, the estimated K^{1+} is approximately (though not exactly) the average recent K^{1+} for the years before the mortality event, whereas in the 'No-event' analysis, the estimate of average recent K^{1+} includes all the recent years, including 1999-2000, and is lower. This is clear from the results, where the baseline estimate of K^{1+} is 25,808 (90% interval 19,752- 49,639), whereas the 'No-event' estimate of K^{1+} is substantially lower, 21,640 (90% interval 18,301-25,762). Further work that could be conducted would be to model K^{1+} with a distribution defined by two parameters, a mean and a variance, to explicitly allow K^{1+} to vary from one year to the next. If such a model included density-dependence in survival, the 1999-2000 event could be modeled as a substantial decline in K^{1+} in those years rather than as a single event affecting mortality. Such an analysis would provide an estimate of average recent K^{1+} that included the low recent years, 1999-2000.

The analysis using the original unrevised estimates is not a sensitivity test in the usual sense. Those results are provided simply to aid in interpretation of the results of the other analyses relative to past results using the unrevised estimates. For example, no previous analyses other than Brandon (2009) had used the 2006-07 abundance estimate, so this sensitivity test provides a comparison in which both analyses use that estimate. In the 'No-event' model, the analyses using the original and revised abundance estimates are nearly identical for estimates of *depletion level* and *OSP ratio*. *K* was estimated to be higher in the analysis that used the original abundance estimates, but even though *K* is lower using the revised abundance estimates, overall the entire time-series is shifted such that the estimates of status relative to *K* are unchanged.

In contrast, in the baseline model, the original abundance estimates give a fairly different result from any other analysis. From the discussion of how correction factors for the abundance estimates were calculated in different years in Laake et al. (2009), it is clear that the revised abundance estimates should be more accurate, and there were shifts of certain sequences of abundance estimates relative to one another that influence the results. For example, the three estimates from 1993-94 to 1997-98 are the three highest estimates in the original time-series, whereas the three estimates from 1984-85 to 1987-88 are the three highest estimates in the revised time-series. This has an effect on the baseline analysis results because the model is trying to fit the drop in abundance that occurred after the 1997-98 abundance estimate. That drop is substantially larger in the unrevised data set than it is in the revised data set, and therefore the results for the baseline model differ somewhat between the revised and unrevised data sets.

The only previous assessment that modeled the 1999-2000 mortality event was that of Brandon (2009), whose point estimates of total natural mortality in those years ranged from 1,300 to 5,200, depending upon a variety of assumptions he explored, lower than the 6,138 estimated here in the baseline model. The difference presumably arises because Brandon (2009) modeled mortality as a function of a sea-ice index for the Bering Sea, following the relationship found between calf production and sea-ice (Perryman et al. 2002). This constrains the dynamics of the mortality in Brandon (2009) to reflect the dynamics of the index to some extent. In contrast, the 1999-2000 mortality was unconstrained in the baseline analysis here and is essentially estimated by what value fit the drop in abundance estimates best. Brandon (2009) noted this difficulty in his analysis, stating it was not possible in his analysis to fit the strandings data for the 1999-2000 mortality event without allowing for some additional process error in the survival rates during those years.

λ_{max} is estimated to be 1.062 (90% interval 1.032-1.088) in the baseline analysis. This is similar to, but a little lower than, the estimate from Wade (2002) of 1.072 (90% interval 1.039-1.126) and the estimates from Wade and Perryman (2002). The posterior for λ_{max} from the 'No-event' analysis is very similar to this, as is that from the 'No-event' analysis using the unrevised abundance estimates, indicating the lower estimates of λ_{max} seen here are not due entirely to the revision of the abundance estimates but are instead partly due to the additional four abundance estimates used here (1997-98 to 2006-07) that were not available at the time the Wade (2002) analysis was conducted. To get an estimate of λ_{max} of 1.062, the posterior distribution favored a low age-of-maturity, a high maximum fecundity, and a high adult survival. λ_{max} appears to be well-defined, as the posterior medians from most of the sensitivity tests are very similar. It should be noted that these are theoretical estimates of the population growth rate at a very low population size, based upon the density-dependent assumptions of the population model; the

ENP gray whale has not been observed to actually grow this rapidly because the population was estimated to be approaching *K* by the time its growth rate was monitored; consequently, the observed population growth rate was less than its theoretical maximum.

The small and endangered western North Pacific population of gray whales has been estimated to have an annual population increase that is between 2.5% and 3.2% per year, but there is concern that this growth rate is low because of possible Allee effects and from ongoing human-caused mortality (Bradford et al. 2008). Best (1993) summarized the growth rates of eight severely depleted baleen whale populations (other than gray whales) and the values ranged from 3.1% to 14.4%. Some of these estimates were not very precise, and Zerbini et al. (in press) has pointed out that the higher rates are implausible given life-history constraints for (at least) humpback whales (*Megaptera novaeangliae*). In more recent studies of other species, a number of estimates of trend have been similar to the estimates of $\lambda_{\max}$ reported here. In a simulation study based on empirical estimates of life history parameters for humpback whales, Zerbini et al. (in press) estimated maximum rates of increase of 7.5%/year (95% CI = 5.1-9.8%) using one approach and 8.7%/year (95% CI = 6.1-11.0%) using a second approach. Calambokidis et al. (2008) calculated point estimates of 4.9% to 6.7% for the North Pacific humpback whale population using data from a recently completed North Pacific study of humpback whale abundance. Zerbini et al. (2006) used line transect data from sequential surveys to estimate an annual rate of increase for humpback whales in shelf waters of the northern Gulf of Alaska from 1987 to 2003 of 6.6% per year (95% CI: 5.2-8.6%), and for fin whales of 4.8% (95% CI 4.1-5.4%). On the other hand, Mizroch et al. (2004) estimated a rate of increase for North Pacific humpback whales in Hawaii using mark-recapture methods for the years 1980-1996 of 10% per year, but the confidence limits were wide (95% C.I. of 3-16%). Other unpublished estimates are available spanning essentially a similar range as originally reported by Best (1993) (i.e., see IWC SC/61/REP6). In summary, the estimates of $\lambda_{\max}$ reported here are similar to trend estimates seen in other species, but there are also lower and higher values that have been recorded.

As noted above, one of the primary management goals of the U.S. Marine Mammal Protection Act is to maintain populations at OSP, which is considered to be a level above their MNPL. The baseline analysis described here estimates the ENP gray whale population to be at a level above their MNPL (i.e., MSYL^{1+}) because the posterior mean for the *OSP ratio* is 1.29 (with a posterior median of 1.37 and a 90% interval of 0.68-1.51), meaning the population is estimated to be at 129% of MNPL. The baseline model estimates a probability of 0.884 that the population is above MNPL (i.e., the probability that the value of the *OSP ratio* is >1.0). These results are consistent across all our model runs. The baseline model also estimates the ENP gray whale population to be close to *K*, and this is also consistent across all the other model runs.

ACKNOWLEDGMENTS

We thank Jeff Laake, Phillip Clapham, Gary Duker, and James Lee for helpful reviews of drafts of this paper. We also thank the many observers who have collected the gray whale abundance data over the last 40 years.

Table 3. -- The parameters and their assumed prior distributions.

Parameter	Prior distribution
Non-calf survival rate, S_{1+}	U[0.950, 0.999] [a]
Age-at-maturity, a_m	U[6,12][b]
Maximum birth rate, f_{max}	U[0.3, 0.6][a]
Carrying capacity, K^{1+}	U[10 000, 70 000] [c]
Population size in 1968, P^{1+}_{1968}	U[5 000, 20 000][c]
Maximum Sustainable Yield Level, $MSYL^{1+}$	U[0.4, 0.8][a]
Maximum Sustainable Yield Rate, $MSYR^{1+}$	U[0, 0.1][a]
Extra mortality, $\tilde{S}$	U[0.2, 1.0][c]
Additional variance, 1+ abundance estimates, CV_{add}	U[0, 0.35][a,c]
Additional variance, calf counts, CV_{add-2}	U[0.2, 0.8][c,d]
Constant of proportionality, ℓnq	U[-∞, ∞][d,e]

a. Equal to the prior distribution used in the most recent assessments (Punt et al. 2004).

b. Bradford et al. (unpublished manuscript).

c. Preliminary analyses provided no evidence of posterior support for values outside this range.

d. Not used in the baseline analysis.

e. The non-informative prior for a scale parameter (Butterworth and Punt 1996).

Table 4. -- Posterior distributions for the key model outputs (posterior mean, posterior median [in square parenthesis], and posterior 90% intervals) for the baseline analysis and the sensitivity tests.

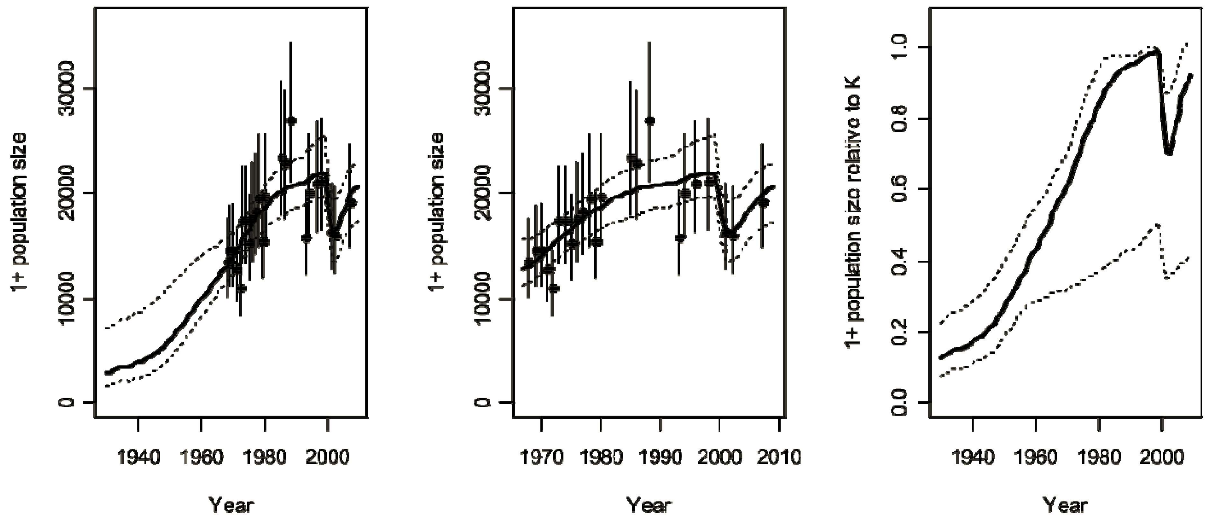

Figure 1. -- Posterior distributions (medians and 90% credibility intervals) for the time-trajectories of 1+ population size (left panels) and 1+ population size expressed relative to (current) carrying capacity (right panel) for the baseline analysis.

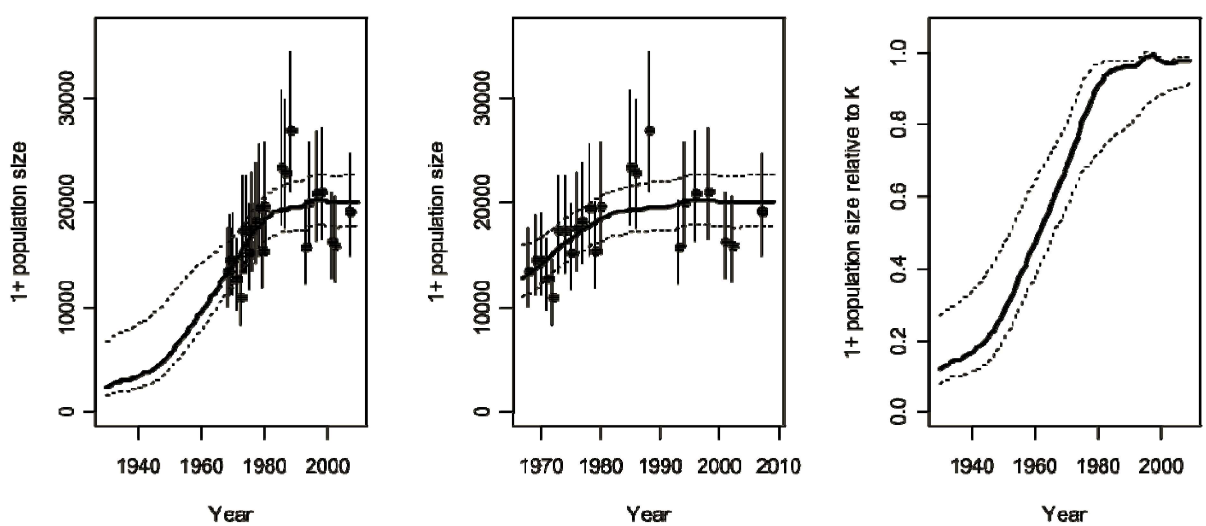

Figure 2. -- Posterior distributions (medians and 90% credibility intervals) for the time-trajectories of 1+ population size (left panels) and 1+ population size expressed relative to (current) carrying capacity (right panel) for the "No event" analysis.

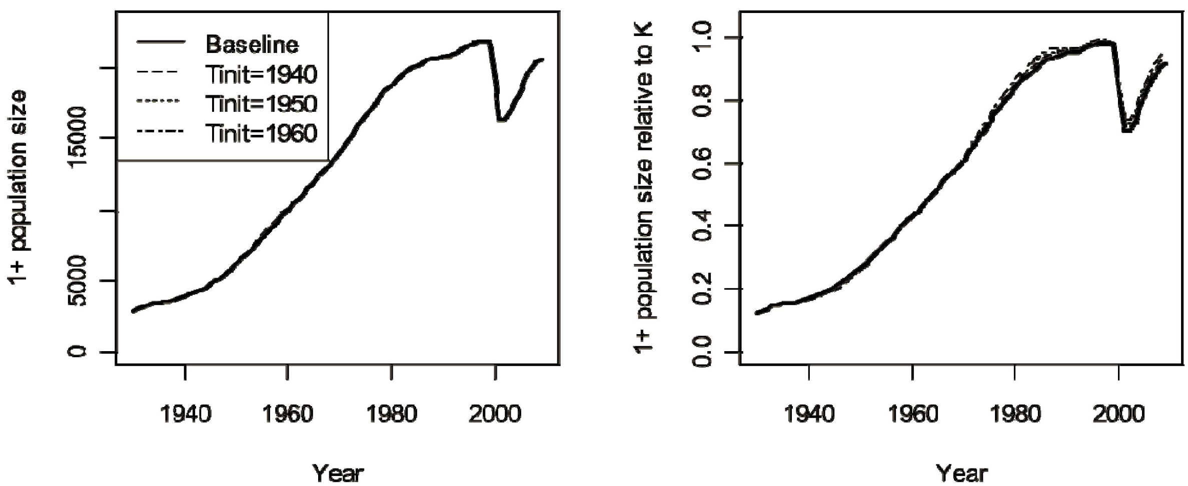

Figure 3. -- Posterior median time-trajectories of 1+ population size (left panel) and 1+ population size expressed relative to (current) carrying capacity (right panel) for the baseline analysis and the sensitivity tests which vary the value for t_{INIT}.

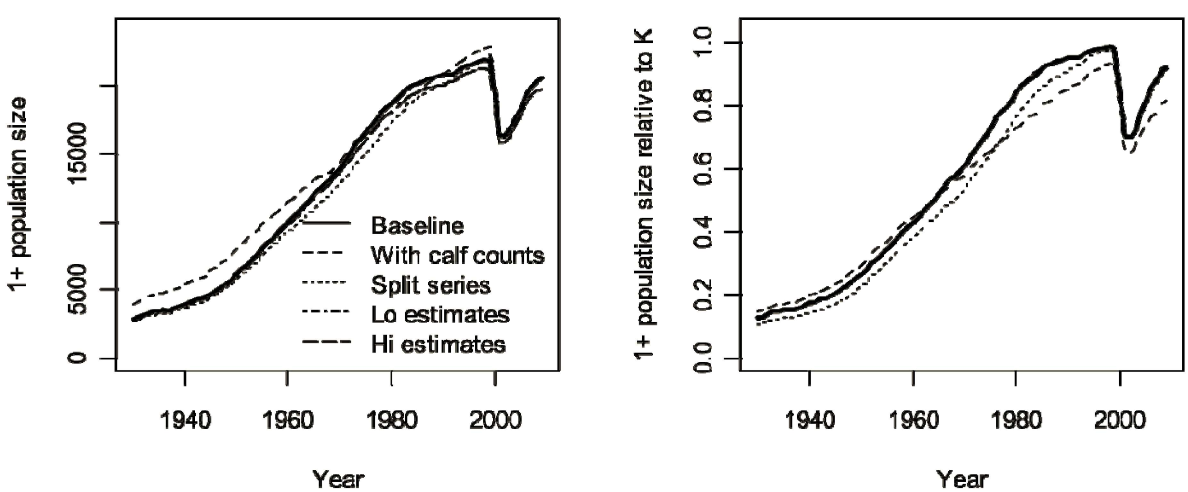

Figure 4. -- Posterior median time-trajectories of 1+ population size (left panel) and 1+ population size expressed relative to (current) carrying capacity (right panel) for the baseline analysis and a subset of the sensitivity tests.

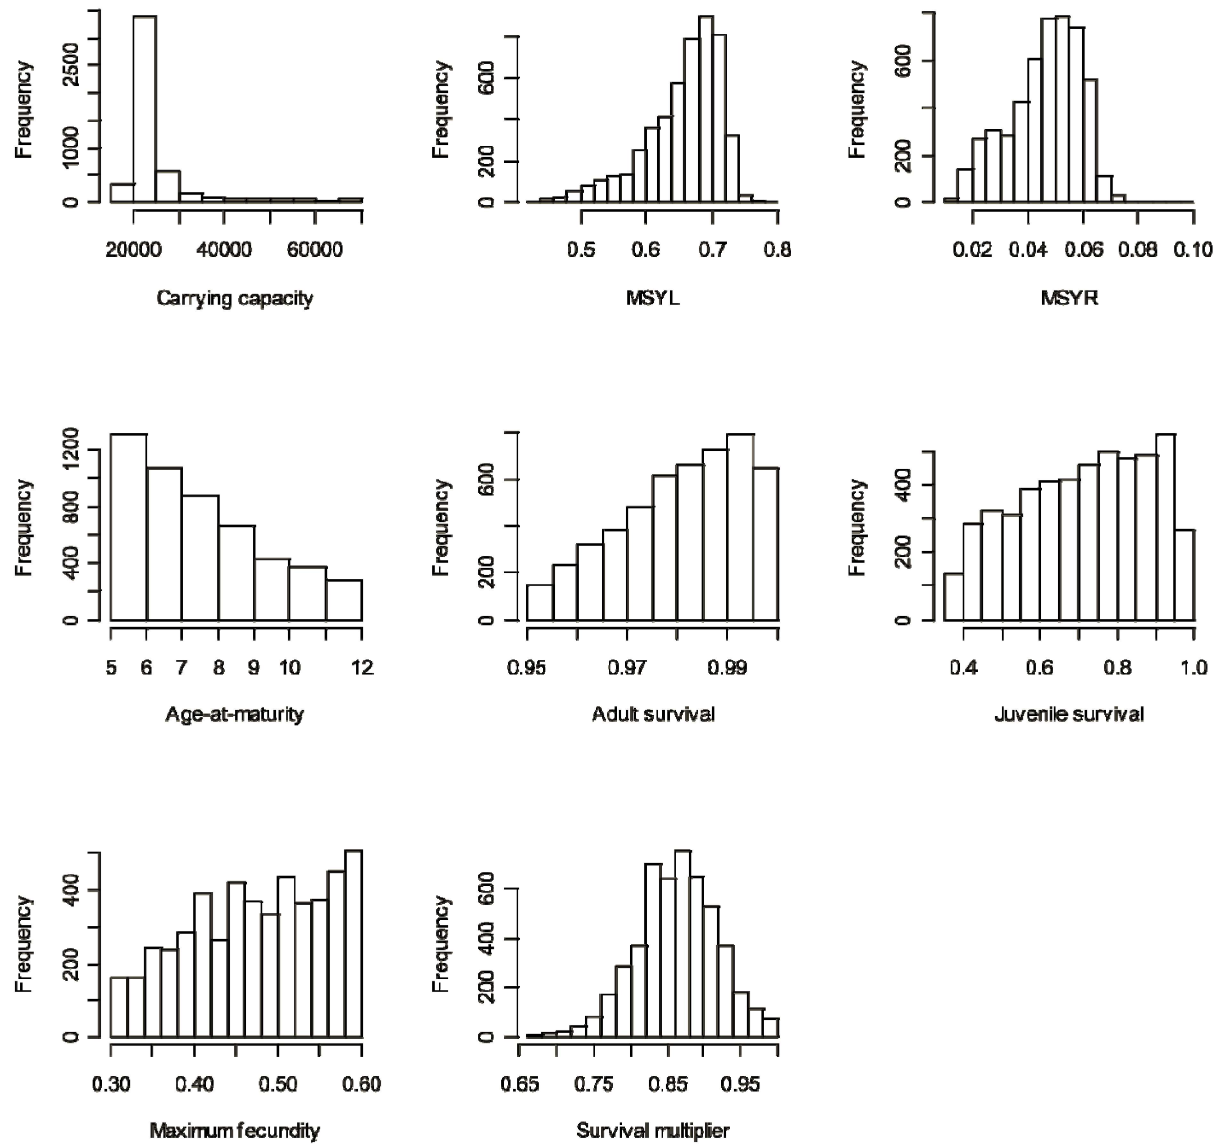

Figure 5. -- Posterior distributions for the parameters of the baseline analysis.

APPENDIX

Analyses Based on the Generalized Logistic Equation

The dynamics of the population are assumed to be governed by the generalized logistic model:

$$N_{y+1} = N_y + rN_y(1-(N_y / K)^z) - C_y \quad , \qquad \text{(App.1)}$$

where N_y is the number of animals at the start of year *y*,

- r is the intrinsic rate of growth,
- z is the extent of compensation,
- K is the (current) carrying capacity, and
- C_y is the catch (in numbers) during year *y*.

The parameters of Equation 1 are *r*, *z*, *K*, and N_{1968} while the data available to estimate these parameters are the estimates of abundance and their associated variance-covariance matrix. The analysis based on the same likelihood function (Eq. 11 of the main text) and priors as the baseline analysis using the age- and sex-structured model.

RECENT TECHNICAL MEMORANDUMS

Copies of this and other NOAA Technical Memorandums are available from the National Technical Information Service, 5285 Port Royal Road, Springfield, VA 22167 (web site: *www.ntis.gov)*. Paper and electronic (.pdf) copies vary in price.

Population status of the eastern North Pacific stock of gray whales in 2009

ANDRE E. PUNT[+] AND PAUL R. WADE*

ABSTRACT

An age- and sex-structured population dynamics model is fitted using Bayesian methods to data on the catches and abundance estimates for the Eastern North Pacific (ENP) stock of gray whales. The prior distributions used for these analyses incorporate revised estimates of abundance for ENP gray whales and account explicitly for the drop in abundance caused by the 1999–2000 mortality event. A series of analyses are conducted to evaluate the sensitivity of the results to different assumptions. The model fits the available data adequately, but, as in previous assessments, the measures of uncertainty associated with the survey-based abundance estimates are found to be negatively biased. The data support the inclusion of the 1999–2000 mortality event in the model, and accounting for this event leads to greater uncertainty regarding the current status of the resource. The baseline analysis estimates the ENP gray whale population to be above the maximum sustainable yield level (MSYL) with high probability (0.884). The posterior mean for the ratio of 2009 (1+) abundance to MSYL is 1.29 (with a posterior median of 1.37 and a 90% probability interval of 0.68–1.51). These results are consistent across all the model runs conducted. The baseline model also estimates the 2009 ENP gray whale population size (posterior mean of 20,366) to be at 85% of its carrying capacity (posterior mean of 25,808), and this is also consistent across all the model runs. The baseline model estimate of the maximum rate of increase, λ_{max}, is 1.062 which, while high, is nevertheless within the range of estimates obtained for other baleen whales.

KEYWORDS: ASESSMENT; GRAY WHALES; WHALING – ABORIGINAL

INTRODUCTION

The eastern North Pacific (ENP) gray whale (*Eschrichtius robustus*) population has been hunted extensively by both commercial and aboriginal whalers. Indigenous peoples of both North America and Russia have hunted gray whales in some locations for centuries and possibly for 2000 years or more (Krupnik, 1984; O'Leary, 1984). The winter breeding grounds of the ENP gray whale (lagoons and adjacent ocean areas in Baja California, Mexico) were discovered by Yankee whalers in the early 19th century, and two commercial whaling vessels first hunted gray whales (in Magdalena Bay) in the winter of 1845–46 (Henderson, 1984). This began a period of intense hunting with large catches of ENP gray whales by Yankee whalers from 1846 until 1873 which decimated the population. Whaling ships and shore-based whalers continued to catch gray whales for the next two decades which drove the population to apparent commercial extinction by 1893. In the 20th century, modern commercial pelagic whaling of ENP gray whales began in 1910 and ended in 1946 when gray whales received full protection under the International Convention for the Regulation of Whaling (Reeves, 1984). Aboriginal catches of ENP gray whales along the Chukotka Peninsula of Russia have continued since 1946 until the present.

From 1846 to 1900 recorded commercial kills numbered nearly 9,000 gray whales, and it is roughly estimated that about 6,500 gray whales were killed by aboriginal hunters during this same period, for a total of more than 15,500 whales caught (Table 1). Since 1900, about 11,500 additional ENP gray whales have been killed by commercial and aboriginal whalers for a total since 1846 of more than 27,000 whales caught (Table 1). The magnitude of the catches, particularly for the period of high exploitation during the 1800s, gives some information on the likely pre-exploitation population size. For example, Jones *et al.* (1984) state that 'most whaling historians and biologists believe the pre-exploitation stock size was between 15,000 and 24,000 animals'.

ENP gray whales migrate along the west coast of North America, and the US National Marine Fisheries Service (NMFS) has taken advantage of this nearshore migration pattern to conduct shore-based counts of the population in central California during December–February from 1967–68 to 2006–07. These survey data have been used to estimate the abundance of the ENP gray whale stock over the survey period (Buckland *et al.*, 1993; Hobbs *et al.*, 2004; Laake *et al.*, 1994; Reilly, 1981; Rugh *et al.*, 2008a; 2005). The resulting sequence of abundance estimates has also been used to estimate the population's growth rate (Buckland and Breiwick, 2002; Buckland *et al.*, 1993), as well as its status relative to the maximum sustainable yield level (MSYL)[1] and carrying capacity (*K*) (Cooke, 1986; Lankester and Beddington, 1986; Punt and Butterworth, 2002; Reilly, 1981; Wade, 2002). However, attempts to model the gray whale population from 1846 until the present, accounting for the catch record and assuming that the stock was at its carrying capacity in 1846, have run into difficulties because the catch history cannot be reconciled with a population that increased at the observed rate from 1967/68 to 1979/80 (Cooke, 1986; Lankester and Beddington, 1986; Reilly, 1981). The

[1] MSYL expressed in terms of 1+ component of the population.

Table 1a

Historical (pre-1944) aboriginal catches from the eastern North Pacific stock of gray whales (C. Allison, IWC Secretariat, pers. comm.).

Years	Annual kill
1600–1675	182
1676–1750	183
1751–1840	197.5
1841–1846	193.5
1847–1850	192.5
1851–1860	187
1861–1875	111
1876–1880	110
1881–1890	108
1891–1900	62
1901–1904	61
1905–1915	57
1916–1928	52
1929–1930	47
1931–1939	10
1940–1943	20

explanation for this is simple; if one assumes a relatively low maximum growth rate, the ENP gray whales would not have been able to increase between 1967/68 and 1979/80 because of the catches during that time, and if one assumes a high maximum growth rate, the population would not be increasing then because it would have already returned to carrying capacity. Butterworth *et al.* (2002) investigated the inability to fit a standard population dynamics model to the data for the ENP gray whales extensively and concluded that the catch history and the observed rate of increase could be reconciled in one of three different ways, which were not mutually exclusive: (1) a 2.5X increase in *K* between 1846 and 1988, (2) a 1.7X increase or more in the commercial catch between 1846 and 1900, and (3) a 3X increase or more in aboriginal catch levels prior to 1846 compared to what was previously assumed (Butterworth *et al.*, 2002).

Given these difficulties, recent gray whale assessments have been conducted by modelling the population since 1930 or later, rather than trying to model the population since 1846 (e.g. Punt and Butterworth, 2002; Wade, 2002). These analyses differed from the earlier assessments by not assuming that the population size in 1846 was *K*. Instead, *K* is essentially estimated by the recent trend in abundance, where a growing population implies that *K* has likely not yet been reached, and a roughly stable population implies the population is at or near *K*. Based on abundance surveys through 1995–96, point estimates of *K* from these analyses ranged from 24,000 to 32,000, but these estimates were relatively imprecise because they had broad probability intervals (Punt and Butterworth, 2002; Wade, 2002). In particular, the results did not exclude the possibility that *K* could be much larger than this range. However, these analyses did suggest that the population was probably close to *K* and at or above its MSYL. For example, Wade (2002) estimated a probability of 0.72 that the population was above $MSYL^{1+}$ in 1996. Punt and Butterworth (2002) also conducted analyses projecting the population from the year 1600 under various assumptions that historic commercial and aboriginal catches were underestimated (as in Butterworth *et al.*, 2002). Those analyses resulted in point estimates of *K* that ranged between 15,000 and 19,000. In those analyses, it was estimated the population was at a very high fraction of *K* in 1996 and had a very high probability of being above $MSYL^{1+}$.

Recently, Rugh *et al*. (2008b) evaluated the accuracy of various components of the shore-based survey method, with a focus on pod size estimation. They found that the correction factors that had been used to compensate for bias in pod size estimates were calculated differently for different sets of years. In particular, the correction factors estimated by Laake *et al*. (1994) were substantially larger than those estimated by Reilly (1981). Also, the estimates for the surveys prior to 1987 in the trend analysis were scaled based on the abundance estimate from 1987–88. This meant that the first 16 abundance estimates used one set of correction factors, and the more recent 7 abundance estimates used different (and larger) correction factors which would influence the estimated trend and population trajectory. In addition, there were other subtle differences in the analysis methods used for the sequence of abundance estimates. Thus, a revaluation of the analysis techniques and of the abundance estimates was warranted to apply a more uniform approach throughout the years. Laake *et al.* (In press) derived a better, more consistent, approach to abundance estimation, and incorporated it into an analysis to re-estimate abundance for all 23 shore-based surveys. These new revised abundance estimates led to the present re-assessment of the ENP gray whale population.

The population is assessed by fitting an age- and sex-structured population model to these revised abundance estimates, using methods similar to those of Wade (2002) and Punt and Butterworth (2002); recent abundance estimates from 1997/98, 2000/01, 2001/02, and 2006/07 that were not available in previous assessments are also used. As in Punt and Butterworth (2002), sensitivity tests are performed to examine various assumptions or modelling decisions.

The analyses also incorporate new information about the biology of the ENP gray whales from recent studies. In particular, it is now recognised that the population experienced an unusual mortality event in 1999 and 2000. An unusually high number of gray whales were stranded along the west coast of North America in those years (Gulland *et al.*, 2005; Moore *et al.*, 2001). Over 60% of the dead whales were adults, and more adults and subadults stranded in 1999 and 2000 relative to the years prior to the mortality event (1996–98), when calf strandings were more common. Many of the stranded whales were emaciated, and aerial photogrammetry documented that migrating gray whales were skinnier in girth in 1999 relative to previous years (Perryman and Lynn, 2002; W. Perryman, SWFSC, pers. comm.). In addition, calf production in 1999 and 2000 was less than one third of that in the previous years (1996–98). In 2001 and 2002, strandings of gray whales along the coast decreased to levels that were below their pre-1999 level (Gulland *et al.*, 2005) and average calf production in 2002–2004 returned to the level seen in pre-1999 years (Table 2). A US Working Group on Marine Mammal Unusual Mortality Events (Gulland *et al.*, 2005) concluded that the emaciated condition of many of the stranded whales supported the idea that starvation could have been a significant contributing factor to the higher number of strandings in 1999 and 2000. Perryman *et al.* (2002) found a

significant positive correlation between an index of the amount of ice-free area in gray whale feeding areas in the Bering Sea and their estimates of calf production for the following spring for the years 1994 to 2000; the suggested mechanism is that longer periods of time in open water provides greater feeding opportunities for gray whales. Whether or not heavy ice cover was ultimately the mechanism that caused the 1999–2000 event, it is clear that ENP gray whales were substantially affected in those years; whales were on average skinnier, they had a lower survival rate (particularly of adults) and calf production was dramatically lower. Given that this event may have affected the status of the ENP gray whale population relative to *K*, an additional model parameter ('catastrophic mortality') has been specified in the model that allowed for lower survival in the years 1999 and 2000 to investigate this effect.

METHODS

Available data

A variety of data sources are available to assess the status of the ENP stock of gray whales. These data sources are used when developing the prior distributions for the parameters of the population dynamics model, when pre-specifying the values for some of the parameters of this model, and when constructing the likelihood function. Table 1 lists the time-series of removals. It should be noted that the catches for the years prior to 1930 are subject to considerable uncertainty, and evaluating these catches remains an active area of research. However, the uncertainty associated with these early catches is inconsequential for this paper because the population projections do not start before 1930.

The key source of information on the abundance of the ENP gray whales is data collected from the southbound surveys that have been conducted since 1967/68 near Carmel, California (Laake *et al.*, In press; Table 2). Information on trends in calf numbers are also available from surveys of calves during the northbound migration (Perryman *et al.*, 2002; W. Perryman, pers. comm.; Table 2). The calf abundance data are not included in the baseline analyses, but are considered in one of the tests of sensitivity.

Analysis methods

The population dynamics model

An age- and sex-structured population dynamics model is used that assumes that all whaling takes place at the start of

the year, and that all animals are 'recruited' to the hunted population by age 5 (i.e. hunting only occurs on animals age 5 and older) (Punt, 1999; Punt and Butterworth, 2002). The dynamics of the population are assumed to be governed by the equations:

$$N^s_{t+1,a} = \begin{cases} 0.5P^M_{t+1}f_{t+1} & \text{if } a=0 \\ N^s_{t,a-1}(1-F^s_{t,a-1})S_{a-1}\tilde{S}_t & \text{if } 1 \le a \le x-1 \\ N^s_{t,x}(1-F^s_{t,x})S_x\tilde{S}_t + N^s_{t,x-1}(1-F^s_{t,x-1})S_{x-1}\tilde{S} & \text{if } a=x \end{cases} \quad (1)$$

where

$N^s_{t,a}$ is the number of animals of age a and sex s (m/f) at the start of year t,

S_a is the annual survival rate of animals of age a in the absence of catastrophic mortality events (assumed to be the same for males and females),

$\tilde{S}_t$ is the amount of catastrophic mortality (represented in the form of a survival rate) during year t (catastrophic events are assumed to occur at the start of the year before mortality due to whaling and natural causes; in general $\tilde{S}_t=1$, i.e. there is no catastrophic mortality),

$F^s_{t,a}$ is the exploitation rate on animals of sex s and age a during year t,

P^M_t is the number of females that have reached the age at first parturition by the start of year t,

$$P^M_t = \sum_{a=a_m+1}^{x} N^f_{t,a} \quad (2)$$

a_m is the age-of-maturity,

f_t is pregnancy rate (number of calves of both sexes per 'mature' female) during year t (note that Equation (1) assumes an equal male : female sex ratio at birth), and

x is the maximum age-class, which for convenience is lumped across older age-classes (i.e. individuals stay in this age-class until they die).

Density dependence on fecundity can be modelled by writing the pregnancy rate, f_t, as follows:

$$f_t = \max\left(f_{eq}\left[1+A\left\{1-\left(\bar{S}_{t-2}P^{1+}_{t-2}/K^{1+}\right)^z\right\}\right],0\right). \quad (3)$$

Where f_{eq} is the pregnancy rate at the pre-exploitation equilibrium, $f(F=0)$[2]:

$$f(F) = 2\left\{\sum_{a=a_m+1}^{x}\tilde{N}^f_a(F)\right\}^{-1} \quad (4)$$

A is the resilience parameter:

$$A = \frac{f_{\max}-f_{eq}}{f_{eq}} \quad (5)$$

f_{max} is the maximum (theoretical) pregnancy rate,

z is the degree of compensation,

P^{1+}_t is number of animals aged 1 and older at the start of year t:

$$P^{1+}_t = \sum_s\sum_{a=1}^{x} N^s_{t,a} \quad (6)$$

K^{1+} is the (current) pre-exploitation equilibrium size (carrying capacity) in terms of animals aged 1 and older, and

$\tilde{N}^s_a(F)$ is the number of animals of sex s and age a when the exploitation rate is fixed at F, expressed as a fraction of the

[2]The pregnancy rate at the pre-exploitation equilibrium can be considered to be the equilibrium pregnancy rate when the exploitation rate, F, is fixed at zero.

number of calves of the same sex s (see appendix 1 of Punt (1999) for details).

Although these equations are written formally as if only the pregnancy rate component of 'fecundity' as defined here is density-dependent, exactly the same equations follow if some or all of this dependence occurs in the infant survival rate (Punt, 1999). Catastrophic mortality is assumed to occur before density-dependence because many of the deaths in 1999 and 2000 occurred before mating was likely to have occurred. Non-catastrophic natural mortality does not appear in Equation 3 because it cancels out. The time-lag in Equation 3 is specified to match the reproductive cycle of gray whales; mature female gray whales mate and become pregnant in early winter, have a gestation period of slightly longer than one year, and give birth at the start of the next year (on average in January) (Rice and Wolman, 1971; Shelden *et al.*, 2004). Their body condition at the end of the summer feeding season will help determine their probability of becoming pregnant the following winter and producing a calf a year later. Therefore, the density-dependent effect on calf production is assumed to be determined by the population size during the feeding season two time-steps prior (approximately 1.5 years earlier).

Following past assessments of the ENP stock of gray whales (e.g. Butterworth *et al.*, 2002; Punt *et al.*, 2004; Punt and Butterworth, 2002), the catch (by sex) is assumed to be taken uniformly from the animals aged five and older, that is:

$$F^s_{t,a} = C^s_t / \sum_{a=5}^{x} N^s_{t,a} \quad (7)$$

Where C^s_t is the catch of animals of sex s during year t.

The population is assumed to have had a stable age-structure at the start of the projection period (year t_{INIT}).

$$N^s_{t_{INIT},a} = N^{Tot}_{t_{INIT}} \tilde{N}^s_a(F_{INIT}) / \sum_{s'} \sum_{a'=0}^{x} \tilde{N}^{s'}_{a'}(F_{INIT}) \quad (8)$$

Where $N^{Tot}_{t_{INIT}}$ is the size of the total (0+) component of the population at the start of year t_{INIT}. The value of F_{INIT} is selected numerically so that:

$$N^{Tot}_{t_{INIT},a} = 0.5 N_0(F_{INIT}) / \sum_{s} \sum_{a=0}^{x} N^s_a(F_{INIT}) \quad (9)$$

Where $N_0(F_{INIT})$ is the number of calves (of both sexes) at the start of the year when $F = F_{INIT}$:

$$N_0(F_{INIT}) = \left(1 - \frac{1}{A}\left[\frac{f(F_{INIT})}{f_{eq}} - 1\right]\right)^{1/z} \frac{K^{1+}}{\tilde{P}^{1+}(F_{INIT})} \quad (10)$$

$\tilde{P}^{1+}(F)$ is the size of the 1+ component of the population as a function of F, expressed as a fraction of the number of calves (of both sexes).

Parameter estimation

Catastrophic mortality is assumed to be zero (i.e. $\tilde{S}_y = 1$) except for 1999 and 2000 when it is assumed to be equal to a parameter $\tilde{S}$. This assumption reflects the large number of dead whales observed stranded along the coasts of Oregon and Washington during 1999 and 2000 relative to numbers stranding there annually historically (Brownell *et al.*, 2007; Gulland *et al.*, 2005).

The parameters of the population dynamics model are a_m; $\tilde{S}$; K^{1+}; the 1+ population size at the start of 1968, P^{1+}_{1968} [3]; $MSYL^{1+}$ (the maximum sustained yield level for the 1+ population, which is the population size at which maximum sustained yield (MSY) is achieved when hunting takes place uniformly on animals aged 1 and older, relative to K^{1+}); $MSYR^{1+}$ (the ratio of MSY to $MSYL^{1+}$); f_{max}; and the non-calf survival rate, S_{1+}. The analysis does not incorporate a prior distribution for the survival rate of calves (S_0) explicitly. Instead, following Wade (2002), an implicit prior distribution for this parameter is calculated from the priors for the five parameters a_m, f_{max} , S_{1+}, $MSYR^{1+}$ and $MSYL^{1+}$. For any specific draw from the prior distributions for these five parameters, the value for S_0 is selected so that the relationships imposed by the population model among the six parameters are satisfied. If the resulting value for S_0 is less than zero or greater than that of S_{1+}, the values for S_{1+}, a_m, f_{max}, $MSYR^{1+}$ and $MSYL^{1+}$ are drawn again[4]. Thus, the prior for S_0 is forced to conform to the intuitive notion that the survival rate of calves must be lower than that for older animals and must be larger than zero (Caughley, 1966).

Under the assumption that the logarithms of the estimates of abundance based on the southbound surveys are normally distributed, the contribution of these estimates to the negative of the logarithm of the likelihood function (ignoring constants independent of the model parameters) is:

$$-\ell nL = 0.5\ell n\left|V + \Omega\right| + 0.5\sum_i \sum_j (\ell n N^{obs}_i - \ell n \hat{P}^{1+}_i)[V + \Omega)^{-1}]_{i,j} (\ell n N^{obs}_j - \ell n \hat{P}^{1+}_j), \quad (11)$$

Where N^{obs}_i is the i^{th} estimate of abundance[5],

$\hat{P}_i$ is the model-estimate corresponding to N^{obs}_i,

V is the variance-covariance matrix for the abundance estimates, and

Ω is a diagonal matrix with elements CV^2_{add} (this matrix captures sources of uncertainty not captured elsewhere; termed 'additional variance' in Wade (2002)).

A Bayesian approach is used to estimate the 'free' parameters of the model based on the prior distributions in Table 3 and the sampling/importance resampling (SIR) algorithm (Rubin, 1988).

(a) Draw values for the parameters S_{1+}, a_m, f_{max}, $MSYR^{1+}$, $MSYL^{1+}$, K^{1+}, P^{1+}_{1968}, $\tilde{S}$, and CV_{add} from the priors in Table 3.

(b) Solve the system of equations that relate S_0, S_{1+}, a_m, f_{max}, $MSYR^{1+}$, $MSYL^{1+}$, A and z (Punt, 1999; Eqs. 18–21) to find values for S_0, A, and z, and find the population size in year t_{INIT} and the population rate of increase in this year, so that, if the population is projected from year t_{INIT}

[3]The 1968 population size is taken to be a measure of initial abundance so that the analyses based on different starting years are comparable in terms of their prior specifications.

[4]The implications of different treatments of how to handle situations in which the calculated value for S_0 is outside of plausible bounds is examined by Brandon *et al.* (2007) .

[5]The abundance estimate for year y/y+1 is assumed to pertain to abundance at the start of year y+1.

to 1968, the total (1+) population size in 1968 equals the generated value for P^{1+}_{1968}.

(c) Compute the likelihood for the projection (see Equation 11).

(d) Repeat steps (a)–(c) a very large number (typically 5 million) of times.

(e) Select 5,000 parameter vectors randomly from those generated using steps (a)–(d), assigning a probability of selecting a particular vector proportional to its likelihood

The above formulation implies that the year for which a prior on abundance is specified (1968) is not necessarily the same as the first year of the population projection (t_{INIT}, baseline value 1930). Starting the population projection before the first year for which data on abundance are available allows most of the impact of any transient population dynamics caused by the assumption of a stable age-structure to be eliminated. Therefore, the model population should mimic the real population more closely by allowing the sex- and age-selectivity of the catches to correctly influence the sex- and age-distribution of the population once the trajectory reaches years where it is compared to the data (i.e. 1967/68 and beyond).

Table 3
The parameters and their assumed prior distributions.

Parameter	Prior distribution
Non-calf survival rate, S_{1+}	U[0.950, 0.999][a]
Age-at-maturity, a_m	U[6,12][b]
Maximum pregnancy rate, f_{max}	U[0.3, 0.6][a]
Carrying capacity, K^{1+}	U[10,000, 70,000][c]
Population size in 1968, P^{1+}_{1968}	U[5,000, 20,000][c]
Maximum Sustainable Yield Level, $MSYL^{1+}$	U[0.4, 0.8][a]
Maximum Sustainable Yield Rate, $MSYR^{1+}$	U[0, 0.1][a]
Catastrophic mortality, $\tilde{S}$	U[0.2, 1.0][c]
Additional variance, 1+ abundance estimates, CV_{add}	U[0, 0.35][a,c]
Additional variance, calf counts, CV_{add-2}	U[0.2, 0.8][c,d]
Constant of proportionality, ℓnq	U[$-\infty$, ∞][d,e]

[a]Equal to the prior distribution used in the most recent assessments (Punt *et al*., 2004); [b]Bradford *et al*. (2010); [c]preliminary analyses provided no evidence of posterior support for values outside this range; [d]not used in the baseline analysis; [e]the non-informative prior for a scale parameter (Butterworth and Punt, 1996).

Output statistics

The results are summarised by the posterior medians, means and 90% credibility intervals for $MSYR^{1+}$, $MSYL^{1+}$, S_{1+}, S_0, $\tilde{S}$, and K^{1+} and the following management-related quantities:

(a) P^{1+}_{2009} is the number of 1+ animals at the start of 2009;

(b) P^{1+}_{2009} / K^{1+} is the depletion level, or the number of 1+ animals at the start of 2009, expressed as a percentage of that corresponding to the equilibrium level;

(c) $P^{1+}_{2009} / MSYL^{1+}$ is the MSYL *ratio*, the number of 1+ animals at the start of 2009, expressed as a percentage of that at which MSY is achieved; and

(d) λ_{max} is the maximum rate of increase (given a stable age-structure and the assumption of no maximum age; Breiwick *et al*., 1984)

P^{1+}_{2009} / K^{1+} is termed the *depletion level* because it provides a measure of how depleted the population is relative to the carrying capacity, as the equilibrium level in a density-dependent model is equivalent to carrying capacity. $P^{1+}_{2009} / MSYL^{1+}$ is referred to as the MSYL *ratio* because it provides a measure of whether the population is above $MSYL^{1+}$ Note that λ_{max} can be equated to r_{max} (e.g. as in Wade, 1998) through the equation $r_{max} = \lambda_{max} - 1.0$.

Sensitivity tests

Our baseline assessment includes the baseline estimates of 1+ abundance (Table 2) and allows for a catastrophic mortality event in 1999–2000. The sensitivity of the results of the analyses is explored to:

(a) varying the first year considered in the population projection (1940, 1950 and 1960);

(b) replacing the estimates of abundance for the southbound migration by the values used in the previous assessment (Table 2, 'Unrevised estimates');

(c) replacing the abundance estimates with the 'Lo' and 'Hi' series (Table 2)[6] ;

(d) ignoring the catastrophic event in 1999–2000 (abbreviation 'No event');

(e) basing the analysis on the generalised logistic equation (see Appendix 1 for details; abbreviation 'Gen Logist')[7];

(f) splitting the abundance series after 1987/88 (abbreviation 'Split series'), where the first abundance series is treated as a relative index of abundance scaled to absolute abundance through a constant of proportionality, and the second series is treated as an absolute index of abundance; and

(g) including the calf counts at Point Piedras Blancas, California (Perryman *et al*., 2002; Perryman, pers. comm.) in the analysis (abbreviation 'With calf counts').

For the last sensitivity test, the contribution of the data on calf counts to the negative of the logarithm of the likelihood function (ignoring constants independent of the model parameters) is based on the assumption that the calf counts are relative indices of the total number of calves and are subject to both modelled and unmodelled sources of uncertainty:

$$-\ell nL = 0.5\sum_i \ell n(\sigma_i^2 + CV_{add-2}^2) + 0.5\sum_i \frac{(\ell nA_i^{obs} - \ell n(q(N_{i,0}^m + N_{i,0}^f)))^2}{\sigma_i^2 + CV_{add-2}^2} \qquad (12)$$

[6]The sequence of gray whale abundance estimates depends in part on the estimates of observer detection probability that were measured with the double observer data. Assessment of matches amongst the pods detected by the observers depends on the weighting parameters for distance and time measurements (Laake *et al*., In press). The weighting parameters used for the baseline abundance estimates were selected such that 95% of the observations of the same pod would be correctly matched. Sensitivity is explored to matching weighting parameters that gave 98% and 90% (table A2; Laake *et al*., In press).

[7]This sensitivity test is provided because the generalised logistic model has been the basis for some previous management advice for this stock (for example, Wade, 2002).

where

A_i^{obs} is the estimate of the number of calves during year i based on the surveys at Point Piedras Blancas;

q is the constant of proportionality between the calf counts and model estimates of the number of calves;

σ_i is the standard error of the logarithm of C_i^{obs} ; and

CV_{add-2}^2 is the additional variance associated with the calf counts.

Prior distributions

The prior distributions (Table 3) are generally based on those used in recent International Whaling Commission (IWC) assessments of ENP gray whales. The prior distributions for S_{1+}, K^{1+}, $\tilde{S}$, CV_{add}, CV_{add-2}, and ℓnq were selected to be uniform over a sufficiently wide range so that there is effectively no posterior probability outside of that range.

The prior for the age-at-maturity differs from that used in previous assessments, Uniform[5,9], based on the review by Bradford *et al.* (2010) who could find no basis for that range in the literature. They concluded that the most relevant data set for age-at-maturity was that of Rice and Wolman (1971), corrected by Rice (1990) for the underestimation of whale ages by one year in the original study, resulting in a median age of 9, and lower and upper bounds of 6 and 12. Bradford *et al.* (2010) note that the only observation of the age-at-first-reproduction (AFR) in ENP gray whales (a known whale observed with a calf for the first time) was 7 years for a whale first seen as a calf in a lagoon in Mexico. In the western Pacific population of gray whales, there have been observations of AFR of 7 and 11 years for the only two whales whose first calving has been documented to date (Bradford *et al.*, unpublished ms). The prior for the maximum pregnancy rate, f_{max}, was set equal to the prior selected for recent assessments (Punt and Butterworth, 2002; Wade, 2002). This prior implies a minimum possible calving interval between 1.67 and 3.33 years.

The prior for the population size (in terms of animals aged 1 and older) in 1968 differs from that used in previous assessments. Rather than combining a uniform prior on 1968 population size with the abundance estimate for 1968 to create an informative prior for P_{1968}^{1+} as was the case in previous assessments, this assessment assumes a broad uniform prior for 1968 population size, and includes all of the estimates of abundance in the likelihood function. This is because the previous approach cannot be applied because all of the estimates of abundance are correlated (Laake *et al.*, In press).

The prior for $MSYR^{1+}$ is bounded below by the minimum possible value and above by a value which is above those supported by the data. This prior is broader than those considered in previous assessments because those assessments assigned a prior to $MSYR^{1+}$ when this parameter is expressed in terms of removals of mature animals only. The prior for $MSYL^{1+}$ has been assumed to be uniform from 0.4 to 0.8. The central value for this prior reflects the common assumption when conducting IWC assessments of whale stocks that maximum productivity occurs at about 60% of carrying capacity. The upper and lower bounds reflect values commonly used to bound MSYL for whale stocks (e.g. those used in the tests that evaluated the IWC's catch limit algorithm).

RESULTS

The baseline assessment estimates that ENP gray whales increased substantially from 1930 until 1999 when a substantial reduction in population size from close to carrying capacity (in terms of median parameter estimates) occurred (Fig. 1). This reduction was associated with an estimated decline in non-calf survival from 0.982 to 0.847 (posterior means, where 0.981 × 0.863 = 0.847) in each of 1999 and 2000. The population is estimated to have been

increasing since 2000. The model fits the data well, although, as in previous IWC assessments, the analyses suggest that the coefficients of variation for the abundance estimates are underestimated (by 14% median estimate). The baseline assessment estimates that this stock is currently well above MSYL^{1+} (posterior mean for P^{1+}_{2009} / MSYL^{1+} of 1.29) (Table 4). The posterior probability that the stock is currently greater than MSYL^{1+} is 0.884.

The posterior probability that the stock is currently above MSYL^{1+} is less for the baseline analysis and for the analysis in which the original abundance estimates are used ('Unrevised estimates' in Table 4) than in some earlier assessments. The reasons for this are explored using the analyses in which no allowance is made for survival having dropped in 1999–2000 ('No Event' and 'Unrevised, No event' in Table 4, see also Fig. 2) because the previous assessments did not explicitly account for the mortality event. This comparison suggests that allowing for the possibility of a catastrophic mortality event in 1999–2000 has reduced the ability to constrain the upper bound for carrying capacity because the lower 5% limit for P^{1+}_{2009} / MSYL^{1+} is notably higher for the analyses which ignore this event (Table 4). Bayes factors comparing the analyses which include a 1999–2000 catastrophic mortality event and those which do not provide support for estimating a parameter for the 1999/2000 event. For example, in the baseline analysis the *ln* (Bayes factor) value is 3.00 compared to the 'No event' model. This is interpreted as strong, but not definitive, support (Kass and Raftery, 1995) for including the catastrophic mortality parameter in the model.

The results are insensitive to changing the first year of the analysis (Table 4, Fig. 3). The key management-related results are also not sensitive to splitting the series in 1987–88, using the calf count estimates and using the 'Lo' and 'Hi' abundance estimates (Fig. 4). The results for the generalised logistic model are most comparable with the two 'No event' analyses because no account is taken of a catastrophic mortality event in 1999–2000 when fitting the generalised logistic model (see Appendix 1). While not entirely comparable, the qualitative conclusions from the generalised logistic model are identical to those from the age-structured model.

Fig. 5 shows the posterior distributions for the parameters for the baseline analysis. These posteriors show that the data update the priors for MSYR^{1+} and MSYL^{1+} to a substantial extent. The posterior for MSYL^{1+} emphasises higher values for MSYL^{1+}, which is not unexpected given that the rate of

increase for the ENP gray whales is assessed to have been high until just before this population (almost) reached its current carrying capacity. The posteriors for the age-at-maturity, maximum fecundity, and adult survival place greatest support on low, high, and high values, respectively. This is consistent with the fairly high growth rates and values for $MSYR^{1+}$. The posterior for the survival multiplier is also updated substantially, with both high (close to 1) and low values (below 0.7) assigned low posterior probability. Sensitivity tests in which the bounds for the priors were widened (results not shown) did not lead to outcomes which differed noticeably from the baseline assessments.

The maximum rate of increase, λ_{max}, is well-defined in all of the analyses. The posterior mean estimates of this quantity range from 1.057 to 1.068 and are fairly precisely determined (Table 4).

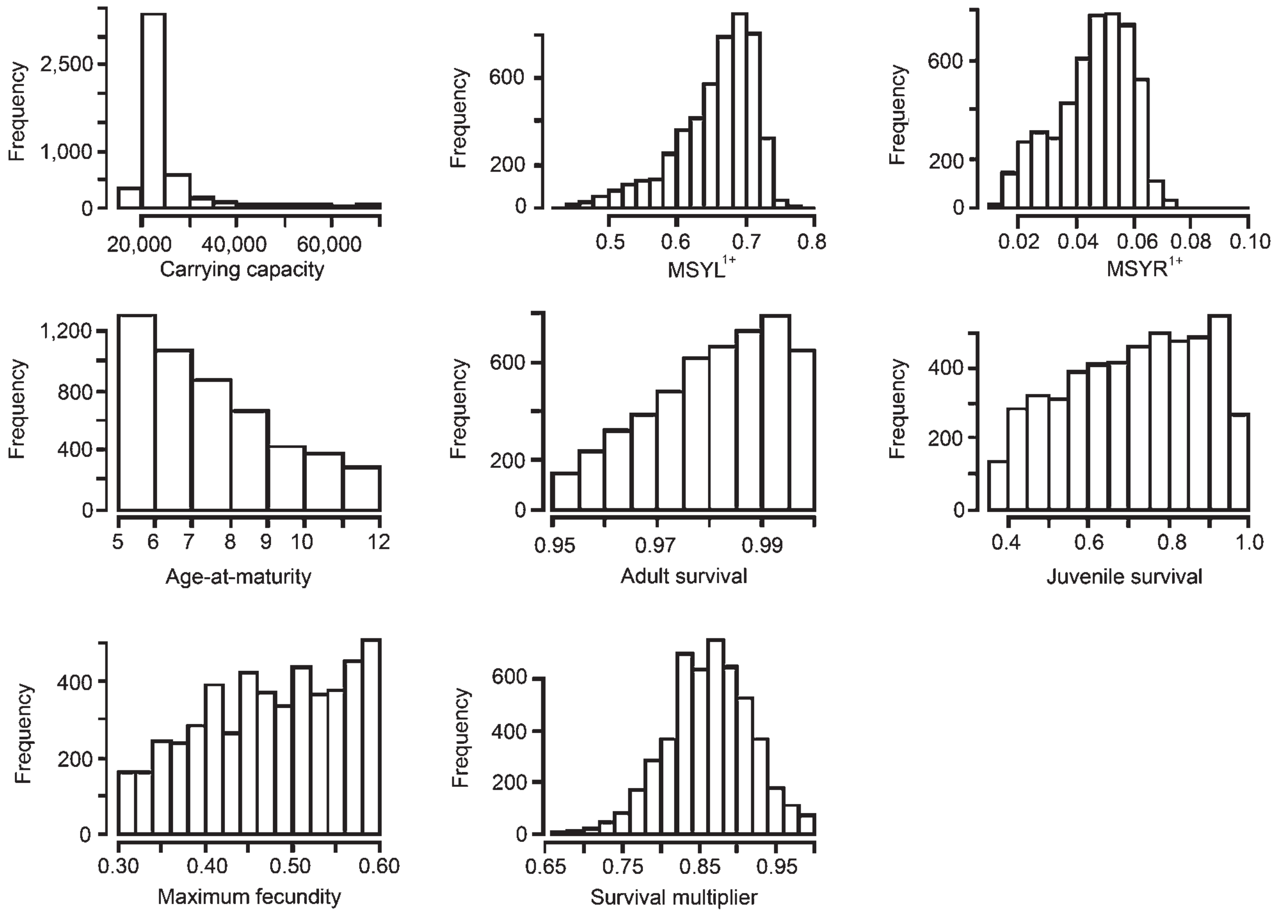

Fig. 5. Posterior distributions for the parameters of the baseline analysis.

DISCUSSION

The sensitivity tests were designed to examine the effect of various assumptions on the assessment results and to examine the effect of changes in the methods that have occurred, particularly related to abundance estimation. Overall, the results are consistent across most of the sensitivity tests with some exceptions. In particular, the baseline model fit to the unrevised abundance estimates had relatively different results from the other analyses. Leaving aside that analysis for the moment, the posterior medians for the parameters of interest were relatively consistent. Across all the other analyses, posterior means for K^{1+} ranged from 21,146 to 27,716, for the *depletion level* ranged from 0.76 to 0.96, and for the *MSYL ratio* ranged from 1.22 to 1.54. Therefore, as in previous assessments, the ENP gray whale population is estimated to be above $MSYL^{1+}$ and approaching or close to *K*. The estimates of *depletion level* and *MSYL ratio* in Wade (2002) and in Punt and Butterworth (2002) are very similar to the results presented here, although our current estimates of *K* are lower. The results in Wade and Perryman (2002) and Brandon (2009), which were the only previous assessments to use abundance estimates from the 1997/98 and subsequent surveys, gave higher and more precise estimates for *depletion level* and *MSYL ratio* than estimated here. However, in common with previous assessments, those results are superseded by this new assessment because it uses the revised abundance estimates of Laake *et al.* (In press).

The posterior means for the life history parameters were very consistent as well, with the posterior means for λ_{max} ranging from 1.057 to 1.068, non-calf survival ranging from 0.972 to 0.983, and calf survival ranging from 0.706 to 0.730. The parameter $MSYL^{1+}$ was updated to strongly emphasise higher values in the baseline analysis. There are theoretical arguments for why MSYL should be relatively higher in marine mammals than, say, marine fishes (Eberhardt and Siniff, 1977; Fowler, 1981; Taylor and DeMaster, 1993), but, in general, there has not been empirical data of sufficient quantity and quality to estimate this parameter well for marine mammals (Gerrodette and DeMaster, 1990; Goodman, 1988; Ragen, 1995). Empirical evidence that is available for large, long-lived mammals has shown convex nonlinear density-dependence in life history parameters such as age-specific birth and mortality rates (Fowler, 1987; 1994; Fowler *et al.*, 1980), which suggest MSYL > 0.5*K*. A relatively long time-series of abundance estimates has documented the recovery of harbour seal (*Phoca vitulina*) populations in Washington state, and Jeffries *et al*. (2003) estimated MSYL to be greater than 0.5*K* for these populations. In the ENP gray whale analysis here, values from 0.40 to 0.54 for $MSYL^{1+}$ have low probability in the posterior distribution (Fig. 5, Table 4) which is consistent with the conclusions of Taylor and Gerrodette (1993) that MSYL was likely to be greater than 0.5*K*. Thus, the posterior distribution for $MSYL^{1+}$ estimated here (posterior means for the baseline analysis of 0.656, range of posterior means 0.611– 0.691), suggests that the ENP gray whale population experienced a decrease in population growth only when it was relatively close to K^{1+}.

The results did not vary much for a large number of the sensitivity tests, providing assurance that the assumptions made for the baseline analysis did not have a substantial influence on the results. Changing the initial year from which the model was projected had little effect on the results, which is similar to the results seen in Punt and Butterworth (2002) for initial years ranging from 1930 to 1968, as used here. The results for the 'Lo' and 'Hi' series of abundance estimates are very similar to the baseline results, suggesting that assumptions made in calculating the abundance estimates do not have a strong influence on the results of the assessment. Additionally, splitting the abundance time series in 1987/88 did not have a substantial effect. This is particularly reassuring, because some changes in the field methods happened at that time, notably the use of a second independent observer during that and subsequent surveys (Laake *et al.*, In press). The generalised logistic model provided similar results to the 'No-event' analysis, with some small differences. This was similar to results seen in Wade (2002), where the quantitative values for some parameters were somewhat different for the generalised logistic, although the qualitative results are nearly identical in this case. That the quantitative results differ between the generalised logistic and our baseline analyses is to be expected because the analysis based on the generalised logistic did not account for the dynamics of sex- and age-structure, and also ignored time-lags in the dynamics.

The baseline analysis fits the abundance data better than in the 'No-event' analysis because it includes the catastrophic mortality event in 1999–2000 (Figs 1 and 2). Furthermore, the Bayes factor confirms that there is strong, but not definitive, evidence supporting the use of a model including the catastrophic mortality. The model estimates that 15.3% of the non-calf population died in each of the years with catastrophic mortality, compared to about 2% in a normal year. In that 2-year period, the model estimates of the population size relative to K^{1+} fell from being at 99% of K^{1+} in 1998 to 83% in 1999 and 71% in 2000, before increasing back up to 91% by 2009. In contrast, the 'No-event' analysis estimates the population had reached a level very close to K^{1+} by ~1995 and has remained there since, which clearly does not match the evidence regarding the biological effects on the population in 1999 and 2000. In the baseline analysis, the estimate of the number of whales that died in 1999 and 2000 was 3,303 (90% interval 1,235–7,988) and 2,835 (90% interval 1,162–6,389), respectively, for a combined total for the two years of 6,138 (90% interval 2,398–14,377). In comparison, the 'No-event' analysis estimates that the number of whales that died in 1999 was 587 and in 2000 it was 447. Comparing the number of strandings (from Mexico to Alaska) reported in Gulland *et al.* (2005) in the years around the mortality event to these estimates of total deaths from the baseline model indicates that only 3.9–13.0% of all ENP gray whales that die in a given year end up stranding and being reported.

The baseline analysis is more conservative regarding status relative to K^{1+} than the 'No-event' analysis. On the other hand, it can be argued that the 'No-event' analysis provides a more accurate estimation of current average K^{1+}. In other words, the baseline analysis does a better job of modelling the actual time-course of the population by including the mortality event, but it might provide an overestimate of the average recent K^{1+} by essentially considering high abundance estimates to be near K^{1+}, but lower abundance estimates to be lower than K^{1+}. The different interpretations hinge on whether K^{1+} is viewed as relatively fixed, with the 1999–2000 mortality event considered to be unrelated to density-dependence (and therefore K^{1+}), or whether K^{1+} is viewed as something that can vary from year to year, with the 1999–2000 years viewed as an event when K^{1+} itself was low. As populations increase in density, the impact of density-independent factors on population dynamics probably becomes more pronounced (Durant *et al.*, 2005; Wilcox and Eldred, 2003). The actual carrying capacity of the environment, in terms of prey available for the ENP gray whale population, is likely to vary from year to year to a greater or lesser extent due to oceanographic conditions affecting primarily benthic production. In terms of the model, the parameter K^{1+} that is being estimated is interpreted as the average carrying capacity in recent years. In the baseline analysis, the estimated K^{1+} is approximately (though not exactly) the average recent K^{1+} for the years before 1999–2000, whereas in the 'No-event' analysis, the estimate of average recent K^{1+} includes all the recent years, including 1999–2000, and is lower. This is clear from the results, where the baseline estimate of K^{1+} is 25,808 (90% interval 19,752–49,639), whereas the 'No-event' estimate of K^{1+} is substantially lower, 21,640 (90% interval 18,301–25,762).

The analysis using the original unrevised estimates is not a sensitivity test in the usual sense. Those results are provided simply to aid in interpretation of the results of the other analyses relative to past results using the unrevised estimates. For example, no previous analyses other than Brandon (2009) had used the 2006/07 abundance estimate, so this sensitivity test provides a comparison in which both analyses use that estimate. In the 'No-event' model, the analyses using the original and revised abundance estimates are nearly identical for estimates of *depletion level* and *MSYL ratio*. K^{1+} was estimated to be higher in the analysis that used the original abundance estimates, but even though K^{1+} is lower using the revised abundance estimates, overall the entire time-series is shifted such that the estimates of status relative to K^{1+} are unchanged.

In contrast, in the baseline model, the original abundance estimates give a fairly different result from any other analysis. From the discussion of how correction factors for the abundance estimates were calculated in different years in Laake *et al.* (In press), it is clear that the revised abundance estimates should be more accurate, and there were shifts of certain sequences of abundance estimates relative to one another that influence the results. For example, the three estimates from 1993/94 to 1997/98 are the three highest estimates in the original time-series, whereas the three estimates from 1984/85 to 1987/88 are the three highest estimates in the revised time-series. This has an effect on the baseline analysis results because the model is trying to fit the drop in abundance that occurred after the 1997/98 abundance estimate. That drop is substantially larger in the unrevised data set than it is in the revised data set, and therefore the results for the baseline model differ somewhat between the revised and unrevised data sets.

The only previous assessment that modelled the 1999–2000 mortality event was that of Brandon (2009), whose point estimates of total natural mortality in those years ranged from 1,300 to 5,200, depending upon a variety of assumptions he explored, lower than the 6,138 estimated here in the baseline model. The difference presumably arises because Brandon (2009) modelled mortality as a function of a sea-ice index for the Bering Sea, following the relationship found between calf production and sea-ice (Perryman *et al.*, 2002). This constrains the dynamics of the mortality in Brandon (2009) to reflect the dynamics of the index to some extent. In contrast, the 1999–2000 mortality was unconstrained in the baseline analysis here and is essentially estimated by what value fit the drop in abundance estimates best. Brandon (2009) noted this difficulty in his analysis, stating it was not possible in his analysis to fit the strandings data for the 1999–2000 mortality event without allowing for some additional process error in the survival rates during those years.

λ_{max} is estimated to be 1.062 (90% interval 1.032–1.088) in the baseline analysis. This is similar to, but a little lower than, the estimate from Wade (2002) of 1.072 (90% interval 1.039–1.126) and the estimates from Wade and Perryman (2002). The posterior for λ_{max} from the 'No-event' analysis is very similar to this, as is that from the 'No-event' analysis using the unrevised abundance estimates, indicating the lower estimates of λ_{max} seen here are not due entirely to the revision of the abundance estimates but are instead partly due to the additional four abundance estimates used here (1997/98 to 2006/07) that were not available at the time the Wade (2002) analysis was conducted. To get an estimate of λ_{max} of 1.062, the posterior distribution favoured a low age-of-maturity, a high maximum fecundity, and a high adult survival. λ_{max} appears to be well-defined, as the posterior medians from most of the sensitivity tests are very similar. It should be noted that these are theoretical estimates of the population growth rate at a very low population size, based upon the density-dependent assumptions of the population model; the ENP gray whale has not been observed to actually grow this rapidly because the population was estimated to be approaching *K* by the time its growth rate was monitored; consequently, the observed population growth rate was less than its theoretical maximum.

The small and endangered western North Pacific population of gray whales has been estimated to have an annual population increase that is between 2.5% and 3.2% per year, but there is concern that this growth rate is low because of possible Allee effects and from ongoing human-caused mortality (Bradford *et al.*, 2008). Best (1993) summarised the growth rates of eight severely depleted baleen whale populations (other than gray whales) and the values ranged from 3.1% to 14.4%. Some of these estimates were not very precise, and Zerbini *et al*. (2010) suggested that the higher rates are implausible given life-history constraints for (at least) humpback whales (*Megaptera novaeangliae*). In more recent studies of other species, a number of estimates of trend have been similar to the estimates of λ_{max} reported here. In a simulation study based on empirical estimates of life history parameters for humpback whales, Zerbini *et al.* (2010) estimated maximum rates of increase of 7.5%/year (95% CI 5.1–9.8%) using one approach and 8.7%/year (95% CI 6.1–11.0%) using a second approach. Calambokidis *et al*. (2008) calculated point estimates of 4.9% to 6.7% for the North Pacific humpback whale population using data from a recently completed North Pacific study of humpback whale abundance. Zerbini *et al.* (2006) used line transect data from sequential surveys to estimate an annual rate of increase for humpback whales in shelf waters of the northern Gulf of Alaska from 1987 to 2003 of 6.6% per year (95% CI 5.2–8.6%), and for fin whales of 4.8% (95% CI 4.1–5.4%). On the other hand, Mizroch *et al*. (2004) estimated a rate of increase for North Pacific humpback whales in Hawaii using mark-recapture methods for the years 1980–1996 of 10% per year, but the confidence limits were wide (95% CI 3–16%). Other unpublished estimates are available spanning essentially a similar range as originally reported by Best (1993) (i.e. see IWC, 2010)). In summary, the estimates of λ_{max} reported here are similar to trend estimates seen in other species, but there are also lower and higher values that have been recorded.

ACKNOWLEDGEMENTS

We thank Jeff Laake, Phillip Clapham and two anonymous reviewers for helpful reviews of drafts of this paper.

Appendix 1

ANALYSES BASED ON THE GENERALISED LOGISTIC EQUATION

The dynamics of the population are assumed to be governed by the generalized logistic model:

$$N_{y+1} = N_y + rN_y(1-(N_y/K)^z) - C_y \qquad \text{(App.1)}$$

where N_y is the number of animals at the start of year y;

r is the intrinsic rate of growth;

z is the extent of compensation;

K is the (current) carrying capacity; and

C_y is the catch (in numbers) during year y.

The parameters of Equation (App.1) are r, z, and K while the data available to estimate these parameters are the estimates of abundance and their associated variance-covariance matrix. The analysis is based on the same likelihood function (Eqn (11) of the main text) and priors as the baseline analysis using the age- and sex-structured model.

Human-caused mortality due primarily to bycatch in fisheries is considered a major threat to some long-lived, slow-growing, and otherwise vulnerable marine species. Under many jurisdictions these species are designated as “protected”, and fisheries are subject to a management system that includes monitoring and assessment of bycatch impacts relative to management objectives. The US management system for marine mammals is one of the most sophisticated in the world, with a limit on human-caused mortality computed using the potential biological removal (PBR), formula. Fisheries are categorized according to their impact relative to PBR, and take reduction teams established to develop take reduction plans (TRPs) when bycatch exceeds PBR. The default values of the parameters of the PBR formula were selected in the late 1990s using management strategy evaluation (MSE), but the system, in particular the classification of fisheries, has yet to be evaluated in its entirety. A MSE framework is developed that includes the PBR formula, as well as the processes for evaluating whether a stock is “strategic”, assigning fisheries to categories, and implementing TRPs. The level of error associated with fisheries classification was found not to impact the ability to achieve the conservation objective established for a stock under the US Marine Mammal Protection Act (i.e. maintain or recover the stock to/at optimum sustainable population). However, this ability is highly dependent on the life history and absolute abundance of the species being managed, as well as on the premise that bycatch is reduced if bycatch is estimated to exceed the PBR. The probability of correctly classifying fisheries depends on both the coefficient of variations (CVs) of the estimates of bycatch and the marine mammal stock’s abundance because classification depends on the ratio of the estimate of bycatch by fishery-type to the stock’s PBR, and the precision of the former depends on the bycatch CV and the latter on the abundance estimate CV. Moreover, the probability of correctly classifying a fishery decreases for smaller populations, particularly when a fishery has low to moderate impact.

Keywords: bycatch, conservation, fishery management, management strategy evaluation, marine mammals, MMPA, PBR, simulation

Introduction

Human-caused mortality due primarily to bycatch in fisheries is considered a major threat to some long-lived slow-growing marine species, including several stocks of marine mammals (e.g. Read *et al.*, 2006; Reeves *et al.*, 2013). Species subject to incidental mortality are often consequently designated as “protected”, and the fisheries that are the source of incidental mortality managed to reduce impacts. The “potential biological removal (PBR) approach”, which involves the calculation of a limit on human-caused mortality, is written into the 1994 amendments to the US Marine Mammal Protection Act (MMPA, originally enacted in 1972), and has been considered for several other long-lived species worldwide subject to incidental mortality. Examples include: marine mammals in Canada (e.g. Hammill and Stenson, 2007;

Stenson *et al.*, 2012) and the United Kingdom (Butler *et al.*, 2008); pilot whales (*Globicephala macrorhynchus*) in Japan (Kanaji *et al.*, 2011); dugongs (*Dugong dugon*) in the Torres Strait, between Australia and Papua New Guinea (Marsh *et al.*, 2004); and sea-birds (Dillingham and Fletcher, 2011), sea-lions (*Phocarctos hookeri;* Maunder *et al.*, 2000), seabirds (Richard and Abraham, 2013), and Hector's dolphins (*Cephalorhynchus hectori*) in New Zealand (Slooten and Dawson, 2008; Slooten, 2013).

The PBR is calculated by applying a harvest control rule (or in this context a removal control rule) that is the product of three parameters: (i) a minimum estimate of abundance that "provides reasonable assurance that the stock size is equal to or greater than the estimate" (N_{MIN}); (ii) one-half of the maximum intrinsic rate of population growth (0.50 R_{MAX}); and (iii) a recovery factor (F_R) between 0.1 and 1.0 (Wade, 1998), i.e.:

$$\text{PBR} = N_{MIN} 0.50\, R_{MAX} F_R \quad (1)$$

Within the United States, the default values of parameters of the PBR formula are $R_{MAX} = 0.04$ for cetaceans and 0.12 for pinnipeds, N_{MIN} = the lower 20th percentile of the (log-normal) distribution for recent abundance estimates, and F_R selected depending on the status of the stock (Wade, 1998). These default values were selected by Wade (1998) using a management strategy evaluation (MSE) approach (Punt *et al.*, 2016) to achieve a primary goal of the MMPA, which is to allow stocks of marine mammals to be maintained at or above their optimum sustainable population (OSP) level (MMPA, 1972). To capture uncertainty associated with management of marine mammal (and other protected) species subject to incidental mortality, the MSE considered scenarios related to productivity, the value for maximum net productivity level (MNPL), the proxy for OSP, the precision and bias with which estimates of abundance are obtained, and how close estimated incidental catches are to the PBR (Wade, 1998).

Although the PBR approach has been the subject of substantial simulation testing (e.g. Wade, 1998; Taylor *et al.*, 2000; Brandon *et al.*, 2017), those simulation studies made assumptions that do not fully capture the actual manner in which human-caused mortality of marine mammals is managed with respect to commercial fisheries in the United States and likely other jurisdictions where fishery interactions with protected species are managed.

Areas were the earlier simulation tests do not mimic the actual US management system include that removals of marine mammals were assumed to be normally distributed about the PBR. In addition, the PBR formula is only one part of the management system. Specifically, the US management system also involves determining whether a stock is "strategic", classifying fisheries based on the magnitude of the mortality and serious injury (MSI) they cause relative to PBR; establishing take reduction teams (TRTs) if thresholds are exceeded, and implementing take reduction plans (TRPs) for those fisheries (Figure 1). Importantly, for the US system, only stocks that are assessed to be strategic and fisheries assessed to have frequent or occasional interactions need to be managed (although restrictions can and have also been placed on fisheries with a low chance of interactions). A full evaluation of the management system that accounts for the common sources of uncertainty associated with making these assessments (whether a stock is strategic and classifying fisheries) is needed since management measures to limit incidental mortality of marine species focus to a large extent on limiting bycatch in fisheries. Systems for management marine mammal bycatch elsewhere in the world (such as that used in New Zealand to manage the impact of the fishery for squid on Hooker's sea lions) are similar to that the US system, but there is no formal process for assessing species to be strategic and classifying fisheries in terms of their impacts on Hooker's sea lions.

This article develops a MSE framework that mimics the US system for managing marine mammal–fishery interactions, to the extent that it is possible to represent this system within a set of rules that can be simulated. It then examines the implications, in terms of achieving the primary goal of maintaining stocks at/above their OSP size, of various uncertainties not considered by Wade (1998), Taylor *et al.* (2000), and Brandon *et al.* (2017),

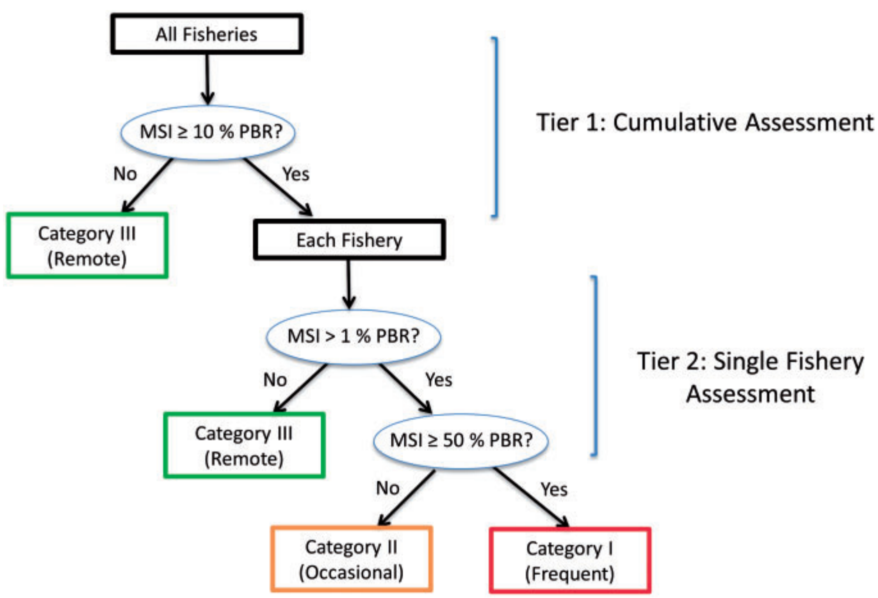

Figure 1. Process followed to develop Take Reduction Plans and establish bycatch reduction goals. MSI = Mortality and Serious Injury; ESA = Endangered Species Act. This study addresses the strategic stock i.e. where the stock is depleted.

in particular the impact of demographic stochasticity, which is likely pertinent for several cetacean stocks as they are of sizes at which demographic uncertainty may be influential. This article then explores the performance of the management system when there are multiple fisheries and different levels of monitoring of abundance and incidental mortality.

The analyses evaluate (i) the probability of mis-classifying a stock as non-strategic and hence the conservation implications of failing to trigger management actions, and (ii) the probability of incorrectly classifying fisheries given uncertainty in estimates of removals and abundance. The use of these performance metrics therefore extends the analyses of Wade and DeMaster (1999) who explored the probability of mis-classifying stocks as strategic. The analyses consider a variety of scenarios to explore the effects of uncertainty. In particular, the analyses consider scenarios that vary the frequency and precision with which estimates of abundance become available as this may have an impact on the ability to correctly identify a stock as strategic and classify fisheries. It also includes scenarios that vary the precision of estimates of bycatch among fisheries, which will also influence the ability to correctly identify a stock as strategic, as well as the ability to correctly identify the fisheries that are likely to be having the largest impacts on the stock. Simulations were performed under two constraints: (i) once a stock is designated strategic it remains strategic throughout the simulation and (ii) classification of fisheries is performed every 5 years.

Methods

Overview of MSE

MSE is the use of simulation to assess the performance of management strategies (combinations of data collection schemes, methods for analysing the data collected, and harvest/removal control rules). MSE has been used extensively to evaluate management strategies for fish, invertebrate and marine mammal stocks (Punt and Donovan, 2007; Punt *et al.*, 2016) and has also been recommended for application in terrestrial situations (e.g. Bunnefeld *et al.*, 2011). It involves the development of an "operating model" that represents the system being managed and how the system is monitored. In this case, the operating model includes the marine mammal stock, the fisheries that cause incidental mortality, and how monitoring occurs for abundance and incidental mortality (Figure 2). Several versions of the operating model are created to allow various sources of uncertainty to be represented. The second major component of an MSE is the management strategy. In the case of the US marine mammal management system, the management strategy includes the PBR formula as well as the rules for determining if a stock is strategic, classifying fisheries in terms of their impact on marine mammal stocks and recommended management measures. The overall steps of an MSE are: (i) develop the operating model; (ii) specify the sources and range of uncertainties to be considered and thereby the "simulation experiments" to be undertaken; (iii) define performance metrics that quantify the management objectives; (iv) select the candidate management strategies; (v) conduct projections; and (vi) summarize the results (Punt *et al.*, 2016).

A MSE for the US marine management system

The PBR applies to all sources of incidental human-caused MSI experienced by stocks of marine mammals. Consequently, human-caused "mortality" in the MSE is understood to encompass both outright deaths and serious injuries, i.e. MSI. For the purposes of this article, only MSI due to fisheries is modelled.

Biological component of the operating model

The biological component of the operating model is an age- and sex-structured population dynamics model that operates on integers (Equation T1.1), where the numbers of births and deaths are binomial random variables. The number of calves produced each year depends on the number of females that have reached the age of first parturition (Equation T1.4) and a birth rate that is density-dependent, with the extent of density-dependence a function of the abundance of animals aged 1 and older relative to carrying capacity (Equation T1.5) (Table 1).

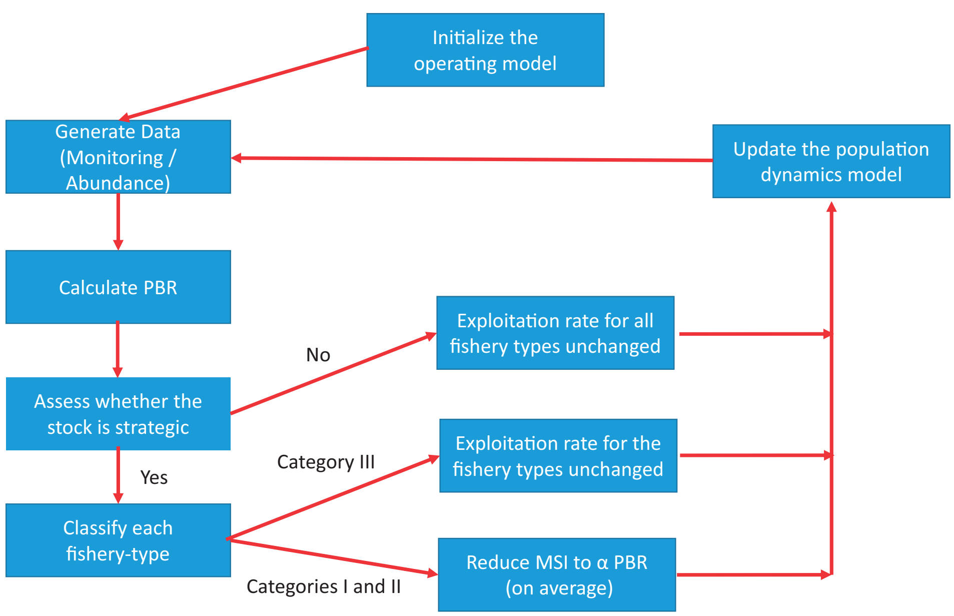

Figure 2. Overview of the steps for the MSE.

Table 1. The population dynamic equations underlying the operating model.

Equation No	Equation	Description
Population dynamics		
T1.1	$N^s_{t+1,a} = \begin{cases} B(C_{t+1}, 0.5) & \text{if } a = 0 \\ B\left(N^s_{t,a-1} - M^s_{t,a-1}, S_{a-1}\right) & \text{if } 1 \le a < x \\ B\left(N^s_{t,x-1} - M^s_{t,x-1}, S_{x-1}\right) + B\left(N^s_{t,x} - M^s_{t,x}, S_x\right) & \text{if } a = x \end{cases}$	Basic population dynamics
T1.2	$B(z,p)$	Binomial distribution with parameters *z* and *p*
T1.3	$C_t = B(P_t, b_t)$	Calf production
T1.4	$P_t = \sum_{a=a_p}^{x} N^{fem}_{t,a}$	Breeding females
T1.5	$b_t = b_{eq}\max\left\{0, 1 + \left(b_{max}/b_{eq} - 1\right)\left[1 - \left(N^{1+}_t/K^{1+}\right)^{\theta}\right]\right\}$	Density-dependent birth rate
T1.6	$N^{1+}_t = \sum_s \sum_{a=1}^{x} N^s_{t,a}$	Number of animals aged 1 and older
T1.7	$M^s_{t,a} = \sum_{f=1}^{N_f} M^{s,f}_{t,a}$	Human-caused mortality by sex and age
T1.8	$M^{s,f}_{t,a} = B\left(N^s_{t,a} - \sum_{f'=1}^{f-1} M^{s,f'}_{t,a}, \phi^{s,f}_s \tilde{F}^f_t\right)$	Human-caused mortality by sex, age, and fishery-type
T1.9	$\tilde{F}^f_t = F^f_t / \left(1 - \sum_{f'=1}^{f-1} F^{f'}_t\right)$	Effective removal rate by fishery-type
Data generation		
T1.10	$\hat{N}_t = \beta N^{1+}_t e^{\epsilon_y - \sigma^2/2}\ \epsilon_y \sim N(0;\sigma^2)$	Estimates of abundance

Table 2 provides the definitions for the symbols.

Table 2. The symbols included in the specification of the operating model.

Symbol	Description
C_t	Number of calves at the start of year *t*
F^f_t	Unconditional removal rate for fully-vulnerable animals during year *t* (i.e. the probability of a fully-vulnerable animal being removed during year *t* by fishery-type *f*)
$\tilde{F}^f_t$	Removal rate for fully vulnerable animals that have survived fishery-types 1, 2,. . ., *f*–1
K^{1+}	Carrying capacity in terms of the number of animals aged 1 and older
$\hat{M}_t$	Estimate of the mortality during year *t*
$\hat{M}^f_t$	Estimate of the mortality by fishery-type *f* during year *t*
$M^s_{t,a}$	Human-caused mortality of sex *s* and age *a* during year *t*
$M^{s,f}_{t,a}$	Human-caused mortality of sex *s* and age *a* by fishery-type *f* during year *t*
N^f	Number of fishery-types
$\hat{N}_t$	Estimate of the number 1+ animals at the start of year *t*
$N^s_{t,a}$	Number of animals of age *a* and sex *s* (m/fem), at the start of year *t*
N^{1+}_t	Number of animals aged 1 and older at the start of year *t*
P_t	Number of females that have reached the age of first parturition (a_p) at the start of year *t*
S_a	Survival rate for animals of age *a*
a_p	Age-at-first parturition
b_t	Birth rate during year *t*
b_{eq}	Birth rate when the population is at carrying capacity; $b_{eq} = (\sum_{a=a_p}^{s} \tilde{N}^{fem}_a)^{-1}$
b_{max}	Birth rate in the limit of zero population size
x	Plus-group age (values for the population dynamics parameters, including human-caused mortality rates, are the same from age *x* onwards)
β	Extent of bias in the abundance estimate
$\phi^{s,f}_a$	Relative vulnerability of animals of age *a* and sex *s* to fishery-type *f*
θ	Shape parameter, which determines where MNPL occurs relative to carrying capacity
σ	The standard error of the observation errors, i.e. $\sigma^2 = \ell n(1 + CV^2_N)$, where CV_N is the coefficient of variation about the true abundance
χ	Relative 1+ population size at the start of the projection period

The number of animals by age and sex in the unfished state (years −500 or −30) are computed based on a pre-specified value for the number of 1+ animals and the relative numbers by age in the unfished state. The age and sex structure at the start of the first year that the management system is applied (year 0) is computed by projecting the population forward to year 0 under a constant probability of being bycaught and solving for this probability, $\bar{F}^f$ (i.e. $F^f_t = \bar{F}^f$) so that the number of 1+ animals at the start of the first year relative to K^{1+} (the carrying capacity in terms of 1+ animals) equals a pre-specified value, χ.

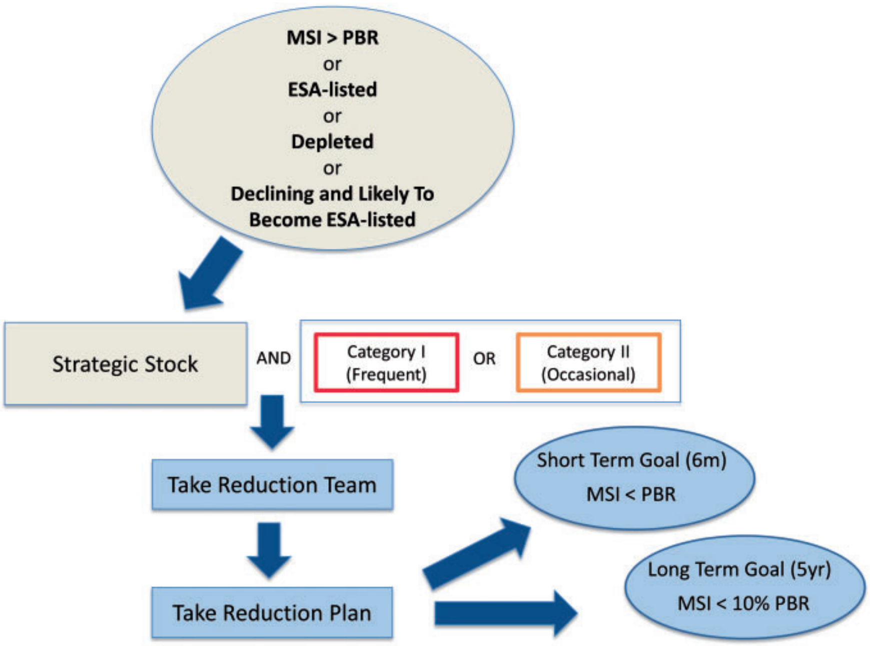

Figure 3. Decision tree for classification of fisheries based on percent of PBR removed annually. MSI = Mortality and Serious Injury. Simulations are performed for the Tier 2 step in 5-year steps.

The operating model assumes that there are several (N_f) fishery-types (i.e. fishing fleets using similar fishing practices in terms of bycatch risk to marine mammal stocks), each of which can potentially lead to mortality or serious injury. Human-caused mortality (Equation T1.7) is hence the sum over fishery-types of the mortality by fishery-type. The fishery-types are assumed to be sequential for computational ease, i.e. bycatch in fishery-type 1 occurs first, followed by bycatch in fishery-type 2, etc (Equation T1.8). The operating model allows vulnerability to differ between sex and age-classes. The fully vulnerable removal rates (i.e. the removal rate for animals for which vulnerability is highest) in Equation T1.8 are set so that the unconditional removal rate for fully vulnerable animals is achieved (Equation T1.9).

The operating model is parameterized for three species of cetaceans, representing baleen whales (the humpback whale *Megaptera novaeangliae*; and the bowhead whale *Balaena mysticetus*) and toothed whales (bottlenose dolphin *Tursiops truncatus*). These species were selected because the goal of the paper was to focus on cetaceans, since this group accounts for the majority of US marine mammal stocks. We include species from baleen and toothed whales to cover a range of life-history types with adequate information available for the parameters required. Also, the species selected have US stocks of high management priority (i.e. strategic stocks managed under the PBR framework) and stocks that are subject to fisheries mortality identified as a threat in the NMFS Stock Assessment Reports. A "generic" marine mammal is included to allow for comparisons with the analyses conducted by Wade (1998).

Data generation

The sampling error for the estimates of estimates of abundance is assumed to be log-normal (Equation T1.10). Estimates of abundance are assumed to become available every fourth year starting in year 9 for the bulk of the analyses. The true bycatch in year t is $M_t = \sum_f \sum_s \sum_a M^{s,f}_{t,a}$. The bycatch used when applying the management system is an estimate based on observing some pre-specified fraction of trips. The estimated bycatch during year t by fishery-type f, $\hat{M}^f_t$, is generated by first generating the observed bycatch (i.e. the bycatch observed if a proportion r^f of hauls/trips is observed) and dividing the resulting value by r^f. Bycatch is assumed to be clumped so the observed bycatch is assumed to be beta-binomial distributed where the actual proportion of bycatch observed, r^f_t is beta distributed with mean r^f and a pre-specified coefficient of variation (CV), and $\hat{M}^f_t$ is then generated from $B(M^f_t, r^f_t)$ where $M^f_t = \sum_s \sum_a M^{s,f}_{t,a}$.

The PBR and classification of fisheries are updated every 5 years based on the estimates of MSI and abundance available at that time. To mimic the actual management system, it is assumed that it takes 2 years to process and analyse bycatch data prior to their use in management (i.e. the bycatch data used when determining management actions for year 0 are for years -2, -3, etc), while this delay is 3 years for the estimates of abundance.

The management strategy

The management strategy being evaluated involves four steps; (i) calculation of the PBR; (i) determination of whether the stock is strategic; (iii) classifying each fishery-type to a Category (I, II, or III); and (iv) implementation of management actions to reduce bycatch rates (if this is warranted given the results of steps a, b, and c) (Figures 2 and 3).

The PBR formula

The PBR formula (Equation 1) depends on three inputs. The minimum abundance estimate (N_{MIN}) is calculated given the assumption of log-normal sampling error:

$$N_{\min} = N' \exp\left(-z\sqrt{\ln(1 + CV(N')^2)}\right) \qquad (2)$$

where $N^{'}$ is the most recent estimate of 1+ abundance, while R_{MAX} depends on whether the species is a cetacean or a pinniped (Wade, 1998). Barlow *et al.* (1995), Wade (1998), and Brandon *et al.* (2017) outline how the default values for z and F_R are calculated using the results of simulated application of the PBR approach. The value of z is set to 0.842 (corresponding to N_{MIN} being the lower 20th percentile of the distribution for the estimate of abundance) following Wade (1998). The default values for F_R may vary between 0.1 and 1, where endangered stocks are assigned a value of 0.1 and threatened, depleted or stocks of unknown status are assigned a value of 0.5. F_R is set to 1 for the bulk of the analyses of this article. Sensitivity to the expected ratio of the bycatch to the PBR (which is equivalent to F_R) is also explored through the scenarios in which management effectiveness (α) is varied (see below).

Assessing if a stock is strategic

In the United States, a stock can be designated as "strategic" if it is listed or likely to become listed under the US Endangered Species Act (ESA), if it is "depleted" (defined under the MMPA as a stock that is below OSP), or if (estimated) MSI exceeds PBR. It is beyond the scope of this article to model how species are listed, or likely to become listed, under the ESA so this aspect of the management system is ignored. Assessing whether a stock is "depleted" involves conducting a regression of log-abundance on year, then calculating the reduction in abundance over the period between the first abundance estimate and the present year, and assessing whether the resulting reduction is >0.5. This procedure mimics the rule of thumb that is used by the NMFS to assess whether a stock is "depleted" (NMFS, 2016). Evaluating whether MSI is greater than PBR involves computing the average of estimates of human-caused mortality over the 5 years prior to the year when the PBR is updated, and comparing that with the PBR for the current year (NMFS, 2016). A stock is designated as strategic if the average bycatch (MSI) exceeds PBR. This evaluation is conducted every 5 years.

Assignment of fisheries to categories

The primary task of the team charged with reducing bycatch is to develop a plan that identifies ways to reduce MSI below PBR within 6 months and to reduce MSI below 10% of PBR within 5 years [i.e. zero mortality rate goal (ZMRG)] taking into consideration the feasibility of proposed measures (costs to the fishing industry, available gear technology, etc.) and existing fishery management plans. Fishery-types are assigned to Categories (Category I: Frequent; Category II: Occasional; Category III: Remote) depending on the (estimated) amount of fisheries bycatch (or MSI) by fishery-type relative to PBR (Figure 3). Each fishery is categorized using the average of the MSI for the most recent 5 years. This fisheries classification is conducted every 5 years, which is a simplification of the actual procedure used to classify fisheries. The 5-year interval was selected to coincide with the timeframe established for the ZMRG (i.e. long-term goal to reduce bycatch).

Implementation of management actions

The impact of the management system on the stock's rate of recovery to MNPL depends on whether the stock is strategic, how each fishery-type is classified, and the extent to which management measures (mandatory or voluntary) to reduce bycatch are implemented. The actual removal rate, F_t^f (Equation T1.9), is beta distributed about its expected value with pre-specified CV, CV^f while the value of the expected removal rate for fleet f depends on the fishery classifications.

(i) The expected removal rate for all fishery-types remains unchanged from that for the previous year if the stock is not yet assessed to be strategic.

(ii) If the stock is strategic, the expected removal rates for fishery-types assigned to Category I or Category II are reduced to a factor (α) multiplied by the ratio of the PBR to the number of available animals, reflecting that the fishery-types should be managed to allow for recovery, i.e. the expected removal rate for fully-vulnerable animals for fishery-type f is given by $\alpha\,\Omega^f\, PBR_t / \sum_s \sum_a \phi_a^{s,f} N_{t,a}^s$ where $\phi_a^{s,f}$ is the relative vulnerability of animals of sex s and age a to fishery-type f, and Ω^f is the proportion of total mortality due to fishery-type f, which is determined by the scenario under consideration. The value of α relates to the extent to which recovery is enhanced, with $\alpha = 0.1$ representing the goal that MSI is reduced to <10% of PBR within 5 years [the zero mortality rate goal (ZMRG)]. The default value for α is 1 following Wade (1998), but sensitivity is explored to alternative values (0.1, 0.5, and 2).

Operating model parameterization

The parameters that define the population dynamics model are: carrying capacity (K^{1+}), age at first parturition (a_p), the survival rates for ages 0 and 1+, maximum birth rate (b_{max}), the parameter that determines the ratio of MNPL to carrying capacity θ, and initial depletion (χ) (Tables 3 and 4). The value for b_{max} is computed based on a pre-specified value for the maximum rate of increase λ_{max}, which is assumed to be 1.04 for most simulations for consistency with the analyses of Wade (1998), while the value of θ is computed from the value for MNPL (Punt, 1999). MNPL is thought to occur between 50 and 85% of carrying capacity for marine mammals (e.g. Taylor and DeMaster, 1993), with the base value for the simulations set to 0.5 following Wade (1998).

The parameter values for the "generic" marine mammal match the assumptions made by Wade (1998) during the development of the PBR formula. Wade's (1998) analyses used a production model as the operating model, but that does not actually represent a life history typical of any marine mammal—this case is included to allow comparison with previous work. To this end (i.e. for comparability with Wade, 1998) initial depletion is assumed to be $0.3K^{1+}$ for most scenarios. The FORTRAN code for the MSE model is available from: https://github.com/PBR-FullMSE.

Scenarios

Table 4 lists the values for the factors considered in the simulations. The range for the bycatch and abundance estimate CVs capture those used in the simulation studies by Wade (1998) and Brandon *et al.* (2017). These factors are used to develop four simulation experiments (Table 5).

(i) Experiment no. 1. Previous evaluations of the performance of the PBR approach ignored demographic stochasticity. This experiment involves conducting projections for the case of a single fishery-type for five levels of carrying capacity, K^{1+} (with lower population sizes leading to greater extents of demographic stochasticity through the assumed

Table 3. The values for the biological and fishery parameters of the operating model.

Parameter	Humpback whale	Bottlenose dolphin	Bowhead whale	Generic[a]
Age-at-first parturition, a_p	11 years (Zerbini *et al.*, 2010)	7 years[b]	18 years (IWC, 2016)	1 year
Calf survival, S_0	0.90 (Zerbini *et al.*, 2010)	0.5 (Wells *et al.*, 2005)	0.944 (IWC, 2016)	0.90
Adult survival, S_a $(a > 0)$	0.95 (Zerbini *et al.*, 2010)	0.951 (Speakman *et al.*, 2010)	0.990 (IWC, 2016)	0.95
Selectivity	Age 1+	Age 1+	Age 1+	Age 1+
Plus group age	Age 15	Age 10	Age 25	Age 5
Baseline Maximum rate of increase, λ_{max}[c]	1.04	1.04	1.04	1.04

[a]Parameters selected to mimic the production model of Wade (1998).

[b]Value selected given the wide range of values reported in the literature (e.g. Stolen and Barlow, 2003; Wells, 2003; Fruet *et al.*, 2015 and a review by Vollmer and Rosel, 2013).

[c]Analyses are also conducted in which λ_{max} is set the values estimated for the Eastern Pacific humpback stock (1.064; Calambokidis and Barlow, 2004), and the Bering-Chukchi-Beaufort Seas stock of bowhead whales (1.03; Brandon and Wade, 2006), and as well as the value for a bottlenose dolphin with an age-at-maturity of 7 (1.035 Reilly and Barlow, 1986).

Table 4. Factors considered in the analyses. The values in bold are the reference values [i.e. values in the studies by Wade (1998) and Brandon *et al.* (2017)].

Factor	Levels			
Population dynamic-related				
Species-types	Humpback, bowhead, Bottlenose dolphin; generic

CV of fishing mortality, CV^f	**0.3**			

binomial birth–death process); and biological parameters either based on the three species concerned or generic parameters that match the assumptions underlying the production function on which the simulations conducted by Wade (1998) were based. The PBR is computed setting N_{MIN} to the lower 20th percentile of the sampling distribution for the most recent estimate of abundance, R_{MAX} to 0.04, and F_R to 1. In addition to the latter default values, simulations were conducted with λ_{max} set to values representative of the species under consideration (Table 3) and F_R to 0.5, 0.2 and 0.1. The MSI starts in year 500 so the population is in quasi-equilibrium by year 0 and the stock is always assumed to be strategic so these simulations are as comparable with those of Wade (1998) and Brandon *et al.* (2017) as possible.

(ii) Experiment no. 2. This experiment extends the previous evaluation of sensitivity to parameters of the operating model conducted by Wade (1998) and Brandon *et al.* (2017) by considering three fishery-types (scenario A) and also including sensitivity to the frequency with which estimates of abundance become available, precision and bias of abundance estimates, life history parameters, the precision of the estimates of bycatch and the extent of management effectiveness. For ease of interpretation this experiment involves changing only one aspect of a reference scenario (Table 3) in turn for simulations based on the life history parameters for the four species-types and for the lowest and highest carrying capacity levels. MSI starts in year 30 for these simulations and the managed stock is always assumed to be strategic.

Table 5. The scenarios considered in the analyses.

Each experiment consisted of 1000 simulations over 100 years. The entries in bold are varied in the experiment. For definitions of "All", see Table 1.

(iii) Experiment no. 3. This experiment explores how well it is possible to detect whether a stock is strategic and to assign a fishery-type to the correct Category (I, II, or III) as a function of precision of the estimates of bycatch and absolute abundance, and how the precision of abundance estimates and bycatch impacts the ability to rebuild stocks to OSP and maintain them there. This experiment is based on the life history parameters for the humpback whale and the bottlenose dolphin. MSI starts in year 30 for these simulations, and analyses are conducted for the lowest and highest carrying capacity levels. MSI is caused by three fishery-types and five scenarios regarding the relative impact of the fishery-types are explored. Unlike experiments 1 and 2, the rules for assessing whether a stock is strategic and classifying fisheries are applied. The value of α was set to 1 for this experiment to ease the interpretation of the probability of over- and under-classification error.

(iv) Experiment no. 4. This experiment explores the ability of the monitoring system to correctly detect whether a stock is strategic and classify fisheries as a function of the number of estimates of abundance before the management system is first applied and the abundance estimate CV, as well as for different levels of initial depletion of the stock (stock size relative to unfished stock size). This experiment is based on the life history parameters for the humpback whale and the bottlenose dolphin. MSI starts in year -30 for these simulations, and results are conducted for the lowest and highest carrying capacity levels. The fishery-types follow scenario A.

Each scenario involves 1000 replicates of a 100-year projection period. This number of replicates is sufficient to enable differences among scenarios to be detected.

Results

Experiment 1

Figure 4a plots the probability that the number of age-1+ animals exceeds MNPL ($0.5K^{1+}$) at the end of the 100-year projection period (henceforth denoted P-MNPL) as a function of K^{1+} and Figure 4b shows the lower 5th percentile of the ratio of the final 1+ numbers to K^{1+} (N_{fin}/K) when there is one fishery-type and the recovery factor, F_R, is set to 1. Results are shown in Figure 4a and b for the four species-types. The expectation would be that P-MNPL would be 0.95 and the lower fifth percentile of N_{fin}/K would be 0.5 (dashed lines in Figure 4a and b). This is indeed almost the case for the "generic" marine mammal when K^{1+} equals the largest three values considered (i.e. $K^{1+} \geq$ 100 000, which corresponds to initial population size > 30 000). However, P-MNPL < 0.95 and $N_{fin}/K < 0.5$ for lower values for K^{1+} for the "generic" marine mammal and for all values for K^{1+} for the other species-types. P-MNPL $\geq$ 0.95 decreases with reductions in K^{1+}, i.e. smaller initial population size for the "generic" marine mammal and increases for the other three species-types. This can be attributed to the effects of demographic uncertainty, which means that the distribution for population size at the end of the projection is wider for lower values of K^{1+} (illustrated for the humpback whale in Figure 4e and f). A consequence of this additional variation is that the probability of being above 0.5 K is higher for cases in which the median value for final population size is less than 0.5 K (Figure 4e) and vice versa (Figure 4f).

The production functions (production above replacement vs. relative abundance) for the four species-types are the same (Figure 5, left panel), but the removal rate at which MNPL is achieved is lower for the humpback whale, the bottlenose dolphin and (particularly) the bowhead whale, with the MNPL removal rate for the bowhead whale being 0.75 of that for the "generic" marine mammal. The four species-groups have very similar rates of natural mortality and identical assumed maximum rates of increase. However, they differ in terms of age-at-maturity, suggesting that the reason for the difference in the removal rate at which production is greatest relates to age-structure effects, with higher ages-at-maturity corresponding to lower values for this removal rate. The lesser productivity for animals with a higher

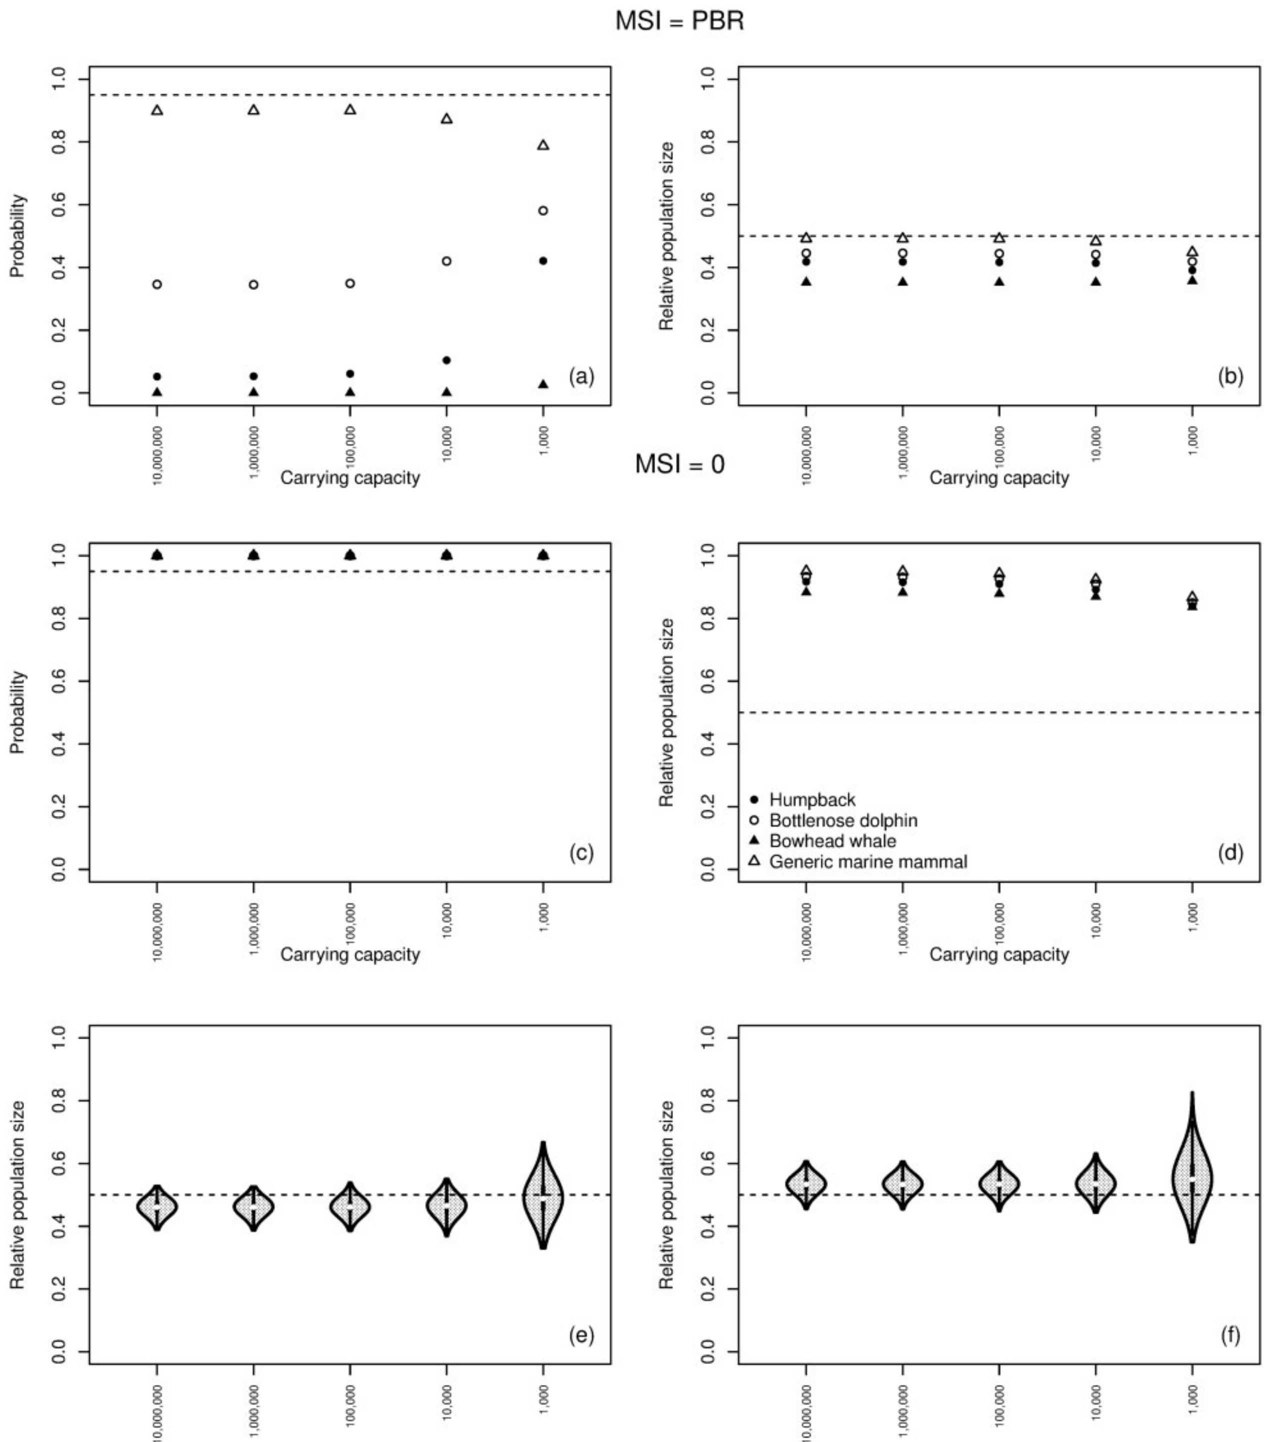

Figure 4. Results for experiment #1. Performance statistics consist of the probability that the number of 1+ animals exceeds MNPL (a, c) and the lower 5th percentile of the ratio of final 1+ population size to carrying capacity (b,d) when expected MSI is equal to PBR (a,b) and when it is assumed to be zero (c,d). The lower panels show the distributions of final 1+ population size relative to carrying capacity for $K^{1+} = 10{,}000{,}000$ (e) and $K^{1+} = 1{,}000$ (f) for the humpback whale when expected MSI is equal to PBR. Dashed lines represent MNPL.

age-at-maturity is also evident in the final size under zero future bycatch (Figure 4c and d). Thus, the lesser ability to achieve the MMPA goal of recovering (or maintaining) stocks to (at) OSP for the humpback, bowhead whales and the bottlenose dolphin compared with the "generic" marine mammal results from the adoption of more realistic biological parameters.

Experiment 2

Experiment 2 examines the impact of various factors [including those considered by Wade (1998) and Brandon *et al.* (2017)] on the recovery of the stock for each of the four species-types as indicated by the lower fifth percentile of final abundance (Figure 6, left column) and probability of exceeding MNPL after 100 years

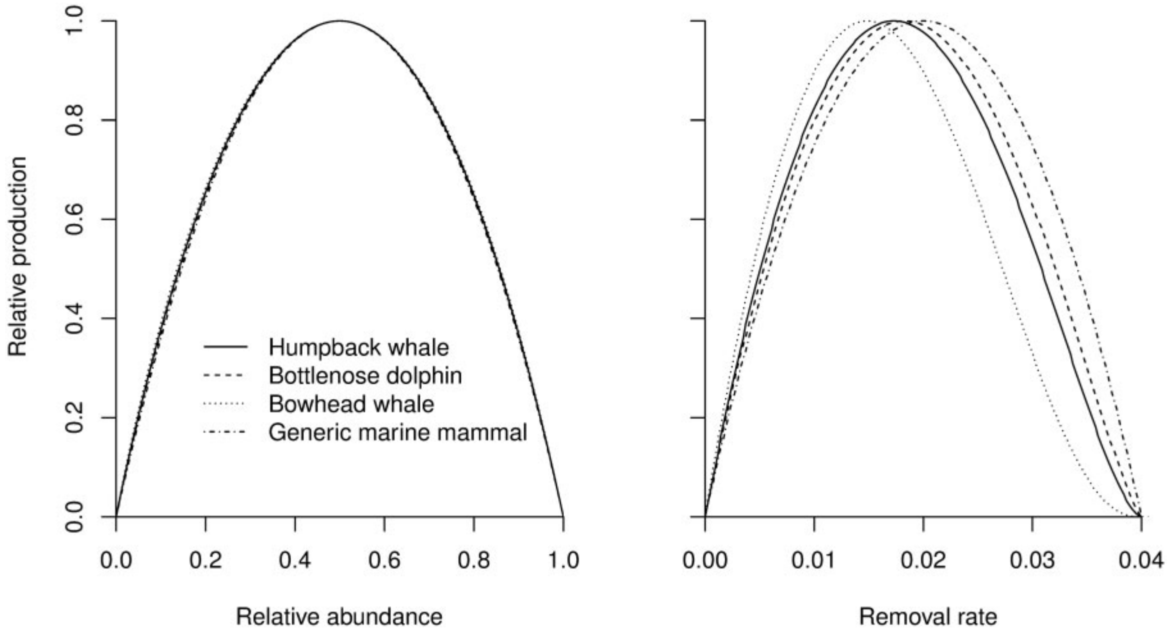

Figure 5. Production (expressed relative to the production at MNPL) versus the ratio of 1+ abundance to carrying capacity for the four species-types (left panel) and production relative to removal rate on 1+ animals (right panel) for these species-types.

(Figure 6, right column). The base case results for this experiment differ from those for Experiment 1 because the historical MSI occurs over 30 rather than 500 years and there are three fishery-types rather than only one. The qualitative impact of the various factors considered matches that of earlier studies (e.g. Wade, 1998; Brandon *et al*., 2017), with lower productivity (λ_{mac}), lower MNPL, a higher abundance estimate CV, positively biased estimates of abundance, and lower management effectiveness leading to lesser lower fifth percentiles of final abundance (and hence P-MNPL), while higher MNPL, and greater management effectiveness leading to the opposite effect (Figure 6 for carrying capacity = 10 000 000; Supplementary Figure S1 for carrying capacity = 1000). Outcomes are particularly sensitive to changes in MNPL and the precision of the estimates of abundance. Most of these changes are expected, noting that in terms of conservation performance, increased management effectiveness (i.e. changing α from 1 to 0.1) is quantitatively equivalent to a scenario where α is held constant and a more conservative value for the recovery factor, F_R is assumed. The results are largely unchanged by the frequency with which estimates of abundance become available, a common observation for these types of management systems (e.g. IWC, 2015) and by the CV of bycatch. However, it should be noted that the effect of frequency with which estimates of abundance become available is being evaluated by computing N_{MIN} based only on the most recent abundance estimate.

The results in Figures 4 and 6 are very similar even though Figure 6 is based on a more realistic situation. As before, there are quite marked differences in results among species-types, with the values for P-MNPL again being highest for the "generic" marine mammal (Figure 6d) and lowest for the bowhead whale (Figure 6c).

Experiment 3

Figure 7 summarizes the results of Experiment 3 in terms of the relationship between population size relative to carrying capacity after 100 years and P-MNPL (columns 1 and 2) and the CVs for the estimates of bycatch and of abundance, as well as the risk of not identifying a stock as strategic when it is (column 3), and the probability of misclassifying a fishery-type to a higher or lower category (under- and over- classification error, columns 4–6) for the humpback whale when carrying capacity is 10, 000, 000 and the fishery impacts follow Scenario A (Table 4). Over-classification would, for example, be assigning a fishery that should be in Category II to Category I, while under-classification error would, for example, be assigning a fishery that should be in Category II to Category III. Over-classification error could lead to unnecessary restrictions on a fishery while under-classification error could lead to a reduction in the rate of recovery of a depleted population.

Bycatch in the model is stochastic which implies, for example, that even though fishery-type 1 constitutes 70% of the bycatch in expectation, variation in bycatch about its expected value may lead to bycatch for this fishery-type being <50% of PBR, i.e. a fishery-type that is in expectation in Category I will at some points in time be in Category II given variation in bycatch. Over-classification in this case in then classifying fishery-type 1 to be in Category I when bycatch during the last 5 years is less than half of the PBR.

The lower fifth percentile of the number of 1+ animals relative to carrying capacity declines as the CV for abundance increases, reflecting again that higher abundance estimate CVs lead to broader distributions for final population size. One consequence of this is that the probability of being above MNPL is larger (but never reaches 0.95) for higher abundance estimate CVs. P-MNPL is largely independent of the CV for the estimates of bycatch, except when the abundance estimate CV is 0.6 and higher (Figure 7, lower two rows). In most cases, it is possible to detect that a stock is strategic when it is in fact at 30% of carrying capacity because MSI is often well in excess of PBR in this case, although there is some chance of requiring a few years to identify that a stock is strategic in this situation when the abundance estimate CV is high (column 3 of the bottom row of Figure 7).

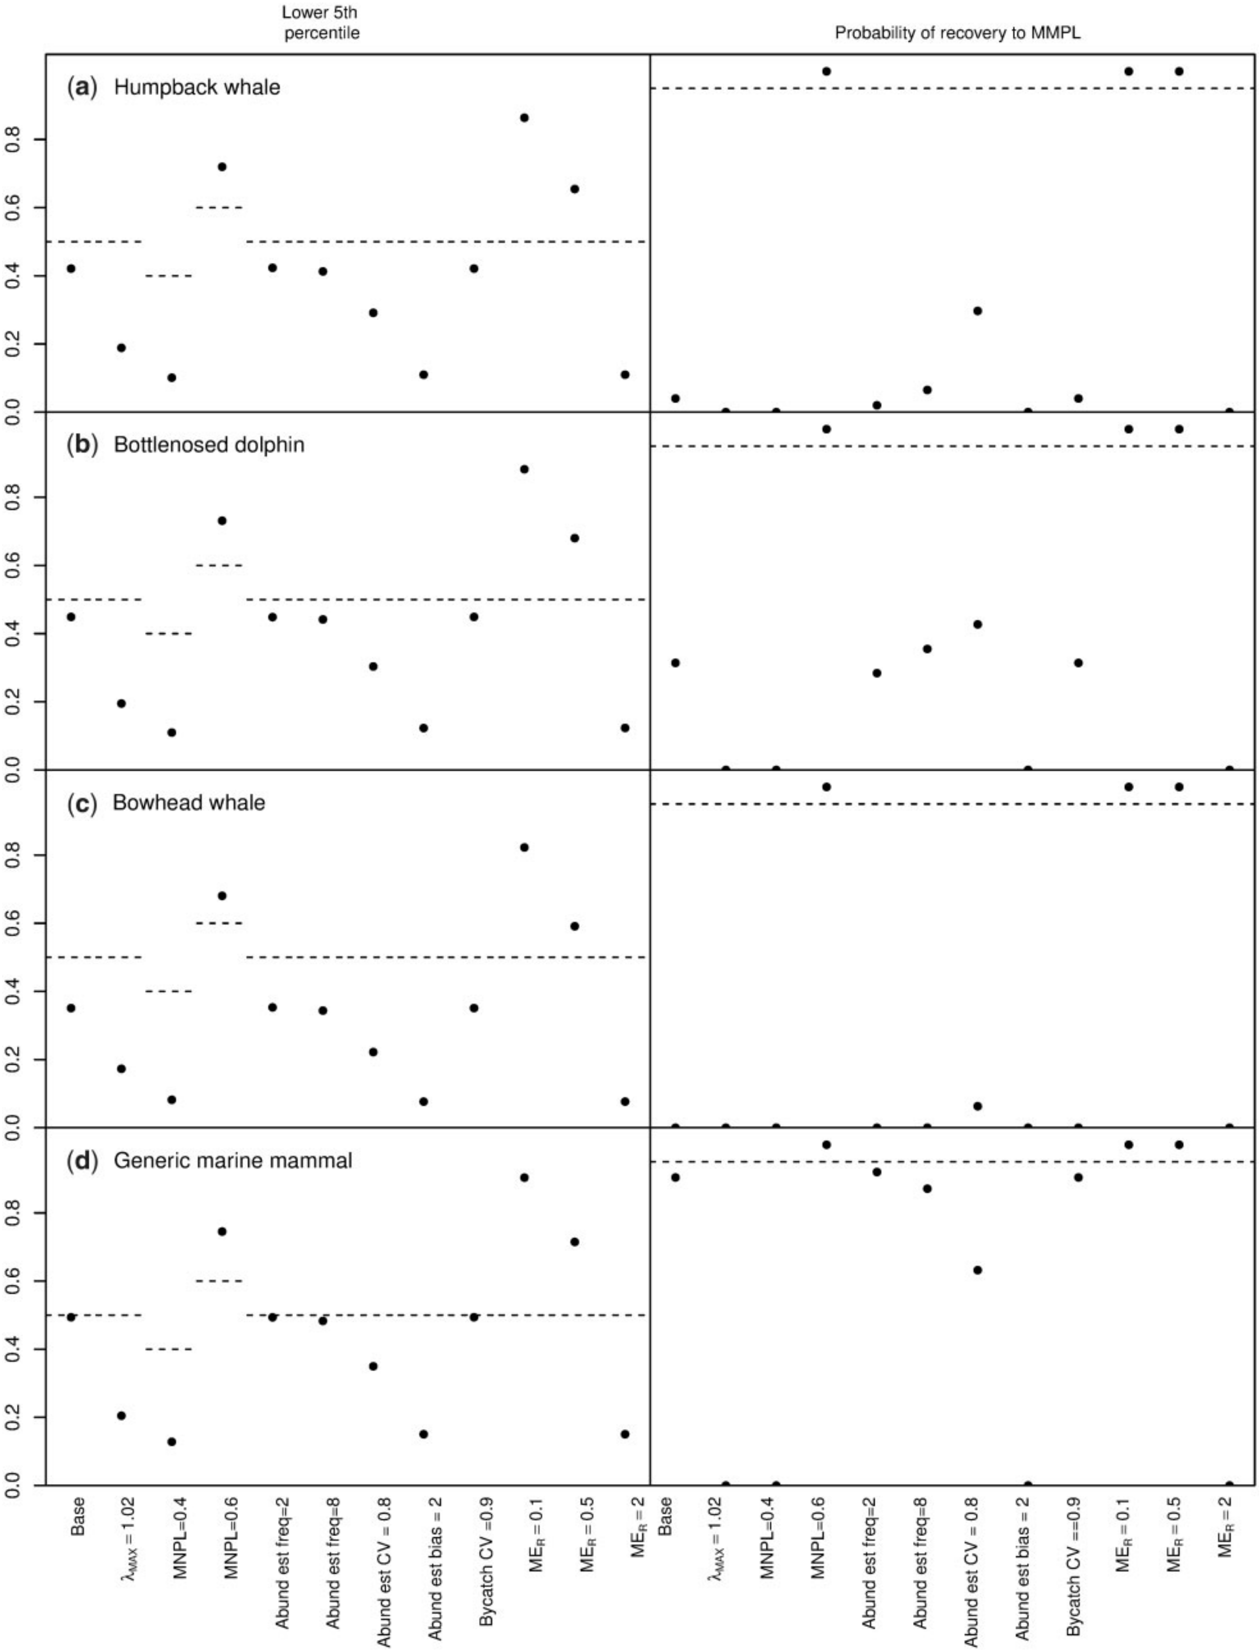

Figure 6. Summary of the results of Experiment #2. The performance statistics for each analysis are: the lower 5th percentile of the relative abundance after 100 years (column 1), the probability that the number of 1+ animals exceeds MNPL after 100 years (column 2). The results in this figure are based on the fishery-types given by Scenario A and carrying capacity equals its largest value $K = 10{,}000{,}0000$. ME denotes management effectiveness (E(Bycatch / PBR), α). Dashed lines are values for MNPL.

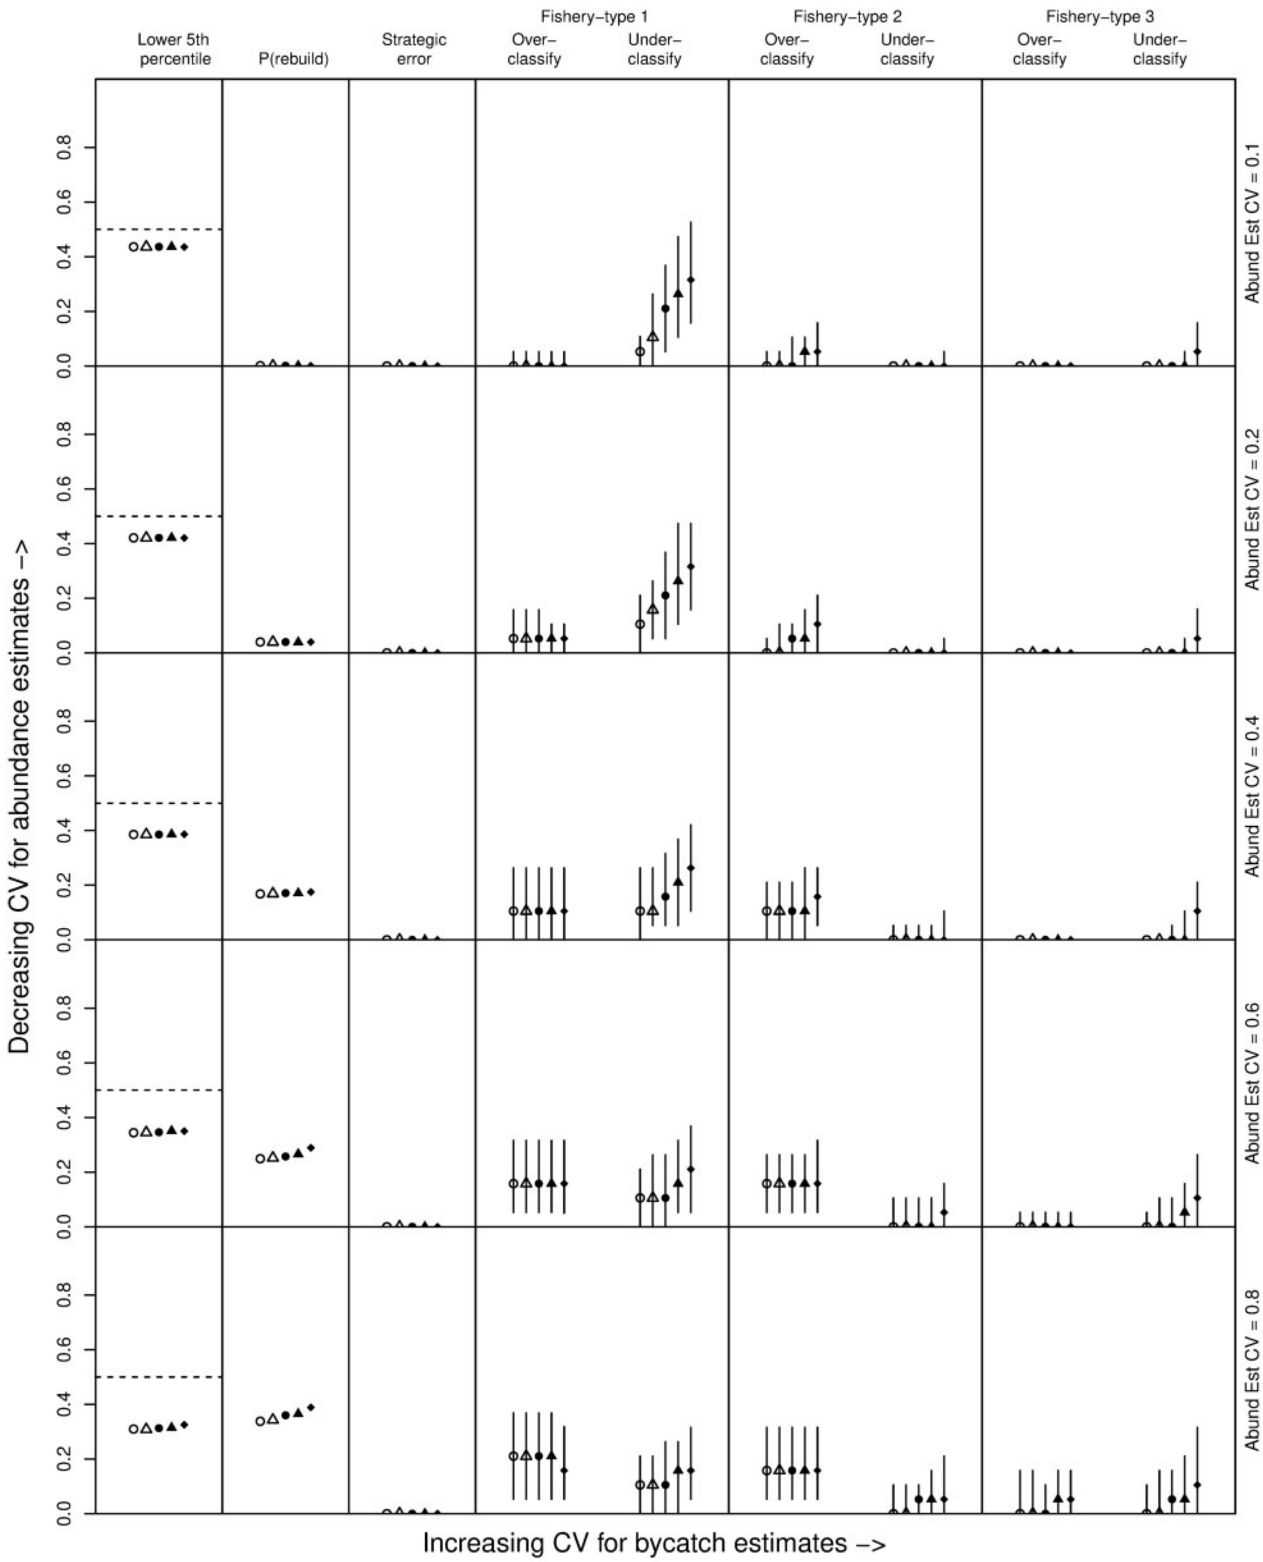

Figure 7. Summary of the results of Experiment #3. The performance statistics for each analysis are: the lower 5th percentile of the relative abundance after 100 years (column 1), the probability that the number of 1+ animals exceeds MNPL after 100 years (column 2), the probability (across years within a simulation) that the stock is identified to be strategic (median and 95% intervals across simulations; column 3), the probability across years within a simulation (median and 95% intervals over simulations) that fishery-types 1, 2 and 3 are assigned to a higher or lower fishery classification than they should be (columns 4-6). The results in this figure pertain to the humpback whale when the relative impact of each of the fishery-types is given by Scenario A and carrying capacity equals its largest value. The rows show results for increasing levels of CV for the abundance estimates and the results within each row pertain to increasing values (left to right) for the CV of the bycatch estimates (CV values are 0.1, 0.3, 0.5, 0.7 and 0.9).

The probability of correctly classifying a fishery-type as Categories I, II, or III depends on its true classification and on its bycatch magnitude, i.e. it is easier to classify a fishery-type when that fishery-type constitutes a high proportion of MSI than when the proportion is close to a threshold level such as 0.5—contrast the rates of classification error for Scenario A with those for Scenario D (Supplementary Figure S2c), where the rate of over-classification error remains high for all levels of abundance estimate CV. The probability of over-classifying a fishery-type (i.e. assigning a fishery that should be in Category III to Category II or a fishery that should be in Category II to Category I) increases with increasing CVs for the estimates of abundance. This is most evident for fishery-type 1 in Figure 7. However, there is relatively little impact of the bycatch CV on the probability of over-classifying fisheries. The probability of under-classifying fisheries is more complex than the probability of over-classification as this probability depends on the impact of fishery-type (contrast the results for fishery-type 1 with that for fishery-type 3 in Figure 7). In addition, there is an interaction between the CV for the estimates of abundance and that for the estimates of bycatch, with the effect of the CV for bycatch being less marked when the CV of abundance is higher (i.e. lower precision for abundance estimates).

The results are not qualitatively sensitive to the allocation of MSI to fishery-type, but the absolute level of classification error varies (as expected) with this allocation. The lowest levels of classification error occur for Scenario E (Supplementary Figure S2d) although the pattern of classification error is the same as for Scenario A. The former result occurs because the allocations of MSI by fishery-type are respectively the highest and (close to) lowest, making classification easier. The results for the bottlenose dolphin (Supplementary Figure S3) are qualitatively similar to those for the humpback whale, except that less recovery occurs for the bottlenose dolphin.

The results in terms of final population size, probability of recovery, and fishery classification error rates are sensitive to the magnitude of carrying capacity (contrast Figures 7 and 8; Supplementary Figures S2–S5). In general, the probability of incorrectly classifying a fishery is much higher for a smaller population, and particularly when the magnitude of the fishery impact is fairly small (e.g. 5 and 25% for fishery-types 3 and 2). This is because smaller populations lead to lower MSI in absolute terms.

Experiment 4

This experiment explores the impact of the number of estimates of abundance prior to first application of the management system, the CV of the estimates of abundance and the initial depletion when the management system is first applied. There is very little impact of having additional estimates of abundance on any of the performance metrics, primarily because although the probability of identifying a stock as strategic (Figure 9, column 3) uses all of the abundance estimates to estimate whether it is depleted to less than half of carrying capacity, the PBR is based only on the most recent estimate of abundance. Although the probability of over-classifying fishery-types with moderate to high bycatch fractions (columns 5 and 4, respectively) increases with the CV of abundance estimates (i.e. abundance estimates with lower precision), over-classification of fisheries with small bycatch fractions (column 6) and under-classification of fisheries are not much influenced by the CV of abundance estimates. There is only a weak interaction between the CV of abundance estimates and number of historical estimates of abundance (the exception being the probability of incorrectly classifying fishery-type 3, Figure 9, column 6). The most marked effect in Figure 9 is the impact of the initial depletion on the probability of recovery to MNPL and the lower fifth percentile of the relative abundance after 100 years of applying the management system, with high initial depletions leading to higher values for the two performance statistics. However, this pattern is to be expected given that changing initial depletion changes the time to recovery all things being equal. There is a slight increase in the number of years to detect a stock is strategic (MSI > PBR), with increasing values for initial depletion, but this number is always low and little impacted by the number of estimates of abundance before the management system is first implemented (Figure 9, column 3). In contrast to Experiment 3, the probability of recovery is generally higher for bottlenose dolphins. Lower abundance estimate CVs lead to lower probabilities of recovery, except for bottlenose dolphins when initial depletion = 0.45 (Figure 9, second column).

Discussion

The management system for regulating marine mammal–fishery interactions is more formal than in most other jurisdictions. The system developed in the US in response to the requirements of the MMPA consists of the PBR formula, the approach used to assess whether a stock is strategic, the process of classifying fisheries in terms of their impact relative to PBR, and when warranted the TRTs and hence any TRPs. The MMPA also contains provisions that fisheries that export fish and fish products from other countries into the United States must have regulations for incidental marine mammal mortality limits that meet the MMPA standards (Williams *et al.*, 2016). The PBR formula, which is central to the management system, was developed using MSE by Wade (1998), with a key goal being that stocks that are depleted to 30% of their carrying capacity be recovered to the population size corresponding to maximum production, MNPL, within 100 years with 95% probability. However, the simulations conducted by Wade (1998) were based on an operating model that did not include age-structure and hence did not account for the time-lags caused by age-structure. Also, Wade's analysis ignored the fact that the relationship between the maximum rate of increase and the rate of increase as the population approaches MNPL depends on vital rates. Most previous attempts to apply the PBR approach to species other than marine mammals have also not considered the impact of demographic factors on the ability to achieve recovery and conservation goals.

The previous MSE was restricted to a single part of the management system: the PBR formula, ignoring feedbacks with components applied to reduce MSI in fisheries. This limits the ability of managers to evaluate some of the trade-offs of improving the precision of abundance and/or bycatch estimates. Furthermore, previous MSEs could not evaluate the ability to correctly classify fisheries. Thus, this MSE more fully informs managers as to which conditions are more likely to result in insufficient or unnecessary regulation of fisheries (due to incorrect under- or over-classification) and which strategies might be more successful, i.e. achieve stock conservation goals while minimizing unnecessary adverse impacts to fisheries, as directed by the MMPA.

Impact of the MSE being based only on the PBR formula

The results for Experiment 1 are based on a scenario in which the stock is always considered to be strategic and there is only one

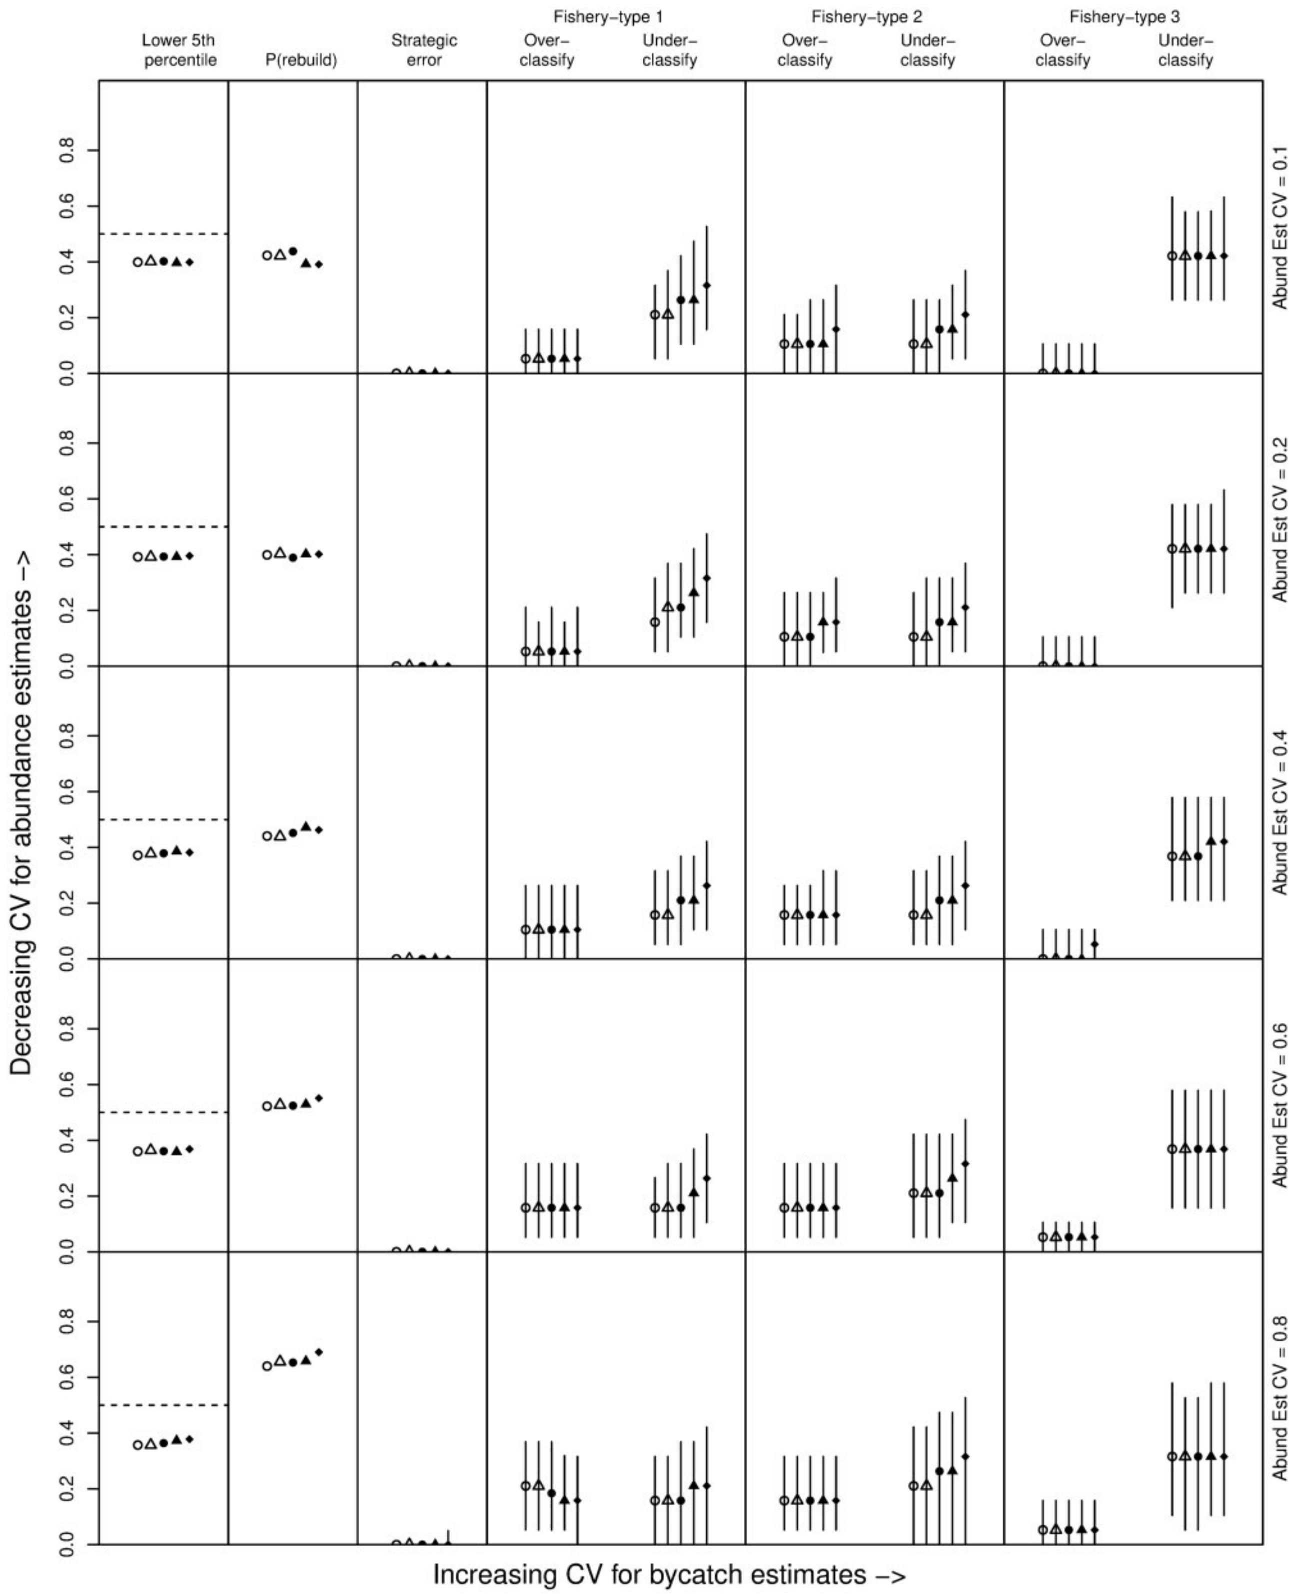

Figure 8. As for Figure 7, except that carrying capacity is 1,000 instead of 10,000,000, i.e. initial abundance is 300 instead of 3,000,000.

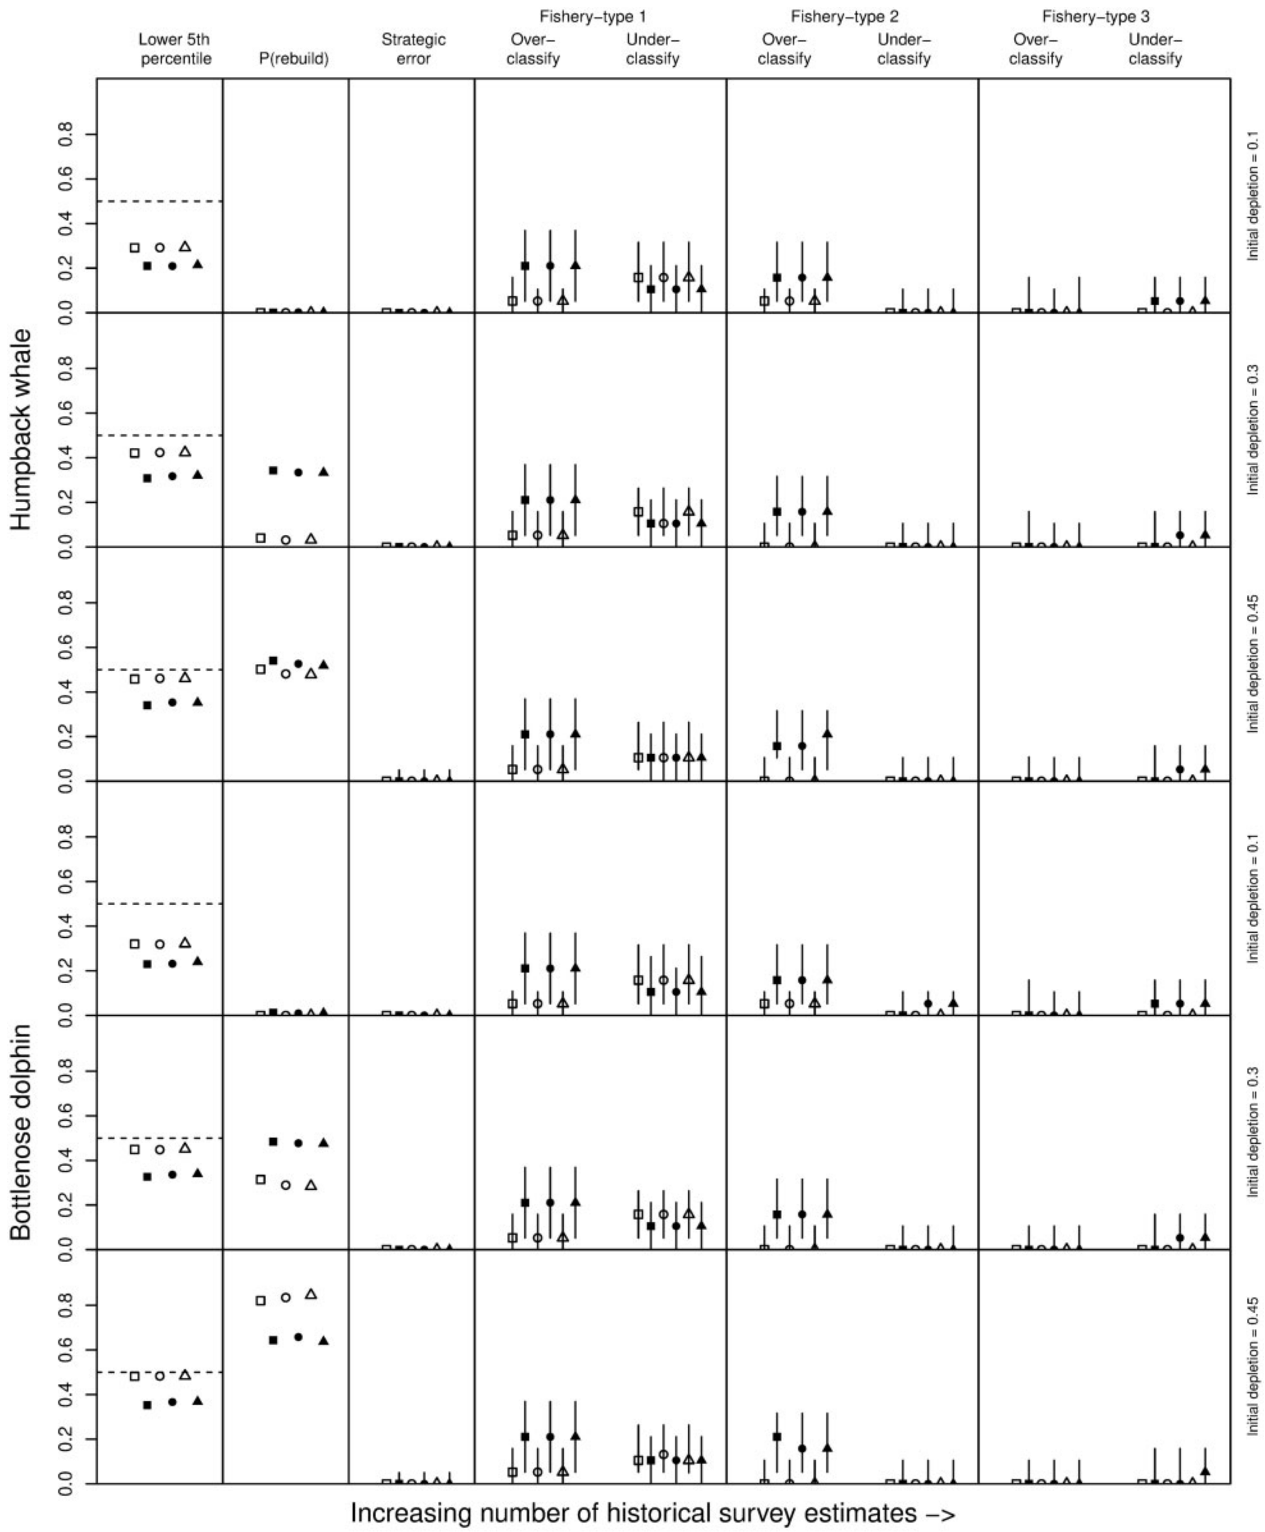

Figure 9. Summary of the results of Experiment #4 consisting of 1,000 simulations over 100 years for humpback whales and bottlenose dolphins. The performance statistics for each analysis are: the lower 5th percentile of the relative abundance after 100 years (column 1), the probability that the number of 1+ animals exceeds MNPL after 100 years (column 2), the probability (across years within a simulation) that the stock is incorrectly identified as not to being strategic (median and 95% intervals across simulations; column 3), the probability across years within a simulation (median and 95% intervals over simulations) that fishery-types 1, 2 and 3 are incorrectly assigned to a higher (under-classified) or lower (over-classified) fishery category than they should be (columns 4-6). The results in this figure are when the relative impact of each of the fishery-types is given by Scenario A (0.7, 0.25, 0.05), carrying capacity equals its largest value (10,000,000) and initial depletion (i.e. fraction of the initial population remaining) varies between 0.1 and 0.45 (rows). The results within each row pertain to different values for the number of estimates of abundance (square = 3, circle = 5, triangle = 7) and the CV of the estimate of abundance (open symbols = 0.2 vs closed symbols = 0.8). Additional details for Experiment #4 in listed in Table 5.

fishery-type, whereas Experiment 3 considered multiple fishery-types and accounted for errors caused by not identifying a stock as strategic and incorrectly classifying and hence managing fishery-types. The results of Experiment 3 are very similar to those of Experiment 1 even though the population is not stable in the first year. This suggests that ignoring assessing whether a stock is strategic and classifying fishery-types as was the case in the simulations conducted by Wade (1998), Taylor *et al.* (2000), and Brandon *et al.* (2017) is largely inconsequential compared with the effects of the values of the parameters of the PBR formula. This is because the probability of not identifying a stock that is depleted to 30% of the unfished level as strategic is very low (Figures 6–8), and the probability of classifying a fishery that should be in Categories I or II to III is likely very low.

Impact of population demographics

The results of Experiment 1 show that the ability to satisfy the management goals is highly dependent on the biological characteristics of the species being managed. The results for the "generic" marine mammal with essentially infinite population size are very similar to those obtained by Wade (1998) using an operating model in which there are no time-lags (Figure 4). However, allowing for more realistic population dynamics (parameterizing the operating model to represent a humpback whale, a bowhead whale or a bottlenose dolphin) leads to lower rates of increase under this management strategy (Figure 4) and hence lower probabilities of recovery to MPNL within 100 years if λ_{max}=1.04. The probability of recovery also depends on the size of the population. This is because the impact of demographic uncertainty is inconsequential for very large populations, but can be consequential for small populations (~300 1+ individuals for a stock with a carrying capacity of 1000 initially depleted to 30%). The increased variation in population size leads to higher probabilities of recovery for species with low age-at-maturity and vice versa for species with higher ages-at-maturity.

The actual values for λ_{max} are likely to differ from 1.04. Supplementary Figure S6 shows distributions for final population size after 100 years for humpback whales, bottlenose dolphins, and bowhead whales when λ_{max} is set to the values in the footnote to Table 3. As expected, the probability of recovery is very sensitive to λ_{max}, with humpbacks (upper panels) predicted to recover with high probability irrespective of the magnitude of carrying capacity and the value for the recovery factor F_R. In contrast, the impacts of demographic parameters are exacerbated when $\lambda_{max} <$ 1.04 (Supplementary Figure S6, centre and lower panels). Setting F_R to 0.5 or lower increases the probability of recovery to 0.5 *K* to 0.95 or higher, except for when K^{1+}=1000 for bottlenose dolphins.

Figure 10 explores the impact of demographic effects further by showing deterministic time-trajectories of population size under zero catch for populations with natural survival rates of 0.95 and different values for the age-at-maturity when the population age-structure for each population was in equilibrium in year 0. The year in which the number of 1+ animals reaches MNPL (half of carrying capacity) ranges from 23 (age-at-maturity = 1) to 28 (age-at-maturity = 16), illustrating how time-lags in population dynamics impact recovery rates (and hence the values for performance metrics in the MSE). These results suggest that the results of the Wade (1998) analysis will be more valid for marine species with lower ages-at-maturity such as seabirds and pinnipeds.

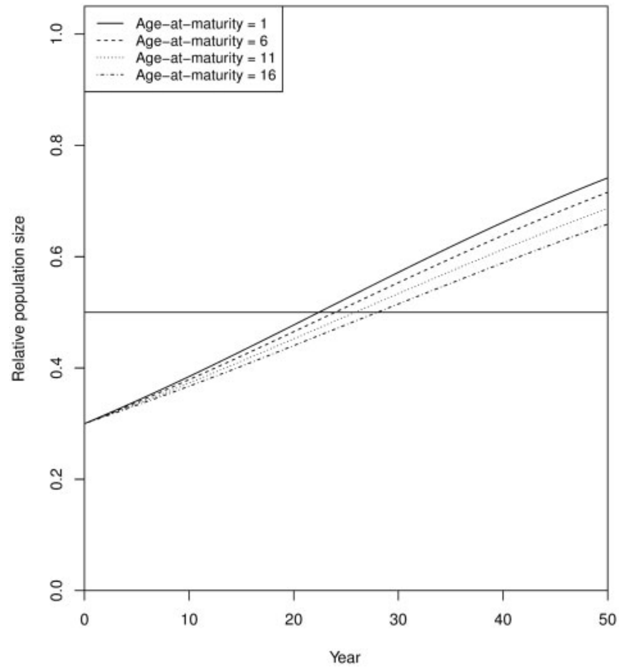

Figure 10. Sensitivity of the time-trajectory of future population size under zero future bycatch to the assumed age-at-maturity. The horizontal line indicates MNPL.

The negative consequences of these two effects on the ability to achieve the performance goals can be overcome by adopting a lower value than one for the recovery factor, F_R that is part of the PBR formula (see, e.g. Supplementary Figure S7). The majority of US cetacean stocks have a recovery factor below one: 100% of the Atlantic/Gulf of Mexico stocks, 97% of the Pacific stocks, and 80% of the stocks in the Alaska region (Carretta *et al.*, 2017; Hayes *et al.*, 2017; Muto, *et al.*, 2017). The results suggest a need to either develop parameters of the PBR by species, i.e. to conduct species-specific MSE analyses, or more practically, to develop parameterizations of the PBR formula for groups of species/stocks that fall into broad categories related to demographics and population size. At present, the value of F_R is linked to perceived stock status—a lower value for F_R for more depleted populations (and higher uncertainty regarding stock status), but this does not account for the fact that the time to recovery also depends on the size of the population in absolute terms.

The results for humpbacks in this paper are less optimistic than those in Brandon *et al.* (2017). Both this paper and Brandon *et al.* (2017) parameterized the density-dependence function in terms of b_{max} and θ. The value for b_{max} was set so that λ_{max} equalled its pre-specified value in both papers. However, Brandon *et al.* (2017) set θ directly to the values for θ in the age-aggregated model used by Wade (1998) whereas this paper set θ to achieve the same value for MNPL as used by Wade (1998). The relationship between θ and MNPL depends on age-structure effects (Punt, 1999), which leads to different model outcomes given differences in the parameterization.

Ability to classify fisheries

The ability to correctly classify fisheries into Categories I–III is strongly related to the proportion of bycatch of the fishery and is more often influenced by the precision of abundance than by the precision of bycatch estimates. Generally, over-classification errors are high when the proportion of bycatch in a fishery-type is moderately high (30–50%) regardless of the precision of abundance and bycatch estimates. However, as the proportion of bycatch in the fishery becomes very high (70–90%), the over-classification errors become more pronounced as the precision of abundance estimates decreases ($CV \geq 0.4$). The starkest contrast between over- and under- classification errors occurs when the level of bycatch of a fishery-type ranges from 20 to 30%. In this case, the under-classification error is low, contrasting with a large over-classification error. There are a few cases, particularly when the precision of abundance estimates is high, where classification errors increase as the precision of bycatch estimates decreases, revealing an interaction between precision of abundance and bycatch estimates. This suggests that improving the precision of bycatch estimates becomes more relevant once a threshold on the precision of abundance estimates is reached.

Despite the errors in classifying fisheries, they tend to be assigning a fishery that is in Categories II to I and vice versa. However, fisheries in Categories I and II are all managed to reduce MSI to PBR and ideally towards the ZMRG. There was a negligible probability of classifying fishery-types in Categories I or II to III (severe under-classification error). The possibility of severe over-classification error (a Category III fishery-type assigned to Categories I or II) is only explored in detail in Scenario D, with the error probability high, particularly for high bycatch CV (Supplementary Figures S2c, S4c, S3d, and S5d, column 6).

Sensitivity analyses

The performance of the management system is as expected when the parameters of the operating model are varied. Of greatest note is the impact of the effectiveness of the management system. Unsurprising, achieving the goal of bycatch <10% of PBR (i.e. the TRP long-term goal) leads to a markedly higher probability of recovery within 100 years than expected from the base case analysis, where management efficiency equals one (Figure 6). However, a higher management effectiveness, i.e. $\alpha < 1$ (or lower values than one for the recovery factor, as discussed earlier), is needed for the management system to be robust to the types of uncertainty such those explored in Experiment 2 that could be reasonably expected when managing bycatch of marine mammal stocks (Wade, 1998). Alternatively, a more robust management system can be achieved by improving the precision of abundance and bycatch estimates to the level recommended by NMFS ($CV \leq 0.3$) (NMFS, 2004; GAO, 2008).

Caveats

The MSE has a closer representation of how marine mammal–fishery interactions are managed in the United States than those conducted previously. However, it is not, and could not be, a perfect representation of the management system. For example, we did not try to mimic the process of concluding a stock is no longer strategic, owing primarily to the lack of rules for making this determination that can be implemented in a simulation study. One of consequences of this is that recovery rates are higher than would be the case if a stock was incorrectly declared to have recovered and hence restrictions on fisheries eased. In addition, the classification of fisheries was performed every five years rather than annually. This mimics the actual process for cases such as fisheries interacting with gray whales in the US Pacific region, where estimates of bycatch and abundance are not updated annually, but not for other cases (e.g. Hawaii deep and shallow set longline fisheries interacting with false killer whales). Given that stocks designated as strategic are always managed as strategic in these simulations means that this assumption is non-consequential for statistics related to recovery rates. Also, conducting the evaluation of classification performance every 5 years means that the probability of classification error can be computed based on subsequent 5-year periods rather than overlapping 5-year periods.

As noted earlier, we also did not try to mimic the process for assessing F_R by stock [in common with Wade (1998) and Brandon *et al.* (2017)] owing to the lack of rules that can be included in a simulation protocol that does not include all the factors taken into account when selecting F_R, some of which are qualitative. However, we did explore this issue generically in Supplementary Figures S6 and S7.

Conclusions

The analysis of the full management system suggests that the PBR formula has the largest impact on the ability to achieve management goals related to marine mammal stock recovery because (for stocks depleted to 10–45% of the carrying capacity) the consequences of not detecting a stock to be strategic and errors classifying fisheries are largely inconsequential. The latter occurs, at least for the scenarios that were investigated, because the errors in assigning fisheries to categories and evaluating whether a stock is strategic were low. In particular, fisheries in Category I were very seldom incorrectly assigned to Category III.

Of most significance to management of marine mammal stocks are the findings of a slower recovery (compared with results from Wade, 1998) when allowance is made for more realistic population dynamics (parameterizing the operating model to represent a humpback whale, a bowhead whale or a bottlenose dolphin) and the notable effect of carrying capacity (i.e. considering scenarios other than the equivalent to an infinite population size as in Wade, 1998). Although more optimistic recovery outcomes were obtained with higher maximum rates of increase ($\lambda_{max} > 1.04$) and by decreasing the recovery factor (F_R=0.5), the recovery objective (stock at/above MNPL after 100 years) was still not achieved for bottlenose dolphin stocks when carrying capacity is low ($<\sim$1000 individuals), which is not uncommon for many of the stocks in bays and estuaries. This further emphasizes the need to examine the behaviour of management systems for specific cases, and if necessary adjusting management controls for groups of species/stocks or even at the individual stock level.

This MSE is a first step toward a better understanding the trade-offs between the precision of key marine mammal assessment estimates (bycatch and abundance) and the ability to correctly classify fisheries over a broad range of scenarios, namely multiple fisheries with low to high bycatch impact. Specifically, this study demonstrates the benefits from improving the precision of abundance and bycatch estimates for achieving the conservation goal of protecting marine mammal stocks and correctly classifying fisheries.

The framework developed here allows the impact of sex and age-structured effects on the performance of systems for managing bycatch to be explored, in addition to the consequences of different monitoring systems (i.e. observer effort) to estimate for bycatch and abundance. The full suite of possible scenarios could be examined in future studies (multiple fisheries, each with different levels of observer coverage, and sex-specific vulnerability to bycatch, etc). The analyses have the broadest application to the US. However, the requirements for nations to have standards equivalent in effectiveness to those of the MMPA to allow them to import seafood into the United States (Williams *et al.*, 2016) means that other jurisdictions need to consider whether their management systems perform as well as the US system, which this article attempts to quantify.

Nineteenth-century Ship-based Catches of Gray Whales, *Eschrichtius robustus*, in the Eastern North Pacific

RANDALL R. REEVES, TIM D. SMITH, JUDITH N. LUND,
SUSAN A. LEBO, and ELIZABETH A. JOSEPHSON

Introduction

In a broad analysis of global whaling, Reeves and Smith (2006) identified no fewer than 22 different whaling "operations" that targeted gray whales, *Eschrichtius robustus*, in the North Pacific Ocean, ranging from aboriginal hunts that began many hundreds or even thousands of years ago, to the more recent factory ship activities using modern searching, killing, and processing methods. Among those 22 operations, they identified five American-style pelagic (or ship-based) operations that took gray whales (Dutch, French, German, Russian, and American; operation numbers 54–56, 61, and 64 in their Appendix). In addition, during this study, we have established that vessels registered in Great Britain and Hawaii also took gray whales (operation numbers 57 and 58 in Reeves and Smith, 2006). These seven operations, along with the other whaling on this species, had reduced gray whale numbers to an unknown, but apparently considerable, extent in both the eastern and western North Pacific by the end of the 19th century.

Randall R. Reeves is with Okapi Wildlife Associates, 27 Chandler Lane, Hudson, Quebec J0P 1H0, Canada (email: rrreeves@okapis.ca). Tim D. Smith is with the World Whaling History Project, 1562 Purple Way, Redding, CA 96003. Judith N. Lund is at 7 Middle Street, Dartmouth, MA 02748. Susan A. Lebo is with Applied Research in Environmental Science, 1031 Nuuanu Avenue, #2104, Honolulu, HI 96817. Elizabeth E. Josephson is with Integrated Statistics, 16 Sumner Street, Woods Hole, MA 02543.

The widely held view that the eastern population (often called the California population or stock) has recovered to its pre-whaling abundance was recently challenged by a study suggesting an average long-term abundance of about 96,000 gray whales in the North Pacific Ocean (Alter et al., 2007). This figure is several times higher than the number of gray whales estimated alive today. If the DNA-based estimate were considered accurate and were applied to the period just before large-scale commercial exploitation began in the 1840's, it would imply that a far greater number of animals had been removed from the California population by whaling than generally assumed. Even without that DNA-based estimate, however, there are concerns about the accuracy of the catch record used in population modeling of eastern North Pacific gray whales (IWC, 1993; Butterworth et al., 2002: Table 2). Wade (2002:85–86), for example, stated:

> "An unresolved issue regarding the eastern North Pacific gray whale is that it has not been possible to reconcile the catch history from the 1800s with the recent time series of abundance data in a simple way. Several attempts have been made to project population models

ABSTRACT—The 19th century commercial ship-based fishery for gray whales, Eschrichtius robustus, *in the eastern North Pacific began in 1846 and continued until the mid 1870's in southern areas and the 1880's in the north. Henderson identified three periods in the southern part of the fishery: Initial, 1846–1854; Bonanza, 1855–1865; and Declining, 1866–1874. The largest catches were made by "lagoon whaling" in or immediately outside the whale population's main wintering areas in Mexico—Magdalena Bay, Scammon's Lagoon, and San Ignacio Lagoon. Large catches were also made by "coastal" or "alongshore" whaling where the whalers attacked animals as they migrated along the coast. Gray whales were also hunted to a limited extent on their feeding grounds in the Bering and Chukchi Seas in summer.*

Using all available sources, we identified 657 visits by whaling vessels to the Mexican whaling grounds during the gray whale breeding and calving seasons between 1846 and 1874. We then estimated the total number of such visits in which the whalers engaged in gray whaling. We also read logbooks from a sample of known visits to estimate catch per visit and the rate at which struck animals were lost. This resulted in an overall estimate of 5,269 gray whales (SE = 223.4) landed by the ship-based fleet (including both American and foreign vessels) in the Mexican whaling grounds from 1846 to 1874. Our "best" estimate of the number of gray whales removed from the eastern North Pacific (i.e. catch plus hunting loss) lies somewhere between 6,124 and 8,021, depending on assumptions about survival of struck-but-lost whales. Our estimates can be compared to those by Henderson (1984), who estimated that 5,542–5,507 gray whales were secured and processed by ship-based whalers between 1846 and 1874; Scammon (1874), who believed the total kill over the same period (of eastern gray whales by all whalers in all areas) did not exceed 10,800; and Best (1987), who estimated the total landed catch of gray whales (eastern and western) by American ship-based whalers at 2,665 or 3,013 (method-dependent) from 1850 to 1879.

Our new estimates are not high enough to resolve apparent inconsistencies between the catch history and estimates of historical abundance based on genetic variability. We suggest several lines of further research that may help resolve these inconsistencies.

forwards from the1800s assuming the population was at carrying capacity prior to the start of commercial whaling in 1846, but such projections cannot produce a trend that agrees with the recent abundance estimates, which indicate the population roughly doubled between 1967 and 1988 … . The catch history and current trend can only be reconciled through fairly dramatic assumptions, such as an increase in the carrying capacity from 1846–1988 of at least 2.5 times, an underestimation of the historic commercial catch from 1846–1900 of at least 60%, or annual aboriginal catch levels prior to 1846 of at least three times the level previously thought (Butterworth et al. 2002)."

Figure 1.—Whole plate ambrotype of the New Bedford whaleship *Saratoga*, labeled "1856 Frederick Slocum, master." The photographer and his location are unknown. Depending on where it was taken, New Bedford or Honolulu, this image would be the oldest or second-oldest known photographic representation of a whaleship. At the time, *Saratoga* was part of the fleet of vessels engaged in whaling for gray whales in Mexico during the winter season. Courtesy of New Bedford Whaling Museum.

In a separate paper in this issue, Reeves and Smith (2010) reviewed and reanalyzed the history of commercial shore-based whaling for gray whales and humpback whales, *Megaptera novaeangliae*, along the coast of California in an initial attempt to address Wade's (2002) "dramatic assumption" that the historic commercial catch has been substantially underestimated. This paper considers another aspect of the gray whale's catch history that bears on the same assumption. Thus, we review commercial 19th century ship-based whaling on gray whales in the eastern North Pacific and evaluate the extent to which previous compilations have led to underestimation of removals by that component of the overall whaling effort on this species.

Previous Gray Whale Catch Estimates in the Eastern North Pacific

By ship-based whaling we mean the whaling by crews of ships (rigged as brigs, schooners, barks, or ships) that went to sea from a home port and hunted whales using this main vessel as a "mother-ship," pursuing the whales from small boats and towing their catch back to the main vessel (or in some scenarios to a "tender" vessel) for processing (Fig. 1). Although ship-based whaling was usually a pelagic activity, in some circumstances, for example when hunting gray whales in their breeding and calving lagoons, the ships were anchored near shore or in a bay while the boats scouted for and caught the whales. Such whaling is sometimes called "bay whaling," a term that is not, however, without ambiguity. For example, Dall (1872 as quoted in Scammon, 1874:22) referred to what has been called shore whaling at Monterey, Calif. (Sayers, 1984; Reeves and Smith, 2010), as "the bay-whaling of that locality." Scammon (1874:23), in contrast, referred to the start of "bay-whaling" for gray whales in 1846 in a clear reference to the start of ship-based whaling in Magdalena Bay, Baja California. Although gray whales were taken in the eastern North Pacific by both offshore or alongshore whaling and by bay whaling, the latter apparently was responsible for the bulk of the removals.

Scammon (1874:23) estimated that no more than 10,800 California (i.e. eastern Pacific) gray whales had been "captured or destroyed" by whalers between 1846 and 1874. Given his estimate of 2,916 killed by shore-based whalers, this would imply that about 7,900 were killed during that period by the lagoon, alongshore, and offshore commercial whalers and aboriginal whalers, combined.

Henderson (1984:169, his Table I) estimated lower total removals (including hunting loss) of gray whales from the "California herd" by commercial whalers (i.e. taking no account of catches by aboriginal whalers): 8,044–8,099 from 1846 to 1874. Of that number, 2,592 were killed by shore whalers, leaving roughly 5,500 (5,452–5,507) to have been taken by ship-based whalers operating in the lagoons (3,235–3,290), alongshore (1,678), and in northern areas (539). Henderson (1972:260), in compiling

Lithograph of a northern whaling scene from Scammon (1874).

his catch record, had deliberately tried to err "on the side of exaggeration" because he was concerned that his estimates were lower than Scammon's. Although Henderson appears to have redressed that bias to some extent in his 1984 reanalysis, the net overall effect of the changes between his 1972 and 1984 estimates was, in his estimation, negligible (Henderson, 1984:166).

Best (1987) estimated even lower catches of gray whales by American ship-based whalers throughout the North Pacific between 1850 and 1879. One of his estimates was based on oil production (2,665 whales landed) and the other on logbook-recorded catch per voyage (3,013 whales landed). However, these estimates are difficult to compare to those by Scammon and Henderson as they include whales taken from the western North Pacific population and do not include catches by non U.S. vessels.

Three related estimates of the catches of eastern North Pacific gray whales over time have been used in modeling the status of the population. Reilly (1981) divided the commercial whaling era into three periods, defined according to the nature of his sources: 1846–1874, 1875–1911, and 1912–1981. For the first period, which is the main focus of this paper, Reilly relied principally on Henderson (1972). The second catch series, compiled by Lankester and Beddington (1986, their Appendix 1), benefited from the comprehensive review and analysis of ship-based whaling by Henderson (1984). Cooke (1986) used the Reilly (1981) catch series in his analysis, noting that it was "very similar to more recent compilations by Henderson (1984) and Lankester and Beddington (1986)." The third series was produced (by Butterworth et al., 1990, 2002) for a special meeting of the IWC Scientific Committee in 1990 to assess gray whales. The commercial component (at least) of that catch series was "based primarily upon Lankester and Beddington's (1986) table" (IWC, 1993:243). Although the Butterworth et al. (1990) catch series was considered the "best available" at the time of the special meeting, participants suspected that it was incomplete and that the commercial catches could have been underestimated by up to 1.5 times (IWC, 1993).

The IWC special meeting agreed (based on Mitchell, 1993) that although Henderson's (1972, 1984) studies of American ship-based whaling for gray whales off Mexico and California had been definitive in some respects, at least two things deserved reconsideration

(IWC, 1993). One was Henderson's use of 35 barrels (bbl)/whale as an average yield for converting oil production statistics into gray whales secured and processed. The other was the smallness of the loss rates (i.e. whales struck but lost as a fraction of the total killed) applied by Henderson (1972, 1984).

A number of additional issues that were not cited in the IWC report deserve attention. One is the possibility that some gray whales taken by non-American ships operating in the North Pacific, including the Mexican lagoons and the Bering Sea, were not accounted for in Henderson's published work. Another is the possibility that the oil returns used by Henderson to estimate catches were not complete. A countervailing (positive) bias might have come from the inclusion of oil from humpback whales, blackfish (mainly pilot whales, *Globicephala macrorhyncha*), and occasionally right whales, *Eubalaena japonica*, fin ("finback") whales, *Balaenoptera physalus*, and blue (sulphur bottom) whales, *Balaenoptera musculus*, in the whale oil returns of vessels visiting the gray whale grounds along the Mexico and California coasts. We have attempted to address all of these concerns, with varying success, in this study.

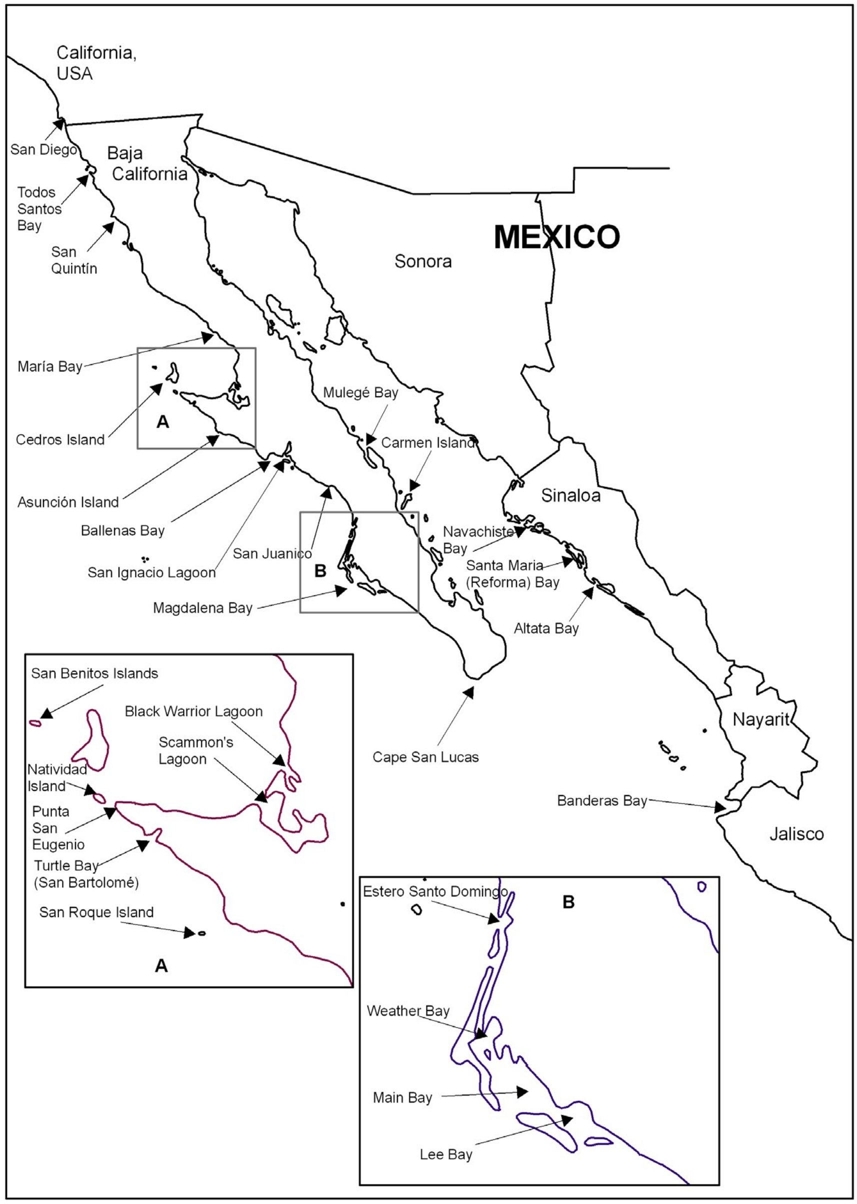

Figure 2.—Map of Baja California and Mexican mainland gray whaling region, with insets of Scammon's Lagoon (A) and Magdalena Bay (B).

Review of Ship-based Gray Whale Fishery

Henderson's Work

A central feature of the present study was a detailed examination of Henderson's published work (1972, 1984) and his extensive notes and files held by the library of the New Bedford Whaling Museum. We reviewed how Henderson made his estimates and attempted to evaluate their accuracy and completeness. The new estimates of catches and removals presented herein are based to a considerable extent on the Henderson material, supplemented by data from our own searches of logbooks, newspapers, and customs records.

Henderson's (1972) monograph on the fishery for gray whales in the eastern North Pacific focused on Scammon's Lagoon (Fig. 2) but included consideration of the entire species range. It was one of the earliest attempts to reconstruct a whale population's catch history from logbook and other data. He used, in particular, period newspapers such as the *Seaman's Friend and Temperance Advocate* and the *Pacific Commercial Advertiser* (Fig. 3), both published in Honolulu, Hawaii, the *Whalemen's Shipping List and Merchants' Transcript*, New Bedford, Mass., and various California newspapers, including the *San Francisco Alta California*, *San Francisco Chronicle*, *San Francisco Bulletin*, *San Diego Herald*, and *San Diego Union*.

In a follow-up study, Henderson (1984) reconsidered his earlier estimates. For his overall catch summary for the eastern Pacific population (his Table I, p. 169), he appears to have relied on a combination of newspaper reports, the Dennis Wood Abstracts (Wood, N.d.),

Figure 3.—Right: List of arrivals at Honolulu port, *Pacific Commercial Advertiser*, 5 April 1860. This illustrates some of the challenges of interpreting ambiguous data. For example, vessels that clearly visited the gray whaling grounds in Baja California in the winter of 1859–60, judging by the “From” column, had been at sea for many months, in some cases almost three years, and had given as their original destination (“Where Bound” column) Arctic, Ochotsk (Okhotsk Sea), or Kodiack (Gulf of Alaska). Much of the whale oil returned by such voyages (the “Wh.” column under “Season’s Catch”) would have been from gray whales taken in the Mexican lagoons and alongshore.

Vessels marked (*) entered the harbor. Those not marked, simply touched outside.

Left: Article in *Pacific Commercial Advertiser*, 1 April 1862, with relatively detailed information on activities of various Honolulu-based vessels in the winter 1861–62 whaling season. Note that for some, the catch is given as whales landed and for others, as barrels of whale oil. Reference is made to activities in all three of the main gray whaling lagoons: Ballenas (San Ignacio), Scammon’s, and Margarita (Magdalena) Bay.

Bottom: Brief, but informative, squib in *Pacific Commercial Advertiser*, 12 April 1860. Note that nearly all of the vessels mentioned here, *Sharon*, *Harmony*, *Ocmulgee*, *Fabius*, *George and Mary*, *Fortune*, *Delaware*, and *Lark*, are not included in the “Spring Fleet of Whalers” listed in the same newspaper a week earlier (see above). This example demonstrates the importance of combining multiple sources of information for a comprehensive accounting of catches.

MEMORANDA.

Report of brig Victoria, Dauelsberg.

Left Ballenas Bay, 13th March, with 450 brls this season. Reports the following vessels:

Brig Kohola, Brumerhop, Feb. 3d, at Scammon's Lagoon, with 11 whales. Brig Comet and schooner Kalama, at same place and date, with 21 whales between them.

At Margarita and Ballenas Bays—Ship Harvest, 37 whales; bark Harmony, 1000 brls.; schooner Emma Rooke, 500; ship C. W. Morgan, 14 whales; ship John Howland, 19 whales; bk Carib, 340 brls; bark Sarah Warren, 300 brls.

☞ Ship *General Teste*, Lopes—Left Honolulu, October 5. Cruised on the coast of New Zealand. In lat. 46° S., long. 160° W., fell in with immense quantities of field ice and very large islands of ice; was four days in going through. Left N. Z. Jan. 22; touched at Marquesas on the passage back, and saw there the Am. sperm whale bark *Sunbeam*, with 400 brls. sperm. Spoke the *General Scott* off New Zealand Jan. 10—he had taken nothing since leaving Honolulu.

☞ Ship *Reindeer*, Raynor, reports—Left Honolulu Dec. 4, and arrived at Margarita Bay on the 26th. Took the first whale on the 5th Jan., but did not fairly commence whaling till the 10th. Found whales most plentiful about the middle of January. Left the Bay February 28, put into Man-o'-War Bay for firewood, and sailed again March 5th. First three days, had light westerly winds, after that strong trades all the way. Arrived at Honolulu March 18, with 1,125 brs. oil this season, having been absent only 3½ months. Reports the following vessels:—In Margarita Bay, March 5. ship Harvest, Manchester, with 1000 brls. oil this season. Heard from, Feb. 22:

Bark Harmony, Molteno......................15 whales.
Schooner Emma Rooke, Wilbur................11 "
Brig Maria..................................3 "

☞ Capt. J. H. Swift, of ship *Sharon*, of Fair Haven, from Coast of California, with 450 brls oil, reports—Arrived at Scammon's Lagoon Jan. 2d; took the first whale on the 3d, and last one the 1st of March. Left on the 6th in company with ship New England, of N. L., and bark Harmony, of Honolulu; arrived at Turtle Bay the 7th; saw a number of whales until the 13th, when they became scarce. Left Turtle Bay on the 15th, in company with ship Ocmulgee and bark Harmony, both bound to the islands. Left at Turtle Bay, ship Fabius, Smith, of N. B., 500 brls this season; barks George & Mary, of N. L. 400 brls, Fortune, Comstock, of N. L., 400, Delaware, Kenworthy, of N. L., 550, Lark, of N. L., 600. The Lark leaves on the 20th for Marguerita Bay, to take the bark Ripple's oil home for her; all the other ships will touch at the islands.

logbooks, and a few published sources. He probably also consulted *The Polynesian*, a Honolulu-based newspaper that provided sometimes-detailed reports on whales taken per vessel, referring to the "California Coast" and at least occasionally to specific locations such as Turtle Bay or Magdalena Bay (Fig. 2). For the northern kills, Henderson used unpublished data provided by John Bockstoce (Bockstoce and Botkin, 1983). Henderson's final conclusion (1984:166) was that his earlier estimate of the total kill of eastern gray whales for the period 1846 to 1874 had been about right, i.e. ca. 8,000 gray whales, even though some of the details differed between his 1972 and 1984 analyses.

Henderson's 1972 book included the identities of the specific vessels that whaled in Scammon's Lagoon in each season from 1857 to 1873. His later book chapter (1984) had a broader focus, encompassing gray whaling in additional lagoons and bays in Mexico between 1846 and 1874, but without specifying the vessels and seasons. His summary totals of whaling vessel visits, which he termed cruises and which we term vessel-seasons, and his associated text led us to conclude that he had identified most, and probably nearly all, of the gray whaling activity in Mexico. We therefore assumed that, by scrutinizing his published work (Henderson, 1972, 1984) and his unpublished notes and files, we would be able to identify most of the vessel-seasons of whaling on the gray whaling grounds, including specific lagoons, bays, and "alongshore" areas.

Henderson's material included references to roughly 300 apparently uniquely named vessels that whaled for at least one season in Mexico beginning in 1846, for a total of roughly 500 vessel-seasons.[1] These vessel-seasons included many that were gray whaling, but also some that were taking sperm whales, *Physeter macrocephalus*, humpback whales, or elephant seals, *Mirounga angustirostris*, either exclusively or in addition to gray whales.[2] Some of the vessel-seasons proved to be spurious because a vessel's name had been spelled differently in different sources; this variation included instances where the appropriate Roman numeral was present in one source but missing in another (e.g. *Congress* vs. *Congress II*). Moreover, for some vessel-seasons, we were unable to determine the species targeted.

Henderson (1972:81) believed that gray whales had been largely or entirely "unmolested" by commercial whalers from 1795, when they were first observed and reported by Captain John Locke of the British whaleship *Resolution* ("the first captain to engage in a genuine whaling venture in the eastern North Pacific Ocean": Henderson, 1972:17, also see Henderson, 1975), to 1846, when, according to Scammon (1874), gray whaling began in Magdalena Bay. This large lagoon complex of smaller bays and channels had been visited by sperm whalers well before 1846, but apparently there is no record of a single gray whale having been taken before then, even though they must have been available in relatively high densities in winter. Henderson (1984:163) concedes that some whalers "chased" gray whales but he concludes that "so far as the record shows they never caught any."

General Characteristics of the Fishery

Henderson's extensive examinations of logbooks and newspapers allowed him to define the typical seasonal rounds, or itineraries, followed by the North Pacific whaling fleets. The ships usually sailed from the Hawaiian (Sandwich) Islands to the summer sperm, right, or bowhead, *Balaena mysticetus*, whaling grounds to the north and returned to Hawaii in the autumn and thence to one or more southern grounds, e.g. off New Zealand or Chile, along The Line (the equator), in the Marianas, or along the Coast of California, which mainly meant the western coast of Baja California (Henderson, 1984:162). Although there is little evidence that ship-based whalers hunted gray whales in low latitudes in the western Pacific as they did in the east (Henderson, 1990), considerable numbers of gray whales were taken in the Sea of Okhotsk (Reeves et al., 2008). This meant that on a given voyage, a vessel may have pursued eastern gray whales in the lagoons or alongshore Mexico and California in the winter, and western gray whales in the Sea of Okhotsk in the summer. In his synthesis, Henderson (1984) appears to have maintained the distinction and included in his Table I (1984:169) northern catches only from the "California herd," i.e. the Bering and Chukchi Seas. Therefore, there is no systematic compilation of gray whale catches by ship-based whalers in the Sea of Okhotsk (see Henderson, 1984:176, footnote 14; Kugler, 1984:157, footnote 6) although these are implicitly included in the estimates by Best (1987).

Henderson (1972:81) reported that American whalers arrived at the shores of Baja (Lower) California in Mexico and Alta (Upper) California in the Unites States in the early 19th century and that there was a "major movement of American whalers into the North Pacific from Hawaii after 1820." The vessels often provisioned at San Francisco and Monterey before heading to the Californias for winter sperm whaling. By the 1830's, scores of vessels were doing this. During 1846–47, the number of ships visiting Magdalena Bay for gray whaling rose rapidly from several to perhaps 50 (according to Scammon) or 20–25 (according to Henderson, 1972:83; 1984:165) in 1847–48. Apparently all of these represented "between the seasons" cruises by New England (especially Connecticut)

[1] Throughout this paper, a vessel-season is understood to encompass the period from late autumn one year to spring the next. Thus, 1846–47 would mean approximately November 1846 through April 1847. In some of the tabular material where vessel-seasons are identified by only one year, this refers to the latter part of the season and thus, in this example, it would be 1847 not 1846.

[2] As an example, *Cynosure* of San Francisco visited grounds between Cedros Island and Cape San Lucas, including Magdalena Bay, in the season 1855–56. The logbook makes no mention of gray whales but records the capture of one humpback whale (another struck/lost), 36 blackfish (pilot whales, *Globicephala* sp.), 22 elephant seals, and 20 turtles. In addition, the crew chased killer whales, *Orcinus orca*, unsuccessfully and struck but lost a blue whale. After a stopover in San Francisco from early February to late March, *Cynosure* returned to the Baja California and mainland grounds south to Central America, chasing right whales and humpback whales in April, and then only sperm whales and blackfish through the summer and autumn before returning to San Francisco in November 1856.

vessels or by foreign vessels (including some from French, Dutch, and German ports) that, in summer, had been engaged primarily in right whaling in the northern North Pacific.[3] There is a suggestion by Henderson that this phase of lagoon whaling was facilitated by the U.S.–Mexico war. As he put it, during the hostilities the Mexican government was "even less able to control, or benefit from, the whaling than prior to 1846" (Henderson, 1972:83).

Interest in gray whaling waned temporarily after 1848, a trend attributed by Henderson (1972:84, citing Williams, 1964; also Henderson, 1984:165) to "the inferior quality and low price of the dark-colored gray whale oil, the low quality and quantity of whalebone from the gray, and the dangers of lagoon whaling." In fact, lagoon whaling for gray whales stopped entirely for three seasons—1848–49, 1849–50, and 1850–51. A San Francisco ship (*Aquetnet*) whaled at Magdalena Bay in 1852–53 (Henderson, 1984:164), followed in the mid 1850's by, among others, the ship *Leonore* and schooner *Hopewell* (Henderson, 1972:84). As Scammon (1874:270) noted, "… Magdalena Bay whaling was resumed with ardor about the years 1855 and 1856, and was continued and extended along the whole coast of both Upper and Lower California." Many vessels returned to San Francisco after the winter season and then went back to Mexico for sperm and humpback whales in the summer.[2] It was not until 1861, when the barks *Sarah Warren* and *Carib* did so, that San Francisco vessels began to participate in the northern summer hunt for bowheads and right whales (Henderson, 1972:86).

By the early 1860's, a gray whaling circuit had been established, consisting of summer cruises out of Hawaii or San Francisco to the Gulf of Alaska, Bering Sea, Arctic Ocean, coast of Kamchatka, or Sea of Okhotsk principally for right whales and bowhead whales, followed by winter cruises to Baja California and along the mainland Mexican coast (Henderson, 1972:85). Some of the ships discharged their cargoes and refitted in Hawaii or San Francisco before going south while others proceeded directly to Mexico, often still carrying their cargo of northern oil and whalebone. Lagoon whaling for gray whales continued to be dominated by Hawaii and New England vessels operating out of Hawaiian ports. So-called "pick-up" cruises by small vessels out of San Francisco going for various whale species in addition to gray whales, plus elephant seals, sea turtles (probably mainly Cheloniidae), and even abalone (family Haliotidae) were also common in the late 1850's and early 1860's (Mulford, 1869; Henderson, 1972:94–6; 1984:171).

Henderson (1972, 1984) recognized three distinct contexts or phases of ship-based gray whaling: lagoon whaling, coastal or alongshore whaling (including kelp-whaling, where the boats were stationed in or near the kelp beds and waited for the whales to swim within shooting range; Scammon, 1874:26–27, 258–259), and pelagic whaling on the northern summering grounds. In his statistical scheme for organizing the catch history of eastern gray whales, Henderson (1972, 1984) divided the 19th century ship-based era into three periods, as follows: Initial, 1845–46 to 1853–54; Bonanza, 1854–55 to 1864–65; Declining 1865–66 to 1873–74.

Unfortunately, the lack of lists of the vessels and voyages included in Henderson's analyses seriously hampers attempts to trace his reasoning and verify his catch totals, which in any event are presented in his various published tables only as quasi-decadal aggregates. Following Henderson, we have organized our review according to three phases (lagoon, alongshore, pelagic), further subdivided by time intervals as appropriate.

Lagoon Whaling

Lagoon whaling was centered in three lagoons along the outer (Pacific) coast of Baja California: Magdalena (Margarita) Bay (a deep basin with appended lagoons and shallow margins where gray whales concentrated; Mulford, 1869; Henderson, 1972:30), San Ignacio (Ballenas) Lagoon (not to be confused with Ballenas Bay on the outside where alongshore whaling occurred), and Ojo de Liebre (Jack Rabbit Spring; see Henderson, 1984:183) Lagoon (now better known as Scammon's Lagoon; Fig. 2). Black Warrior Lagoon (Laguna Guerrero Negro), although named after the whaling bark *Black Warrior* of Honolulu, was not a significant whaling lagoon, and Henderson (in Scammon, 1970:38, note 52) concluded that it was only visited in 1858–59 when "the captains of the few vessels from Honolulu which entered the lagoon probably mistook the mouth for that of Scammon's Lagoon."

In the Initial Period, there was no lagoon whaling in 3 of the 9 years (1848–49, 1849–50, and 1850–51). The entire lagoon catch in this period was in Magdalena Bay, where ships sailing from Connecticut ports predominated, accounting for about half of the 50–60 vessel-seasons. Also, vessels from Havre (5 seasons), Bremen (1), and Amsterdam (1) visited Magdalena Bay and whaled for gray whales there. Presumably, Henderson's (1984:165, 169) estimate of the lagoon catch in this period (400–450 by 50–60 cruises) includes the activities of non U.S. registered vessels. He accounted for the downward revision of his earlier estimate of 500–550 for this period (Henderson 1972, his Table I) by suggesting that about 100 catches of sperm and humpback whales had been inadvertently included with the earlier tally (Henderson, 1984:165).

Henderson (1984:165) stressed that some vessels and crews were especially adept at gray whaling in the lagoons (and perhaps also alongshore) and took many whales, while others left the grounds "without a drop of oil." The difficulty of approaching and securing the whales could well have increased with time. Even by the mid 1850's, Mulford (1869) found, for example, that the gray whales in Magdalena Bay were extremely wary:

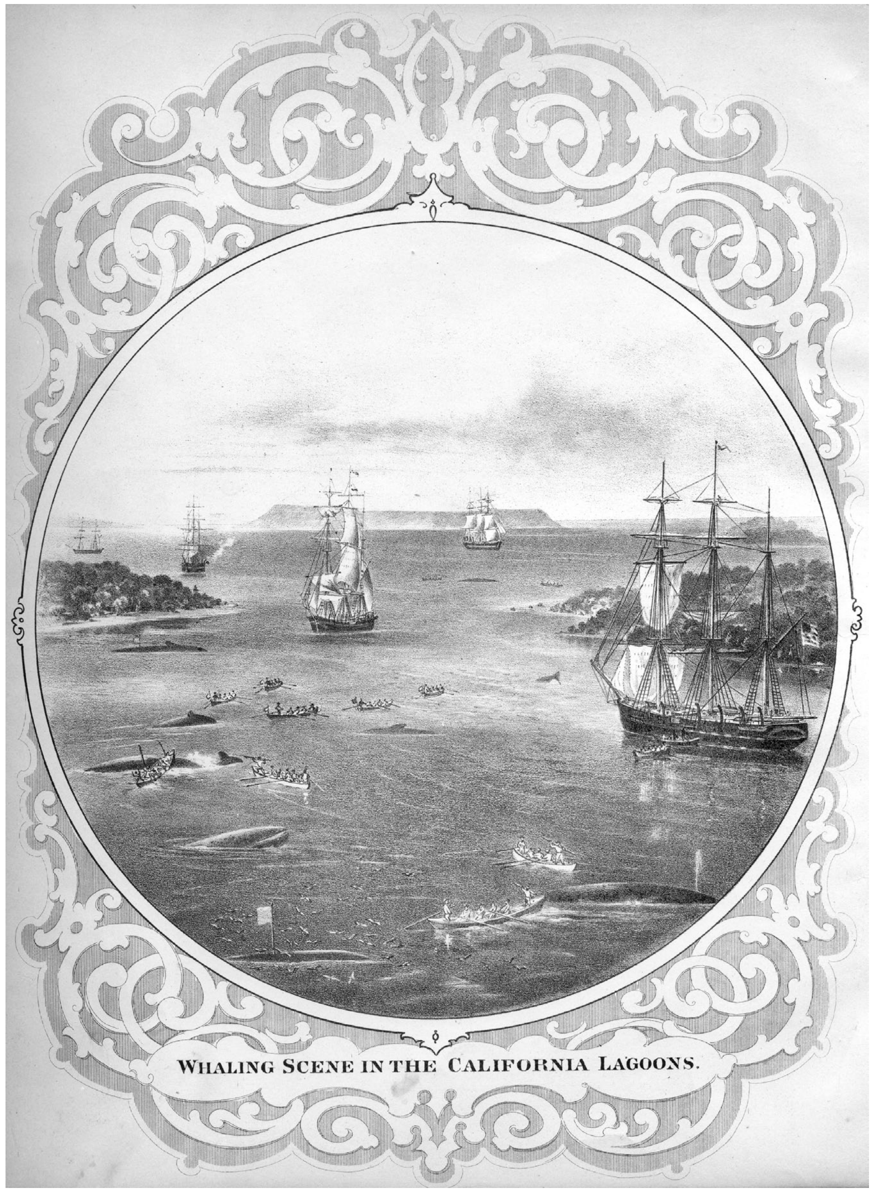
> "Near as the Graybacks came to the schooner, they were shy of the boats. They had been chased before and know something of our deadly intentions. Two hours

[3] In the 3 years from 1846 to 1848, 32 American, 4 French, and 2 Dutch vessels reportedly took 338 whales in Magdalena Bay (Henderson, 1972:83).

elapsed before we managed to creep up near one of the great fish. The oars were handled without noise; the men spoke not a word; they came within a few yards of the black mass; the suspense and half dread was akin to that experienced by the soldier in the hush before the battle."

Indeed, the literature (not just Henderson) consistently characterizes lagoon whaling for gray whales as a specialized endeavor that attracted only a particular subset of whalemen. Scammon (1874:268–269) claimed that lagoon whaling was not equally attractive to all who tried it. For example, many of the 50 ships that visited Magdalena Bay in the winter of 1848 left after only a few days, choosing instead to spend the between-seasons period sperm whaling in the open sea. This pattern described by Scammon may have changed to some extent in later years (the Bonanza period) when in some seasons a very high proportion of the Honolulu- and San Francisco-based fleets were engaged in lagoon (and alongshore) whaling for gray whales. Improved practices, techniques, and equipment, particularly wider use of the bomb-lance (see later), evidently made gray whaling in and outside the lagoons more feasible and less dangerous (Henderson 1984:171).

The catch (and kill) in lagoon whaling was strongly biased toward adult females and calves of the year. In Magdalena Bay, there was a distinct break in timing between the cow/calf season (approximately late December through mid February) and the season for "the bulls" (approximately the second half of February), and the two seasons were also spatially separate, with mothers and calves being hunted in Lee (Almejas) Bay and bulls in Weather or Main Bay (*Saratoga*, 1857–1858, logbook; Fig. 4). Some shifting of the center of whaling activity through the season also occurred in Scammon's Lagoon. For example, in the 1858–59 season, Scammon (1970:66–8) took most of his whales (apparently all cows and calves) in the inner lagoon in January and early February, then relocated toward the outer (Weather) lagoon in mid February where whaling continued into early March.



Lithograph from Scammon (1874).

Modern studies of gray whales in the Mexican lagoons (mainly centered in San Ignacio Lagoon) indicate that mother-calf pairs tend to remain inside the lagoons about three times longer than single whales (including males as well as females unaccompanied by calves) (Urbán et al., 2003). Calving females are among the earliest whales to arrive at the lagoons and the cows, with their calves, are the last to leave on the spring northward migration (Norris et al., 1983; Swartz, 1986). There is a sharp distinction between the cow-calf pairs and "courting" whales in how they use the lagoons. The former tend to occupy the very shallow channels deep inside the lagoons while the latter generally remain in and near the lagoon entrances. Also, although cow-calf pairs do circulate among the different lagoons to some

extent, the turnover rate of courting animals appears to be higher.

For some years, there is precise information on lagoon catches. For example, at the end of *Paulina*'s 1858–59 season, its logbook entry for 21 February summarizes the Magdalena Bay catches to that date in two parts of the Magdalena Bay complex, as follows: in the outer or Main Bay—*L.C. Richmond* 12 whales, *Majestic* 6, *Benjamin Morgan* 6, *Paulina* 10, *Fortune* 6, *Hibernia* 3, *Hawaii* 1; in Weather Bay—*Reindeer* 8, *Rambler* 8, *Addison* 8, *Scotland* 5, *Massachusetts* (of Nantucket) 7, *Levi Starbuck* 5, *Benjamin Rush* (no report), *Euphrates* (no report), *Dromo* 8, *Tenedos* 6, *Hercules* 4. The *Paulina* log also notes that there was no definite information from vessels whaling in the upper lagoon, "but they are reported as doing extraordinarily well." If all of the whales taken in Main Bay and Weather Bay were grays, this would mean that well over 103 had been secured in the Magdalena Bay complex that season prior to 21 February.

Henderson (1984) assumed that in lagoon and alongshore whaling, one whale was killed and lost for every ten secured (loss rate factor: 1.1). This appears to have been intended to account for non-calf whales that were harpooned or shot but never secured and processed, and thus would not account for killed, injured, or orphaned calves (discussed later). According to Henderson (his Editor's footnote 86 in Scammon, 1970:68), "Scammon may not have bothered to record all of the calves killed or he may have instructed his men to stay clear of the calves in order to avoid infuriating the cows." *Ocean Bird*'s tally in 1858–59 consisted of 47 cows and 5 calves. "It would appear that, after taking four calves with the first seven whales killed [in 1858–59], Scammon's boat crews had tried to avoid killing calves and thus enraging the cows, or that Scammon simply ceased recording the calves taken" (Henderson, in Scammon, 1970:57, Editor's footnote 74). In a later voyage on *Ocean Bird* (1860–61), Scammon "captured many calves along with their mothers" in San Ignacio Lagoon (Henderson, in Scammon 1970:68, his note 86; and see Henderson, 1972:138–139). "The calves, however, were not calculated in the catches of the gray whalers. Some very large calves killed at end of the season at the lagoon may have been counted as adult whales" (Henderson, Editor's footnote 86 in Scammon, 1970:68, citing *San Francisco Alta California* 1 January 1860:4).

The detailed, legible logbook of *Saratoga* (1857–1858) provides further insights. Of 14 gray whales landed by *Saratoga* in the 1857–58 season in Magdalena Bay, 13 were "cows" and only one a "bull" (Fig. 5). In a number of instances, the logbook offers hints at how the whalers did, or did not, strike the calf to improve their chances of securing the cow. For example, on 20 January 1858 one of the boats passed between a mother and calf, and the calf was harpooned —"in an instant the cow stove the stern of the boat," then wreaked havoc. Two days later, a cow was taken whose calf was judged to be less than 24 hours old, and "way too small to fasten to, as an iron would have killed it and the cow then, would have made 'music' among the boats." The next day, one of *Saratoga*'s boats was "stove" (damaged) by a calf. On 29 January the logbook records that a boat from another vessel (*Splendid*) "struck a calf … and killed it instantly, the cow then left, before they could fasten to her, and they lost her." A day later, the crews from *Saratoga* and *Draper*, working together ("mated"), struck both members of a cow-calf pair but the lines fouled and "parted," and the whale (singular) was lost. The same approach was taken on 1 and 6 February, but these times successfully, with the cow secured and the fate of the calf not mentioned in the logbook. Also on 6 February, a *Saratoga* boat "fastened" to another calf but the iron "drew" and "they lost the cow." On 10 February *Saratoga* and *Draper* killed three cows but lost one of them, "the calf drawing the irons out of the cow, the lines being foul and she sinking." Yet another description was provided by Mulford (1869:64), who mentioned an incident in which a harpooned cow became enraged and smashed the whaleboat after her calf had "received the lance intended for the mother." Although it is impossible to be sure, it seems that in this instance the whalers had not intended to lance the calf.

The notion that more calves were at least struck, if not killed outright, than is suggested in the tallies of whales killed, or indeed than is implied by the amounts of oil landed, was echoed by other authors, including Scammon himself. He stated (Scammon, 1874:259), "A cow with a young calf is usually selected, so that the parent animal may be easily struck." Although the usual practice was to avoid striking calves, they were lanced at least occasionally by accident when they got in the way at a critical moment during the capture of the cow (Scammon, 1874:29). Also, at times the whalers deliberately harpooned the calf instead of the cow. Scammon (1874:29) described two occasions when a particularly wary cow was taken only after the calf was harpooned and hauled into shallow water where the attendant

mother could be shot with a bomb-gun from the beach. The published journal of a whaleman's wife who spent the 1846–47 season in Magdalena Bay (Druett, 1992:177) states that gray whales "can only be taken when they have a young one which they [the whalemen] fasten to and by this means secure the mother who will never forsake it till dead. … When dead they tow the whale [i.e. the mother] to the ship. …"

Overall, Henderson (1984:178) found that tactics varied. "Whalers handled attacks on calves in two ways: some preferred to harpoon the calf first so that the cow would stay close by; others left calves alone out of fear that wounded and dying calves provoked the cows into more destructive behavior." Regardless of whether calves were struck, killed, or left alone by the whalers, however, their death was virtually certain, and therefore it is reasonable to infer that one calf was killed for every cow killed in the lagoons (Fig. 5). Again, Mulford (1869:42) provides a clear example of what must have been a typical outcome:

> "We towed the upturned carcass to our vessel. But the poor calf still followed the dead mother. It was playing about the body in the morning, ... and still after we had stripped from the carcass the blubber and turned it adrift to float up and down the lagoon … the poor, helpless, starving creature still swam by the dead mother's side."

Henderson (1972:132) observed:

> "… as the catch on the calving grounds consisted largely of cows, many of which had calves that were killed or died without their mothers, the current and future reduction of the population exacted in the calving waters was far greater than the actual reported catch there, which usually did not account for calves, would indicate."

Scammon (and presumably other whalers in the mid 19th century) regularly used explosives ("bombs") to hunt

at the mizen peak, and a signal at the fore topgallant head, to notify our boats that there was something up and to keep a bright look out. the Captn also had a blue signal flying from his boat while chasing, the signal of our boats, after chasing about 10 miles, the other boats seen them, and came to their assistance, the third mate of the Draper, fastened to the calf, and in an instant his boat was knocked into a "cocked hat" by the cow, who gave it to her "right and left" but none of the crew was injured, some of the other boats picked up the crew, and fastened to the cow several bomb lances were given her, when she suddenly went into her "flurry" or death struggle, when she threw her entire head across the stern of one of our boats, the 4th mates, breaking the gunwale, steering oar, two other oars, and the mast in 4 pieces, rolling the boat over, The crew thinking, there was not sufficient room for all in one small boat, when they the whale entered they left, jumping overboard, giving her whaleship full possession The boat was but little damaged, and the crew uninjured, at 11 P.M. the whale was towed to the Draper, Our boats had been fast in the morning the 2nd mate fastening to a calf, but the iron drawing they lost the cow

Sunday Feby 7th Begins with pleasant weather and light airs from the Northward employed in boiling, at daylight finished and cooled down the works, After breakfast commenced repairing the bow boat and finished it during the day, so that she was all ready to lower when the other boats lowered, no ships boats lowered

Figure 5.—A page from the logbook of the ship *Saratoga*, 6–7 February 1858, with the vessel at anchor in Magdalena Bay. The sketches in the margin indicate that one cow was killed and secured and another whale was struck but lost when the "iron drew." The text for 6 February refers to a boat from *Draper* having harpooned a calf, then being "knocked into a 'cocked hat' by the cow." The cow was finally killed and towed to the mother ship, but not until it had damaged two boats and forced their crews overboard. Earlier in the day a boat from *Saratoga* had harpooned another calf and then its mother, which was lost when the iron drew. Courtesy of New Bedford Whaling Museum.

gray whales in the lagoons (Scammon, 1970:31, 46; Henderson, Editor's footnote 41 in Scammon, 1970:30). A bomb lance was a small, metal cylinder filled with gunpowder and fitted with a time-delay fuse that allowed it to explode a few seconds after entering the whale (Bockstoce, 1986). It was fired from a shoulder gun. The use of bomb lances allowed the operation in Scammon's Lagoon to become a "shoot and salvage" operation (Reeves et al., 2002), with the whalers simply shooting the whales and hoping to retrieve the floating carcasses either soon afterward or the next day (Scammon, 1874:264; Henderson, 1984:178–179). This practice of shooting the whales without first fastening to them with a harpoon would have contributed to hunting loss although in lagoon whaling the prospects of recovering bombed whales that escaped or sank certainly would have been higher than in the open ocean (Henderson, 1984:166). Some whalers clearly fastened first and then fired bombs, but even then the whale could be lost. For example, in Magdalena Bay in 1861, boats from the Hawaiian schooner *Maria* reported having "fastened to another cow whale, and fired two bomb lances, which set her spouting thick blood, but unfortunately the iron drew and we lost the whale, being close to the passage at the time" (*Pacific Commercial Advertiser*, 18 April 1861, 5(42):2).

Within the confines of a lagoon, carcasses could be found "washed ashore or drifting . . . if the internal decomposition had generated gasses to float the whales" (Henderson, Editor's footnote 43 in Scammon, 1970:32). Sometimes the position of the carcass was marked with a buoy to aid in relocating it (Editor's footnote 49 in Scammon, 1970:34; Henderson, 1984:178). It seems consistent with both the circumstances (i.e. sheltered or enclosed conditions) and the evidence from logbooks to infer that the rate of recovery of gray whale carcasses was much higher inside the lagoons than outside.

At least one "shore party" was active in Magdalena Bay in the late 1850's (*Saratoga*, 1857–1858 logbook; also see Henderson, 1972:100, 126–127; 1975; 1984:170). On 18 January 1858 a trypot and three empty casks from *Saratoga* were towed to shore where a group of "Spaniards" had agreed to "take the oil from the carcasses, on halves." We interpret this to mean that the team on shore received whale carcasses after the blubber had been stripped for cooking aboard the vessel, and that for their efforts they were allowed to keep half of the oil produced from the flensed carcasses. On 23 January 1858 the *Saratoga* logbook notes:

> "The shore party of Spaniards came off and assisted us [in cutting in a gray whale taken the day before]. They try out the carcasses for us and two other ships on halves. . . . They keep a sharp look out on shore with a telescope and when they see either of the three ships cutting, immediately put off in their boat, and when we have finished cutting, tow the carcass on shore to their works."

On 31 January, the logbook records that *Saratoga* received 6 bbl of oil and "settled up" with the shore party, as did the other two ships. The shore camp was dismantled on 19 February but there is no further mention in the *Saratoga* logbook of oil received from the camp.

"Carcassing" (Henderson, 1972:127; 1984:170) complicates catch estimation for lagoon whaling in a number of ways. The returns of vessels whaling in Magdalena Bay were sometimes reported in terms of "body" oil versus "carcass" oil. For example, *Massasoit* was reported as "full" in April 1861 (*Polynesian*, 20 April 1861, 17(51):3), having taken 20 whales yielding 860 bbl of "body" and 93 bbl of "carcass" oil. The latter may refer to oil obtained from carcasses found and tried out by the crew of *Massasoit*. *Massasoit* reportedly also "bought 78 bbls besides," which could refer to oil obtained from carcassers.

In some instances, operations on shore seem to have been directly integrated with the ship's whaling strategy (as could be true of the *Saratoga* example, above, but it is impossible to know for certain). In 1860, when the Hawaiian schooner *Maria* arrived at Magdalena Bay on 3 December, the crew immediately went ashore, constructed tryworks and huts, and prepared a scow for transporting blubber to land (*Pacific Commercial Advertiser*, 18 April 1861, 5(42):2). From 24 December, when the first gray whale was observed, through the end of March, *Maria*'s crew, along with those from several other vessels, apparently deployed from the anchorage and took more than 65 gray whales.

Floaters or "stinkers" that were found by a ship's crew or a shore party may have yielded lower-than-average amounts of oil, whether due to putrefaction and leakage or to scavenging by sharks. Best (1987:417) noted that in Townsend's (1935) sample of logbook data, 11 of the gray whales processed had been found dead (representing 4.4% of the total listed as landed). Best considered this an underestimate of the true proportion and assumed that most found carcasses were of whales that had died as a result of whaling-related injuries (as opposed to natural causes). "If so, this fact should be borne in mind when corrections are applied to the landed catch to account for whales struck and lost that subsequently died" (Best, 1987:417). On one occasion when *Saratoga* (mated with *Draper*) lost a cow in Magdalena Bay due to sinking, the carcass was secured two days later "but was so much blasted that it was a stinker in every sense of the word" (*Saratoga*, 1857–1858, 12 February 1858 logbook entry). Still, the whalemen managed to make 40 bbl from it. Scammon made no mention of shark damage, but Henderson (Editor's footnote 43 in Scammon, 1970:32) cited evidence from other whalemen that this could be a serious problem (e.g. in Banderas Bay and in Estero Santo Domingo at the northern end of Magdalena Bay).

Coastal or Alongshore Whaling

Whaling outside the lagoons but along continental or island coasts was generally a mixed-species hunt: humpback whales and sperm whales were as or more likely to be taken than gray whales (humpbacks were also taken in

Magdalena Bay). Henderson (1984) estimated that only 25 grays were taken alongshore in five vessel-seasons during the 9-year Initial period (1845–46 to 1853–54). However, the intensity of alongshore whaling increased greatly thereafter, with Henderson (1984:168) estimating about 900 grays taken in 80 vessel-seasons during the 11-year Bonanza period (1854–55 to 1864–65). Referring to the seasons of 1858 and 1859 (presumably meaning 1857–58 and 1858–59), Scammon (1874:270) stated:

> ". . . not only the bays and lagoons were teeming with all the varied incidents of the fishery, but the outside coast was lined with ships, from San Diego southward to Cape St. Lucas. A few vessels of this fleet cruised near the shore by day, standing a little way off at night; but by far the largest number anchored about the islands, points, and capes, wherever the animals could be most successfully pursued."

Henderson (1972:97) concluded that 1860–61 was the peak year of alongshore whaling for gray whales.

The principal places for alongshore whaling included: San Quintín, Natividad Island, Punta San Eugenio, Turtle Bay (San Bartolomé), San Roque Island, Asunción Island, San Juanico, Cape San Lucas, and the near-shore waters off and inside Todos Santos, Ballenas, and María Bays (Henderson, 1972:97). Some gray whales may have been taken near the San Benitos Islands and Cedros Island as well (Henderson, 1984:168). Although generally not viewed as part of the main theater for gray whaling, several bays along the mainland Mexico coast of Sonora, Sinaloa, and Jalisco were used by gray whales and were visited by the whalers. These included Altata (Scammon, 1970:16, his note 10), Navachiste, Santa María (Reforma), and Banderas Bays (Henderson, 1972:31; also see Gilmore et al., 1967).

One additional area where gray whales were hunted, but which has not been mentioned by previous authors, is Mulegé Bay on the eastern coast of the Baja California peninsula. The New Bedford bark *South America* hunted gray whales (referred to as "devilfish" and "ripsacks") in the bay for most of January and February 1858, taking two large whales (27 January, 2 February; Fig. 6). The 27 January whale was taken "in company" with the New Bedford bark *Sarah Sheafe* and therefore at least one other vessel was hunting gray whales in Mulegé Bay that season. The logbooks of both *South America* and *Saratoga* provide insights on the apparently opportunistic nature of some coastal gray whaling. In early December 1857, *South America*, *Saratoga*, *Sarah Sheafe*, the bark *Islander* of Nantucket, and the bark *Tybee* of Stonington were all "endeavoring to work up the Gulf [of California]." Working in company until mid December, *South America*, *Saratoga*, and *Sarah Sheafe* reached as far north as Carmen Island (lat. 25°57′N, long. 110°50′W), where the crew of *Saratoga* went ashore and interrogated local people concerning whales. On 16 December, the logbook of *Saratoga* states: ". . . giving up all further intention of proceeding up the gulf and starting for Magdalena Bay." In contrast, *South America* and *Sarah Sheafe* continued sailing northward and stayed in the gulf, coming to anchor in Mulegé Bay in the third week of December and remaining in the area until 27 February. Time was spent on shore—fishing, clamming, and gathering wood—from their arrival in the bay until mid January. Humpback whales were sighted "bound up the bay" on 6 January (*South America* log), but no effort was made to chase them. On 13 January, the log notes, "waiting for whales, expect them any day," implying that the whalers had come to Mulegé Bay for the explicit purpose of hunting gray whales. More humpbacks were seen on 23 and 25 January, and then "a few California grays" were chased on the 26th.

After taking their second gray whale (on 2 February), *South America*'s crew saw whales on only four more days before leaving the bay on about 20 February. Two of those sightings were of humpbacks, one of which was chased without success. *South America* sold 372 gallons of oil and 7 barrels of "slush"[4] locally—the oil being a reminder that catch estimates based on oil returns may be negatively biased. While working out of the Gulf of California (en route to Hawaii, where it arrived at the port of Wohoo on 21 March), *South America* struck but lost a "sulphur bottom" (blue whale). Also, the boats were lowered for humpbacks as the bark passed Cape San Lucas on 2 March.

Henderson (1972:166, also his Table I) seems simply to have guessed that about 150 grays were secured between southern Sonora and Banderas Bay during the Bonanza period, and the same number again during the Declining period. He noted that the whalers who whaled there were interested primarily in sperm and humpback whales—they "probably took gray whales only when sperms and humpbacks were scarce or absent" (Henderson, 1972:166). Without explanation, Henderson (1984:174) concluded that the gray whale catch along the Mexico mainland during the Declining period was only 50 (in 10 vessel-seasons), rather than 150 as he had estimated earlier (Henderson, 1972, above). A recent study of gray whale usage of these mainland sites found that calving no longer occurs there, and that this situation is unlikely to change given present levels of fishing activity and maritime traffic in the region (Findley and Vidal, 2002). We are unaware of recent investigations in Mulegé Bay and therefore cannot comment on whether some gray whales still visit that area.

As mentioned earlier, some coastal whaling was described as "kelp-whaling," where the boats were stationed in or near the kelp beds and waited for the whales to swim within shooting range. In later years of the fishery, when the whales had become wary of the whaleboats, small 2-man boats were used, with one man to scull and the other to

[4] Slush was the fatty residue left from boiling salt horse (dried beef and/or pork). It was allotted to the cook in his contract and he was able to sell it for added profits to himself. Later, that term was used for the grease that was used to grease the mast and spars.

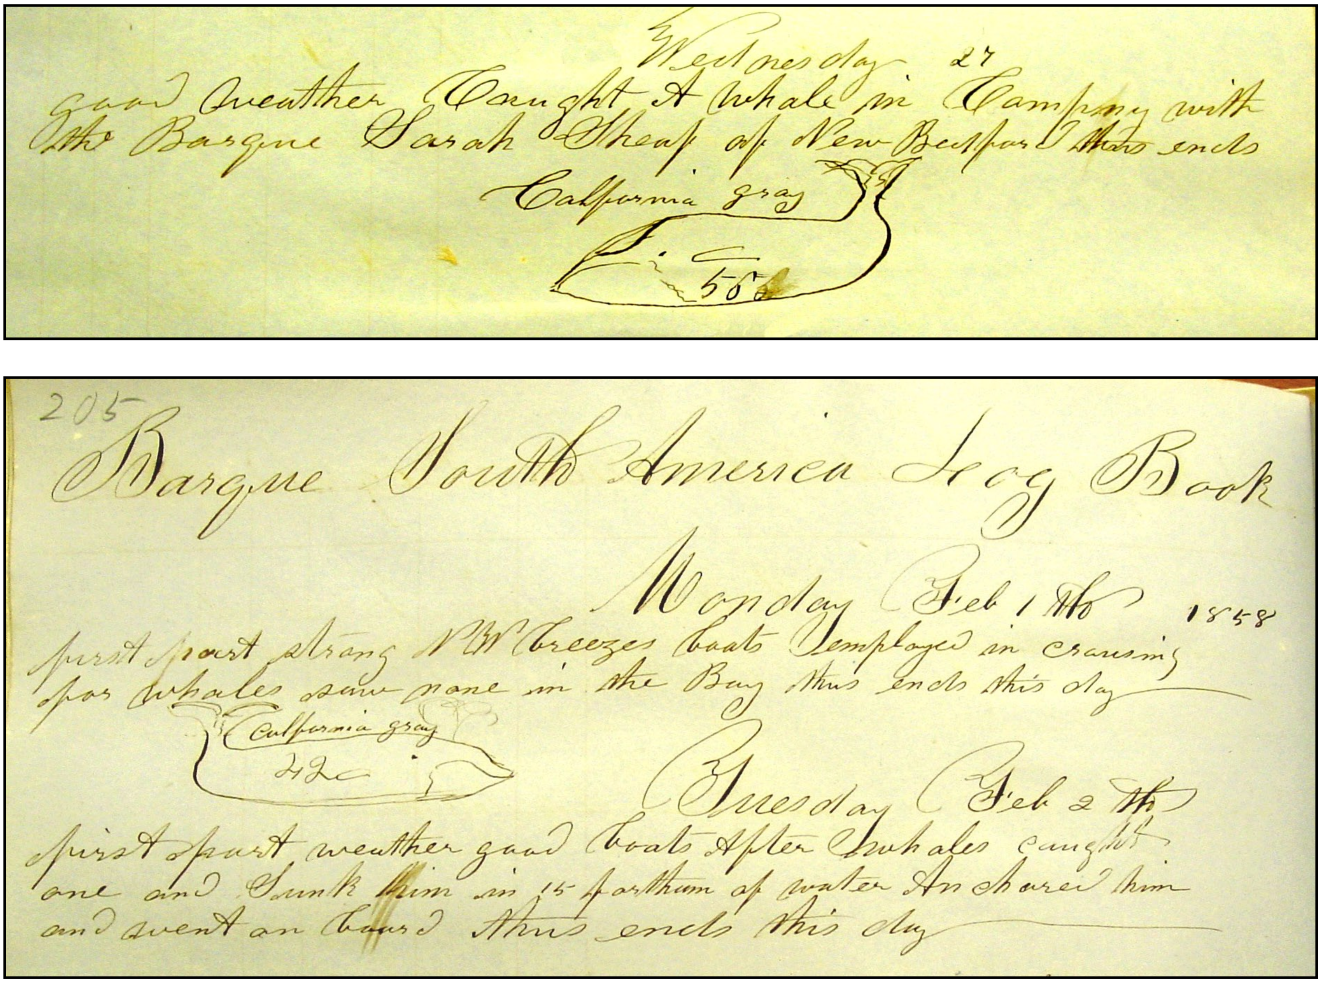

Figure 6.—Top: Detail of a page from the logbook of the bark *South America* for 27 January 1858, while in Mulegé Bay on the east coast of Baja California, describing the taking of a large (55 barrel) gray whale "in Company with" the bark *Sarah Sheafe.* Bottom: Another page from the logbook of *South America*, referring to the capture of a "California gray" in Mulegé Bay, Gulf of California, this one on 2 February 1858. shoot. Still later, as the whales passed farther offshore, the whaleboats were anchored outside the kelp, chasing the whales as they passed inshore. Evidently, much of the whaling was "shoot-and-salvage." Even if a line was secured before the whale died, the carcass often sank and would only be secured after it rose to the surface as much as a day later. Sometimes the blubber was tried out in "pots set for that purpose upon the beach" although most often the flensing was conducted alongside the ship. Scammon described another variant of coastal whaling for gray whales as "whaling along the breakers" (Henderson, 1972:96).

As indicated above, Henderson (1984) used the same loss rate factor for adjusting catches in alongshore whaling as in lagoon whaling even though he acknowledged that the chances of eventually securing a struck/lost whale were better inside a lagoon or embayment than outside in the open ocean. Our own findings in this regard are discussed later.

Pelagic Whaling

Almost no whaling for gray whales occurred in offshore waters of Mexico and California, presumably because the whales themselves tended to remain close to shore and congregated mainly in bays or lagoons. Most of the pelagic catch therefore centered in high latitudes, particularly in the Bering and Chukchi Seas. Although whalers searching for right whales in the Gulf of Alaska chased gray whales occasionally (Henderson, 1972:26), there is no evidence to suggest that they made significant catches there. Henderson (1984:166), with unaccounted-for precision, gave "probably … only about 52" as the number taken in 20 vessel-seasons on the northern grounds in the Initial period, followed by about 175 (80 vessel-seasons) in the Bonanza period, and 175 (40 vessel-seasons) in the Declining period for a total catch of 402

(539 killed) over the entire period from 1845–46 to 1873–74 (1984:169). He further stated (1984:170–171) that on the northern grounds, many gray whales were lost under the ice or in foggy conditions and that "more whales were lost [there], relative to those caught, than in any other sector of the gray whale fishery."

Bockstoce (1986:72–73, 132) estimated that about 500 gray whales were taken over the entire life of the ship-based commercial fishery for bowheads in the Bering Sea and Arctic Ocean (1848–1914), and that about 300 more were killed but lost (implying a loss rate factor of 1.6, as compared with 1.34 implied by Henderson's numbers [539/402]). In considering why so few gray whales were taken, Bockstoce (1986:72–73, 132) noted that 1) they lacked commercially valuable baleen, 2) they yielded comparatively little oil, which in any event was priced at about 5 cents less per gallon than "whale" oil, 3) they were both difficult and dangerous to subdue, and 4) most importantly (according to Bockstoce), by the mid 1860's their numbers had been reduced considerably by the lagoon whaling in Mexico.

Regarding the difficulty of capturing gray whales, noted whaling captain Thomas Welcome Roys described them as fast swimmers that "generally could not be taken with hand harpoons from open boats" (Schmitt et al., 1980:25). Further, according to Roys (in Schmitt et al., 1980:64), gray whales, along with humpback whales and blue whales, "will not generally allow a boat to come nearer than three or four rods of them, hence the difficulty of fastening."

Bockstoce and Burns (1993:568) stated that by 1866 the bowhead whale population in the Bering and Chukchi Seas was in "steep decline" owing to nearly two decades of intensive commercial whaling. As a result, the American whalers tried to "offset poor catches" by hunting walruses, *Odobenus rosmarus*, and gray whales during the "middle season" between late spring and autumn. Elsewhere (Bockstoce and Botkin, 1982:184), it was suggested that most of the walrus hunting took place between mid June and early August, at a time when the bowheads were "generally inaccessible to the whaleships."

In their analysis of the walrus kill, Bockstoce and Botkin (1982) extrapolated from logbook data covering 516 complete cruises, or about 19% of the total number of whaleship cruises to the western Arctic from 1849 to 1914. No similar extrapolation to estimate the total kill of gray whales has been published, but Bockstoce and Burns (1993) stated that the kill amounted to "about 840 . . . , of which 539 were captured (Bockstoce in Henderson, 1984: Table I) and another 300 were lost (Bockstoce 1986:73)." Those authors' statement is not consistent with Henderson's (1984) conclusion (his Table I) that only 402 gray whales were "captured" on 140 cruises to the "Northern Summer Grounds" from 1845 to 1874, the total killed (including hunting loss) amounting to 539. Nowhere is it made clear whether the values of 402 and 539 refer to numbers of gray whales recorded in the logbooks of 516 cruises examined by Bockstoce and Botkin (1982, 1983), or instead are extrapolations meant to account for the whales taken on those plus the other 81% of the total cruises to the western Arctic between 1849 and 1914.

Non-American Whaling Vessels

As mentioned earlier, whaleships from countries other than the United States visited the coasts of Baja and Alta California during the 19th century. The British whaler *Toward Castle* wrecked on the Malarrimo coast just southwest of the mouth of Scammon's Lagoon in 1836 (Henderson, Editor's footnote 16 in Scammon, 1970:20; but see Henderson, 1984:182, footnote 18). The French ship *Valiant* of Havre wrecked near the entrance of Magdalena Bay at the end of December 1847 with 600 bbl of oil on board (*The Friend*, 1 April 1847, as quoted in Druett, 1992:184, footnote 33). Some of *Valiant*'s oil (200 bbl) was salvaged by *J.E. Donnell* of New Bedford and is presumably subsumed within that vessel's returns (which included 3,066 bbl of whale oil for its voyage of 1845–49; Starbuck, 1878:422–423).

German and French whalers, as well as one Russian vessel (from Finnish Russia, captained by a Swede), participated in lagoon whaling for gray whales between 1854–55 and 1864–65 (Henderson, 1984:172). Henderson (1972, his Table II, p. 261–263) included in his list of vessels whaling in Scammon's Lagoon between 1857–58 and 1872–73 the following foreign vessels: bark *Cleopatra* from New Granada (presumably present-day Colombia; probably sailing out of San Francisco with New Granada as a "flag of convenience" according to Henderson, 1984:184), brig *Stoofursten Constantin* of Russia, brig *Comet* from the German port of Oldenburg (purchased in Honolulu and put under the Hawaiian flag in 1868), and a variety of vessels from Honolulu—four barks (*Faith*, *Metropolis*, *Harmony*, *Cynthia*), two schooners (*John Dunlap*, *Kalama*), and two brigs (*Victoria*, *Kohola*). *Kalama* was a tender to the brig *Comet* at Turtle Bay in 1862.

There is ambiguity concerning the rig and name of the so-called *John Dunlap*, which apparently also cruised as a brig under the name *Alice*, but in any event it whaled for gray whales at Scammon's Lagoon in at least the 1858–59 season (Henderson, Editor's footnote 68 in Scammon, 1970:50). Some gray whales may have been taken by French whalers between 1842 and 1868 (Du Pasquier, 1986:274). In Du Pasquier's (1982) list of voyages, 15 are identified as having visited locations in California or Mexico where they could have taken gray whales between 1843 and 1864. At least three of those voyages included visits to Magdalena Bay (Ste-Marguerite or Baie Ste-Marguerite) and at least one to Lower California (Basse Californie). The voyage of *Valiant* of Havre, which wrecked in 1847 as noted above, is not among the 15.

The ship-based fisheries for right whales in the North Pacific Ocean and Bering Sea and for bowhead whales in the Bering Sea and Arctic Ocean were both dominated by vessels from the United States. Scarff (2001:266), however, estimated that non-U.S. ships might have constituted as much as 15–20% of the fleet on the right whale grounds, whereas Bockstoce (1986:94) referred to ships from Bremen, Havre, Nantes, and Hobart (Tasmania) as having flocked along with the American fleet to the Bering Strait in 1850 immediately after discovery of the bowhead whaling grounds there. According to Bockstoce and Botkin (1983:110), the western Arctic fishery included vessels from the United States, Hawaii, Germany, France, and Great Britain (Australia). Some foreign vessels stopped to recruit crew and obtain provisions at Hawaiian ports, primarily Honolulu and Lahaina. Beginning in the early 1850's, some of these vessels were purchased by a small number of foreign residents in Hawaii. This burgeoning Honolulu-based fleet included vessels that continued to sail under foreign flags. By 1856, many vessels in this fleet began to be placed under the Hawaiian flag, including some whose owners did not meet the legal requirements for obtaining Hawaiian registry.

Oil Returns and Average Yield

As mentioned earlier, concern has been expressed that the average oil yield used by Henderson to estimate catches from oil production data may have caused him to underestimate the number of gray whales taken (Mitchell, 1993). A large proportion of Henderson's (1972, 1984) catch estimates was derived from oil returns. However, the idiosyncratic nature of his catch tallying method makes it impossible, in many cases, to determine whether the catch attributed to a given voyage represents a count of whales taken (e.g. as reported in the voyage logbook) or instead an estimate made (after the fact) by converting an amount of oil on board or returned to port.

Often, the latter was clearly true, and therefore the average oil yield used by Henderson as the denominator for his conversions takes on particular importance. He recognized that some oil was shipped from the whaling grounds on cargo vessels or "sent home" on a different vessel, and he attempted to account for this in his compilation of catches (Henderson, 1972:259). He nevertheless cautioned that reports emanating from the whaling grounds (e.g. as a result of message exchanges between vessel captains) tended to exaggerate the amounts of oil inboard (we have not been able to corroborate this statement by Henderson).

Another consideration is whether oil inboard or returned by a given vessel came from gray whales rather than from one or more other species. The oil inboard a "gray whaler" obtained from sperm whales, elephant seals, and other seals was, according to Henderson (1972:259), "regularly distinguished," but so-called polar oil from right or bowhead whales taken in the previous summer season, humpback oil, and oil from other balaenopterids (such as fin and blue whales) "usually was not distinguished from the gray whale oil." In Henderson's view, this meant that oil-based estimation of gray whale catches are inherently positively biased. However, there must have been an economic incentive to mix gray whale oil with that of other species as, according to Scammon (1874:269), it was "of an inferior quality." Therefore, it would have been more profitable to adulterate other oils with gray whale oil rather than vice versa.

In our own reading of one logbook, it was noted that when *Mary and Helen II* had taken and processed three gray whales in the northern Sea of Okhotsk, the logbook entry for 24 September 1885 stated, "... stowing in lower mainhold the oil of the last Bowhead taken and what we have boiled of these last [gray or "ripsack"] whales mixed together." In this instance, without checking the logbook, the whale oil returned by the voyage would be considered to have come entirely from bowhead (and right?) whales as there would be no way to distinguish the contribution made by gray whales.

Mixing gray whale oil with other more valuable oils that would be reported and landed as such would tend to bias the data toward underestimation of the gray whale catch. At the same time, however, humpback whales, in particular, were hunted along the coast of Baja California and even inside Magdalena Bay during the gray whale season (Henderson, 1972:89; *Josephine*, 1863–1867, 5 January 1866 logbook entry), and they were at least seen in San Ignacio Lagoon in May and June (Henderson, 1972:195). This creates the potential to overestimate gray whale catches if it is assumed that all whale oil from a given cruise in the Mexican whaling grounds came from gray whales.

Henderson (1972) noted that "coast oil," at least in the context of San Francisco-based whaling in the mid 19th century, generally meant oil from gray whales. For example, the bark *Carib* of San Francisco returned to port in April 1859 after 10 months at sea with 800 bbl of coast oil, 50 bbl of sperm oil, and 300 bbl of humpback oil, and Henderson (1972:89) explicitly considered the coast oil to be from gray whales. In his catch compilations, Henderson (1972) sometimes corrected what he assumed were reporting errors. For example, the New London barks *Tempest* and *Ripple* were reported as returning 550 and 500 bbl, respectively, of humpback oil to Honolulu following a 1859–60 cruise to Scammon's Lagoon, but Henderson (1972:265) concluded that "the kind of oil ... must have been in error," noting that "no other vessel was ever reported to have taken humpback whales" in this lagoon. In another instance, Henderson inferred that a newspaper report of 400 bbl of sperm oil returned to Honolulu by the New London bark *Pearl* (1863–64) "may have been erroneous" because this vessel had been reported at Scammon's Lagoon with 190 bbl of oil (unspecified) on board two months earlier. He assigned a gray whale catch of "5+" to *Pearl* for that season.

Scammon's *Ocean Bird* returned to San Francisco in 1859 with a cargo of 1,600 bbl of oil from 47 gray whales (all "cows"), which led Henderson to conclude that 35 bbl/whale was a reasonable average yield (Scammon, 1970:68). One whale secured by Scammon in December 1858 yielded 55 bbl (Scammon, 1970:37), and one large cow taken in Magdalena Bay by *Saratoga* yielded 62 bbl, another 63½ bbl, both in January 1858 (*Saratoga*, 1857–1858, logbook). Scammon (1874), who had extensive first-hand knowledge of gray whales and the ship-based whaling industry, gave the average yield of gray whales as 20 bbl, with males sometimes producing up to 25 bbl (1874:21) and "some individuals" as much as 60–70 bbl (1874:20).

Rice and Wolman (1971:35) observed that the mean body weights and yields of oil, meal, and meat from southbound gray whales were 2.5–3.0 times those of northbound whales. As summarized by Sayers (1984:123), gray whales taken during the "going down" season (December–February) were "fat, well nourished, and rendered a fine quality of oil," whereas those taken during the "going up" season (February–April) were much leaner as a result of fasting and, in the case of adult females, nursing their calves. In addition to the variability in oil yield due to seasonal changes in body condition, towing distance, shark scavenging, sea conditions, and various other circumstances could affect processing efficiency.

Bockstoce (1986) considered the average yield of gray whales on their northern feeding grounds to be 25–30 bbl (1986:72), 25 bbl (1986:132), or 30 bbl (1986:95). Henderson (1972, 1984), who was convinced that 35 bbl/whale was a good overall average for gray whales, acknowledged that yields tended to be lower on the northern grounds, reasoning as follows (1972:137):

> "Captures of small, young gray whales probably were more common on the northern summer grounds than along the coast of California, where the few slaughtered calves were not usually counted as part of the catch, and where rapidly growing young whales, returning to their place of birth, were at least a year old."

The question of average oil yield becomes relevant in the present context only, or at least primarily, if it is to be applied in catch estimation. In one of the earliest efforts to estimate whale catch from both oil returns and logbook data, Ross (1974:95) ended up averaging the "conflicting figures [on bowhead whale catches by American whalers in Hudson Bay] obtained by different methods . . . , there being no satisfactory criteria for choosing either one or the other." Similarly, Mitchell and Reeves (1983) presented estimates from both "oil yield" (from Starbuck, 1878 and Hegarty, 1959) and "catch-per-voyage" (from logbooks), and then arbitrarily used midpoints of the two in their table of annual catches of humpback whales in the West Indies attributed to the ship-based American fishery. Both Bockstoce and Botkin (1983) and Smith and Reeves (2003) employed data on oil returns to stratify vessel-seasons and to guide logbook sampling, but in the end used only average numbers of whales landed per vessel-season (mainly from logbooks and newspaper accounts) as the basis for estimating catches of bowhead whales and humpback whales, respectively. Finally, in his multispecies study of the American 19th century ship-based fishery for baleen whales, Best (1987) estimated catches in 5-year intervals using both production (oil averages to 1879 and whalebone thereafter until 1909; all from Starbuck, 1878 and Hegarty, 1959) and whale catch per voyage (1805–1914, from Townsend, 1935). He made no attempt to reconcile the two alternative sets of estimates but instead simply reported them as a range, such as 2,665 ("based on oil production") to 3,013 ("as calculated from the catch per voyage") gray whales taken over the period 1850–1879 (1987:416). Best found that the two approaches gave "somewhat similar" results, differing by less than 10% in all cases except three: for South Atlantic right whales, *E. australis*, and humpback whales, the overall production-based estimates exceeded the catch per voyage estimates by 13% and 29%, respectively, and for gray whales, the overall catch per voyage estimate exceeded the production estimate by 13% (as indicated above).

Although Henderson (1984) appears to have depended primarily on oil returns to estimate gray whale catches, our own extensive experience with production data has led us to share the skepticism expressed by Bockstoce and Botkin (1983:110), who note the difficulty of allocating quantities of products to vessel-seasons (as opposed to entire voyages) and the risk that oil from multiple species (especially humpback whale and pilot whale oil in the present context) has often been included in whale oil returns. Therefore, like those authors, we consider data on numbers of whales taken, as recorded in logbooks and newspapers, to provide a more direct and reliable basis for interpolation and extrapolation, as explained in the following section.

New Catch Estimates from Voyage and Vessel-season Analyses

Our review of the literature and of Henderson's files and notes in the library of the New Bedford Whaling Museum (described earlier) led us to an approach for producing a more detailed alternative catch series. Rather than adopting Henderson's method of tracking and evaluating the intricacies of whale oil reports, newspaper snippets, and logbook entries in a largely opportunistic and ad hoc fashion, we chose to rely primarily on two sets of data sources for estimating the ship-based catch of gray whales.

First, we used the catch data in a sample of voyage logbooks (including some also checked by Henderson) and newspaper sources to estimate the average number of gray whales taken (both secured/processed and struck/lost) per vessel-season in Mexico. Second, we used the information from a broad search of published and unpublished sources to identify and count the vessels that whaled for gray whales in Mexico (and to a limited extent southern California) each year beginning in the winter of 1845–46.

Together, these two sets of sources allowed us to estimate the number of gray whales taken each year by the ship-based fishery in the winter season. Because the greatest catches of gray whales were made in Mexico on the whales' calving and breeding grounds, we focused our logbook sampling and catch estimation on the winter portions of voyages spent there rather than on portions of voyages in the northern summering areas. For the ship-based catches in northern waters, we had no reason to believe that we could improve significantly on the gray whale catch and removal estimates (approximately 400–500 and 800, respectively; see earlier) presented by Henderson (1984) and Bockstoce (1986).

Logbook and Newspaper Sampling

Photocopied sections of some logbooks were available in the Henderson material in New Bedford, and these were examined for information on numbers of whales secured. We also checked (either directly or on microfilm) the relevant sections of additional logbooks selected to make the overall sample as representative as possible, especially over time. For those logbooks that provided sufficient detail, we also extracted the information on "condition" of whales that escaped (e.g. whether the harpoon iron drew, the line broke, the whale sank or was "spouting blood" when it escaped), the sex of caught whales, and the presence and fate of any calves mentioned.

To supplement that logbook sample, we used 1) Townsend's (1935) worksheets containing logbook data for about 800 voyages by vessels with names beginning with the letters A through J and 2) data that we had collected in previous studies from logbooks of about 160 voyages. Further, we used gray whale catch data found in 19th century Hawaiian newspapers. In a few cases, the same vessel-seasons were represented in two of the four types of sources, allowing us to check for consistency. For example, the numbers of gray whales indicated on three Townsend worksheets (5, 46, 10) were both higher and lower than those indicated in newspaper entries (4, 47, 14, respectively). Similarly, the Townsend data, which normally include only landed whales, were generally consistent with the more detailed data (catch, struck/lost whales, daily positions) taken directly from logbooks.

In some instances, logbook entries fail to identify whales to species. Where possible, we inferred the species from the circumstances surrounding the whaling activity or from the described behavior or other characteristics of the whales. Unless there was a marked change in whaling pattern or location, the other catches (including struck/lost) for that vessel-season were assumed to have been gray whales. For unidentified whales tried out during vessel-seasons for which catches of both gray whales and humpback whales were reported, we prorated the unidentified whales according to the ratio of grays and humpbacks reported in the logbook for that vessel-season.

Table 1.—Mean numbers of gray whales landed per vessel-season (WPV), their standard errors (SE), and numbers of vessel-seasons sampled (N) from logbooks (directly or via Townsend worksheets) and newspapers.

Period	WPV	SE	N
1846–1854	14.0	3.32	7
1855–1860	14.0	2.28	23
1861–1865	10.1	1.14	30
1866–1874	7.9	1.36	18

Data on landings were available for 94 unique vessel-seasons. Of that number, 51 were covered by logbooks read specifically for this analysis, 18 were covered by the Townsend worksheets, 17 were covered by newspaper accounts, and 8 were covered by logbooks read for our previous studies. Seventy-seven of the 94 vessel-seasons involved gray whaling while the other 17 focused entirely on other species, notably humpback whales, sperm whales, and pilot whales. The mean number of gray whales taken (i.e. secured and processed) per vessel-season for the 78 vessel-seasons that involved gray whaling was calculated for four time periods selected to reflect the varying intensity of the fishery (without regard to Henderson's Initial, Bonanza, and Declining periods, noted earlier), and ranged from 14.0 down to 7.9 whales. The rates were higher in the earlier periods (Table 1).

Some information on the sex and maturity status of struck whales was obtained for a portion of the vessel-seasons covered by logbooks read specifically for this study. As expected, given the information summarized from the literature (above), 32 of the 35 whales (92%) for which sex was identified were cows. Although, as noted earlier, whaling inside the lagoons often involved calves, this was mentioned only 11% of the time (52 of 460 logbook entries). The subsample of logs with entries referring to calves included 18 vessel-seasons, and the percentage of strikes involving calves for those vessel-seasons averaged 29.7%, with a range from 6.2 to 100%. The logs of three vessel-seasons indicated that more than 60% of the strikes involved calves. The fates of 40 of the 52 calves (76.9%) were reported, with 39 of them struck or killed but apparently only one of them processed for its oil. Although this information from logbooks on sex of adults taken and the involvement of calves is clearly incomplete, it reinforces the general understanding from the literature (see above) that lagoon whaling in Mexico focused primarily on adult females and that calves were involved, often dying as a result.

Table 2.—Proportions (P) of 408 struck gray whales that were reported lost under different conditions: when the harpoon drew or the line parted (Drew-Parted), when the animal sank or escaped spouting blood (Sank-Bleeding), and combining those two conditions. Also shown are the standard errors of the proportions (SE(P)), the ratios of the number struck to the number landed (loss rate factor, LRF), and their standard errors (SE(LRF)).

Conditions	P	SE(P)	LRF	SE(LRF)
Drew-Parted	0.24	0.021	1.32	0.037
Sank-Bleeding	0.05	0.011	1.06	0.012
Combined	0.29	0.023	1.42	0.050

Using a subset of the logbook data for 36 vessel-seasons for which sufficient detail was recorded, we estimated the proportion of struck animals that were lost. The 408 struck whales were each assigned to one of three classes: 1) landed and processed, 2) escaped when the harpoon drew or the line parted, and 3) either escaped spouting blood (interpreted to mean the whale was mortally wounded) or actually died and sank before being secured by the whalers. The proportion lost when the harpoon drew or the line parted was much higher than that for animals that escaped spouting blood or sank (28% and 6%, respectively; Table 2). This makes it difficult to estimate total removals. Although it can be assumed that the 5% of struck animals that were lost because they sank or escaped spouting blood were effectively dead, at least some of the 24% of the struck animals that escaped when the harpoon drew or the line parted probably survived, considering that wounds and scars from previous encounters with whalers have been observed on some caught whales (Jordan, 1887; Starks, 1922). We have no basis for estimating the proportion that survived.

Following Henderson's suggestion that the loss rate was higher in alongshore gray whaling (i.e. "outside" rather than "inside" the bays or lagoons), we also classified the reported vessel locations for strikes reported in the logbooks according to whether they were "inside" or "outside" and computed the respective loss rate factors. The alongshore Drew-Parted (DP) LRF (1.41, SE = 0.080) and the Sank-Bleeding (SB) LRF (1.08, SE = 0.027) were both larger than the corresponding "inside" LRF's (DP: 1.26, SE = 0.043 and SB: 1.05, SE = 0.016, respectively). One-sided t-tests suggest that the outside Drew-Parted LRF was significantly greater than the inside (p=0.013), while the difference between the two Sank-Bleeding LRF's was not significant (p=0.084).

However, for most vessel-seasons we were unable, in the absence of the relevant logbook data, to distinguish catch locations on a sufficiently fine geographic scale to apply loss rate factors differentially. As Henderson (1984:168) noted, it was "sometimes difficult to determine if a particular ship captured a whale inside or outside the lagoon itself; only if one has logbook records at hand, rather than newspaper accounts, can he determine how many whales were taken inside or outside the lagoon." For example, the newspaper *Polynesian* reported (29 March 1862, 18(48):3) that the Hawaiian brig *Victoria* arrived in Honolulu in late February from the "coast of California" with 400 bbl of oil on board, having left Margarita (Magdalena) Bay 14 days earlier. The report indicates only that the oil had been obtained "in Bollnas [Ballenas] and Margarita Bays." In order to apply differential loss rate factors, it would be necessary to know or estimate the fraction of the 400 bbl obtained alongshore (i.e. in Ballenas Bay) rather than in the Magdalena Bay complex, which is classified as a lagoon-whaling site. Like Henderson (1984), then, despite the significant difference in loss rates, we had to use the same loss rate factor to estimate total kills from numbers secured in both lagoon and coastal whaling.

Number of Vessel-seasons

In addition to the vessel-seasons identified directly from the Henderson material, we made use of port and newspaper records concerning arrivals and departures of whaling vessels in Hawaii compiled by Lebo for this paper. The Hawaii data generally included the vessel's name (adjusted for obvious misspellings) and its dates of arrival and/or departure in Hawaiian ports. Most of the records also included the vessel's nationality of registry, master, and rig (e.g. schooner, bark, ship). In many instances, the records indicate where the vessel had come "in from" or where it was "bound for." Some of these geographical entries refer to specific places that are well known for gray whaling, such as Magdalena (more often given as "Margarita") Bay, but many are more general. These latter include the obvious and uninformative (e.g. "Pacific") and the somewhat more specific and informative (e.g. "South Pacific," "Japan," "Okhotsk"). Some entries are informative but difficult to interpret at first glance, such as "coast of cala," clearly meaning Coast of California but leaving open various possibilities other than the Mexican gray whaling grounds (e.g. humpback whaling around the Socorros or Revillagigedos Islands, sperm whaling off Cedros Island or in the Gulf of California, whaling for one or several species, including gray whales, along the coast of what is now the U.S. State of California).

For voyages with incomplete or conflicting information, we consulted the Dennis Wood Abstracts (Wood, N.d.),which include, for example, selected dates and specific locations where the vessel was known to have been during the voyage and the quantities of oil and whalebone on board at the time.

We combined the Hawaii arrival and departure records with those obtained from the Henderson material (and supplemented by any relevant details found in the Dennis Wood Abstracts) into a single list of vessel-seasons of whaling in Mexico, using a stepwise procedure as follows.

First, we used the Henderson material, maps, and our general understanding of the fishery to identify a set of geographical entries likely to represent whaling areas in the region. We then selected those vessels that arrived in Hawaiian ports late in or soon after the gray whaling season (i.e. between about February and May, or "spring") or that departed shortly before the season (i.e. between October and December, or "autumn"), with locations (either outgoing or incoming) indicative, or least suggestive, of time spent in Mexico. We did not try to account for vessels in the Hawaii records associated with only generalized geographical locations (e.g. Pacific or North Pacific), but see later discussion.

Second, we compared the two lists of vessel-seasons (one Henderson-based and one Hawaii-based) to two lists of whaling voyages, the American Offshore Whaling Voyage list (AOWV) (Lund et al., 2008; available through National Maritime Data Library, www.nmdl.org) and the French whaling voyages listed in Annex 7 of du Pasquier (1982:242–9; numbered in our system as 30,000 plus the numerical sequence). We thus attempted to identify specific multiyear voyages corresponding to each vessel-season, accounting for dates, master, and rig as available.

Because some vessels had the same name and because key information was missing from some records, it proved impossible to assign all of the vessel-seasons to their appropriate voyage with certainty. Also, we were hampered by the lack of systematic voyage lists from nations other than the United States and France. However, the registry information reported in the Hawaii arrivals and departures records, especially for the Hawaiian fleet, made it possible to identify the nationality for most of the non-American and non-French vessels.

Where more than one vessel had the same name, and especially in the few cases when such vessels were whaling in Mexico in the same season, it was sometimes impossible to pin down and track the vessel-season with complete confidence. Newspapers and other sources proved useful for resolving some of these problems. For example, they allowed us to distinguish among the American *Maria*, the Hawaiian *Maria,* and the Chilean *Maria* in the 1861 and 1862 seasons. The latter two vessels were gray whaling in Mexico, while the first was on a sperm whaling voyage.

Third, we merged the Henderson and Hawaii lists, and this resulted in 660 unique vessel-seasons that were considered candidates for having involved some whaling in Mexican waters between 1846, when gray whaling began there, and 1875, by which time it had essentially ended there (although some killing of gray whales in the northern feeding areas continued into the 1880's). Of these 659, 480 were identified from the Henderson material and 179 from other sources only, especially the Hawaii port records. We then used the multiple sources of information available to classify each vessel-season according to the likelihood that it involved gray whaling in Mexico. For some vessel-seasons, we found no information that could be used as a basis for classification. For others, there was enough information to classify as definitely or likely gray whaling, definitely or probably not gray whaling, or possibly gray whaling. For analysis, we established four categories of the likelihood of gray whaling, as follows: Yes (definitely or probably gray whaling), Maybe (possibly gray whaling), No (definitely or probably not gray whaling), and Unknown.

The proportions of vessel-seasons that fell into these categories varied according to the source (Table 3), with, for example, 17% (82/478) of the vessel-seasons identified from the Henderson material judged as "definitely not" gray whaling compared to 29% (52/179) of those from the Hawaii port records. The proportions also varied over time, with, for example, a higher proportion Unknown after 1860.

Table 3.—Numbers of vessel-seasons according to the original sources of information and our judgments on the likelihood that they involved gray whaling.

Source	Yes	Maybe	No	Unknown	Total
Henderson	323	45	82	28	478
Hawaiian	54	32	52	41	179
Total	377	77	134	69	657

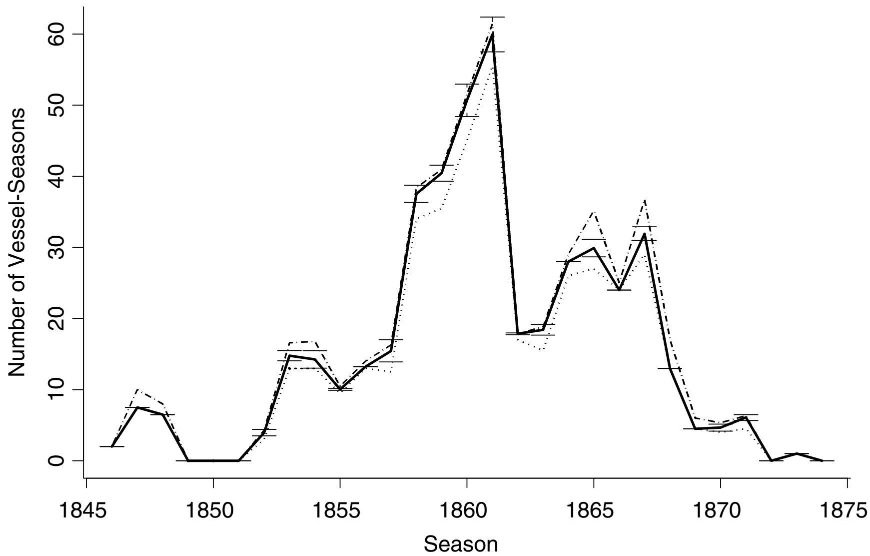

Figure 7.—Estimated numbers of vessel-seasons of gray whaling in Mexico from 1846 to 1874, by year, with three ways of accounting for uncertainty (as described in the text). Cases: low = dotted line, medium = solid line, high = dashed line. The 95% confidence intervals about the estimates are shown for the medium case.

To account for such differences, we addressed the uncertainties in the vessel-season data separately by source (i.e. Henderson vs. Hawaii) and by year. We addressed the uncertainty inherent in the Maybe and Unknown categories in two ways. First, we assumed that at least half of the vessel-seasons categorized as Maybe gray whaling were in fact gray whaling (i.e. we treated that half as Yes). Second, we prorated the number of Unknown vessel-seasons according to the frequency of Yes, Maybe, and No vessel-seasons.

We then considered three cases—low, medium, and high—to compute the total number of vessel-seasons. For the low vessel-season case, we took the total vessel-seasons to be the number categorized as Yes and half the number categorized as Maybe. For the high case, we took the total to be the sum of those categorized as Yes, those prorated to be Yes, and those prorated to be Maybe. Finally, for the medium case, we summed the number categorized as Yes and prorated as Yes, plus half of the number categorized as Maybe and half of the number prorated as Maybe. This procedure resulted in total numbers of vessel-seasons of 416, 466, and 489 vessel-seasons for the low, medium, and high cases, respectively, with standard errors due to the proportions used in the prorating. The numbers of vessel-seasons for the three cases for each year are shown in Figure 7, along with 95% confidence intervals for the medium case.

The identified vessel-seasons of whaling in Mexican waters are listed in the Appendix, which includes each combination of vessel name and season, the vessel's known or likely nationality, whether the vessel-season was identified from the Henderson material, and the likelihood that the vessel-season involved some gray whaling. Also included, where available, are the known or probable vessel and voyage identification numbers (see above). In some cases, we indicated a likely AOWV vessel number corresponding to the vessel name, even though a precisely corresponding voyage number could not be identified because the departure and arrival dates were not consistent with the vessel's being in the gray whaling grounds at the appropriate season. It is possible that a few vessel-seasons are listed twice because of inaccuracies and inconsistencies in vessel names, although we tried to minimize this by evaluating the voyage records carefully to account for vessels with similar names.

Vessels with American registry were responsible for nearly 89% of the whaling activity, with 272 vessels involved in some 587 vessel-seasons. Hawaii-registered vessels were the next most common, with 17 vessels involved in 32 vessel-seasons, followed by French-registered vessels, with 6 involved in 10 vessel-seasons. In addition, vessels registered in German states (e.g. Bremen), the Netherlands, Russia, Great Britain, Colombia, and Chile were identified as having spent one or more seasons in the Mexico whaling grounds. Only 14 vessels were unidentified as to nationality, and they were responsible for 14 vessel-seasons.

Estimates of Gray Whale Catches and Total Removals

The number of gray whales taken (i.e. secured and processed) was estimated for each gray whaling season between 1846 and 1874 (Fig. 8; with, for example, the 1858–59 season denoted as 1859) as the product of the estimated number of vessel-seasons that were, or maybe were, gray whaling in the low, medium, and high vessel-season cases (Fig. 7) times the average number of gray whales secured per vessel-season in the respective time periods (Table 1). The standard errors of the estimated takes were computed from the corresponding sample standard errors of the number of vessel-seasons and of the mean gray whales landed per vessel-season for each of the three cases (Table 4). For the medium case, the estimated catch reflects a combination of differences in the average catch rates by period and the variability in numbers of vessels whaling each year, with the number of vessel-seasons rising to a peak in the early 1860's and then declining rapidly (Fig. 7).

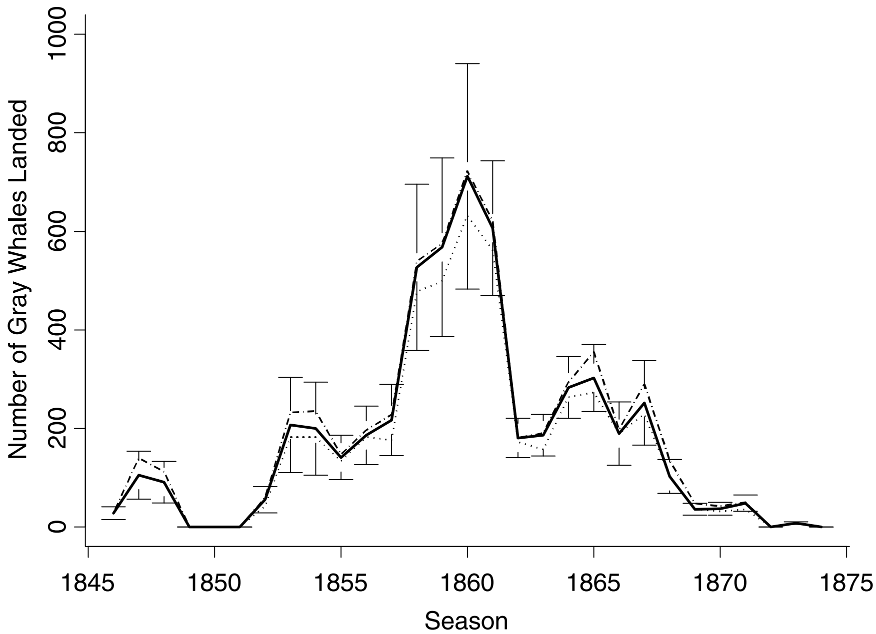

Figure 8.—Estimated numbers of gray whales landed in Mexico from 1846 to 1874, with the three cases for addressing uncertainty as to whether vessels were gray whaling (as described in the text). Vessel-season cases: low = dotted line, medium = solid line, high = dashed line Confidence intervals about the estimates (95%) are shown for the medium vessel-season case.

Table 4.—Estimated gray whale landings (whales) in Mexico from 1846 to 1874, with the three vessel-season cases (Low, Medium, High) to account for uncertainty regarding whether vessels were gray whaling. SE = standard errors of the estimates.

	Low Case		Medium Case		High Case	
Season	Whales	SE	Whales	SE	Whales	SE
1846	28	6.6	28	6.6	28	6.6
1847	105	24.9	105	24.9	140	33.2
1848	91	21.6	91	21.6	112	26.6
1849	0	0.0	0	0.0	0	0.0
1850	0	0.0	0	0.0	0	0.0
1851	0	0.0	0	0.0	0	0.0
1852	42	10.0	55	13.5	60	14.3
1853	182	43.2	207	49.4	232	55.3
1854	182	43.2	200	48.2	235	56.4
1855	133	21.7	141	22.9	147	23.9
1856	183	29.6	186	30.2	197	31.9
1857	176	28.5	217	37.0	228	38.6
1858	477	77.5	527	86.0	539	88.0
1859	499	80.9	568	92.6	575	93.7
1860	632	102.6	712	116.8	723	118.5
1861	561	63.5	606	69.7	621	71.4
1862	172	19.4	181	20.4	181	20.4
1863	157	17.7	186	21.4	190	21.8
1864	263	29.7	283	32.0	293	33.2
1865	273	30.9	303	34.8	355	40.6
1866	189	32.7	189	32.7	197	34.1
1867	229	39.5	252	43.7	290	50.1
1868	103	17.7	103	17.7	134	23.2
1869	36	6.1	36	6.1	47	8.2
1870	32	5.4	37	6.7	42	7.5
1871	36	6.1	48	8.5	50	8.7
1872	0	0.0	0	0.0	0	0.0
1873	8	1.4	8	1.4	8	1.4
1874	0	0.0	0	0.0	0	0.0
Total	4,789	199.5	5,269	223.4	5,624	234.7

There is a greater spread between the estimated landings for the three vessel-season case lines in some years than in others, especially during the middle years of the fishery, which are also the years that contribute most to the cumulative catch. In most of those years, the spread between the estimated landings for the three case lines is less than the width of the confidence intervals around the medium-case estimates (Fig. 8). In other words, the uncertainty in the estimated landings due to the standard errors (as reflected by the confidence intervals) is greater than the uncertainty due to the cases (as reflected by the spread between the case lines in the figure). We interpret this to mean that our estimation of landings would be improved most efficiently by reading more logbooks and not by simply trying to resolve more of the Unknown or Maybe gray whaling vessel-seasons.

The estimated total number of gray whales taken (secured and processed) by whalers in Mexican waters was 5,269 (SE = 223.4) for the medium vessel-season case, and ranged to roughly 9% lower and 7% higher for the low and high cases, respectively (Table 4). To estimate the total number of whales removed, an adjustment needs to be made to account for whales that were struck and lost (Table 2). At a minimum, a LRF of 1.06 can be applied to landings to account for the animals that were lost because they sank, because of poor weather, or because they escaped spouting blood (considered by the whalers as an indication of certain death). Alternatively, landings can be multiplied by 1.42 to account for all whales struck, regardless of their "condition" (Table 5).

Table 5.—Estimated numbers of gray whales removed by ship-based whalers in Mexican whaling grounds from 1846 to 1874 for the Low, Medium, and High cases for numbers of vessel-seasons and using the "Sank-Bleeding" or "combined" loss rate factor (LRF) (see Table 2), with standard errors (SE) accounting for the standard errors of both the landings and the LRF. See text for details.

Case	Low		Medium		High	
LRF	N	SE	N	SE	N	SE
1.06	5076	219.2	5585	245.1	5961	257.8
1.42	6800	371.1	7482	412.5	7986	436.2

Thus, actual removals would be at least 5,076 to 5,961, using the LRF of 1.06, although it is unreasonable to assume that no other struck whales died of their injuries. The estimated total number of struck whales would be between 6,800 and 7,986. However, it is also unreasonable to assume full mortality of all struck whales. Even though, as mentioned earlier, bomb lances were frequently used to subdue gray whales in the Mexican whaling grounds, not all bomb lances exploded. This is evidenced by the report from one California shore station where the equipment was said to be "of marginal quality" and "two thirds of the whales wounded were lost due to the harpoon's failure to explode" (Nichols, 1983:109, citing the diary of a judge who visited the whaling station at Ballard Point in 1860). In another example from the shore fishery (at Point Conception, California, 1879–80), all but one of 16 gray whales secured bore wounds attributed to previous strikes by bomb-lances (Jordan, 1887).

We are aware of two other studies that attempted to address the struck-lost issue in novel ways. Bannister et al. (1981), in their study of sperm whaling on the Japan Ground, sorted logbook records into three classes: whales tried out, whales struck and lost, and whales lost spouting blood. They then provided alternative LRF's, dependent on assumptions—one that only those lost spouting blood were "removed" (LRF: 1.20) and the other that all struck whales were removed (LRF: 1.61). This allowed them to offer two alternative estimates of total removals by year, essentially one high and one low, i.e. "a range within which total removals from the stock may lie during the study period …" (Bannister et al., 1981:830). Because their main interest was in trends in catches and catch per unit of effort, rather than in aggregate totals of whales removed (as here), Bannister et al. apparently saw no need to comment on which of their sets of estimates was likely the more accurate.

The other study (Mitchell and Reeves, 1983) assigned logbook records of humpback whale catches to six classes: 1) whales tried out, 2) whales known to have been killed but that were lost, 3) whales struck and lost but with no specific details on the circumstances, 4) whales struck and lost because the "iron drew," 5) whales struck and lost carrying gear, and 6) calves whose mothers were known to have been killed (i.e. they were orphaned on the calving grounds). These authors then developed a single LRF (1.86), based on the assumption that all of the whales in classes 1, 2, 5, and 6 and half of the whales in classes 3 and 4 were removed. They then used this single LRF to estimate removals from landings.

We are not able to evaluate in a meaningful way the potential of gray whales to survive various types of encounters with 19th century ship-based commercial whalers on the breeding grounds. Therefore, we have chosen to present multiple options according to assumptions, essentially following the lead of Bannister et al. (1981).

To account for the total effect of ship-based whaling on the gray whale population, the estimated 539 whales removed on the feeding grounds in the Bering and Chukchi Seas (Henderson, 1984) would need to be added.

Discussion

Comparisons to Earlier Estimates

Estimates of catches or total removals of gray whales by other authors have accounted for the various relevant whaling operations in different ways, and this makes it difficult to compare those estimates with ours. Henderson (1984) estimated that 4,466–4,516 eastern gray whales were secured and processed by ship-based whalers in Mexico between 1846 and 1874. This compares with our medium-case estimate of total landings of 5,269 (SE = 223.4). Henderson's estimates of landings were based largely on reported whale oil production, while ours are based on average landings per vessel-season. Our decision to consider the medium case for vessel-season uncertainty (Table 4) as providing our "best" estimates of total landings reflects our considered judgment concerning the many uncertainties surrounding the 19th century commercial catch history.

Henderson (1984) assumed that on the Mexican grounds, one whale was "mortally wounded" for every 10 secured, so his loss-adjusted estimate of total removals from those grounds was 4,913–4,968. Our medium-case estimate of total removals is 5,585 when we account only for whales that were lost due to sinking or escaped spouting blood and 7,482 if we assume (unrealistically) that all struck whales eventually died of their wounds. Thus, our medium-case estimate of removals in Mexico is somewhere between about 12 and 52% higher than that of Henderson (1984). We have made no attempt to investigate catches in the northern summering areas and therefore accept Henderson's (1984) estimate of an additional 402 eastern gray whales landed there, which he adjusted to 539 removed, assuming that in the north one whale was mortally wounded for every five secured. Adding that value to our range of Medium-case estimates suggests that a total of 6,124 to 8,021 gray whales were removed from the eastern North Pacific population.

Scammon (1874:23) stated: "From what data we have been able to obtain, the whole number of California Gray Whales which have been captured or destroyed since the bay-whaling commenced, in 1846, would not exceed 10,800." Because Scammon was well acquainted with whaling activities throughout the range of this gray whale population, we infer that his figure of 10,800 was meant to include all removals (catches plus hunting loss) by 1) ship-based commercial whalers in the Mexican breeding areas as well as in the northern feeding areas, 2) shore-based commercial whalers in California (Scammon, 1874:251), and 3) shore-based aboriginal whalers in northern latitudes (Scammon, 1874:29–32). We are not aware of any specific estimates of commercial ship-based catches by Scammon, but he gave the shore-based commercial catch between about 1850 and 1874 as "not less than 2,160," to which he proposed adding 20% to account "for the number of whales that escaped their pursuers, although mortally wounded, or were lost after being killed either by sinking in deep water or through stress of weather" (1874:251).

Scammon did not attempt to quantify the removals by aboriginal whalers but made a number of statements implying that he was aware of how widespread this whaling was and of its importance to some aboriginal communities. For example, in describing gray whale hunting by Indians of Washington and British Columbia and by Eskimos in the Arctic, he notes (1874:32) that in those northern latitudes the gray whale "is exposed to attack from the savage tribes inhabiting the sea-shores, who pass much of their time in the canoe, and consider the capture of this singular wanderer a feat worthy of the highest distinction." Given the incompleteness of information on how Scammon derived his estimate of total removals from the population, we cannot meaningfully evaluate the differences between his estimate of the ship-based commercial component and our own.

Finally, our estimates are considerably higher than those of Best (1987), who estimated landings on a voyage by voyage basis in two ways: 1) using published oil returns and Henderson's estimate of 35 barrels/whale for an estimate of 2,665 gray whales secured, and 2) using an average catch per voyage derived from Townsend (1935) for an estimate of 3,013 gray whales. He made no attempt to account for whales struck but lost. Moreover, he suggested that his catch estimates were 6–19% too low because he, unlike Henderson (1984), did not account for catches by non-U.S. registered vessels. Importantly, Best (1987) made no attempt to distinguish between eastern and western gray whales even though whales from both "stocks" were included in the oil data and the Townsend tabulations. It is unlikely that our inclusion of non-U.S.-registered vessels would account for the differences between our estimates and Best's estimates, considering that American vessels were responsible for 89% of the total ship-based gray whaling activity.

Uncertainties in the Estimates

Several of the uncertainties in our estimates of gray whale landings and removals are accounted for in the estimation variances, including the variability in the number of whales landed per vessel-season, the loss rate factor, and the prorating of the vessel-seasons for which we had no information about gray whaling activity. In sum, the width of the confidence interval for the medium-case estimate of total landings (4,811–5,726, Table 4), which reflects the sampling uncertainty, is 17% of the estimate. That percentage is similar to the difference between the low-case estimate and the high-case estimate (4,789 and 5,624, respectively), which is 15.8% of the medium-case point estimate and reflects the case variability.

We also explored the sensitivity of our estimates to the arbitrary assumption that half of the vessels in Mexican waters judged to have been "maybe" gray whaling actually were gray whaling. To do this, we computed estimates assuming that as few as one quarter or as many as three quarters of the "maybe" vessels actually were gray whaling. This resulted in differences of less than 5% in the estimated total landings. Thus, the magnitude of this uncertainty is small compared to that of uncertainty due to sampling variability and also small when compared to the differences among the three cases of numbers of vessel-seasons.

Another point to consider is that it was not always possible to distinguish vessels that gray whaled unsuccessfully (i.e. chased gray whales but made no catch) from those that pursued only other species (e.g. humpback whales or sperm whales). This inability to identify such "zero-catch" vessel-seasons would have biased our list of gray whaling vessel-seasons downward, but at the same time it would have biased our estimates of the average catch of gray whales per vessel-season upward. The two effects would tend to offset each other to an unknown extent, but the latter would likely be greater than the former because of the relatively small size of the sample used to estimate average catch per vessel-season.

Temporal Changes in Catch Levels

Gray whaling in the eastern North Pacific by 19th century ship-based whalers was concentrated in a 3-decade period, with the bulk of the landings occurring between 1853 and 1863. Levels of both whaling activity (Fig. 7) and landings (Fig. 8) increased steadily over the decade beginning in 1853. Effort dropped abruptly in 1861, at the start of the U.S. Civil War, although it rapidly recovered to levels lying between the 1861 low and the pre-1861 high. Landings per vessel-season declined disproportionately as whaling became much less productive, with landings dropping by 45% from the peak level of 14.0 from 1856 to 1860 to a low of 7.9 from 1866 to 1874 (Table 1).

The decline in ship-based whaling activity paralleled the decline in shore-based gray (and humpback) whaling along the coast of California (Reeves and Smith, 2010). It is unlikely that the decline in either fishery was due to changes in the price of whale oil because, although the price declined briefly in the 1860's, it had recovered by the 1870's, even as gray whaling continued to decline. It is difficult to judge whether catch rates or effort to kill gray whales in the northern feeding areas also declined, given the relatively small catches there and the fact that the available tabulations (Henderson, 1972, 1984) provide only very coarse temporal resolution (i.e. totals approximately by decade).

The overall decline in gray whale catches in the 1860's was interpreted by some contemporary observers as a reflection of whale depletion. For example, when an American employee of a land-concessions company visited Baja California in 1866, he claimed that lagoon and alongshore whaling was no longer profitable and nearly abandoned, noting that two whaleships in Magdalena Bay had taken only two whales so far that season "though they had scoured the waters of the bay for two months" (Browne, 1966:60–61, as cited by Nichols, 1983:33). Scammon (1874:33) described the large bays and lagoons "where these animals once congregated, brought forth and nurtured their young" as "nearly deserted" by the early 1870's.

Gray whaling in the eastern North Pacific nearly ceased after the mid 1870's and until the early 20th century, except for aboriginal whaling (Mitchell, 1979; O'Leary, 1984; Mitchell and Reeves, 1990), small and sporadic catches by California shore whalers (Reeves and Smith, 2010), and occasional ship-based whaling on the feeding grounds (Bockstoce, 1986). Even if the eastern gray whale population was as depleted as suggested by first-hand observers in the late 1860's and 1870's, the lower intensity of whaling in subsequent decades should have allowed it to recover to some degree in the latter 19th and early 20th centuries. The extent of such recovery has not been revealed by assessment models that incorporate previous estimates of 19th century removals (as discussed above), which appear to be inconsistent with the population increases observed in the latter half of the 20th century.

Modern factory-ship whaling on gray whales began in 1914, and, by 1946, Norway, the United States, the Soviet Union, and Japan had taken a total of about 940 eastern gray whales in various parts of the population's range (Reeves, 1984). In addition, an uncertain number of gray whales (possibly several hundred) were taken in the 1930's off southern California by the U.S. factory ship *California* (Brownell and Swartz, 2007). The biological or population-level significance of these removals would have been considerable if the population was near extinction in the early 20th century as assumed by some contemporary observers (Andrews, 1916; Starks, 1922). The degree of depletion of eastern gray whales caused by 19th and early 20th century commercial whaling remains uncertain, but a recent assessment model, which incorporates 20th century population increases but uses only the record of removals since 1930, suggests that the population was on the order of a few thousand in 1930 (Brandon and Punt, 2009).

Implications for Population Assessment

We have no doubt that this effort of ours to build upon the legacy of David Henderson has provided a more complete and accurate picture than was previously available of the numbers of whales removed by ship whalers in the 19th century. The total estimates presented here for 19th century ship-based whaling in Mexico, along with those in our recent reanalysis of 19th century California shore-based gray whaling (Reeves and Smith, 2010), are not, however, substantially different from previously available estimates of removals by these two components of the overall commercial fishery.

Further, we are not aware of any substantial improvements on the earlier estimates for aboriginal gray whaling (IWC, 1993) and ship-based gray whaling north of Mexico (Henderson, 1984). The only significant improvement on estimates of 20th century landings is the previously overlooked 20th century removals by *California* (see above). Therefore, judging by the sensitivity analyses of Butterworth et al. (2002) and Wade (2002), there is no reason to expect that uncertainties about population status associated with previous population modeling approaches would be resolved by incorporating our new estimates of removals.

It is relevant to consider the possibility that lagoon whaling had a more severe effect than would be evident solely from the record of removals. As indicated above, our logbook data confirm that lagoon whaling in Mexico focused on adult females with calves. Further, although calves apparently were seldom tried out (i.e. secured and processed), many were wounded if not killed outright as the whalers attempted to secure their mothers, and many more were orphaned when their mothers were killed. Given that logbooks do not consistently record the presence and fate of calves, it is unlikely that data needed for rigorous quantitative estimates of calf "removal" levels can be obtained.

Although we currently have no way of apportioning the aggregate catch data by area, i.e. inner lagoons vs. lagoon entrances vs. outer coasts (alongshore whaling), it is possible that, with closer scrutiny of logbooks and other sources, this could be done. For example, in the early years of exploitation of a given lagoon, the hardest hit group may have been the cows with calves in the inner reaches. Only after a few years, as that component became depleted, would the whalers have spent substantial time pursuing the more difficult-to-catch and individually lower-yield quarry (bulls, juveniles, and resting females) that congregated in the outer parts of the lagoons and along the outer coasts (Norris et al., 1983; Swartz, 1986). Thus, the composition of catches (specifically the proportion of calving/nursing cows and, in turn, the numbers of killed, mortally wounded, or orphaned calves) could be estimated, based on the pattern of discovery and exploitation of each lagoon.

In any event, the lagoon fishery for gray whales must have had a greater effect on the population than either an unbiased removal regime or a regime biased toward an age or sex class other than adult females (Cooke, 1986). Friday and Smith (2003) showed that the harvest pattern associated with lagoon whaling would have the highest per capita impacts of any pattern considered. A complete assessment of the status of the population will require accounting in some way not only for the sex ratio of the adults removed, but also for the calves that were killed or orphaned, and presumably died, as a consequence of whaling operations.

Further Research

As noted above, our new estimates of the commercial catch history do not come anywhere near to the 60% increase needed to fit existing population models of the eastern gray whale population (Butterworth et al., 2002; Wade, 2002). Also, our numbers, when combined with the relatively well-documented catch levels of the 20th century and the best available estimates of aboriginal catches, do not appear consistent with the genetically derived estimate of average long-term abundance of about 96,000 by Alter et al. (2007), which refers to the entire North Pacific basin and thus encompasses both eastern and western populations.

Thus, two major problems remain. One is the difficulty of obtaining reasonable estimates of historical carrying capacity from catch-based population models. The other is that estimates of historical abundance derived from analyses of genetic variability seem far too high, given what is known about total removals by whaling and recent or current estimated population size.

At least four avenues of investigation to address these problems come to mind: 1) further reconstruction of the catch history, 2) reassessment of the demographic and social effects of lagoon whaling, especially in regard to calving, nursing, and breeding, 3) searching for a better understanding of environmental or ecological factors that determine carrying capacity for gray whales, and 4) reevaluation of the underlying assumptions and methods of genetic variability-based estimates of abundance.

With regard to the first of these, catch history, we suggest that future effort should focus on the poorly documented but long history of whaling for gray whales by aboriginal people throughout the North Pacific, including the Bering and Chukchi Sea coasts (Mitchell, 1979; O'Leary, 1984; Krupnik, 1984; Mitchell and Reeves, 1990) and on the better documented but incomplete history of gray whaling in the western North Pacific. Although there are reasonably good records from Japan (Omura, 1984; Kato and Kasuya, 2002), this is not the case for Korea and China (e.g. Reeves et al., 2008).

In addition, improvements could be made in our present estimates for the eastern North Pacific by sampling additional logbooks to determine landings per vessel-season. Linking the vessel-season data in the Appendix to information in the American Offshore Whaling Voyage database (Lund et al., 2008) reveals that we have sampled about 25% of the extant relevant logbooks. Sampling more logbooks would address uncertainties in our estimation procedures in two ways: 1) by reducing the numbers of Maybe and Unknown vessel-seasons (Table 3) and 2) by reducing the standard errors of the average numbers of whales taken in vessel-seasons that we know involved gray whaling (Table 1).

The resources available for this study were not sufficient to allow additional logbook sampling, but with the information provided here concerning the uncertainties, together with the information in the Appendix and the AOWV database on logbook availability, it should be possible to design an efficient sampling scheme to improve our estimates in a number of ways. Such a scheme would allow greater statistical precision and, with more emphasis on catch locations (e.g. deep inside the lagoons, in the lagoon entrances, or along the outer coast) than was possible in this study, allow us to partition removals by area and hence age/sex class, at least to some extent. It is also worth noting that the estimate of ship-based landings north of Mexico (Henderson, 1984) is not well documented, and further examination of the data on which it is based could be useful.

With regard to the second avenue of investigation, the effects of lagoon whaling, it may be useful to explore population models that would better account for the effects of whaling on a population's breeding grounds. This issue was raised previously by Cooke (1986) and subsumed by Butterworth et al. (2002:66) under the rubric of depensation, which they defined as "the phenomenon of a decrease in the per capita growth rate of a resource when population size is reduced below a certain level." However, the issue deserves further exploration and should explicitly include consideration of the differential sex ratio of the catches, the deaths of calves, and the disruptive effects of whaling at the point in the life cycle when females give birth, nurse their young, and conceive (Friday and Smith, 2003).

With regard to the third avenue, carrying capacity, there has been considerable speculation in the literature on how and to what extent the environmental carrying capacity for gray whales has changed over time. For this species, with its long-distance migration and the sharp geographical separation between its feeding and breeding habitat, population size could be limited either by the size and condition of Mexican lagoons or by the extent and productivity of boreal and Arctic shelf waters. Half a century ago, there was lively debate concerning how much gray whale breeding habitat had been lost in southern California and Mexico, whether due to inshore vessel traffic (Gilmore and Ewing, 1954), cooling sea temperatures (Hubbs, 1959), or sea level fluctuations and other geophysical processes (Gilmore, 1976).

More recently, the emphasis has been on food limitation. A large-scale die-off along the west coast of North America in 1999 fueled speculation that foraging conditions for gray whales in the Bering and Chukchi Seas had deteriorated, leading to poor survival and low calf production (Le Boeuf et al., 2000). The die-off continued in 2000, with a relatively high proportion of the mortality consisting of subadult and adult whales and with some but not all of the dead animals exhibiting signs of nutritional stress (Gulland et al., 2005). Annual strandings returned to background levels from 2001 through 2006 (Brownell et al., 2007), and Moore et al. (2001) concluded, "The causes of the recent spate of gray whale deaths may never be discovered." The factors determining carrying capacity for gray whales are not clearly known, and alternative model formulations may be useful for exploring this issue further.

Finally, with regard to the fourth avenue, the reliability of genetic variability-based estimates of average long-term abundance, concerns have been raised about such things as the mutation rate attributed to gray whales, the relationship of effective and census population size, the demographic and social characteristics assumed, and the applicability of genetic variability-based estimates of abundance to contemporary (or recent historic) populations (Palsbøll et al., 2007; Alter and Palumbi, 2007; Palsbøll, 2009). Although such concerns were addressed to some degree by Alter et al. (2007) and Alter and Palumbi (2007), further testing is needed of both the methodology and the assumptions leading to those authors' seemingly very high estimate of average long-term abundance compared to estimates of pre-whaling abundance derived from other methods.

Acknowledgments

This study was funded by the Lenfest Oceans Program of the Pew Charitable Trust through Stanford University. We thank Steve Palumbi for his pivotal role in securing the grant. Both he and Liz Alter provided constructive prodding, which forced us to look harder and deeper at the historical records than we otherwise might have. We appreciate the New Bedford Whaling Museum for allowing and facilitating our access to the Henderson material in their collection, and for permitting the use of Figure 1. Figure 3 is used courtesy of the Hawaiian Mission Children's Society Library. Thank you to Richard Donnelly for his assistance in reproducing the logbook images used in Figures 4, 5, and 6. We also acknowledge the generosity of the reviewers, whose thoughtful critical comments helped us refine our approach and correct deficiencies. Finally, we appreciate the support of Willis Hobart and Jacki Strader in helping us illustrate the article.

Appendix

Identity of vessels whaling in Mexico during the gray whaling winter season from 1846 to 1874 showing the vessel name (Vessel), the nationality of registry (Nat), the vessel number (Ves), and the voyage number (Voy). Also shown are the source of information on each vessel-season (VS) and the likelihood that each vessel-season involved gray whaling (GW). For vessel-seasons where we had information on landings, the estimated number of gray whales taken during that season (EGW) and the nature of the source of those landings (LS) is indicated. Voyage and vessel numbers for American vessels are from the American Offshore Whaling Voyage database (Lund et al., 2008) and the voyage numbers for the French vessels are from Annex 7 of du Pasquier (1982:242–9, as 30,000 plus the numerical sequence). Details of the American vessels and voyages can be obtained by tracing the Ves and Voy values given here into the National Maritime Data Library (www.nmdl.org).

Coded Fields:

VS (Vessel Source): H = Henderson (1972, 1984, and unpublished notes and files), O = Other, primarily Hawaii port records

GW (Gray Whaling): Y = Yes, M = Maybe, N = No, U = Unknown

LS (Landings Source): L = logbook we read, T = logbook read by Townsend (1935), N=newspaper.

Bycatch and ship strikes of gray whales in U.S. and Canadian waters, 2008-2012

ABSTRACT

The IWC held a workshop from 8 April to 11 April, 2014 to review the range-wide population structure and status of North Pacific gray whales. One of the objectives of the meeting was to develop a modelling framework to better assess the status of gray whales and the potential impact of human activities. The impacts of some human activities, such as hunting, are well documented whereas the impact of other human activities like shipping and fishing are not. In this paper we assessed the human-caused mortality, other than hunting, in Canada and US waters for 2008 through 2012. Whales observed alive with injuries from ship strikes or entanglement that likely had a compromised chance of survival were given a prorated level of mortality based on the observed known fate of North Atlantic right whales with similar distress following procedures established by NOAA (2012). We separated all observed incidents of human-caused mortality into regions defined as California (US border to 41°N), Pacific Coast Feeding Group (PCFG) Range (41°N to 52°N), Puget Sound, Southeast Alaska, Kodiak Island, and northern waters (>52°N) and by season to either migratory or feeding. We report three different models for apportioning the observed mortalities and injuries to the PCFG, Far North feeding group (FN), and Sakhalin Island feeding group (SI). We evaluated sighting data from the Cascadia Research Collective database of gray whale sightings to determine the availability of PCFG whales in each of the regions during the migratory and feeding seasons. The availability of PCFG and FN whales was used to proportion observed mortalities and serious injuries to these two feeding groups. To determine the possible proportion of whales that were from the SI group we multiplied migratory incidents by the median risk of 0.07 estimated by Moore and Weller (2013). During the 5-year period we observed 27.1 serious injuries and mortalities. We apportioned those mortalities and injures using three methods which resulted in a range of mortality of 7 to 13 for PCFG, 25.1 to 31.1 for FN, and 0.05 for SI over the five-year period resulting in an annual rate of 1.4-2.6, 5.0-6.2, and 0.01 respectively. These estimates are minimum estimates because it is not likely that all whales killed by human activities are reported or drift to shore where they can be examined and documented.

INTRODUCTION

From 8 April through 11 April the IWC held a workshop to review the range-wide population structure and status of North Pacific gray whales. One of the objectives of the meeting was to develop a modelling framework to better assess the status of gray whales and the potential impact of human activities. Some human activities that directly cause whale mortality, such as hunting, are well documented whereas the impact of other human activities like shipping and fishing are not. Mortalities due to ship strikes and entanglement in fisheries gear and other marine debris cause conservation concern for other cetacean populations (e.g. North Atlantic right whales: Knowlton and Kruas 2001 and vaquita: D'agrosa *et al.* 2000). It is our goal in this

[1]Marine Mammal Program, Makah Fisheries Management, Makah Tribe, Neah Bay, Washington
[2] Protected Resources Division, Southwest Fisheries Science Center, NOAA Fisheries, San Diego, California
[3] Pacific Region Marine Mammal Program, Pacific Region, Department of Fish and Oceans Canada, Vancouver, British Columbia

paper to estimate the rates of this non-hunting human-caused mortality in US and Canadian waters for modeling by the IWC Scientific Committee to determine if these sources of mortality are a conservation concern for Pacific Coast Feeding Group (PCFG), Far North feeding groups (FN), or the Sakhalin Island (SI) feeding group. It is not our intention for this paper to be used in domestic marine mammal management in Canada or the US.

METHODS

Gray whale mortalities and injuries were documented through fisheries observer programs, fisher and sailing captain self-reports, reports from the public, and through examination of dead whales on the beach. Every report was documented in a database by the Canadian or US government in their respective areas.

All whales in which human interactions were assumed to have caused the mortality were recorded as a 1 for mortality. We utilized methods developed by NOAA (2012) to account for the likelihood of mortality for whales injured due to a ship strike or entanglement. Each injured whale was classified according to the large whale injury criteria table in NOAA (2012; Appendix 1). NOAA (2012) utilized the known fate of whales monitored in the past with similar injuries to determine a prorated value of mortality between 0 and 1 for each of the classifications.

The goal of this study is to apportion the observed mortalities to the Far North (FN) feeding group, Pacific Coast Feeding Group (PCFG), or Sakhalin Island feeding group (SI). The first step of apportioning these mortalities is to determine the region and season in which the mortality occurred. We assigned all mortalities and serious injuries (hereafter mortality) to the regions of FN (north of 52°N) with Kodiak Island and Southeast Alaska accounted separately for one analysis, Puget Sound, PCFG (41 to 52°N), and California (north of US/Mexico border and south of 41°N). All observations from June through November with one exception were assigned to the feeding season and all observations from December through May were assigned to the migratory season. The one exception for the feeding season was a whale observed on 15 June 2012 at Nitinat, British Columbia anchored to the bottom with multiple ropes in very decomposed condition. We decided to count this whale as having died in the migratory season given that its state of decomposition suggested it most likely died prior to 1 June.

Much of the observed mortality occurred at times or locations where the three feeding groups are mixed or are potentially mixed. As a result, without more information than time and location, it is not possible to allocate mortalities among the three feeding groups with certainty. To address this challenge we developed three methods for apportioning the observed mortalities. In all methods we assigned mortality in the PCFG during the migratory season equal to the availability of PCFG whales in Northwest Washington. We chose to use Northwest Washington rather than the availability of gray whales at all research segments in the PCFG because in areas outside Northwest Washington researchers target whales they believe are PCFG whales during surveys. Availability of PCFG whales was calculated by number of sightings of PCFG whales divided by total sightings in Northwest Washington during the time period of December through May. The first method used the strict definition of PCFG whales as only feeding in the range of 41° to 52° N and mortalities outside that range during the feeding season were assigned 100% to the FN. The second method assumed that all mortalities in California during the feeding season were of PCFG whales since the feeding group is spatially much closer to this region than is the FN or SI. For both methods one and two, the availability of PCFG whales during the migration in California was assumed to be equal to the ratio of the two population sizes. The last method used empirical data from the sighting database maintained by Cascadia Research Collective to determine the availability of PCFG whales within all region and season combinations except for in the FN where data is too limited. Availability was calculated as the number of sightings of gray whales that met the IWC definition of PCFG whales divided by the total number of sightings within the region and season of interest for all sightings in the catalogue through 2012. Data for this analysis was accessed from the sighting database on 10 April 2014.

RESULTS

During the time period of 2008 through 2012 we observed 50 serious injuries and mortalities due to ship strikes or entanglements in US and Canadian waters (Appendix 2). To our knowledge, none of the whales were identified as PCFG whales in the Cascadia Research Collective catalog or were matched with the photo catalog for SI whales. Four whales were downgraded to a non-significant injury after being first documented as a serious injury because they were either successfully disentangled or disentangled themselves. The majority of human-caused injuries (70%) were due to entanglements in fishing gear or other marine debris. Five of the 35 entanglements occurred in Canada. We also recorded 15 ship strikes with one reported in Canada.

Availability of PCFG by region and season

Availability of PCFG whales by region and season was calculated from the sightings in the database maintained by Cascadia Research Collective and is reported in Table 1.

Table 1: Observed availability of PCFG whales by season and region with total numbers of observations reported.

	Feeding Season			Migratory Season		
Region	Observations of PCFG	Total Observations	Availability	Observations of PCFG	Total Observations	Availability
Kodiak	42	225	0.19	0	2	N/A
Southeast Alaska	21	37	0.57	0	0	N/A
Puget Sound	4	70	0.06	4	896	0.00
PCFG	16,321	17,316	0.94	97	270	0.36
California	13	43	0.30	3	35	0.09

Total observed mortality by region

Using method 1 we assigned whale mortalities during the feeding season using a strict application of the IWC definition of PCFG whales. During the migratory season we assigned whale mortalities in California and Puget Sound (PS) proportionally to the population size of the two groups (200 PCFG: 20,000 FN), resulting in an availability of 0.01. We assumed that no mortalities in the FN were PCFG whales. We assigned 0.2% of mortalities during the migration to SI whales based on the estimated risk to on an individual SI whale conducted by Moore and Weller (2013). This assessment concluded that the median estimate of the Makah hunt encountering a SI whale was 0.2% and assumed that there was zero probability of taking an SI whale during the feeding season. We estimated a total mortality of 7.0 PCFG, 31.1 FN, and 0.05 SI whales with an annual average of 1.4, 6.2, and 0.01 respectively from 2008 through 2012.

Table 2: Total observed non-hunting human-caused mortality for US and Canadian waters in 2008-2012 by region and season and apportionment of mortality to feeding group using a strict application of the IWC definition of PCFG whales.

	Feeding Group Proration						Observed Mortalities		Estimated mortalities		
Region	PCFG Feeding	PCFG Migrating	FN Feeding	FN Migrating	SI Feeding	SI Migrating	Feeding	Migrating	PCFG	FN	SI
Far North	0	0	1	1	0	0	2.75	1.5	0.0	4.3	0.00
Puget Sound	0	0.01	1	0.99	0	0.002	0	1	0.0	0.0	0.00
PCFG	1	0.359	0	0.641	0	0.002	4.02	7.75	6.8	5.0	0.02
California	0	0.01	1	0.99	0	0.002	6	16.05	0.2	21.9	0.03
Total							12.8	26.3	7.0	31.1	0.05
Average (2008-2012)									1.4	6.2	0.01

Method 2 used similar assumptions as method 1 with the exception that all mortalities in California during the feeding season were assigned to the PCFG because they are the closest feeding group spatially to where the mortality occurred. Using this method we estimated 13.0 PCFG, 25.1 FN, and 0.05 SI mortalities with an annual average of 2.6, 5.0 and 0.01 respectively for the 2008 through 2012 time period.

Table 3: Total observed non-hunting human-caused mortality for US and Canadian waters in 2008-2012 by region and season and apportionment of mortality to feeding group using the assumption that all mortalities in California during the feeding season were PCFG whales.

	Feeding Group Proration						Observed Mortalities		Estimated mortalities		
Region	PCFG Feeding	PCFG Migrating	FN Feeding	FN Migrating	SI Feeding	SI Migrating	Feeding	Migrating	PCFG	FN	SI
Far North	0	0	1	1	0	0	2.75	1.5	0.0	4.3	0.00
Puget Sound	0	0.01	1	0.99	0	0.002	0	1	0.0	0.0	0.00
PCFG	1	0.359	0	0.641	0	0.002	4.02	7.75	6.8	5.0	0.02
California	1	0.01	0	0.99	0	0.002	6	16.05	6.2	15.9	0.03
Total							12.8	26.3	13.0	25.1	0.05
Average (2008-2012)									2.6	5.0	0.01

Method 3 utilized the database of gray whale sightings maintained by Cascadia Research Collective to inform the availability of PCFG whales in each region by season. We added the regions of Southeast Alaska and Kodiak Island to provide better resolution to the availability estimates. Using this method we found 11.3 PCFG, 26.7 FN, and 0.05 SI mortalities with an annual average of 2.3, 5.3, and 0.01 respectively for the 2008 through 2012 time period.

Table 4: Total observed non-hunting human-caused mortalities for US and Canadian waters in 2008-2012 and apportionment by region and season using empirical data from the database of gray whale sightings maintained by Cascadia Research Collective.

	Feeding Group Proration						Observed Mortalities		Estimated mortalities

Average (2008-2012)									2.3	5.3	0.03

DISCUSSION

We presented three methods for apportioning the total observed non-hunting human-caused mortality that occurs in US and Canadian waters to the PCFG, FN, and SI. All three methods count more mortalities than were documented because mortalities were 100% apportioned to the PCFG and FN before accounting for possible SI mortality. The risk of bycatch or ship strike of a SI whale is low enough that this weakness in the analysis is likely negligible. Of the three methods, method 3 is the strongest estimate because it uses observed values for the availability of PCFG whales by region and season rather than estimates based on the IWC-defined area and season of PCFG whales. Based on sighting data we know that some PCFG whales do feed in the FN during the summer but we felt that the available data was too limited to provide a meaningful estimate of the availability of PCFG whales in that region during the feeding season.

The methods used in this paper contrast strongly with the methods used in the US stock assessment report (SAR) for gray whales. In the SAR the IWC-defined area and season of PCFG whales is applied strictly and only mortalities from June to November in the range of 41°N to 52°N are included (Carretta *et al.* 2014a). At present the method employed by the US government may produce a stronger estimate than the methods in this paper because our methods assume that the likelihood of a whale being struck by a vessel or entangled in fishing gear or marine debris is equal to the proportion of times a whale observed by a research vessel was or was not a PCFG whale. Factors such as the whale's activity or sensitivity to boat noise will make it more or less available to be photographed by researchers. It is possible that the availabilities we used are biased high for PCFG whales during the migratory season because it is more likely that PCFG whales are feeding south of the Bering, Beaufort, and Chukchi seas feeding grounds and a feeding whale is easier to approach in a research vessel and easier to photograph. Accepting this potential bias in our methods, we calculated the availability of PCFG whales from sightings in the gray whale catalogue maintained by Cascadia Research Collective to make an informed assessment of how to apportion mortality based on the area and season in which the mortality was observed rather than making assumptions. In the future we recommend that photographs of whales recorded as dead or a serious injury be compared to the Cascadia

Research Collective's catalogue to determine if the apportionment estimates in this paper, particularly method 3, are accurate. As stated in the introduction, the purpose of this paper is inform the modeling associated with the range-wide workshop on gray whale stock structure and is not intended to replace domestic processes in the US or Canada for accounting of gray whale mortality.

Many of the mortality and serious injury reports used in this analysis were reports from the public. In most cases the reports are sound and very helpful but in many cases they lack sufficient detail to evaluate the nature of a whale's injury and to discern whether a single whale is reported on multiple occasions. Another limitation of reports from the public is that there are many PCFG gray whales known to have very visible, large, healed wounds (Figure 1). If these whales are reported by the public then they are included as a serious injury even though a trained observer would note that the injuries have healed.

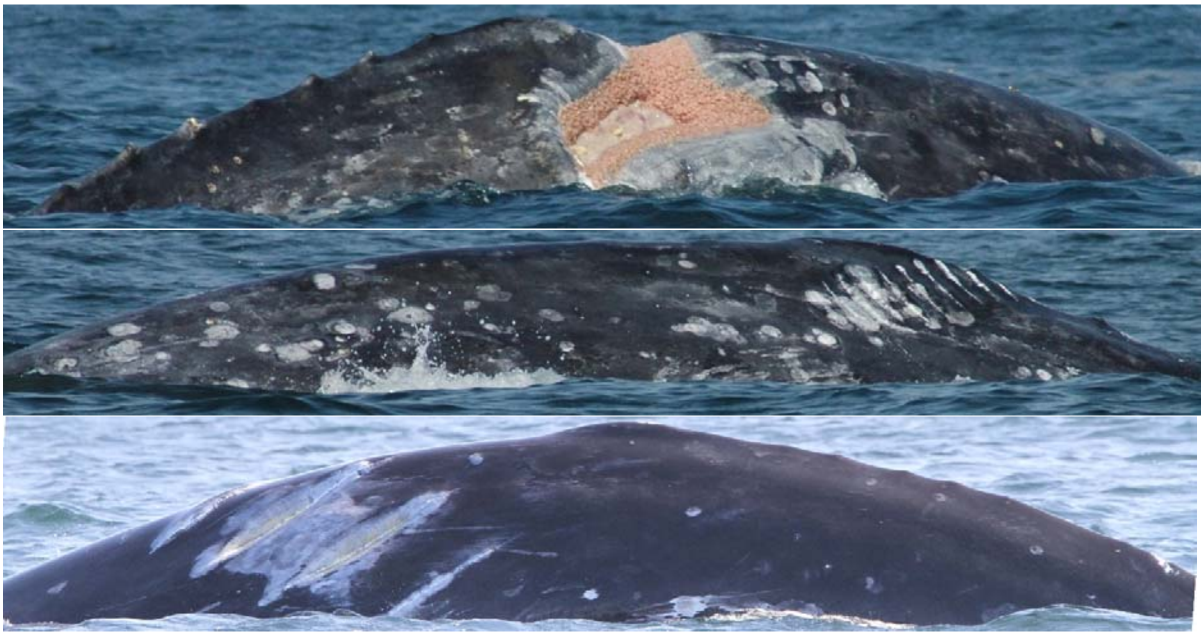

Figure 1: Large wound on CRC 204 (top) and propeller wounds on CRC 6 (middle) and CRC 144 (bottom) that may be reported by the public as a new injury despite the age of these wounds.

Scordino and Mate (2011) conducted a similar analysis of non-hunting human-caused mortality for California through British Columbia for 1990 through 2010. In that analysis they documented an annual PCFG mortality rate of 1.845 whales per year. This rate was 25% less than the estimate in this paper using method 3 (2.3 PCFG whales per year for 2008 through 2012). The difference in results may be due differences in methods such as the 2011 report not including Alaskan mortalities or the differences in how injuries were accounted as either a mortality or not. The different results may also show an increase in bycatch and ship strikes in recent years as compared to 1990 through 2010. Even with the greater estimates in this report, the total estimates of non-hunting human-caused mortality reported are minimum estimates because it is not likely that all whales killed by human activities are reported at-sea or drift to shore where they can be examined and documented and because this report does not report mortalities in Mexico.

Appendix 1: Summary of Large Cetacean[1] Injury Categories and Criteria (Table 1 from NOAA 2012)

Instructions: Each large cetacean injury event is recorded to the appropriate injury/information category using all available information and scientific judgment, as described in the Procedural Directive. Criteria L10 - L12 accommodate events that lack details necessary for assignment to a more specific category. For a single injury event to which several categories apply, the injury determination with the highest level of severity is assigned. More detailed information or extended observation on an individual case/animal may justify a determination differing from the guidance of this table. An animal that is fully disentangled would generally be considered not seriously injured, unless there is additional evidence of a serious injury. Any injury leading to apparent significant health decline (e.g., skin discoloration, lesions near the nares, fat loss, increased cyamid loads) is a serious injury.

Category	**Injury/ Information**	**Injury Determination**	**Criteria**
L1	Ingested gear[2] or hook(s)	SI[3]	Swallowed, not simply draped through mouth
L2	Constricting wrap	SI	Tightly wrapped line anywhere on body that indents the skin or does not shift with whale's movement, or line that is likely to become constricting as the whale grows. Indication that a whale that is heavily weighted, anchored or has a discolored appendage is sufficient evidence of constricting gear
L3	Loose wrap, bridled or draped gear	NSI[4]	Loosely wrapped gear that moves or shifts freely with whale's movement. Absence of constricting gear must be confirmed
L4	External hook	NSI	Fishing hook of any size on any part of the body (i.e., not ingested)
L5a	Deep lacerations[5]	SI	Laceration with the potential to affect major artery (e.g., laceration or severing at insertion of flipper/fluke), penetrating body cavity, or cutting bone
L5b	Superficial laceration	NSI	Laceration not deeper than blubber layer, does not affect major artery, or cut bone
L6a	Vessel much greater in size than whale or vessel ≥65' and >10 knots	SI	Struck by vessel much greater in size than the whale and traveling greater than 10 knots, or struck by vessel equal or greater than 65' and traveling greater than 10 knots, and no information

9

			on injury to the whale
L6b	Vessel smaller in size than whale or vessel <65' and >10 knots	Prorate[6]: 0.20	Struck by vessel smaller in size than the whale and traveling greater than 10 knots, or struck by vessel less than 65' and traveling greater than 10 knots, and no information on injury to the whale. A strike to a calf by a vessel of any size and traveling greater than 10 knots will be considered a serious injury
L6c	Vessel any size ≤10 knots	NSI	Struck by vessel of any size traveling at equal or less than 10 knots and no information on injury to the whale
L7a	Vessel much greater in size than whale or vessel ≥65' and speed unknown	Prorate: 0.56	Struck by vessel much greater in size than the whale traveling at an unknown speed, or struck by vessel equal or greater than 65' and traveling at unknown speed, and no information on injury to the whale. A strike to a calf by a vessel of any size when speed is unknown will be considered a serious injury
L7b	Vessel smaller in size than whale or vessel <65' and speed unknown	Prorate: 0.14	Struck by vessel smaller than the whale traveling at an unknown speed, or struck by vessel less than 65' and traveling at unknown speed, and no information on injury to the whale. A strike to a calf by a vessel of any size when speed is unknown will be considered a serious injury
L8	Dependent[7]	SI	Dependent calf of a dead or seriously injured mother
L9	Brought on deck	SI	Whale removed from water and brought on deck

L10	Evidence of entanglement	Prorate: 0.75	Confirmed entanglement but insufficient information available to place in any of the L1-L4 criteria with a high degree of certainty
L11	Vessel strike laceration	Prorate: 0.52	Whale confirmed with non-entanglement related laceration but lacking details to place in either criteria L5a or L5b with a high degree of certainty. Includes observation of blood in water
L12	Vessel strike observed	Prorate: 0.36	Confirmed vessel strike report where there is insufficient detail to assign event to criteriaL6a – L7b with a high degree of certainty. A strike to a calf by a vessel of unknown size traveling at an unknown speed will be considered a serious injury

ABSTRACT

Gray whales (*Eschrichtius robustus*) in northwest Washington were studied, with the aims to: (1) increase understanding of gray whale use of the study area; (2) document the annual and seasonal fluctuations in the numbers of whales utilising the area; and (3) assess the fidelity of whales to the study area within and between years. Together these goals establish a baseline of gray whale behaviour during summer and autumn in the region of the Makah Tribe's proposed whale hunt. From 1984 to 2011, a total of 225 unique gray whales were observed, with 49% being observed again in a future year. There was significant variability in observation rates of gray whales by month and year. During the feeding season, the observation rate increased to a peak in August in the north research segment in the Pacific Ocean and to a peak in October in research segments in the Strait of Juan de Fuca and in the southern research segment in the Pacific Ocean. Gray whales were most commonly observed at depths of 5–15m over rocky substrates and often near kelp forests, although the locations where they fed were dynamic by both month and year. Some whales habitually returned to northwest Washington, however the average whale in the study area was observed in only 31.6% (SE = 1.6%) of the possible years in which they could have been observed. Gray whales in the study area had an average minimum tenure (residency time) of 24.8 days out of a possible 183 days of the feeding season. A discovery curve analysis did not reach an asymptote over the 27 years of this study showing that there is no population closure to the research area. Based on these findings, it can be concluded that even though northwest Washington is an important feeding area, most Pacific Coast Feeding Group (PCFG) gray whales do not have strong fidelity to this one region within the IWC defined PCFG range. The findings presented in this paper provide a baseline for evaluating the impact of Makah hunting activities on the behaviour of PCFG whales that utilise the Makah's traditional hunting area once hunting activities resume.

KEYWORDS: GRAY WHALE; PACIFIC OCEAN; FEEDING GROUND; MOVEMENTS; SITE FIDELITY; NORTHERN HEMISPHERE; SURVEY–VESSEL

INTRODUCTION

Most Eastern North Pacific (ENP) gray whales (*Eschrichtius robustus*) migrate from wintering grounds in Baja California, Mexico, to feeding grounds in the Bering, Chukchi and Beaufort seas. A small subset of the ENP gray whale population does not complete the migration to arctic feeding grounds and instead spends the summer and autumn at feeding grounds along the coast of the Pacific Ocean from California through Southeast Alaska (Calambokidis *et al.*, 2002). This group of whales has been referred to by many names since it was first studied in the 1970s and is currently recognised as the Pacific Coast Feeding Group (PCFG) by the International Whaling Commission (IWC, 2011) and the US Government (Carretta *et al.*, 2013). The IWC defines the PCFG as gray whales seen in more than one year in the months of June to November within the range of northern California to northern British Columbia (41°N–52°N), excluding gray whale sightings in Puget Sound, Washington (IWC, 2012). The range is restricted to 52°N even though PCFG whales are known to frequently occur as far north as Kodiak Island, Alaska (Gosho *et al.*, 2011) and have been observed in the Beaufort Sea (Calambokidis *et al.*, 2014). The IWC-defined range of the PCFG is narrower than previous definitions of this group. This is primarily because most photo-identification surveys have been focused on 41–52°N. Population estimates are therefore more reliable for this range. There are few historic or projected future catches of gray whales north of 52°N and south of the Bering Sea, making the more narrowly defined range more applicable to management (IWC, 2012). The abundance estimate for the PCFG in 2012 was 209 whales (Calambokidis *et al.*, 2014).

Recent genetic studies have found small but statistically significant differences in frequencies of mtDNA haplotypes between samples collected from PCFG whales and other ENP whales in other portions of their range (Frasier *et al.*, 2011; Lang *et al.*, 2014). No statistically significant differences have been found in the frequencies of nuclear DNA (D'Intino *et al.*, 2013; Lang *et al.*, 2014). Despite the significant difference in mtDNA haplotype frequency, PCFG and ENP whales had similar haplotype diversity which suggests that immigration into the PCFG could be occurring (Lang *et al.*, 2014). The results of a genetics simulations study (Lang *et al.*, 2012) and photo-identification work (Calambokidis *et al.*, 2014) were consistent with immigration from other portions of the ENP range into the PCFG having a significant role in the

population dynamics of the group. Given that there is evidence both for the PCFG having open population dynamics and evidence for matrilineal recruitment, there is currently debate on whether or not the PCFG is a stock. NOAA Fisheries used a panel of experts to evaluate whether the PCFG is a stock; the panel could not agree whether the PCFG is a stock for US domestic purposes but did agree that more research is needed (Weller *et al.*, 2013).

Interest in PCFG whales has been inspired by concern regarding the possible impacts on the PCFG of the Makah Tribe resuming their treaty protected right to hunt whales. In 1855, the Makah Tribe protected its whaling rights in the Treaty of Neah Bay. In the 1920s, the Tribe voluntarily suspended whale hunting due to the impacts of commercial whaling on gray and humpback whale populations (Renker, 2012; Thompson, 2006). In 1994, when the gray whale was removed from the US Endangered Species List, the Makah Tribe informed the US Government of its intentions to resume traditional whale hunting. The US Government has obtained aboriginal whaling catch limits for the harvest of gray whales from the IWC to be used by the Makah Tribe since 1997. However, since that time the Makah Tribe has only landed one gray whale due to domestic court cases and regulatory processes suspending the hunt in 2000. The Tribe has submitted a proposed management plan to the US Government and the IWC for review. The management plan restricts the hunt to the migratory season in the Pacific Ocean portion of the Makah Usual and Accustomed (U&A) fishing grounds to minimise the risk that a hunt takes a PCFG whale. Nonetheless, it is recognised that the hunt may still take PCFG whales, so the management plan also has a provision to limit the number of PCFG whales landed through a conservative calculation based on the abundance of PCFG whales (IWC, 2013). The IWC evaluated the impact of Makah hunting on PCFG population dynamics and found that the Tribe's proposed management plan meets the conservation goals of the IWC of ensuring the PCFG will remain above 60% of its carrying capacity over a 100-year simulation (IWC, 2013).

Past studies have documented the behaviour of PCFG whales throughout their entire range (Calambokidis *et al.*, 2002; 2010; 2012; 2014). This paper reports on the behaviour of gray whales in the coastal waters of northwest Washington during the summer and autumn feeding season. Data were collected from 1984–2011 with the goals of: (1) increasing our understanding of gray whale use of the study area; (2) documenting the annual and seasonal fluctuations in the numbers of whales utilising the area; and (3) assessing the fidelity of whales observed within the study area within and between years. Together these three goals establish a baseline of gray whale behaviour in the region of the Makah Tribe's proposed whale hunt to evaluate (once the hunt is approved) whether the hunt impacts gray whale behaviour in the northwest Washington.

METHODS

Study area

Research effort was conducted along the northwest tip of Washington State, USA (Fig. 1). Northwest Washington is bounded by two bodies of water: the Strait of Juan de Fuca

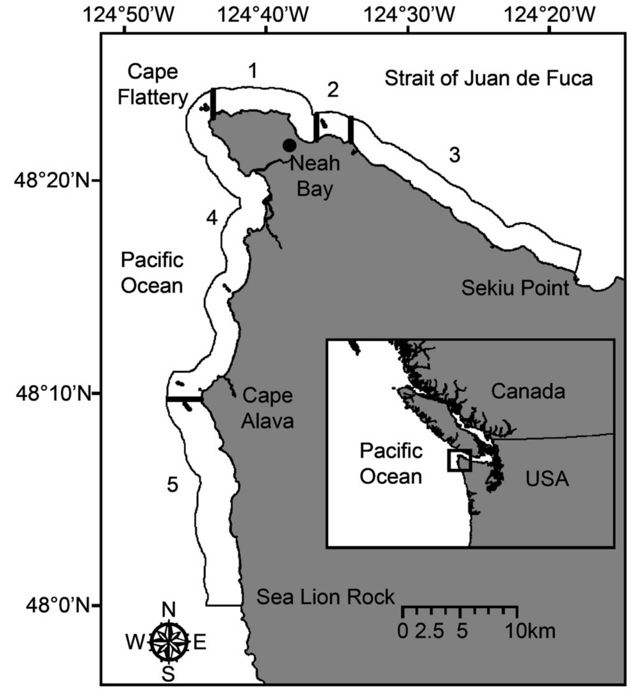

Fig. 1. Map of the gray whale survey region in northwest Washington with the focal survey area shown enclosed with a line. The numbered survey segments are: (1) West Strait; (2) Neah Bay Entrance; (3) East Strait; (4) North Ocean; and (5) South Ocean.

to the north and the Pacific Ocean to the west. The rocky shorelines are interspersed with sandy beaches, and rocky underwater habitats dominated by forests of bull kelp (*Nereocystis luetkeana*) and giant kelp (*Macrocystis spp.*) in waters 5–15m deep. The waters of northwest Washington have high biological productivity due to the confluence of currents from the California Current and the drainage of Puget Sound through the Strait of Juan de Fuca, and seasonal winds causing upwellings (Marchetti *et al.*, 2004). The study area encompasses most of the nearshore habitat of the Makah U&A and the entire area in which the Makah Tribe has proposed for hunting gray whales (Makah Tribal Council, 2011).

Survey methodology

The northwest Washington survey area is too large to be surveyed effectively in one day. One day of survey effort covered the area to the east of Neah Bay along the shores of the Strait of Juan de Fuca to Sekiu Point, approximately 25km from Neah Bay. The other survey day covered the area west along the shores of the Strait of Juan de Fuca to Cape Flattery and then south following the shoreline of the Pacific Ocean to Sea Lion Rock (47°59.58'N, 124°43.45'W). The total distance covered in the southbound leg is approximately 60km. Surveys for gray whales were generally conducted within 1–2km of shore because gray whales feeding in northwest Washington primarily congregate near shore. Portions of the survey in the Pacific Ocean, particularly south of Cape Alava, were conducted further from shore due to poorly charted submerged rocks.

Survey effort was variable by year. The early years of survey effort in northwest Washington were conducted opportunistically with three years of surveys in the 1980s (1984, 1986 and 1989) by Cascadia Research Collective

(CRC). Starting in 1992 surveys were conducted annually by the National Marine Mammal Laboratory (NMML) and CRC but effort was low and opportunistically conducted during studies of other marine mammal species. After 1996, surveys were standardised and were generally conducted on a bi-weekly basis from June through November as weather and ocean conditions allowed with NMML and the Makah Tribe as the primary research groups. The objective was to collect photo-identification of whales. Thus, if the researchers had good reason to suspect that survey effort in the Strait of Juan de Fuca would result in limited or no photographs of gray whales, then effort was focused on the Pacific Ocean and vice versa. The Pacific Ocean survey area was generally surveyed monthly regardless of anticipated opportunities to photograph gray whales because the surveys were also used for monthly California and Steller sea lion research. All research effort was conducted from small vessels of 6–9m in length.

During surveys, observers periodically recorded time and location and variables that could have influenced the probability of sighting a whale such as cloud cover and Beaufort sea state. When gray whales were sighted, their location, depth and activities were recorded. Observers then attempted to take photographs of the dorsal ridge along both flanks as well as the flukes. Photographs were taken using digital SLR cameras with a 70–300mm lens (35mm film cameras were used prior to 2004). The lens magnification allowed photo-documentation of unique colouration patterns on the lateral sides and flukes of the whales (Darling, 1984). The frame numbers from the photographs were recorded on the field data sheet with the sighting information.

Photo-identification methodology

All gray whale photographs of suitable quality were compared to a catalogue of gray whales previously seen in the PCFG as described in Calambokidis *et al.* (2012) by CRC. If a photographed whale was matched to a catalogued whale then the catalogue number of the whale was recorded. If a match could not be made, and the photograph was of sufficient quality, then the photographed whale was assigned a new catalogue number. All catalogue numbers of sighted gray whales were recorded in a database along with attributes of the sighting such as date, time, water depth, location and whale behaviour.

Data exploration

The three primary goals of this research were: (1) to increase understanding of gray whale use of the study area; (2) to document seasonal and annual fluctuations in the numbers of whales using the study area; and (3) to assess fidelity of whales to the study area. The analyses conducted could be interpreted as achieving one or more of these goals but for the purpose of explaining each method, and why it was conducted, each method is listed by research goal. For all analyses observations of uniquely identified whales were used instead of all gray whale observations to prevent pseudo-replication. Research effort and data collection was not consistent in all years (as described above) and as a result some analyses could not use all collected data whereas others could (Table 1).

To address the goal of increasing understanding of gray whale use of the study area four analyses were conducted. The first analysis was to characterise the depth range and habitat types where gray whales were observed. The second analysis was to document the occurrence of new whales in the study area. The purpose of this analysis was to determine the turnover of individuals in the study area. New whales were simply defined as whales not previously observed in the study area although they may have been observed within the PCFG in the past. For each year the number of new whales observed and the proportion of those that were observed to 'recruit' into the study area and be observed again in a subsequent year were determined. The third analysis documented how many calves were observed and calculated an estimate of proportion of newly observed whales that were calves (see Calf Analysis below). The last analysis determined if there is population closure to the study area. Calambokidis *et al.* (2010) concluded that gray whales who utilise northwest Washington have fidelity to a region at least as large as Oregon to Southern Vancouver Island. Despite the findings of Calambokidis *et al.* (2010), domestic processes for evaluating the impact of the proposed Makah whale hunt still question what the local area should be for analysis. To evaluate closure discovery curves were constructed both for all whales observed and for whales that were observed to have some fidelity to the area and were observed in more than one year.

Two analyses were used to document seasonal and annual fluctuations of whales in the study area. In the first analysis

Table 1

Years of data used and justification for each analysis.

Analysis	Years of data used	Justification
Depth	1984–2011	All depths recorded were used for the analysis.
Temporal and spatial distribution of sightings	1996–2011	Data prior to 1996 was not used for analysis because effort was opportunistic in nature and could not be quantified to research segment.
Mapping	2004–2011	We used 2004–11 only because during prior years whale locations were not recorded precisely leading to challenges in interpreting maps.
Fidelity to research area	1984–2011	All data was used.
Minimum tenure	1996–2011	Survey effort was standardised for 1996–2011 in all years but 2004 with effort throughout the summer and fall feeding season.
Occurrence of new whales	1996–2011	All years were used in the analysis. Some of the analysis focused on 1996–2011 to ensure that new whales were not whales that commonly use the study area but had not been 'discovered' yet.
Photo analysis of new whales	2004–2011	The analysis was performed at Makah Fisheries and only photographs after 2004 were available for analysis.
Population closure in study area	1984–2011	All data was used.

all sightings were divided into five research segments (Fig. 1). The five research segments were: (1) East Strait (Sekiu Point to Third Beach); (2) Neah Bay Entrance (Third Beach to Waadah Island); (3) West Strait (Waadah Island to Tatoosh Island); (4) North Ocean (Tatoosh Island to Cape Alava); and (5) South Ocean (Cape Alava to Sea Lion Rock). The number of sightings were divided by the number of surveys in the research segment and the length of the research segment in km to standardise the number whales observed per segment for comparison purposes, hereafter this standardised sighting rate will be referred to as 'observation rate'. Observation rates were compared by month and year within each research segment using ANOVA. The second analysis used was mapping and is described in more detail below. The purpose of these analyses was to provide a baseline of habitat use behaviour in the area.

To evaluate gray whale fidelity to the study area, two analyses on different temporal scales were used. Fidelity was evaluated on an annual basis by analysing sighting histories of individual whales to determine the proportion of individuals that were observed in a subsequent year after being first observed. The average percent of years whales were observed in the study area was determined by dividing the number of years each whale was seen in the study area by the number of possible years it could have been observed in the study area. Fidelity was also evaluated within each feeding season by calculating the average 'minimum residency time' for each identified individual by year. For this analysis, minimum residency time was defined as the number of days between the first and last day a whale was seen during the June through November survey time period. The residency time estimate is a minimum because it was possible that a whale was present before the first day (or after the last day) it was sighted during a given year. This estimate may also overestimate residency time because whales could have left the survey area for some unknown length of time between the first and last sighting of the year. Minimum residency time calculations are sensitive to the number of days of survey effort within a year and the temporal distribution of surveys within the survey season. Calambokidis *et al.* (2014) noted that whales observed in the PCFG range during the summer can generally be described as 'transient' whales who are only observed in one year and then not observed in the future and 'PCFG whales' who show some level of fidelity to the IWC defined PCFG range. Fidelity analyses were conducted both for all whales including transients and for whales that have been seen in more than one year. This analysis was conducted to determine a baseline of gray whale fidelity to the area where hunts were planned.

Mapping

To analyse trends in monthly and annual gray whale use of northwest Washington coastal water, the number of photo-identifications made during a whale survey were mapped onto a grid of 1km^2 cells that were aggregated into one of five regions: (1) East Strait; (2) Neah Bay Entrance; (3) West Strait; (4) North Ocean; and (5) South Ocean. Each of these regions extended 2km offshore except the South Ocean which extended 3km, and according to the survey protocol, any survey effort in one of these regions was counted as a full day of effort.

To develop spatial statistics for the survey effort, latitude/longitude coordinates from whale sightings were spatially joined to the 1km^2 grid in ArcGIS 10.1 and exported to MS Excel where total whale counts per 1km^2 grid cell were divided by the survey effort from the same monthly or yearly period to determine sighting density of whales corrected for effort. The sighting densities for each grid cell were re-imported to ArcGIS and plotted as estimates of areal use by gray whales. The grid cells with whale sighting density less than 0.1 were ranked as 'Rare'; cells with sighting density greater than 0.1 but less than 0.3 were ranked as 'Seldom'; cells with sighting densities greater than 0.3 but less than 0.6 were 'Common'; and cells with sighting density greater than 0.6 were ranked as 'Very Common'. This coding was standardised for monthly and annual maps.

The objective of mapping was to document what areas within the larger study area were most important to gray whales and to document how use of those sites changed by month and year.

Calf analysis

During the surveys a whale was recorded as a calf if it was in close association with a much larger individual and appeared to be less than 8m in length. It is possible that calves weaned prior to when they were first observed in the study area as cow-calf pairs in the PCFG have been observed separated as early as the beginning of July (Calambokidis *et al.*, 2012). To make an estimate of what proportion of new whales observed in the study area are calves, photographs were analysed following methods developed by Bradford *et al.* (2011). The analysis was limited to new whales in the study area that were also seen in the PCFG for the first time in that year. Only whales with suitable photo-quality of the

Table 2

Number of gray whale dedicated surveys tallied by year for each segment of research area and total opportunistic surveys by year.

*20 surveys were conducted during effort to monitor the Makah setnet fishery. All of these surveys transited the West Strait and into the Northern Ocean research segment.

head and postcranial region were used for the analysis. Whales with evidence of only recently attached barnacles, no old barnacle scars, and white pigmentation mottling the postcranial region were recorded as calves (Bradford *et al.*, 2011). The goal of this analysis was to determine how important northwest Washington was as a site for cow-calf pairs and for recently weaned calves.

RESULTS

Effort to photographically identify gray whales in northwest Washington was conducted between 1984 and 2011. From 1996–2011, surveys were conducted on a more dedicated and rigorous basis resulting in 516 surveys in the research area. Survey effort was greatest from 1996–1998 and 2008–11 (Table 2). By month, effort during dedicated surveys was greatest in the late summer and early autumn (Table 3). The majority of field effort during the autumn was conducted within the Strait of Juan de Fuca due to weather conditions in the Pacific Ocean and the distribution of gray whales. Research effort resulted in the collection of photographs from 225 gray whales that could be identified as unique individuals during the months of June through November from 1984 through 2011.

Gray whales were most often observed in water 5–15m deep, often associated with either kelp forests or emergent offshore rocks (Fig. 2). Sightings of gray whales in waters greater than 20m or less than 5m were rare and were not associated with any obvious habitat type (Fig. 2).

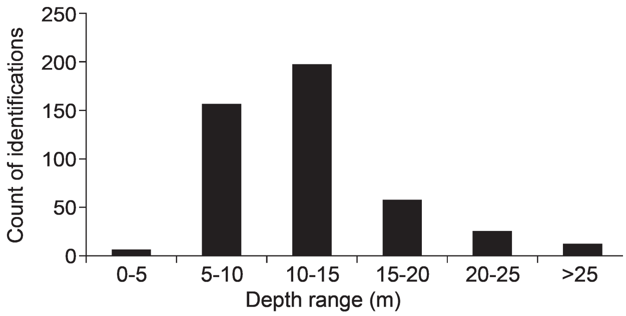

Fig. 2. Histogram of the count of gray whale identifications by depth binned in 5m increments.

Table 3

Number of surveys tallied by month for each segment of research area during gray whale dedicated survey effort from 1996 through 2011.

Temporal and spatial distributions of sightings

Gray whale distribution in the Strait of Juan de Fuca (hereafter Strait) varied widely by month and year. Gray whale use of feeding sites in the West Strait and East Strait

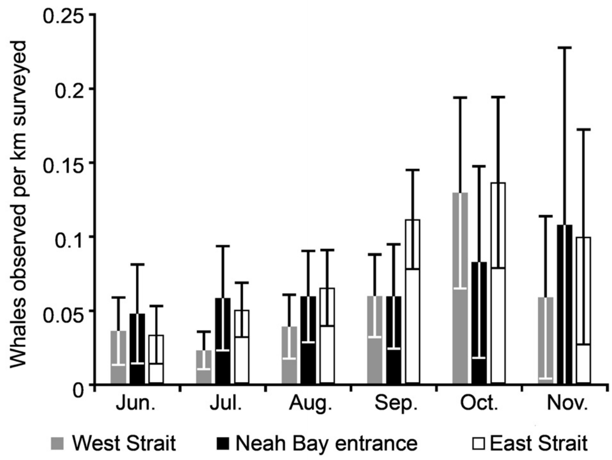

Fig. 3. Average observation rates in the three research segments in the Strait of Juan de Fuca by month for the years 1996 to 2011. Error bars are two times the SE.

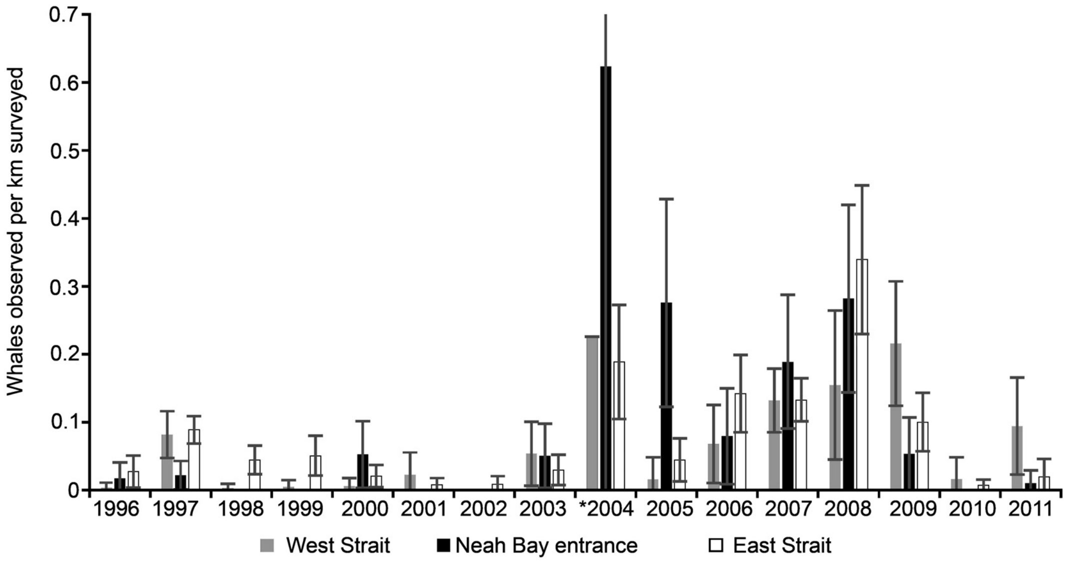

Fig. 4. Average observation rates in the three research segments of the Strait of Juan de Fuca by year with months of the feeding season, June to November, pooled. Error bars are 2 times standard error. * 2004 had much lower effort than other years of the study.

research segments increased through the summer and early autumn until use peaked in October (Fig. 3). The average observation rate varied significantly between months in both the West Strait (ANOVA, df = 368, $p < 0.001$) and the East Strait (ANOVA, df = 246, $p = 0.004$) as the observation rate increased from June to a peak in October. At the entrance to Neah Bay, no significant differences in observation rate by month were detected (ANOVA, df = 515, p = 0.73).

Significant differences in observation rate by year were observed in the Strait of Juan de Fuca in all three research segments (ANOVA: West Strait, df = 325, $p < 0.001$; Neah Bay, df = 514, $p < 0.001$; East Strait, df = 249, $p < 0.001$) (Fig. 4). From 1996 to 2003 (particularly 2000–03) and from 2010 through 2011, there were low observation rates in all three of the research segments (Fig. 4). In contrast, the time period 2004–09 had higher observation rates (Fig. 4).

Gray whale distribution in the Pacific Ocean (hereafter Ocean) also varied by month and year. Within the North Ocean survey area (Cape Flattery to Cape Alava), the observation rate varied significantly by month (ANOVA, df = 266, $p = 0.001$), peaking in August and with lows in June and November (Fig. 5). In the South Ocean research segment (Cape Alava to Sea Lion Rock), there were no significant differences in observation rate by month (ANOVA, df = 148, $p = 0.34$).

Similar to the Strait, significant year to year variability in observation rate was observed in both ocean survey segments (ANOVA: North Ocean, df = 266, $p < 0.001$; South Ocean, df = 148, $p < 0.001$) (Fig. 6). Years of high and low observation rates were not the same years as observed for the Strait (Fig. 4, Fig. 6). Like the Strait survey areas, the Ocean research segments had low observation rates during the early years of the time series from 1996 to 2001. Opposite the Strait, the observation rate increased in 2001 through 2003 and was also high in 2010 and 2011. The years with greatest observation rates were 2005–11. The South Ocean showed more year to year variability than the North Ocean.

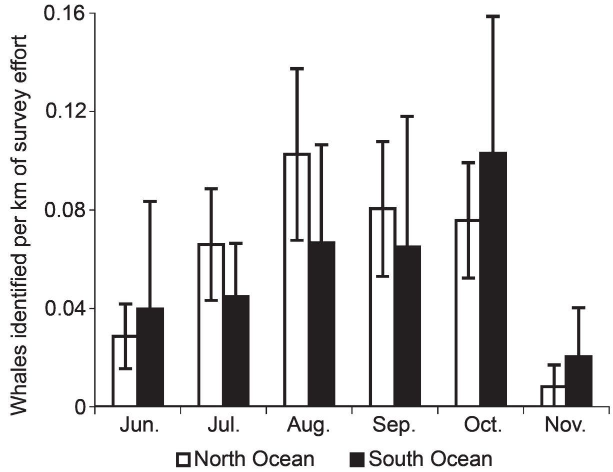

Fig. 5. Average observation rates in the two research segments of the Pacific Ocean by month for the years 1996 to 2011, error bars are two times standard error.

Maps were made using the average number of whales identified per km^2 of research area to examine finer scale trends in gray whale distributions in northwest Washington by month and year. Trends observed in whale densities by month reaffirm our findings that the number of gray whales identified per survey increased to greatest densities and greatest spatial coverage in September and October in the Strait and in August and September in the North Ocean (Fig. 7). Some sites were consistently used both in the Strait and in the Ocean each month; whale densities at these sites increased through the summer and into autumn in the Strait

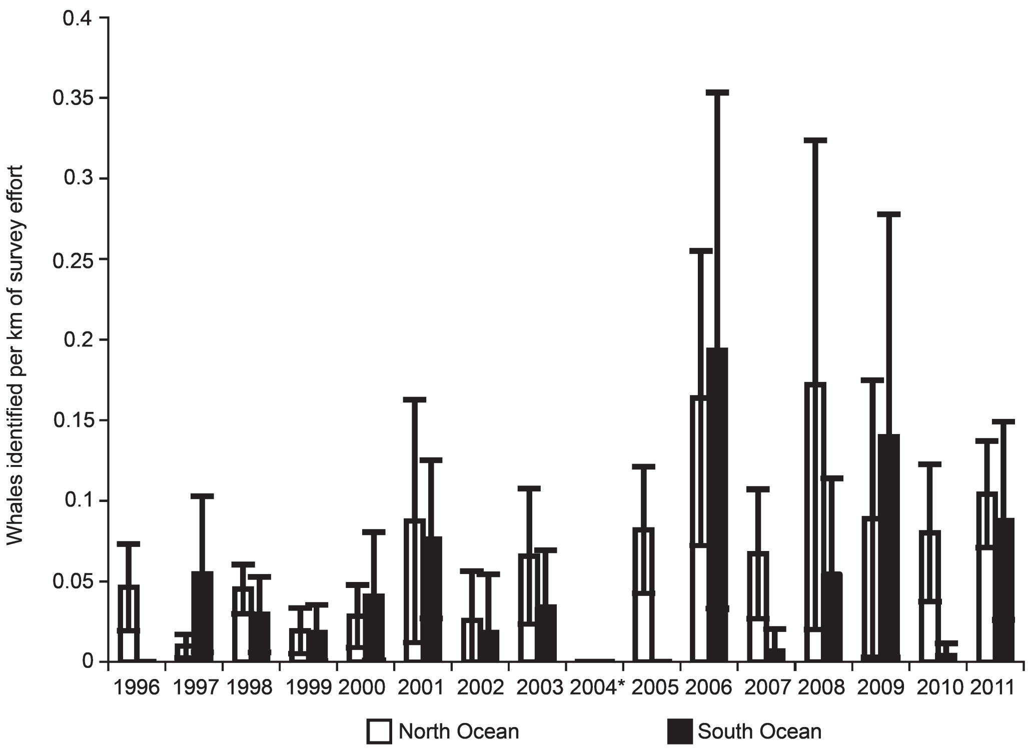

Fig. 6. Average observation rates in the two research segments of the Pacific Ocean by year for the months of the feeding season, June to November. Error bars are two times standard error. *No surveys were conducted in the ocean in 2004.

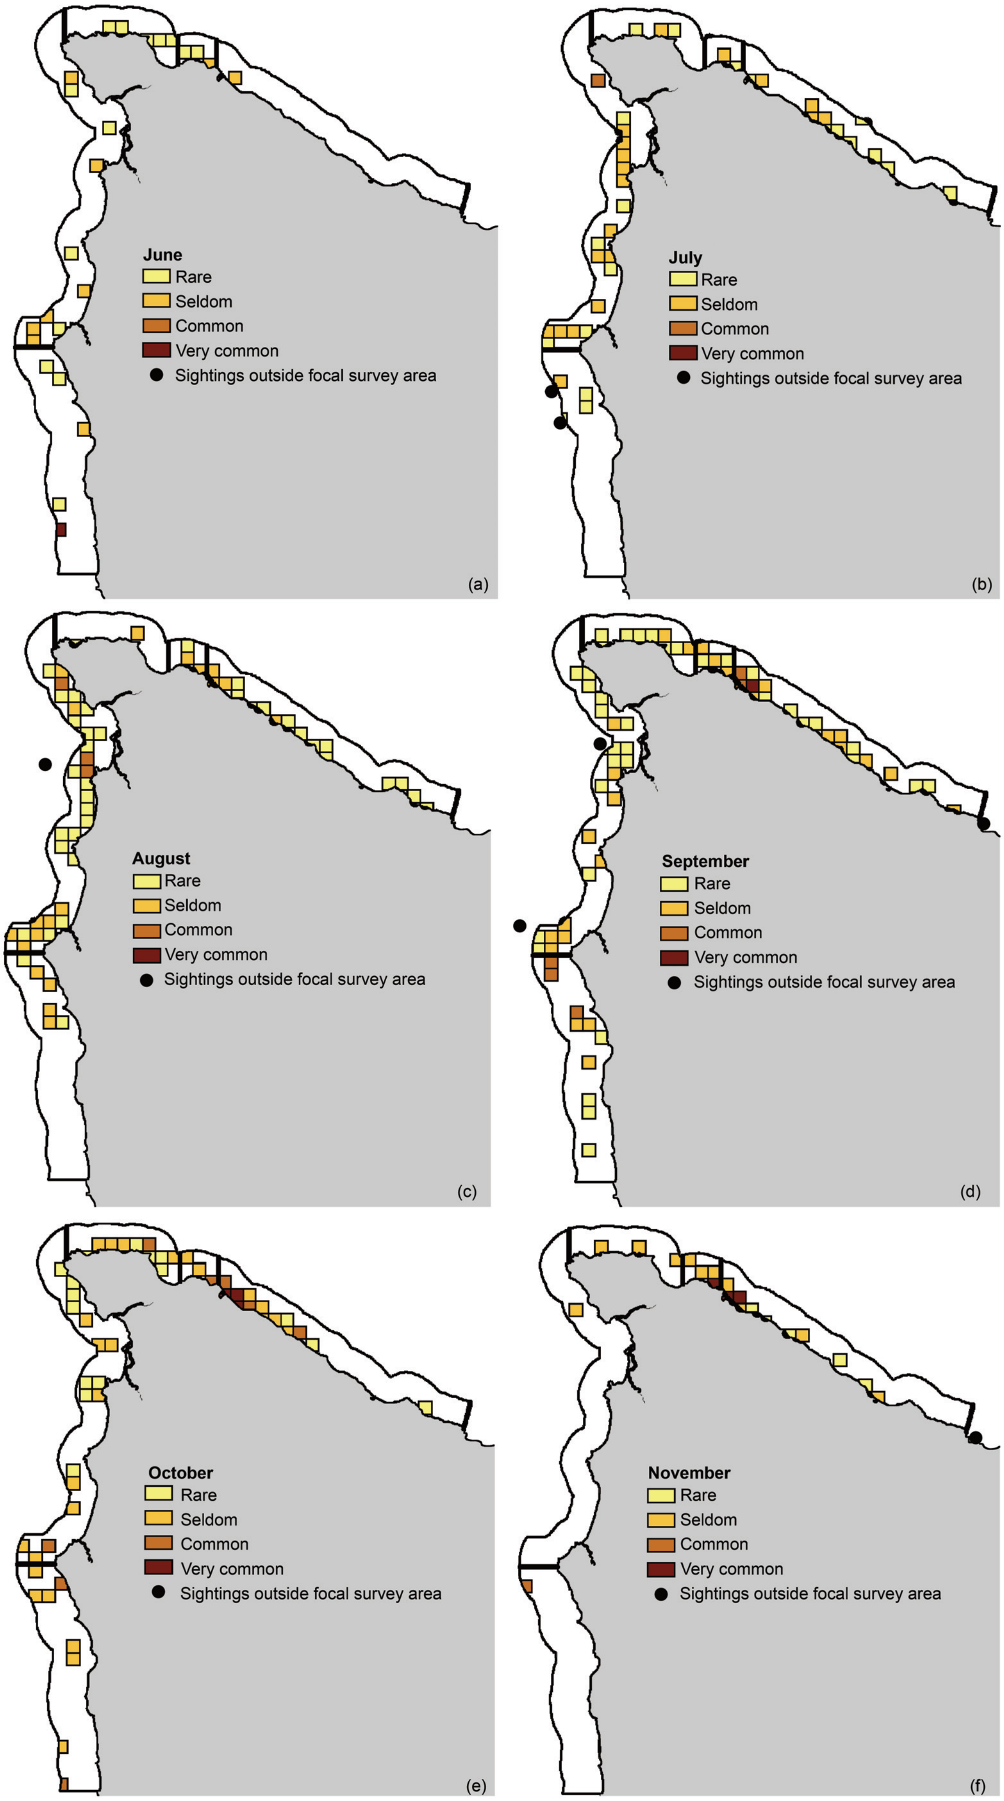

Fig. 7. Sighting density of gray whales identified per km^2 in northwest Washington per day of research effort in 2004 to 2011 by month: (a) June; (b) July; (c) August; (d) September; (e) October; and (f) November. Grid cells with sighting densities of less than 0.1 whales were ranked as 'Rare', cells with sighting density greater than 0.1 and less than 0.3 whales were ranked as 'Seldom', cells with sighting densities greater than 0.3 and less than 0.6 whales were ranked as "Common" and cells with sighting densities greater than 0.6 whales were ranked as 'Very Common'.

and increased until late summer/early autumn in the Ocean (Fig. 7). A review of nautical charts and knowledge of the area show that sites with high use were generally characterised by rocky bottoms and large kelp forests, whereas sites with low use were characterised by sandy bottoms. The maps do show sightings of whales in areas of sandy bottoms, however these sightings were primarily of whales that were presumed to be travelling or resting. The greater distance from shore of gray whale distributions in the ocean as compared to the Strait was likely due to the gradual slope of the bottom in the ocean as compared to the steep drop off in the Strait.

Maps of the yearly distribution of whales display greater variability in gray whale site use, where whales appeared to use some areas frequently for a number of years and then subsequently either abandon those areas or use them intermittently (Fig. 8). This phenomenon can be observed by examining the area just east of the Neah Bay research segment. From 2006 to 2009, high densities of whales were observed in this area and then were not observed using the site at all in 2010 and only rarely in 2011. Other areas appeared to be used intensively for one year and then not used again. This can be seen most easily by looking at the southern border of the South Ocean research segment and noting the changes in gray whale sighting density through the years.

Fidelity to the research area

Fidelity to the research area was examined by comparing the number of individual whales that returned to the northwest Washington research area after the first year observed and estimating how long individual whales used the research area within a given year. Some gray whales were observed to use the waters of northwest Washington consistently after they were first observed. Sixteen percent of whales were observed in six or more years in the study area, although not necessarily in consecutive years. Roughly half (51%) of the whales identified in this study were only observed in the area during one year (Fig. 9). The average whale was observed in 2.48 years (SE = 0.14). Removing the individuals that were only observed in one year, the average whale was seen in 4.01 years (SE = 0.20). Whales first observed in 2010 or earlier were observed in an average of 31.6% (SE = 1.6%) of possible years after they were first observed (number of years observed divided by total number of possible years to be observed for each whale); removing whales only seen in one year increased the average percentage to 38.7% (SE = 1.9%) of possible years. Among the whales that were first identified prior to 2010 and therefore have more than one year in which they could have been resighted, only two whales were seen in all possible years after the first observation; these whales were seen in every year after being first observed in 2004 and 2006, respectively.

The length of time a whale used the study area during the feeding season was estimated by calculating minimum tenure, in this case the minimum number of days an individual whale resided in the research area assumed to be equal to the difference in time between the date of first and last observation. The average minimum tenure calculated for whales observed in the northwest Washington research area

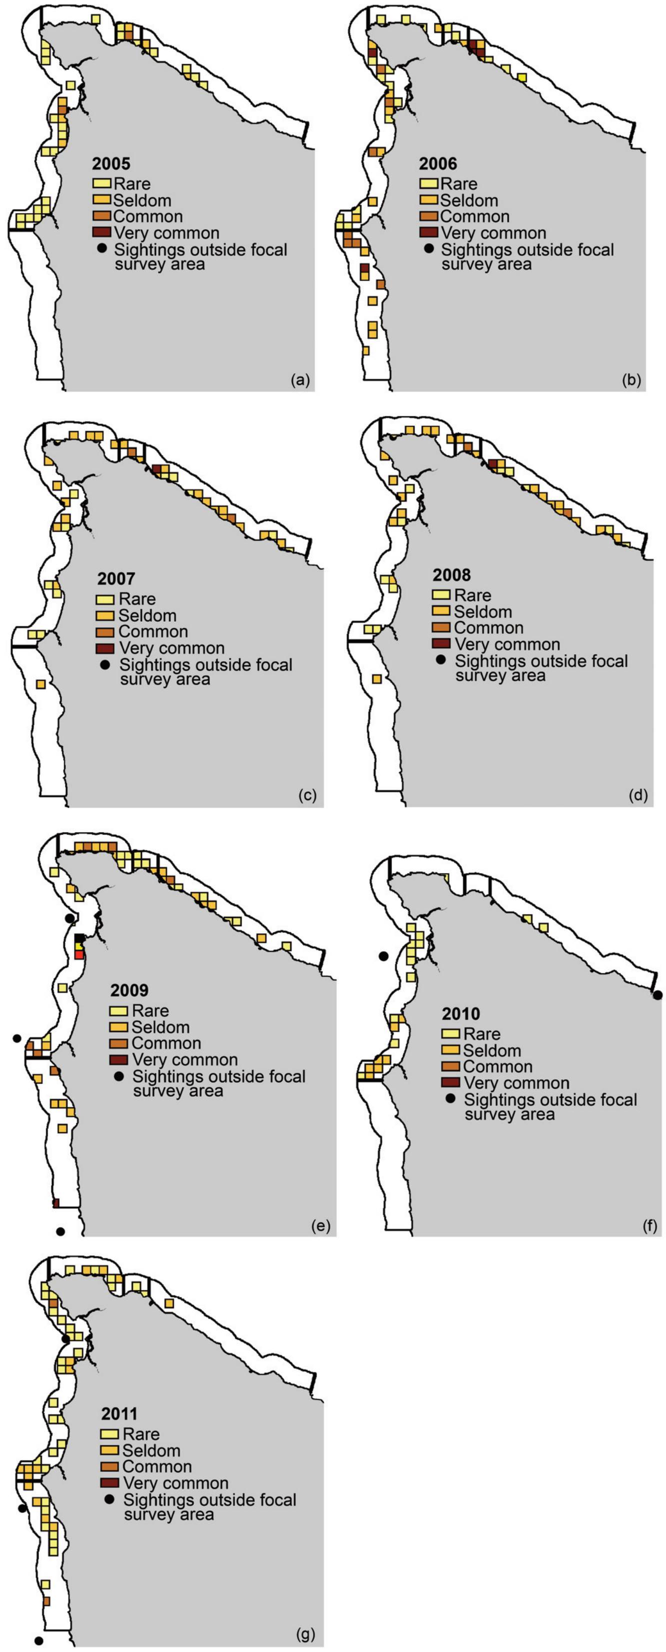

Fig. 8. Sighting density of gray whales identified per km^2 in northwest Washington per day of research effort in the feeding season, June through November by year: (a) 2005; (b) 2006; (c) 2007; (d) 2008; (e) 2009; (f) 2010; and (g) 2011. Grid cells with densities of less than 0.1 whales were ranked as 'Rare', cells with sighting density greater than 0.1 and less than 0.3 whales were ranked as 'Seldom', cells with sighting densities greater than 0.3 and less than 0.6 whales were ranked as 'Common' and cells with sighting densities greater than 0.6 whales were ranked as 'Very Common'. No map was provided for 2004 because data collection lacked spatial and temporal resolution.

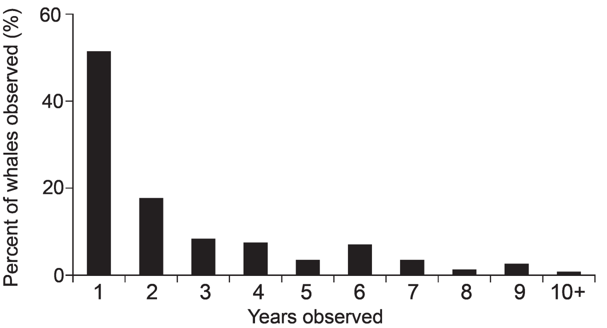

Fig. 9. Count of unique whales observed by the number of years a whale was observed.

was 24.8 days (range 1 to 151 days) out of a possible 183 days in the June to November feeding season. A large degree of variability in minimum tenure by year was observed in the research area (ANOVA, df = 493, $p < 0.01$) (Fig. 10).

No evidence was found that the number of years a whale has been observed in northwest Washington affected average minimum tenure during the study (ANOVA, df = 202, $p = 0.62$) (Fig. 11). However, it was found that average minimum tenure was a good predictor of whether a whale would be seen in the following year. Whales seen in year *Y* and in the following year (*Y*+1) had an average minimum tenure of 28.3 days, which was significantly greater than whales seen in year *Y* but not year *Y*+1 (19 days; Two-sample *t*-test, df = 506, $p = 0.002$).

Occurrence of new whales

From 1996 through to 2011, an average of 10.8 new whales were observed per year (SE = 1.8) in the northwest Washington study area. From 1996 through 2010 (excluding 2011 to allow a year for recruitment), an average of 5.6 new whales per year (SE = 1.1) were observed again in a future year. The number of new whales observed was not consistent between years. High numbers of new whales (> 15) were observed in 1993, 1995, 1998, 2001, 2006 and 2008 (Table 4). It is possible that the high numbers of new whales observed in 1993 and 1995 were not actually new whales to the research area; rather it is likely that some of these whales regularly used the area but had not been seen previously due to low research effort in the early years of the study. In a time series of population estimates, Calambokidis *et al.* (2014) found a large increase in PCFG gray whale abundance in the late 1990s and early 2000s that they postulated was caused, at least in part, by immigration from

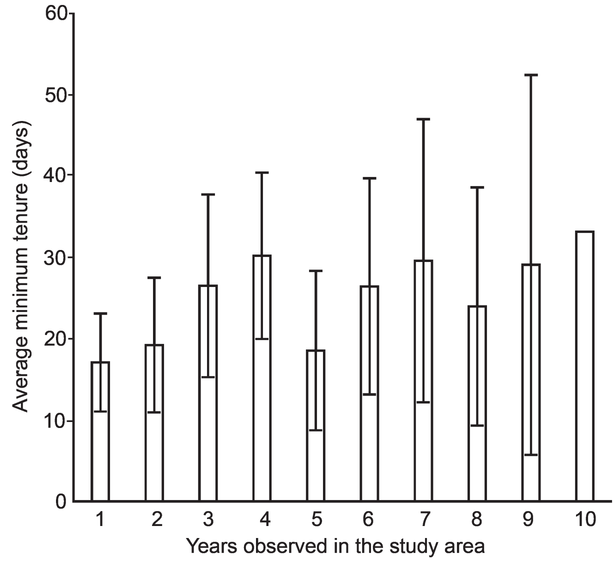

Fig. 11. Average minimum tenure of whales in days compared to the number of years they have been observed in northwest Washington.

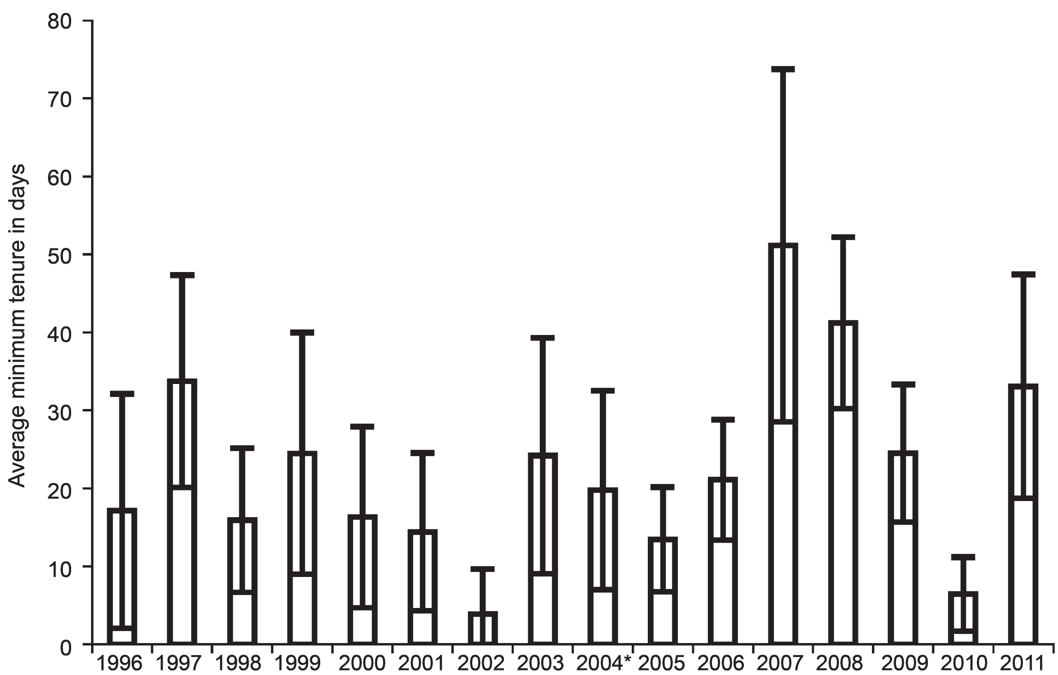

Fig. 10. Average minimum tenure (residency time) computed as the number of days between the first and last sighting of an individual in a given year. *2004 had lower total survey effort and lower temporal coverage of survey effort than other years, and the estimate of minimum tenure is likely underestimated.

Table 4

This table shows the sighting history of whales by the first year they were observed (row). Column totals report the number of uniquely identified whales from each cohort in each feeding season. The first value in each row is the number of new whales observed for that year.

Year	1984	1986	1989	1992	1993	1994	1995	1996	1997	1998	1999	2000	2001	2002	2003	2004	2005	2006	2007	2008	2009	2010	2011

northern feeding grounds during the 1999/2000 mortality event (Gulland *et al.*, 2005). Based on the findings of Calambokidis *et al.* (2014) a large increase in the number of new whales observed and of new whales observed in a future year during the time period of 1998–2002 was to be expected. Instead, the average number of new whales observed from 1998–2002 was lower than the 1996–2010 average, with 9.2 new whales (SE = 4.3) of which 4.3 whales (SE = 1.5) were seen in a future year. The percentage on average of new whales observed from 1998–2002 that were seen in a future year (44.3%, SE = 18.4%) was also lower than the 1996–2010 average.

Calf analysis

There were seven mother-calf pairs observed during surveys (Table 5), showing that some of the new whales observed in this study were internally recruited. One mother, CRC 67, was observed with three calves: a suspected calf (CRC 169) in 1995 and a confirmed calf in both 2004 (CRC 819) and 2011 (CRC 1350). Four other females were each observed with one calf (Table 5).

Some new whales were first observed later in the year (i.e. autumn) than when calves become independent of their mothers (Bradford *et al.*, 2011; Calambokidis *et al.*, 2012). To determine the proportion of new whales which are actually calves digital photographs taken between 2004 and 2011 were analysed. Only new whales for which photographs had already been obtained from the first year they were seen in the entire PCFG (i.e. not just the first year seen in northwest Washington) were analysed. Twenty one photographs of new whales for which the first year they were sighted in northwest Washington was also the first year they were sighted in the PCFG were available. Of those, 18 photographs showed the head and post-cranial region clearly in order to be able assess if they were calves. Of the 18 whales evaluated, 4 (22%) were either confirmed calves (CRC 819 and CRC 1350) or were most likely calves (CRC 1047 and CRC 1054) and the other 14, based primarily on observation of old barnacle scars, were not calves of that year. CRC 1047 and CRC 1054 were both first observed in 2008.

The occurrence of calves in northwest Washington shows that the site is used by cow-calf pairs and recently weaned calves. The number of calves observed during the study were low suggesting that the site is not a very important for cow-calf pairs for the PCFG as a whole although it does appear important for CRC 67.

Table 5

All known mother-calf pairs observed in northwest Washington from 1984–2011 with whales only suspected to be calves noted with an asterisk.

Mother	Calf	Dates observed together
105	104	09/07/94
43	107	09/07/94 to 04/08/94
67	169*	19/07/95 to 23/07/95
596	595	26/06/01
216	860*	26/07/03 to 28/07/03
67	819	27/08/04
67	1350	23/06/11 to 01/09/11

Population closure in the study area

If population closure exists within the study area (no immigration or emigration), one would expect that over the 17 years of research effort that all of the whales in the 'population' would have been photographed and identified and the best fit line would approach a horizontal asymptote. To test if there is closure a discovery curve was plotted with the number of new whales observed for 1984 through 2011 and the number of whales observed in more than one year for 1984 through 2010 (Fig. 12). The function best fitting the discovery curve was linear for all new whales ($y = 9.15x$–

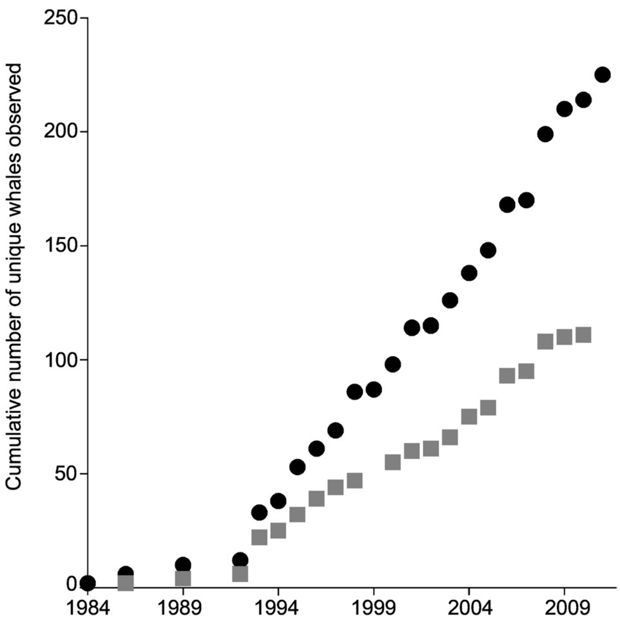

Fig. 12. Plot of the cumulative number of whales observed during the duration of this project for all whales (black dots) and whales observed in greater than one year (grey squares).

18,193, $r^2 = 0.95$) and whales observed in more than one year ($y = 5.07x–10,076$, $r^2 = 0.97$), suggesting that closure is not occurring for the northwest Washington survey area.

DISCUSSION

Temporal and spatial distribution of whales

There was large annual variability in the numbers of whales identified per survey in all research segments and large amounts of inter-year and intra-year variability in where whales were observed. Observation of variability is similar to Darling *et al.* (1998) who concluded that year-to-year variability in timing, prey type and feeding location is the key feature of gray whale observations from the central coast of Vancouver Island. Gray whale researchers of the PCFG have noted that the whales are commonly observed to exhibit benthic feeding behaviours (Avery and Hawkinson, 1992; Darling *et al.*, 1998; Dunham and Duffas, 2001; Kvitek and Oliver, 1986; Oliver *et al.*, 1984). However, in the present study mud plumes were rarely observed, suggesting that benthic feeding is uncommon in the northwest Washington area. Within the dynamic nature of site use it was found that more whales were observed per day of survey effort in the autumn in both the Strait of Juan de Fuca and the South Ocean research segment, whereas in the North Ocean research segment peak use was late summer. Also, the vast majority of gray whales were observed in waters between 5 and 15m of depth. This depth range coincides with the primary depth range of the mysid shrimp (small epibenthic and planktonic crustaceans of the family *mysidae*, suborder *pericarida*) (Nelson *et al.*, 2009). The primary mysid species consumed by gray whales off Vancouver Island were *Holmesimysis sculpta, Acanthomysis pseudomaropsis* and *A. anassa californiensis* (Murrison *et al.*, 1984; Darling *et al.*, 1998; Dunham and Duffus, 2002; Feyrer and Duffas, 2011) and they are also likely to be the primary prey species in northwest Washington. Feyrer and Duffus (2011) found that average mysid density was significantly correlated with the average number of whales in the survey area near Vancouver Island. We hypothesise that shifting mysid density and fluctuations in abundance caused the observed variability in gray whale counts in northwest Washington since most of the gray whale sightings occurred in optimal mysid habitat. Systematically monitoring prey at sites commonly used in northwest Washington would allow testing of this hypotheses on prey preference and specifically the influence of mysid abundance on whale distributions.

A consistent pattern observed through the years was lower observation rates in June compared to later in summer and autumn. This fits with the movements of migrating gray whales which generally reach Arctic feeding grounds from May to June (Swartz *et al.*, 2006). To date, there have been three publications on the movements of six satellite tagged PCFG whales, each of which had active tags between April and June; of these six whales, four were observed to migrate steadily north into southeast Alaska before their transmitters stopped transmitting (Calambokidis *et al.*, 2014; Ford *et al.*, 2013; Mate *et al.*, 2010). Given that 66% (4 out of 6) of the PCFG whales with documented spring movement patterns travelled north of the PCFG area, it is quite possible that other whales that feed in the PCFG also feed further north in the spring and early summer before returning south to the PCFG area later in the summer and autumn. It should be noted that the migratory behaviour of four of the six individuals may not be representative of all PCFG whales, as the three tags applied by Ford *et al.* (2013) targeted whales presumed to be migrating past Vancouver Island and one tag applied to a PCFG whale by Calambokidis *et al.* (2014) targeted a feeding whale.

Occurrence of new whales in northwest Washington

From 1996 to 2011, an average of 10.8 new whales were observed each year, of which 5.6 were observed in a future year. Many of the whales that were new to the northwest Washington study area had been seen previously in another research area of the PCFG. For whales that were photographed in northwest Washington during the first year they were seen in the PCFG, analysis of photographs using techniques described by Bradford *et al.* (2011) found that 22% of the whales were calves. Thus 78% of the new whales observed in our research area and to the PCFG were either born in a previous year in the PCFG and were not observed, or were non-calves who emigrated from another feeding area into the PCFG.

An analysis of the time series of population estimates of PCFG whales shows a large increase in the number of whales in the PCFG from 1998 through 2002 concurrent with the timing of the 1999 gray whale mortality event (Calambokidis *et al.*, 2014). Somewhat surprisingly, a smaller average of new whales (9.2) was observed from 1998 to 2002. The lower number of new whales observed in that time period could have been a result of poorer feeding conditions in Washington compared to later years in the data series. Of the new whales observed during those five years, a smaller portion was observed again in a subsequent year (44.3%) than the average for the whole data series. Based on the calculated population increase of the overall PCFG, we would have expected the average proportion of new whales and new whales seen in more than one year to be much greater from 1998 to 2002 than was observed in this study.

CONCLUSION

Northwest Washington is a small but important region within the summer and autumn feeding range of PCFG gray whales. Individual gray whale use of this region is variable, with some individuals observed regularly whereas most do not show strong site fidelity to this region. This study allowed examination of trends in site use over multiple decades within northwest Washington and it was found that rocky habitat in the 5–15m depth range is very important to gray whales and that gray whale use of these habitats is dynamic by year. The impacts of the Makah gray whale hunt are a debated issue, thus it is hoped that the baseline of gray whale behaviour provided here can be used to help evaluate if there are discernible effects on PCFG whale behaviour in the proposed hunt area when hunting resumes.

ACKNOWLEDGEMENTS

Field work by the Makah Tribe was funded by the Species Recovery Grant to Tribes Program and the Bureau of Indian Affairs. Field work by the National Marine Mammal Laboratory was funded by NOAAs Northwest Regional Office. We would like to thank the many people who have contributed to data collection during the many years of this project. We would especially like to thank Nate Pamplin who was the primary investigator for the Makah Tribe from 2004–06. Matching of identification photographs at Cascadia was led by Amber Klimek and Alie Perez. Research was conducted under permits 540–1502, 540–1811 and 16111 to John Calambokidis and permits 782–1438, 782–1719 and 14245 to the National Marine Mammal Laboratory.

PURPOSE

This report reviews the efforts by the National Marine Fisheries Service (NMFS) to assess marine mammal stocks as required by Section 117 of the Marine Mammal Protection Act of 1972 (MMPA, the Act, 16 U.S.C. et seq.).[1] Congress passed the MMPA in 1972 to conserve marine mammals and ecosystems. In the Act (16 U.S.C. 1361), Congress found that—

Humpback whale with calf in NOAA's Hawaiian Islands Humpback Whale National Marine Sanctuary. (NOAA)

> (1) certain species and population stocks of marine mammals are, or may be, in danger of extinction or depletion as a result of man' s activities; [and]
>
> (2) marine mammal species and population stocks should not be permitted to diminish beyond the point at which they cease to be a significant functioning element in the ecosystem of which they are a part, and, consistent with this major objective, they should not be permitted to diminish below their optimum sustainable population[2]...;

Importantly, Congress also found that—

> (3) there is inadequate knowledge of the ecology and population dynamics of such marine mammals and of the factors which bear upon their ability to reproduce themselves successfully….

To address these findings, Congress directed that a science-based approach be developed to manage marine mammals and the human-related risks that threaten their persistence. To assess marine mammal stocks, Section 117 of the Act (16 U.S.C. 1386, as amended in 1994) specifies that each stock in U.S. waters be assessed with regard to the following information—

(1) geographic range;

(2) minimum population estimate, current and maximum net productivity rates, and current population trend;

(3) human-caused mortality and serious injury rate;

(4) interactions with commercial fisheries;

(5) current status; and

(6) potential biological removal level (PBR).

---

[1] The Service is responsible for assessing the status of all marine mammal stocks that occur in U.S. waters except the manatee, polar bear, sea otter, and walrus, which are studied and managed by the Fish and Wildlife Service (16 U.S.C. 1375a).

[2] With respect to any particular stock, the MMPA defines the "optimum sustainable population" to mean "the number of animals which will result in the maximum productivity of the population or the species, keeping in mind the carrying capacity of the habitat and the health of the ecosystem of which they form a constituent element" (16 U.S.C. 1362(9)).

APPROACH

The Commission reviewed stock assessment reports available as of 2014[3] (the most recent reports available at the time of this review) to evaluate performance of NMFS in gathering, assessing, and reporting on some of the information required by section 117. The review starts by underscoring the importance of stock identification, a necessary precursor of stock assessment. The review then highlights NMFS's progress in obtaining information on three of the six requirements of Section 117 (requirements 1, 2, and 6). Those three requirements provide the foundational information necessary to manage any stock: where and when it occurs (requirement 1), the number of animals in the stock (requirement 2), and whether there is enough information to derive a management metric. In the case of marine mammals the management metric is potential biological removal (PBR) (6th requirement). Without this basic information the status of a stock cannot be confidently ascribed (requirement 5 of Section 117). Nor can the stocks be managed effectively even if commercial fisheries interactions (requirement 4) and other human caused mortality and serious injury (requirement 3) are well known and reported in the stock assessments. The review includes several recommendations intended to support NMFS in its efforts to improve stock assessments.

STOCK STRUCTURE

Congress identified the stock (or population stock) as the primary management unit for marine mammals (16 U.S.C. 1362.11). It defined a stock to mean "a group of marine mammals of the same species or smaller taxa in a common spatial arrangement, that interbreed when mature."

North Atlantic right whale off the coast of Florida. Photo taken under NOAA research permit #775-1875. (Florida Fish and Wildlife Conservation Commission)

An accurate understanding of stock structure is therefore the cornerstone for stock assessment, management, and conservation even though not explicitly listed among the Act's six specified information needs. Historically, marine mammal scientists identified stocks using morphologic, demographic, behavioral, and geographic range/distribution patterns (e.g., Dizon et al. 1992). However, detecting such patterns depends largely on field observations, which often are not sufficient to reveal the reproductive barriers indicative of stock structure. Stocks can be difficult to identify for a variety of reasons, such as remote distributions, cryptic behavior, and physical similarity to, and geographic overlap with, other stocks. More recently, scientists have relied heavily on genetic methods to identify and distinguish marine mammal stocks, as those methods provide important insights not always discernible through direct observations. NMFS scientists have excelled in the use of genetic tools, but inadequate resources often have undermined their efforts in this regard. Efforts to

3 The 2013 reports are available at http://www.nmfs. noaa.gov/pr/sars/region.htm.

identify marine mammal stocks would therefore be enhanced by funding for genetic studies (including both sampling and analyses). Beyond genetics NMFS scientists recently reviewed each of the various lines of evidence to judge their respective strengths in distinguishing stocks, and provided initial guidelines for the use of such evidence (Martien et al. 2015). The Commission acknowledges and applauds those efforts and supports NMFS's continued pursuit of improving stock structure determinations, using multiple lines of evidence.

GEOGRAPHIC RANGE

Adult male northern elephant seal. Picture taken under NMFS permit #87-1743. (Sam Simmons, Marine Mammal Commission)

The first requirement of a stock assessment according to section 117 of the MMPA is to describe "the geographic range of the affected stock, including any seasonal or temporal variation in such range."

IMPORTANCE

Understanding a marine mammal stock's geographic range is essential to conservation and management effort because that range provides information relevant to the—

- stock's potential habitat requirements; that is, the physical, chemical, biological, and ecological conditions necessary for the stock's persistence;
- human activities that may affect the stock; and
- areas where stock assessment, research, and conservation may be most useful.

CHALLENGES TO DESCRIBING THE RANGE OF STOCKS

The distribution and range of most marine mammals varies in accordance with multiple factors, such as—

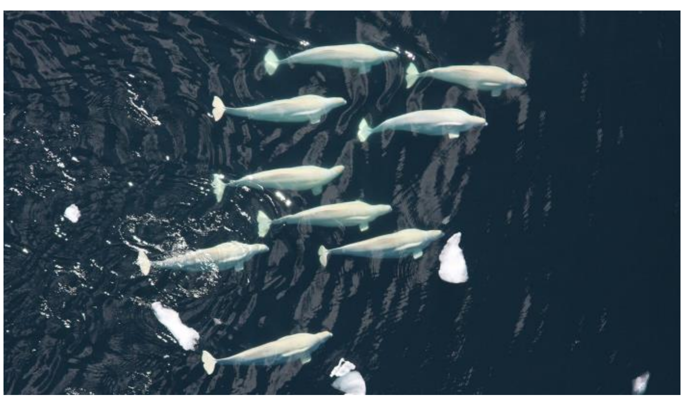
- season: annual migrations are examples of seasonal variation in habitat use. Winter ranges, in particular, often are poorly described or largely unknown (e.g., eastern population of North Pacific right whales, southern resident killer whales, North Atlantic right whales);
- year: marine mammal stocks may vary their distributions and use of habitat annually depending on oceanographic conditions, or the timing and extent of sea ice formation and breakup (e.g., bowhead whales, gray whales);
- age: mature individuals of some species may have larger ranges or occupy different latitudes than immature animals (e.g., northern fur seals, Steller sea lions), but juveniles often disperse widely and vary their habitat-use patterns;

- sex: females and males may have overlapping ranges during the breeding season, but have more-or-less distinct ranges during the remainder of the year (e.g., sperm whales);
- reproductive status: certain portions of a stock (e.g., individuals that are either sexually immature or senescent) may use habitat different from that used by reproductively active individuals (e.g., North Atlantic right whales);
- prey availability and predator avoidance: during and outside the reproductive season, variability in prey availability and predator distribution are likely major determinants of marine mammal habitat-use patterns; and
- human-caused disturbance: may cause marine mammals to abandon or alter optimal use of key habitat depending on sources of anthropogenic disturbance.

For all these reasons, describing a stock's range and associated use of habitat is not a simple, singular challenge, but rather one that requires frequent and ongoing assessment under variable conditions. The need for frequent and ongoing assessment of range is even greater in light of potential alterations to ranges driven by climate change, which may render long-standing stock boundaries of many stocks obsolete. Determining a stock's range can be especially challenging when two or more stocks of similar-appearing individuals have overlapping ranges. For example, the ranges of the genetically distinct coastal and offshore bottlenose dolphins along the U.S. Atlantic coast overlap and because the stock affiliations of individuals cannot be visually distinguished in the field it is difficult to determine their seaward or coastal stock boundaries, respectively.

Additionally, international cooperation is needed to determine stock ranges and habitat-use patterns for stocks that occur in both national and international waters.

POPULATION PARAMETERS



Beluga whale pod in the Chukchi sea. Photo taken under Marine Mammal Permit: 782-1719. (Laura Morse, NOAA)

Section 117's second requirement is to provide "… [a] minimum population estimate, the current and maximum net productivity rate, and current population trend, including … the information upon which these are based" for each stock.

MINIMUM POPULATION ESTIMATE

Abundance information is critical for determining a stock's status, trend, and vulnerability to human activities. Stocks with low abundance generally are more easily depleted and subject to a higher risk of extinction. Examples include the AT1 killer whale stock (7 individuals), eastern North Pacific right whale stock (~30), Gulf of Mexico Bryde's whale stock (~33), southern resident killer whale stock (~80), Hawaiian insular false killer whale stock (~130), Cook Inlet beluga whale stock (~350), and North Atlantic right whale stock (~450). However, low abundance is not the only factor that could raise concern. A strong negative trend in population size can also raise concerns. Stocks that once numbered in the hundreds of thousands (e.g., western Steller sea lion stock) or even millions (e.g., Arctic ringed seal stock) have declined or are expected to decline rapidly in the foreseeable future, increasing their risk of extinction.

Scientists are rarely able to determine the exact abundance of a marine mammal stock and must characterize the reliability of their estimates using associated measures of confidence. Reliability is measured by precision (random measurement or estimation error) and bias (a systematic tendency to over- or underestimate).

False killer whales, October 15, 2010. (Robin Baird, Cascadia Research)

The MMPA recognizes uncertainty in abundance estimates and addresses it in a precautionary manner by requiring use of a "minimum population estimate" to calculate a stock's PBR level. The MMPA defines minimum population estimate (N_{min}, 16 U.S.C. 1362.27) as an estimate of the number of animals in a stock that "(A) is based on the best available scientific information on abundance, incorporating the precision and variability associated with such information; and, (B) provides reasonable assurance that the stock size is equal to or greater than the estimate."

To review NMFS's assessment of stock abundances, the Commission tallied the stocks for which NMFS provided a minimum population estimate (N_{min}) and a best available estimate (N_{best}) with a coefficient of variation (CV; a measure of precision) less than or equal to 0.3 in the 2013 reports. A CV of 0.3 indicates about 95% confidence that the true abundance lies between 40 and 160 percent of the best estimate for an unbiased and normally distributed estimate. For example, if scientists estimated a stock's abundance as 10,000, a CV of 0.3 would indicate they could be 95% confident that the true abundance is between 4,000 and 16,000. A CV of 0.3 is considered a reasonable degree of precision for management purposes by NMFS.

Thoroughness. The 2013 stock assessments indicate that NMFS had N_{min} estimates for 138 of the 248 (56%) stocks assessed. NMFS provided an N_{min} estimate for 30 of the stocks along the Atlantic Coast (58%), 20 stocks in the Gulf of Mexico (35%), 44 stocks each along the Pacific Coast (i.e., Washington, Oregon, and California) and in the Pacific Islands (73%), 24 stocks in Alaska (53%), and none in the Caribbean (0%) (Figure 1). The 73% figure for the Pacific Islands (including Hawaii and the Pacific Territories) is misleading because it is estimated that over 100 stocks exist in the central and western Pacific but have yet to be assessed and a stock assessment drafted.

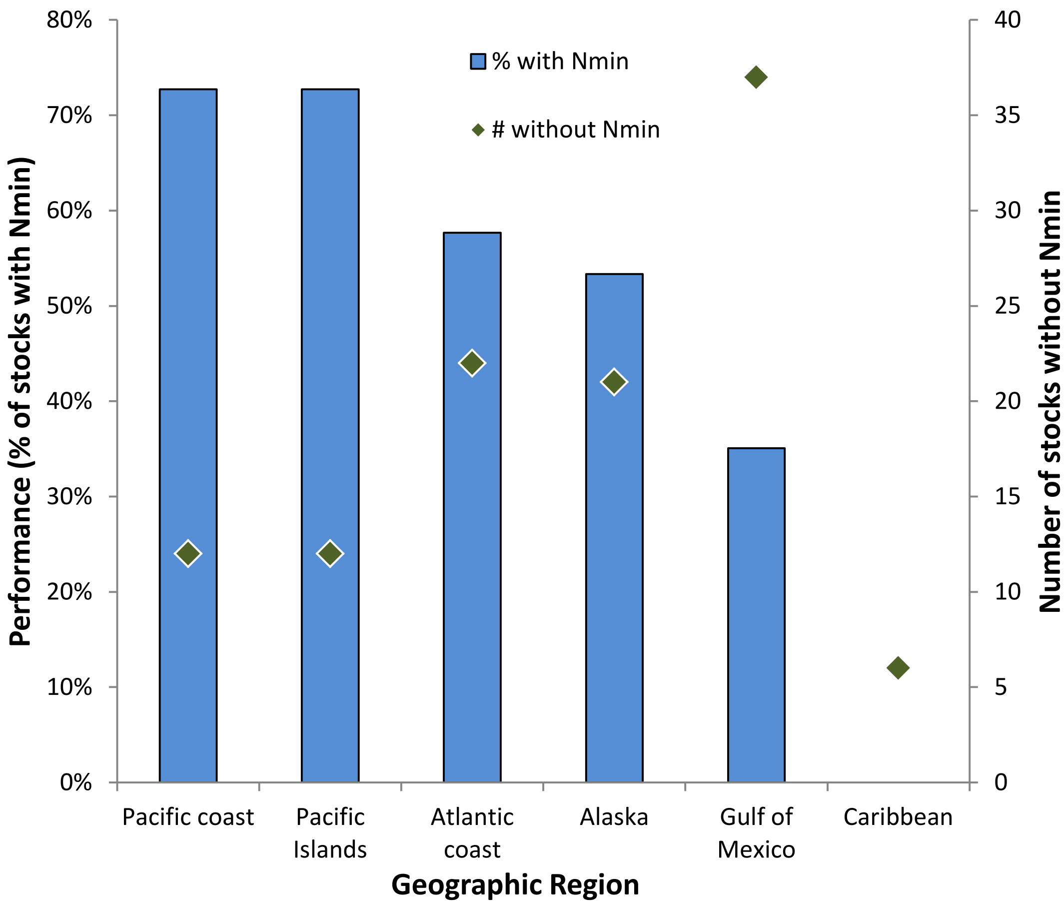


Figure 1: Performance of NMFS in the 2013 assessment reports by geographic region, with regard to % of stocks for which an Nmin was provided. The number of stocks without an Nmin is also presented (right axis) to illustrate what is required to reach 100% in each region. For example along the Pacific coast an Nmin for an additional 12 stocks would result in a 100% performance.

Precision. The 2013 stock assessments indicate that NMFS had N_{best} estimates with an associated CV less than or equal to 0.3 for 50 of the 248 stocks reported (20%). This includes 9 stocks along the Atlantic Coast (17%), 6 in the Gulf of Mexico (11%), 9 along the Pacific coast (20%), 10 in the Pacific Islands (23%), 16 in Alaska (36%), and none in the Caribbean (0%) (Figure 2).

Bias. The 2013 stock assessments reveal several sources of systematic error in N_{best} estimates.

- No estimates: NMFS scientists were not able to estimate abundances for a substantial number of stocks. Some stocks have long been neglected (e.g., Caribbean), others have only recently been recognized (e.g., spinner dolphin stocks in the Northwestern Hawaiian Islands), and still others have yet to be identified (e.g., in the central and western Pacific Ocean and Caribbean).

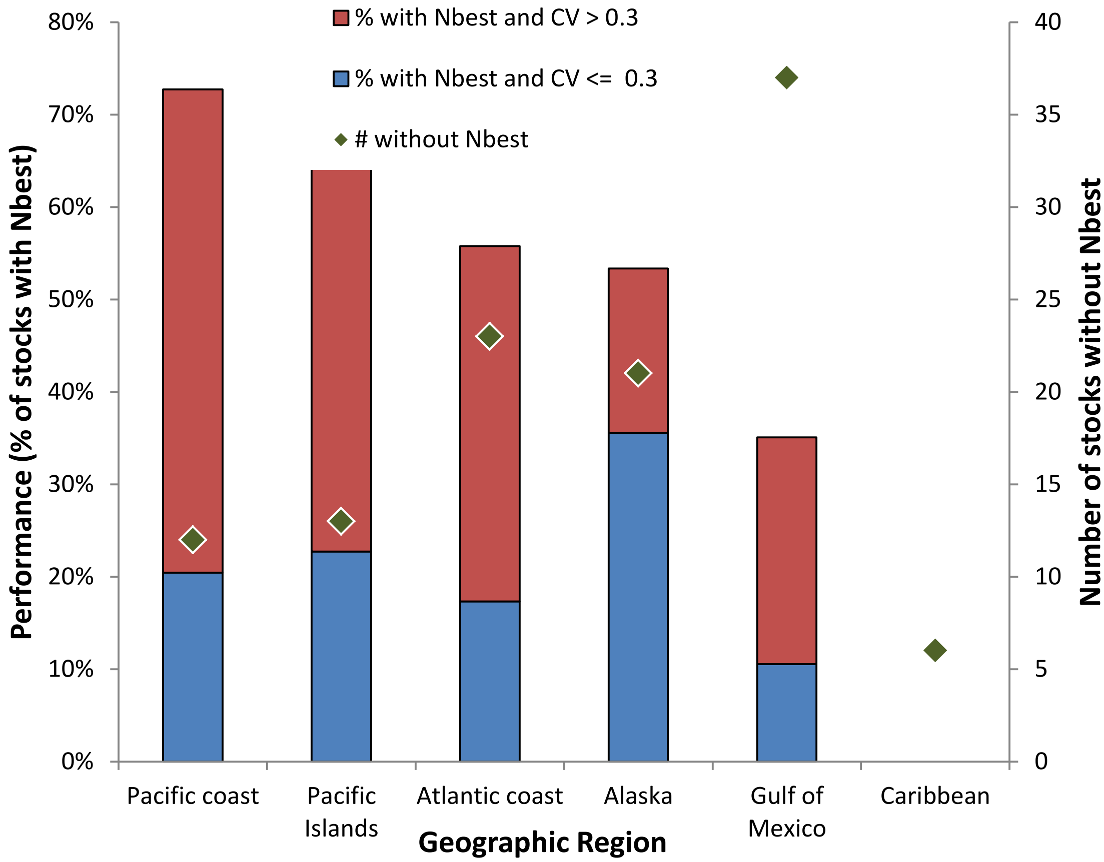

Figure 2: Performance in the 2013 assessment reports by geographic region, with regard to % of stocks for which an Nbest was provided, either with a CV(N) <= 0.3 (and therefore of reasonable precision for management purposes) or with a CV(N) > 0.3. The number of stocks without an estimate of Nbest is also presented (right axis) to illustrate what is required to reach 100% in each region, e.g., along the Atlantic coast an Nbest for another 23 stocks would result in a 100% performance.

- Stock pooling: NMFS scientists occasionally have provided a single, pooled estimate for groups of stocks of similar appearance, behavior, or natural history (e.g. beaked whales in the Atlantic, Gulf of Mexico, and Pacific regions and pygmy and dwarf sperm whales in the Atlantic and Gulf of Mexico). Pooling does not mean those stocks are of equal abundance. Indeed, this is almost certainly not the case and therefore adds a degree of bias.
- Temporal bias: Stock abundance estimates are available for many stocks but are considered by NMFS to be outdated if they are based on data that are more than eight years old—a cutoff supported by the Commission. Older data are useful for determining trends, but they are not considered reliable indicators of current abundance. The fact that abundance estimates are outdated for a number of stocks generally reflects insufficient research resources, including funding and infrastructure (e.g., vessels, aircraft), which prevents repeating surveys before eight years have elapsed. The lack of up-to-date data

for several Gulf of Mexico stocks was a major obstacle to assessing the impact to marine mammals of the 2010 Deepwater Horizon oil spill.

- Spatial bias: Abundance estimates for many stocks are based on surveys that cover only portions of their respective ranges, a form of spatial bias. If the unsurveyed areas are not representative of the surveyed areas, then abundance estimates will be systematically too high or low. Typical examples include Arctic stocks (e.g., bearded, ringed, ribbon seals), stocks that may occur in waters relatively close to shore but also occur in oceanic (pelagic or offshore) habitat, making comprehensive surveys particularly challenging (e.g., pantropical spotted, striped, rough-toothed, Clymene, Fraser's, Pacific white-sided, and Risso's dolphin), and transboundary stocks.
- Availability and perception biases: Abundance estimates also may be distorted if they are not corrected for availability or perception biases. Availability biases (not available to be seen) are more common for stocks or species with poorly understood natural history traits (e.g., diving or haulout patterns), whereas perception biases (difficult to see when available) are most severe for stocks or species that are difficult to detect at the surface (e.g., beaked whales, pygmy and dwarf sperm whales because of a low surface profile).

Current and maximum net productivity rate

A stock's current net productivity rate is a measure of its observed rate of increase under current conditions. Its maximum net productivity rate is a measure of its maximum potential for growth, which—in accordance with density-dependence theory—is expected to occur when a stock is at relatively low abundance. Both rates are determined by the stock's rates of reproduction and survival.

The MMPA allows NMFS scientists to use either a theoretical or an empirically estimated maximum net productivity rate for purposes of estimating a stock's tolerance for human impacts. In the 2013 assessments, empirically estimated rates were used for only 5% of stocks and theoretical (default) rates for 95%. That is to be expected for the most part because scientists rarely have an opportunity to observe a stock growing from a low abundance without impediment.

Current population trend

Marine mammals are large-bodied with low rates of reproduction and growth, many invest in extended parental care of their young, and have the capacity to live long lives. Those qualities help them cope with environmental variation but also mean that their populations are slow-growing and—depending on risk factors—can decline much faster than they can recover.

Whereas measures of a stock's abundance provide a snapshot of its status at a point in time, a stock's trend indicates changes in status over time. Whether growing, stable, or declining, a stock's trend reflects its inherent capacity for growth as affected by any relevant risk factors. Even when risk factors cannot be identified and evaluated with confidence, a declining trend in abundance may be the first indication that a stock is being exposed to one or more risk factors. Similarly, information on trends can be helpful for determining whether management efforts are achieving their conservation objectives. Some recovery plans (e.g., Steller sea lions) use positive growth over a set period, rather than achieving a target stock abundance, as a measure of recovery.

For any given stock, the value of trend analysis depends on the length of the time series involved and the quality of the data. To evaluate NMFS efforts to assess stock trends, the Commission counted the number of 2013 stock assessment reports that provided quantitative or qualitative trend analyses. The number of quantitative trends that spanned at least 15 years and included at least some data that were not more than 8 years old was also tallied.

Of the 248 stock assessment reports, 76 (31%) contained some trend information, including 33 (13%) with a quantitative trend analysis and 43 (17%) with a qualitative description. Of the 33 quantitative analyses, 27 (11% of the total) spanned at least 15 years and included at least some data that were not more than eight years old. Results are summarized in Table 1.

Table 1. Number of stocks with quantitative trend analysis, qualitative trend analysis, or no trend analysis. Numbers in parentheses indicate the number of stocks with at least 15 years of trend data, at least some of which were less than or equal to 8 years old in 2013.

Region	Stocks	Quantitative analysis (high quality)	Qualitative analysis	No trend data
Atlantic coast	52	1 (1)	6	45
Gulf of Mexico	57	0 (0)	2	55
Pacific coast	44	16 (10)	20	8
Pacific Islands	44	2 (2)	0	42
Alaska	45	14 (14)	15	16
Caribbean	6	0 (0)	0	6
Total	**248**	**33 (27)**	**43**	**172**

Taylor et al. (2007) illustrated how inadequate trend information undermines NMFS's ability to detect stocks in trouble. Among other things, those authors—

- defined a decrease in abundance of 50% or more in 15 years as a precipitous decline;
- noted that a stock experiencing such a decline could be designated as depleted under the MMPA;
- assessed three categories of cetaceans, two categories of pinnipeds, and a category consisting of polar bears and sea otter stocks; and
- found that given information available, declines would be detected statistically for 28% of large whales, only 10% of beaked whales, 22% of dolphins/porpoises, 0% of pinnipeds breeding on ice, 95% of pinnipeds breeding on land, and 45% of polar bear/sea otter stocks.

The stock assessment reports and the results of Taylor et al. (2007) indicate that, given the best scientific information currently available, the majority of marine mammal stocks could decline significantly without detection. Clearly, the ability of scientists to assess trends is influenced by marine mammal natural history (e.g., land-breeding versus ice-breeding pinnipeds; long, deep-divers such as beaked whales versus rapidly surfacing and relatively shallow divers such as harbor porpoises), but it also is determined by the availability (or current lack thereof) of the research infrastructure (e.g., vessels, aircraft) and the resources required for field surveys/studies.

POTENTIAL BIOLOGICAL REMOVAL LEVEL

The sixth requirement of Section 117 is to estimate each stock's tolerance for human-caused mortality and serious injury, using the potential biological removal level (or PBR) metric.

IMPORTANCE

Harbor seal ready to be released. (Dave Withrow, Alaska Fisheries Science Center, NOAA Fisheries)

The MMPA established the objective of maintaining each marine mammal stock within, or returning it to, its optimum sustainable population range (OSP).[4] With that objective in mind, Congress directed NMFS to develop a stock-specific reference value for judging when direct human-caused mortality or serious injury poses an unacceptable risk of stock depletion. That threshold is called the stock's potential biological removal (PBR) level, defined as "the maximum number of animals, not including natural mortalities, that may be removed from a marine mammal stock while allowing that stock to reach or maintain its optimum sustainable population" (16 U.S.C. §1362.20). PBR is calculated as the product of—

(a) the minimum population estimate of the stock (N_{min});

(b) one-half the maximum theoretical or estimated net productivity rate of the stock at a small population size (R_{max}); and

(c) a recovery factor of between 0.1 and 1.0 (F_r).

Hence, PBR = N_{min} x 0.5 R_{max} x F_r.

APPLYING THE PBR CONCEPT

The PBR formulation accounts for uncertainty in a stock's abundance by using N_{min} (rather than N_{best}). It accounts for variability in the stock's tolerance of human impacts by allowing the Service to vary the recovery factor based on a stock's status (i.e., threatened, endangered, depleted), trend (i.e., increasing, stable, decreasing), and abundance relative to its optimum

[4] NMFS's implementing regulations define OSP to be the range between a stock's maximum net productivity level and its environmental carrying capacity (50 C.F.R. § 216.3).

sustainable population level (NMFS 2005). The maximum net productivity rate can be based on an empirical estimate or a theoretical value.[5]

Although the PBR concept may appear straightforward, applying it has been compromised by insufficient abundance data to calculate reliable, up-to-date PBR estimates. Of the 248 stocks evaluated, 134 (54%) had PBR estimates, 51 (21%) had outdated PBR estimates, 59 (24%) had no estimates, and the reports for 4 stocks (2%) were described as having population dynamics inconsistent with application of the PBR concept (Figures 3a and b).

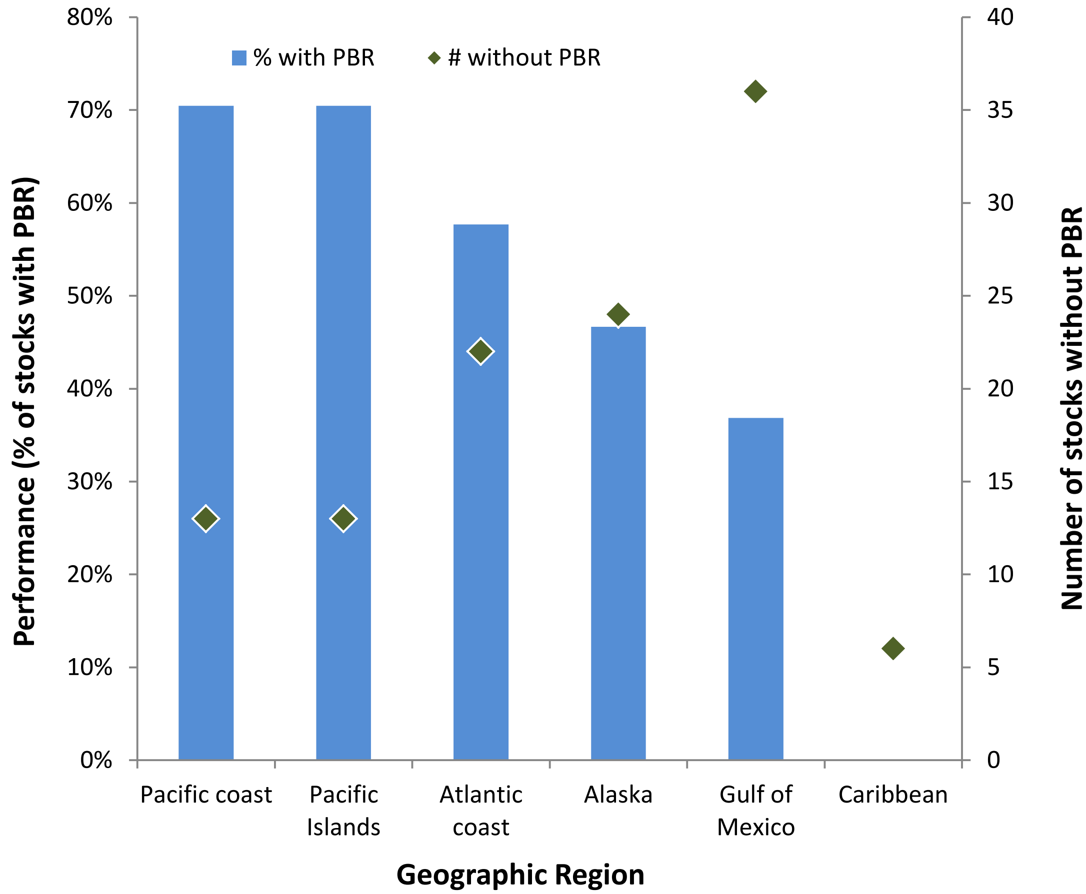

Figure 3a: Performance of NMFS in the 2013 assessment reports by geographic region, with regard to % of stocks for which a PBR estimate was provided. The number of stocks without a PBR is also presented to illustrate what is required to reach 100% in each region. For example, in the Gulf of Mexico to reach 100% performance a PBR must be estimated for an additional 36 stocks.

[5] In practice a default theoretical value that is specific to species group (cetaceans or pinnipeds) was used for most stocks in the 2013 assessments

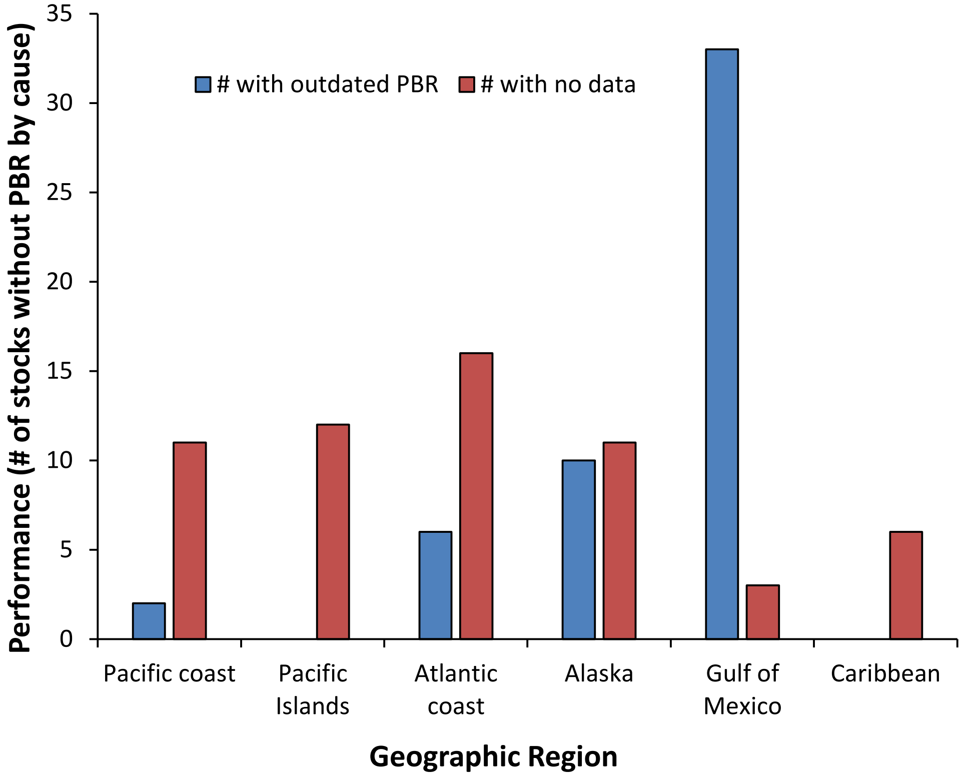

Figure 3b: Reason for the lack of a PBR estimate by geographic region. "Outdated PBR" indicates stocks that had some survey effort but those surveys are now more than eight years old and considered outdated. "No data" indicates stocks on which no significant survey effort has been focused. For example, in the Gulf of Mexico of the 36 stocks without a PBR in the 2013 assessments 33 are due to outdated survey data and 3 are due to no data.

CHALLENGES APPLYING THE PBR CONCEPT

The 2013 stock assessments indicate a number of problems that undermine the PBR approach or its application under current conditions.

1. As noted above, calculation of PBR requires an estimate of N_{min} and 110 (44%) of the 248 stocks in the 2013 stock assessments do not report an N_{min} estimate; therefore, the Service could not estimate a PBR for those stocks.
2. If NMFS has an N_{min} estimate for a stock, but the estimate is based on data older than eight years, then any PBR calculated using that N_{min} is deemed unreliable. In the next two years, ten abundance estimates will become outdated if NMFS does not have the resources to collect new abundance data.
3. Recovery factors strongly influence PBR estimates and are based in part on stock trend, but trend information is not available for 172 (69%) of the stocks.
4. A single PBR estimate for a pooled group of stocks will overestimate the tolerance for human-related effects of at least one stock in each pooled group. If this approach is to be used at all, it should be used sparingly and on a temporary basis only because such

pooling poses greater risk to pooled stocks with relatively smaller abundances, slower growth rates, greater vulnerability to human-related risk factors, or less resilience to those factors.

DISCUSSION AND RECOMMENDATIONS

The MMPA is a statement of conservation responsibility by Congress on society's behalf. It establishes a science-based framework for conserving marine mammals and the ecosystems upon which they depend. When they are complete, stock assessment reports provide a valuable basis for managing the adverse effects of human activities on marine mammals. This review indicates that although considerable progress has been made, on the whole, existing stock assessment reports fall far short of meeting the objectives set forth in the MMPA.

Three humpback whales dive together.

Of the 248 stocks in the 2013 reports NMFS provided—

- minimum estimates of abundance for only 138 stocks (56%);
- estimates of maximum productivity rates (i.e. not use a default value) for only 12 stocks (5%);
- population trend information for 76 stocks (31%), including quantitative analysis in 33 stocks(13%) and qualitative analysis in 43 stocks (17%); and
- a current potential biological removal level for only 134 stocks (54%). Of the remaining stocks 51 (21%) had outdated PBRs, 59 stocks (24%) had no PBR, and the reports for 4 stocks (2%) were described as having population dynamics inconsistent with application of the PBR concept.

Based on discussions with NMFS in regard to the shortcomings, the most obvious and prevalent problem appears to be lack of resources (funding and logistical) to support the science needed for management purposes. NMFS's staff have demonstrated that they have the capacity to do excellent scientific work, but they cannot do so if they do not have the resources needed.

Inadequate information in the stock assessment reports compromises NMFS's ability to prioritize its management and recovery actions in any meaningful or effective way. It also impedes the accurate evaluation of impacts from permitted sectors such as fisheries, energy, and defense, as well as impacts of catastrophic events such as the Deepwater Horizon Gulf Oil Spill, exposing marine mammal stocks to unnecessary risks.

The Commission therefore recommends that Congress support NMFS in its efforts to—

- improve understanding of stock structure, particularly for marine mammals in the Gulf of Mexico, central and western Pacific, and Arctic regions;
- identify and survey the ranges of marine mammal stocks to more accurately estimate abundance and distribution of stocks and hence better manage human interactions, risks of injury and mortality, and detect changes in stock status;
- implement a national stock assessment strategy that describes the infrastructure and resources needed to adequately conduct required stock assessments coordinated across regions, incorporates efforts to identify new stocks, and follows a schedule that ensures that NMFS has the status and trend information needed to identify, manage, and conserve depleted, threatened, or endangered stocks. NMFS currently undertakes some of these activities as part of its "Protected Resources Science Investment and Planning Process (PRSIPP);" [6] and
- identify and prioritize, on a national rather than regional basis and as part of the PRSIPP, those stocks for which an estimated PBR level cannot be calculated.

Specifically, the Commission recommends that Congress—

- work with leadership in NOAA, the Department of Commerce, and other Administration officials, to identify and secure the resources necessary to implement Section 117 of the MMPA and produce high quality, thorough, stock assessment reports nationally.

To improve stock assessments particular focus should be placed on vessel, ground, and aircraft surveys of the U.S. EEZ and adjacent waters conducted with consistent methodology at least twice in an eight-year period (to estimate the abundance and trends of all marine mammal stocks in U.S. waters), development of alternative survey technologies, and genetic analyses to better identify and define discrete marine mammal stocks in U.S. waters

The Commission would welcome the opportunity to discuss the results of its review with NMFS, NOAA, the Department of Commerce, the Administration, and Congress. The Commission believes that, with adequate resources, NMFS can fulfill the vision and mandates set forth in the MMPA for stock assessment.

ACKNOWLEDGMENTS

The Marine Mammal Commission would like to thank Timothy Ragen, Tiffini Brookens, Kristine Lynch, Robert Gisiner, Nina Young, and Dennis Heinemann. This report would not have been completed without your ideas, discussions, and contributions.

[6] NMFS has a proposal for conducting rotational surveys on a predictable schedule to increase efficient use of resources nationally but lacks the funding to support this initiative.

IMPLICATIONS OF NON-LINEAR DENSITY DEPENDENCE

BARBARA L. TAYLOR

DOUGLAS P. DEMASTER[1]

La Jolla, California 92038-0271

ABSTRACT

Ranges of the ratio of maximum net productivity level (MNPL) to carrying capacity (K) are explored in general models for pinnipeds and odontocetes. MNPL/K is used in management of marine mammals but no empirical evidence exists to limit the range of values expected. Density dependent changes in age-specific birth and death rates have been used to infer MNPL/K. Non-linearities in these rates do not translate directly to population growth curves. The simple models demonstrate: (1) density dependence is likely to involve more than a single parameter (such as birth rate), (2) MNPL/K can be greatly reduced from that inferred from one strongly non-linear parameter when changes in other parameters are linear, (3) ranges of MNPL/K depend on biological limits on ranges of fecundity and survival rates, and (4) the magnitude and sign of bias incurred by inferring MNPL/K from functional forms of single parameters cannot be determined. Given current empirical evidence the range of MNPL/K for marine mammals as a group is large. Although MNPL/K should not be inferred from single parameter non-linearities, distributions of MNPL/K values can be generated through models which account for single species ranges for birth and death rates and maximum population growth rate.

Key words: demography, density dependence, logistic, marine mammal, non-linear dynamics, odontocete, pinniped, population dynamics.

Density dependent population dynamic models are used routinely in the management of marine mammals (Gerrodette and DeMaster 1990). Populations are typically managed relative to the population level where the maximum sustainable yield is realized (Donovan 1989) or the population level where net productivity is maximized. Maximum net productivity level (MNPL) is defined as (Gehringer 1976), "... the greatest net annual increment in population numbers or biomass resulting from additions to the population due to reproduction and/or growth less losses due to natural mortality." Empirical data

[1] Present address: National Marine Mammal Laboratory, 7600 Sand Point Way, N.E. Bldg. 4, Seattle, WA 98115.

concerning population growth rates at different population sizes for marine mammals are limited. Population growth is usually represented by deterministic models which describe the future state of a population given the current state. The state is given in terms of numbers of individuals. These population growth models, such as the logistic or various modified logistic models, consider all individuals to be equal with respect to future prospects of birth and death, that is, age structure is not explicitly used in the models.

Although the data for the relationship between population growth and population size are sparse for marine mammals, data on some age-specific birth and death rates are available for a few species. Based on these data, MNPL has been inferred to be above $0.5K$ (Fowler *et al.* 1980, Fowler 1987). From a model using an evolutionary argument, Fowler *et al.* (1980) state: "We would expect a whale population with a maximum specific productivity of 0.04 to show its greatest productivity levels between 88 and 92 percent of its equilibrium level." However, using the relationship from Fowler (1987), with a generation time of 20 yr and a maximum specific productivity of 0.04, would result in MNPL/K of 0.67. The purpose of this paper will be to explore the range of MNPL/K values possible for different combinations of density dependent age-specific changes in birth and death rates. Special attention will be given to biases which could result from inferring MNPL/K from density dependent changes in a single age-specific parameter. Two simple models will be used to explore whether what is known about non-linearities in age-specific birth and death rates justifies acceptance of any particular range of MNPL/K values. The first model is a generalized pinniped model which represents the marine mammal life history with the fastest population growth rate. At the other end of the spectrum, a generalized odontocete model is used to represent life history strategies with slow growth rates.

Empirical evidence—General reviews of empirical evidence for density dependence in large mammals, with separate sections on marine mammals, are presented in Fowler (1987) and Fowler *et al.* (1980). The intent of this paper is not to focus on any particular species but rather to present what general forms may pertain to specific demographic parameters. Fowler (1984) reviews density dependence in marine mammals and finds evidence of regulation for fecundity in nine species, age of first reproduction (AFR) in ten species, juvenile survival in five species and adult survival in one species. These frequencies may reflect ease of gathering data. For example, although adult survival may be density dependent, estimation is difficult and power to detect a change would be low for the amount of change required to affect population growth rates. The lack of empirical evidence makes the form of density dependence for adult survival purely speculative.

A recent reanalysis (de la Mare 1992) of some data reviewed by Fowler *et al.* (1980) shows the inability to draw general conclusions about the shape of recruitment functions. The following statements can be made based on empirical data (Fowler *et al.* 1980, de la Mare 1992): (1) marine mammals show density dependent responses, (2) for species for which data are available over a range of population sizes, density dependent responses are not abrupt (knife-edge),

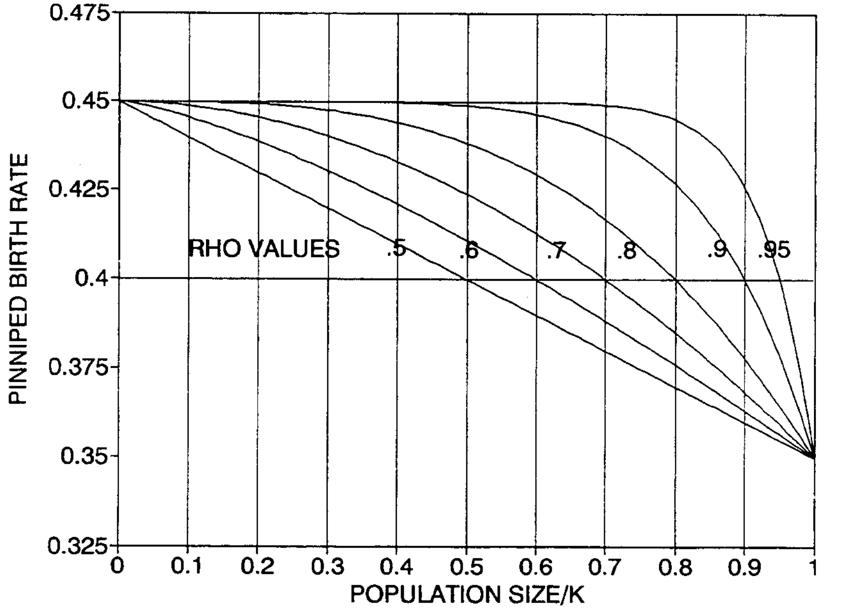

Figure 1. Curves for the Allen equation (Equation 3) for different ρ-values for birth rates for pinnipeds. The horizontal line indicates the point of 50% change in the parameter range. Note the intersections of the functions for different ρ-values with this line.

and (3) density dependent responses have not been shown to be concave (higher rates of change at low density), though the power is low. In this paper, a concave curve is one in which the value for any point between two endpoints is less than the value which would be a linear interpolation. Given the endpoints (0, 1) and (1, 0), a linear relation would yield a y-value of 0.5 when $x = 0.5$. A curve passing through any y-value <0.5 at $x = 0.5$ would be concave. None of the curves in Figure 1 are concave. A theoretical argument has been given by de la Mare and Cooke (1992) that concave responses are possible by allowing spatial variation in the environment. For the purposes of this paper, responses are limited to range from linear to strongly convex (most density dependent response at levels very close to K). Given current quantities and qualities of empirical data, it is not possible to further limit functional forms of age-specific density dependent responses for marine mammals as a group.

Theoretical arguments—Although MNPL is defined in population terms, empirical data exist primarily for age-specific demographic rates. We now consider how each approach is represented theoretically. Density dependent population growth is commonly represented by the generalized logistic equation (Pella and Tomlinson 1969, Gilpin *et al.* 1976) (altered below for discrete growth).

$$N_{t+1} = N_t + (\lambda_{\max} - 1)N_t\left[1 - \left(\frac{N_t}{K}\right)^{\theta}\right] \quad (1)$$

where N = population size, t = time, K = carrying capacity, λ_{max} = maximum discrete rate of population growth, and θ = shape parameter. Goodman (1980) showed distortion in the population growth curve caused by age structure: a linear change in birth rate caused the population growth curve to be convex. The convex shape of density dependent birth and survival functions argues generally for a maximum growth rate which is greater than $K/2$ ($\theta > 1$).

The θ-logistic equation does not include age-specific mortality or fecundity, but rather uses a single parameter, discrete population growth rate (λ, where $\lambda_{Nt} = N_{t+1}/N_t$), to predict the next population size given the current population size. For any given set of age-specific birth and death parameters there is a unique population growth rate which satisfies the equation:

$$1 = \sum_{x=AFR}^{\omega} l_x m_x \lambda^{-x} \tag{2}$$

where x = age, AFR = age of first reproduction, ω = oldest age, l = survivorship, m = fecundity, and λ = discrete rate of growth. Population growth is sensitive to different parameters in varying strengths. For example, equal proportional changes (called elasticity, Caswell 1989) in adult and juvenile survival rates will result in different changes to λ. For long-lived animals which have high adult survival rates and typically relatively low maximum population growth rates, λ is most sensitive to changes in adult survival rate (Goodman 1981). Relatively large changes in birth and juvenile survival rates result in rather small changes in λ. For example, consider a case where the survival rate for the first year is 0.50 and is 0.95 thereafter. Let $AFR = 1$, $\omega = 20$, and $m = 0.5$ giving $\lambda = 1.051$. A 10% reduction in adult survival, juvenile survival, and birth rate results in λ values of 0.972, 1.026, and 1.038 or changes of −7.5%, −2.4%, and −1.2% respectively. For this reason it is difficult to intuit how non-linear changes in birth or juvenile survival rates will affect λ and the MNPL. Therefore, simple models will be used to investigate the translation of density dependent changes in birth and death rates into population growth rates.

Methods

Introduction to the life history models—The translation of several age-specific density dependent functions into a single population growth function is best illustrated with simplified population models. The following parameters characterize the demography: mean fecundity (m), annual adult survival rate (p_a), annual juvenile survival rate (p_j—from age zero to one), AFR, oldest age (ω) and maximum discrete rate of growth (λ_{max}). We chose parameter values based loosely on the life history of fur seals (*Callorhinus ursinus*) for the pinniped model (Ragen 1990), and the bottlenose dolphin (*Tursiops truncatus*) for the odontocete model (Scott *et al.* 1990, Wells and Scott 1990). Default values for each parameter were selected to give the growth rate expected at $K/2$ within known ranges for pinnipeds (Ragen 1990) and odontocetes (Scott *et al.* 1990,

Table 1. Default parameters to yield λ at K/2 assuming a linear decrease in per capita growth.

Model	$\lambda(N = K/2)$	m	AFR	p_j	p_a	ω
Pinniped	1.05	0.40	5	0.423	0.960	20
Odontocete	1.02	0.12	10	0.593	0.980	50

Brault and Caswell 1993) (Table 1). Density dependent population growth was achieved by adjusting one or more of the above parameters.

Changes in single parameters—We begin examining the effect of changes in age-specific parameters on population growth rate by changing only a single parameter. The required single parameter changes needed to obtain growth rates from $\lambda = \lambda_{max}$ to $\lambda = 1$ could then be solved given equation 1. Change between the minimum and maximum parameter values was governed by:

$$X_N = X_{N=K} + (X_{N=0} - X_{N=K})\left[1 - \left(\frac{N}{K}\right)^z\right] \tag{3}$$

where N = population size, K = carrying capacity ($\lambda = 1$), $X_{N=0}$ = the value of the parameter when $N = 0$, $X_{N=K}$ = the value of the parameter at K, and z = shaping parameter. Because z-values are difficult to interpret, we have used a different scale. Let ρ be the N/K value reached when the z-value has changed half its range. Equation 3 can be rearranged to solve for z given the desired ρ-value.

$$z = \frac{\ln(0.5)}{\ln(\rho)} \tag{4}$$

Using Equation 4, we find that if we want a given parameter to have changed 50% of its range when $N/K = 0.9$ then $z = 6.58$. We investigated ρ-values between 0.50 ($z = 1$) and 0.95 ($z = 13.5$). The knife-edge limitation is therefore defined as $\rho = 0.95$, when the parameter has changed 50% of its range in 0.95 (N/K). Equation 3 (Allen 1976) is shown for different ρ-values in Figure 1 for birth rate for pinnipeds.

Changes in multiple parameters—In order to reduce the number of permutations of multiple parameters, changes were allowed which met two criteria: (1) parameter values must be biologically reasonable, and (2) changes in z must

Table 2. Minimum and maximum values allowed to maintain biological realism. Birth rate parameters assume a sex ratio of 0.5 and a maximum pregnancy rate of 90%. For the odontocete model calving interval is three years when $N = 0$ and five years when $N = K$.

Model	λ $X_{N=0}$	AFR $X_{N=0}$	AFR $X_{N=K}$	m $X_{N=0}$	m $X_{N=K}$	p_j $X_{N=0}$	p_j $X_{N=K}$
Pinniped	1.10	4	6	0.45	0.35	0.67	0.24
Odontocete	1.04	8	12	0.15	0.09	0.66	0.51

follow known empirical evidence (*i.e.*, density dependent changes are not knife-edge in form: $0.5 \leq \rho \leq 0.95$). Minimum and maximum values are given in Table 2.

Results

Single parameter changes—Figure 2 shows MNPL for different ρ-values for changes in single parameters as shown in Table 3. Results are shown for the odontocete model as values from the pinniped model never differed by greater than 1%. There are several items to note from this figure. First, as shown by Goodman (1980), not all linear density dependent changes ($z = 1$) produce a MNPL/K at $K/2$ (MNPL/K = 0.5). In particular, juvenile survival and birth rate produce a MNPL/K of 0.55. These two rates are the same because the

Table 3. Demographic parameter values required to achieve specified λ by changing a single parameter from the default values in Table 1, for use in Equation 3.

Model	λ	m	AFR	p_j	p_a
Pinniped ($X_{N=K}$)	1.00	0.232	10.510	0.245	0.914
Pinniped ($X_{N=0}$)	1.10	0.643	1.840	0.680	1.000
Odontocete ($X_{N=K}$)	1.00	0.072	22.681	0.355	0.961
Odontocete ($X_{N=0}$)	1.04	0.189	2.875	0.935	0.999

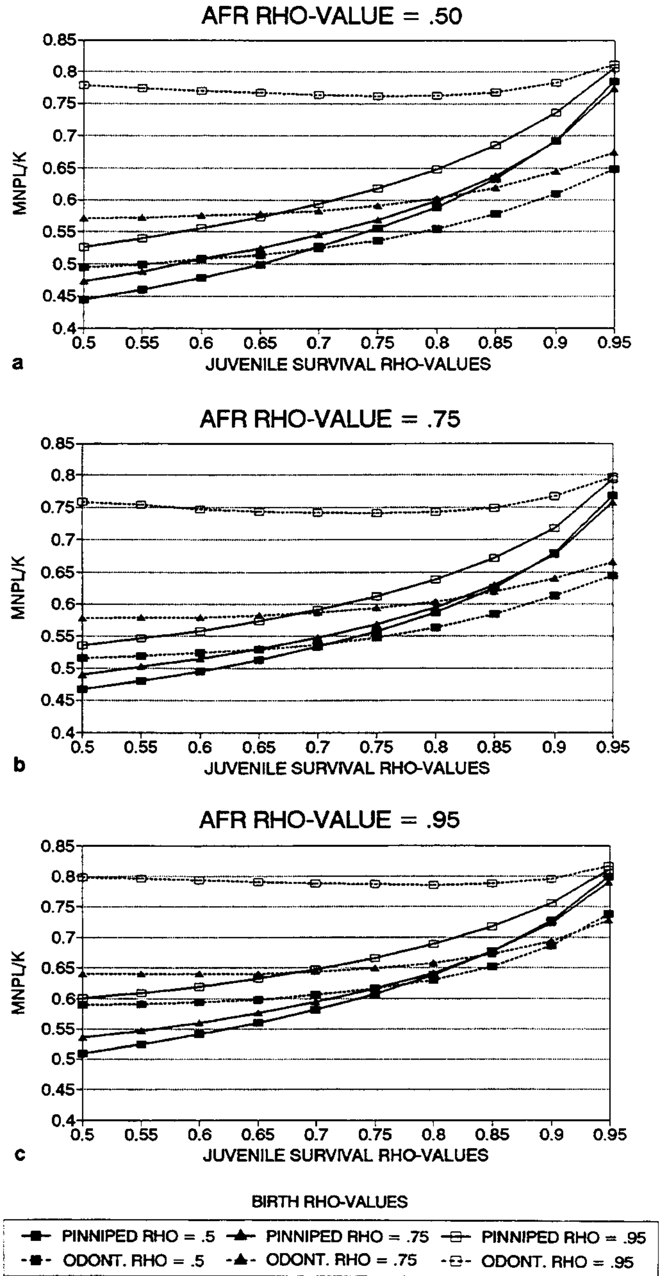

Figure 3. Multiple parameter changes resulting in a reduction in growth rate from $\lambda = \lambda_{max}$ to $\lambda = 1.0$. Figures a, b, and c correspond to *AFR* ρ-values of 0.50, 0.75, and 0.95 respectively. Pinnipeds (solid lines) and odontocetes (dashed lines) are shown for birth ρ-values of 0.50, 0.75, and 0.95. Lines between symbols are given for visual clarity.

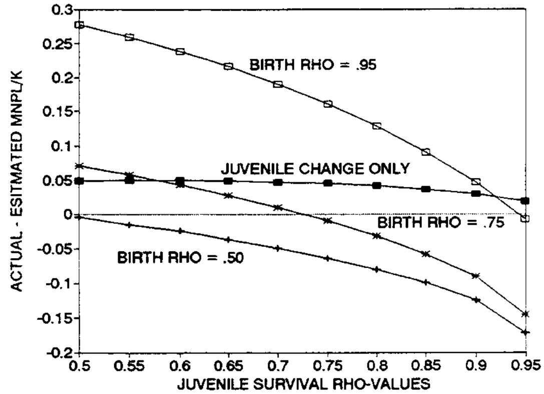

Figure 4. Bias in estimates of MNPL/K from assuming that $\theta = z$-value for juvenile survival. To obtain the actual MNPL/K value, the bias must be added to the value estimated from the z-value. The case shown is for odontocetes where juvenile survival is the only regulating mechanism and for three cases where AFR changes linearly ($z = 1$) and birth ρ-values are 0.50, 0.75, and 0.95.

elasticities are the same for these parameters. Recall that elasticity is the response in λ to a proportional change in the parameter. With only one year of juvenile survival, a reduction in juvenile survival or a reduction in birth rate cause the same reduction in the number of individuals recruited into the population. The small range of MNPL/K values for a given ρ-value irrespective of which parameter is being altered is not surprising. Even though λ is more sensitive to p_a, Table 3 reveals that much smaller proportional changes in p_a are required to produce the growth rate change. It may be surprising to note that even strong non-linearities ($\rho = 0.95$) do not produce MNPL/K >0.85. Higher ρ-values will, of course, yield MNPL/K values >0.85, but such highly concave functions imply no density dependent response until the population is very close to K. There are no empirical data to support such a knife-edge density dependent response. The final item to note is that the change required for a single parameter to accomplish all the density dependent change is often biologically unreasonable and sometimes (in the case of birth rate and AFR) biologically impossible. For example, in the pinniped model, AFR ranges from a minimum age (1.84) which is physically impossible to a maximum age (10.51) which is unlikely and was not observed when fur seals were thought to be near K in the 1950s (Scheffer 1955). Because marine mammals produce a single offspring and have a sex ratio of 0.5, values for birth rates cannot exceed 0.5. The maximum value in Table 3 for pinnipeds ($m = 0.643$) is therefore impossible. Similar arguments can be made for the same parameters in the odontocete model.

Changes in multiple parameters—All combinations of AFR, juvenile survival and birth rates for $\rho = 0.50$–0.95 were investigated. Results are shown in Figure 3. Note that changes in more than one parameter yield MNPL/K values which are less than those for equal ρ-values for changes in only a single parameter (also found in Fowler *et al.* 1980). The combination of three linear changes for the pinniped model ($\rho = 0.5$ ($z = 1$) for AFR, juvenile survival, and birth rate) actually yields an MNPL/K that is less than 0.5. Comparison of the pinniped model to the odontocete model shows that MNPL/K of the former to be more sensitive to changes in juvenile survival rate ρ-values and the latter to birth rate ρ-values. This is due to the differing magnitude of allowed change in these parameters (Table 2): birth rates vary more for odontocetes and juvenile survival rates vary more for pinnipeds. Thus, the models are sensitive to the minimum and maximum values. Changes in *AFR* ρ-values affect both models similarly when other ρ-values are low but have almost no effect on either when other ρ-values are high.

Consider the scenario where only data concerning juvenile survival were available. If we were to use the z-value from a fit of juvenile survival as the θ in Equation 1 how would our estimated MNPL/K compare to the actual MNPL/K when all birth and death functions are known? Figure 4 gives one example of bias for odontocetes. It can be seen that for a given ρ-value, even the sign of the bias cannot be inferred. The magnitude of the bias depends on the ρ-values of both the juvenile survival and birth rates. Therefore, it is not valid to infer MNPL/K from the functional form of a single demographic parameter. MNPL/K can be estimated either from population size estimates or from complete demographic models.

Discussion

Although it is likely that MNPL is found at values greater than $K/2$, the argument that MNPL should be very close to K (MNPL/$K > 0.8$) is unsupported. The only parameter for which empirical evidence lends credence to strong non-linearities is for juvenile survival in fur seals (Ragen 1990). Even here, many deterministic models have been used to fit the data with values for MNPL/K ranging from 0.43 to 0.93 (Ragen 1990). It is clear that when data are available for marine mammals, one of the primary density dependent regulating mechanisms is age of first reproduction (Fowler 1984). There is no evidence for non-linear change for this parameter (Fowler 1984, Lett *et al.* 1981), though power is undoubtedly low. As shown in Table 3, biological constraints make the likelihood of this parameter being the sole regulatory mechanism unlikely. It is therefore likely that population growth is regulated by several mechanisms, only some of which may be non-linear (Smith and Polacheck 1981). When several parameters change in a density dependent fashion, the result is that MNPL/K is less than that achieved by only a single non-linear growth rate regulating mechanism. If z-values for all parameters are high, MNPL/K values differ very little from values estimated for MNPL/K assuming $\theta = z$. On the other hand, disparities can be large if some parameter changes are linear.

The generalized pinniped and odontocete models were chosen to bracket the range of population growth rates observed in marine mammals. It may be argued, however, that these choices do not bracket the range of possible MNPL/K

values. Fowler (1988) argues that MNPL/K is related to rate of increase per generation. The generalized models have similar rates of increase per generation. To investigate the influence of rate of increase per generation on the conclusions of this paper, we chose the most extreme outlier in Fowler's work: *Stenella.* This genus has a similar rate of increase to the odontocete model but a shorter generation time. Choice of parameter ranges were from Chivers (1992). Results were very close to the odontocete model and did not compromise the conclusions from the generalized models.

Non-linearities in population regulation mechanisms which lead to linear decreases in per capita growth rates (MNPL/K = 0.5) have been noted in several laboratory systems (Barlow 1992, Kerfoot *et al.* 1985). Further, Barlow's experiment with guppies (*Poecilia reticulata*) (1992) showed highest sensitivity to density dependent somatic growth. Although mammals express determinate growth, AFR seems to be an important regulatory mechanism which may link body growth rate to population growth (Lett *et al.* 1981).

Unfortunately, we are only a little closer to defining likely ranges of MNPL/K. It seems likely that $0.5 < \text{MNPL}/K < 0.85$. For a given species, the range may be able to be reduced. For example, if we know that for fur seals z-values were $z = 1$, $1 \leq z \leq 3$, and $3 \leq z \leq 9$ for *AFR,* birth and juvenile survival rates respectively, then $0.58 < \text{MNPL}/K < 0.73$. A much more realistic fur seal model (Ragen 1990) calculated a distribution of MNPL/K from simulations using permutations of possible ranges of demographic values and z-values. MNPL/K occurred at highest frequency between 0.60 and 0.65 (corrected values; Ragen, personal communication). Unfortunately, there are few species for which we have the quantity of data available as for the fur seal.

Eberhardt (1977) proposed a general model for self-regulation in long-lived species which gave an order for age-specific density dependent responses. Such rigidity in growth regulation was questioned by a comparison of population dynamics of three species of Antarctic seals (Siniff 1984). These species, living in proximity to one another, showed varied responses which were attributed to different reactions to environmental variance. Thus, even within the Antarctic ecosystem and among closely related species, marked differences in density dependent age-specific birth and death rate responses exist. The deterministic equations discussed in this paper assume no environmental variance. Clearly, populations must evolve to respond to the stress caused by environmental changes. Marine environments change markedly over short time periods (El Niño events, fluctuations in prey availability in cold water regimes, *etc.*). Some marine mammal species are relatively fixed in space due to breeding or feeding requirements while others may be free to move over large distances to locate resources. It seems an act of faith to believe that all the likely different density dependent age-specific regulatory mechanisms would result in a narrow range of MNPL/K values. The exercise in this paper has demonstrated that even if dynamics were deterministic, without knowledge about all the density dependent age-specific birth and death rates, a single value of MNPL/K cannot be inferred. Distributions of MNPL/K for each species given a range of parameter estimates may be more appropriate considering the current amount and quality of data.

ABSTRACT

A simulation method was developed for identifying populations with levels of human-caused mortality that could lead to depletion, taking into account the uncertainty of available information. A mortality limit (termed the Potential Biological Removal, *PBR*, under the U.S. Marine Mammal Protection Act) was calculated as the product of a minimum population estimate (N_{MIN}), one-half of the maximum net productivity rate (R_{MAX}), and a recovery factor (F_R). Mortality limits were evaluated based on whether at least 95% of the simulated populations met two criteria: (1) that populations starting at the maximum net productivity level (*MNPL*) stayed there or above after 20 yr, and (2) that populations starting at 30% of carrying-capacity (*K*) recovered to at least *MNPL* after 100 yr. Simulations of populations that experienced mortality equal to the *PBR* indicated that using approximately the 20th percentile (the lower 60% log-normal confidence limit) of the abundance estimate for N_{MIN} met the criteria for both cetaceans (assuming $R_{MAX} = 0.04$) and pinnipeds (assuming $R_{MAX} = 0.12$). Additional simulations that included plausible levels of bias in the available information indicated that using a value of 0.5 for F_R would meet both criteria during these "bias trials." It is concluded that any marine mammal population with an estimate of human-caused mortality that is greater than its *PBR* has a level of mortality that could lead to the depletion of the population. The simulation methods were also used to show how mortality limits could be calculated to meet conservation goals other than the U.S. goal of maintaining populations above *MNPL*.

Key words: bycatch, cetacean, conservation, incidental fisheries mortality, management, mortality limit, *PBR*, population modeling, pinniped, U.S. MMPA.

Human activities sometimes cause the mortality of marine mammals. This mortality ranges from the obvious, such as intentional takes by commercial or subsistence harvesters, to the not-so-obvious, such as incidental mortality in fishing operations. Correctly assessing the significance of incidental mortality to marine mammal populations can be difficult. In cases where the incidental fisheries mortality is perceived to be high, such as for the well-known 1960s case of eastern tropical Pacific dolphins killed in the tuna purse seine fishery (Perrin 1969, Wade 1995), it can seem obvious that the mortality should be reduced. However, when human-caused mortality is more moderate, it becomes less obvious whether that mortality should be of concern from the standpoint of preventing the depletion of a population. Of course, some may argue that no mortality should be tolerated, but even some of the least-harmful fisheries still have the potential to cause the death of a marine mammal. Other human activities that are apparently innocuous can also cause incidental mortality, such as ships colliding with large whales (*e.g.,* Kraus 1990), yet it would be impractical to stop all ship traffic. Most people would probably agree that an activity could be considered acceptable if it only rarely caused the incidental mortality of a marine mammal (*e.g.,* one animal in 20 yr). The difficulty is how to decide when a level of mortality is no longer acceptable. This paper describes a method for setting a limit in mortality for identifying marine mammal populations with levels of human-caused mortality that may be too high.

Before a management scheme can be designed, the management goal must be defined. The management goal of the U.S. Marine Mammal Protection Act (MMPA) is to prevent populations from "depletion." The U.S. National Marine Fisheries Service (NMFS) considers a population depleted if it falls below its maximum net productivity level (*MNPL*) (Fig. 1). For marine mammals, this level is thought to be between 50% and 85% of carrying capacity and is more likely to be in the lower portion of that range (Taylor and DeMaster 1993). Therefore, populations are considered depleted by the U.S. Government if they are directly estimated to be below their *MNPL,* or if they are estimated to be below 50%–70% of a historic population size which is thought to represent carrying capacity (Gerrodette and DeMaster 1990). Although maintaining populations above *MNPL* is an excellent management goal, basing management decisions entirely on assessing status relative to *MNPL* has proven inadequate. Assessment methods such as *dynamic response* (Goodman 1988) or *back calculation* (Smith 1983) require a quantity of data unavailable for most species and cannot always be applied (Gerrodette and DeMaster 1990).

Alternatively, management actions could be triggered by criteria using trends in abundance. In fact, a series of abundance surveys were planned to monitor spotted dolphins (*Stenella attenuata*) in the eastern tropical Pacific (Holt *et al.* 1987). The goal was to detect a 10% annual decline over five years (six surveys) with 90% assurance, assuming a coefficient of variation (CV) of 12% for each annual abundance estimate. In reality, the estimated CV averaged 30% over the five surveys actually performed (Wade and Gerrodette 1992). Given that level of precision, it would take nine years (10 surveys) to detect a 10% annual decline, assuming a survey was done every year (Gerrodette 1987). Thus, the time required to estimate the trend implies that a management scheme based on detecting a significant decline in abundance would not initiate any management action until a previously unexploited population became depleted; a population declining at 10% per year would be at only 39%

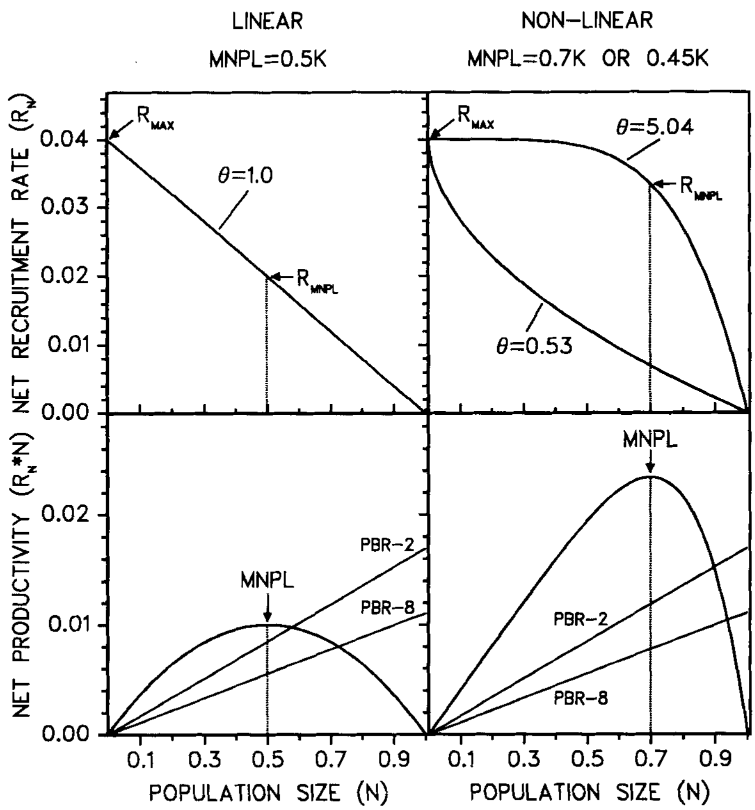

Figure 1. Illustration of density-dependent response specified by generalized logistic model (Equation 2), showing relationship between quantities discussed in text. Two panels on the left show linear model ($\theta = 1.0$). Top panel shows linear decline of net recruitment rate (*per capita* population growth rate) with population size (expressed as fraction of carrying capacity [K]). Bottom panel shows net productivity curve, which is product of net recruitment rate and population size. For linear model, net productivity curve is symmetric, with maximum (*MNPL*) at 0.5K. Net recruitment rate at *MNPL* (R_{MNPL}) is ½ the maximum rate (R_{MAX}). Two straight lines in bottom panel represent expected *PBR* (Equation 1) calculated as product of 20th percentile of abundance estimate, ½ R_{MAX}, and value of 1.0 for recovery factor (F_R), assuming CV of abundance estimate of 0.2 (*PBR*-2) or 0.8 (*PBR*-8). Top panel on right shows two types of possible non-linear density-dependent responses of net recruitment rate. Higher curve represents example of convex density dependence ($\theta = 5.04$), where net recruitment rate declines slowly at low population size but declines more rapidly at higher population size. Bottom panel on right shows net productivity curve associated with this value of θ, which is not symmetric and has maximum at 0.7K. If $\theta > 1.0$, then $MNPL > 0.5K$, and $R_{MNPL} > ½ R_{MAX}$. Lower curve in top panel represents example of concave density-dependent response ($\theta = 0.53$), where net recruitment rate declines more rapidly at lower population sizes than at higher population sizes. Associated net productivity curve not shown in lower panel, but *MNPL* is 0.45K for this value of θ. If $\theta < 1.0$, then $MNPL < 0.5K$, and $R_{MNPL} < ½ R_{MAX}$.

of its initial population size after nine years. This problem becomes even more acute for small populations because the precision of abundance estimates decreases as abundance decreases (Taylor and Gerrodette 1993), and thus conceivably a small declining population could become extinct before it could be found to be significantly declining.

Thus, management which is dependent on detecting a trend in abundance is unlikely to maintain above *MNPL* all populations which have high levels of human-caused mortality. Gathering trend data for management would also require frequent surveys, which would be costly for the 153 defined stocks of marine mammals in U.S. waters, most of which have been subject to some form of human-caused mortality (Barlow *et al.* 1995*b*). If a decline in abundance is detected, this should, of course, initiate management response, but it may often be appropriate to take action well before it is possible to prove that a decline in abundance is occurring.

A better management scheme would use data that can be dependably gathered to initiate management actions before populations become depleted. Fortuitously, it is easier to detect the circumstances that will lead to a decline in abundance than it is to detect the actual decline itself. We can often estimate the level of human-caused mortality of marine mammals when the source of the mortality is known. Therefore, a management scheme can be based on calculating a mortality limit. Mortality above the limit would trigger management actions beyond basic monitoring.

It is obvious that such a limit has to be unique and scaled to each population and therefore must be based on mortality relative to population size, not on an absolute level of mortality. For example, it is unlikely that the kill of a single common dolphin (*Delphinus delphis*) off the coast of California would have any significance to a population recently estimated at 225,821 (Barlow 1995). However, the kill of a single individual may be of importance to a very small population such as that of the western North Atlantic right whale (*Eubalaena glacialis*), currently estimated to number only about 295 animals (Knowlton *et al.* 1994).

If we had perfect knowledge of a population's human-caused mortality, abundance (N) and dynamics, including its growth rate at the maximum net productivity level (R_{MNPL}) (Fig. 1), we could exactly determine a mortality limit that would prevent depletion to below the *MNPL*, as the product of N and R_{MNPL}. Instead, we usually have only estimates of abundance and mortality and a plausible range of growth rates based on life-history information (*e.g.*, Reilly and Barlow 1986). We also have empirical estimates of rate of increase for a few populations, such as recovering populations of pinnipeds (*e.g.*, Cooper and Stewart 1983) or baleen whales (*e.g.*, Best 1993). To ensure a robust management strategy, a mortality limit that is calculated from such information should explicitly account for the precision and bias of the available estimates of abundance and mortality, as well as for the uncertainty of the population growth rate.

Several years ago, NMFS scientists with experience in the management of marine mammals recognized the deficiencies of previous management schemes, as discussed above, and proposed a management strategy based on calculating a mortality limit (Proposed regime to govern interactions between marine mammals and commercial fishing operations, National Marine Fisheries Service Legislative Proposal, November 1992, available from the Office of Protected Resources, National Marine Fisheries Service, Silver Spring, MD). This proposal was the initial basis for what became the 1994 amendments to the MMPA, which introduced the concept of a mortality limit, termed the "potential biological removal level" or *PBR*. The proposal and the subsequent amendments attempted to implement several principles that have been developed to promote better conservation of wild, living resources, particularly that assessment should precede the use of resources and that managers should recognize the possible consequences of uncertainty and act accordingly (Mangel *et al.* 1996). Therefore, the *PBR* management scheme implemented by the 1994 amendments, and the methods I present here for calculating *PBR*s, may have value beyond the narrow focus of management of marine mammals in U.S. waters. For convenience, however, I use the (admittedly idiosyncratic) terminology of the MMPA.

The relevant specific rules, as modified by the 1994 amendments, are stated as follows in the Definitions (Section 3) of the MMPA:

> "(19) The term 'strategic stock' means a marine mammal stock—(A) for which the level of direct human-caused mortality exceeds the potential biological removal level; . . . ."
>
> "(20) The term 'potential biological removal level' means the maximum number of animals, not including natural mortalities, that may be removed from a marine mammal stock while allowing that stock to reach or maintain its optimum sustainable population. The potential biological removal level is the product of the following factors:
>
> (A) The minimum population estimate of the stock.
>
> (B) One-half the maximum theoretical or estimated net productivity rate of the stock at a small population size [see Fig. 1].
>
> (C) A recovery factor of between 0.1 and 1.0."
>
> "(26) The term 'net productivity rate' means the annual *per capita* rate of increase in a stock resulting from additions due to reproduction, less losses due to mortality."
>
> "(27) The term 'minimum population estimate' means an estimate of the number of animals in a stock that—(A) is based on the best available scientific information on abundance, incorporating the precision and variability associated with such information; and (B) provides reasonable assurance that the stock size is equal to or greater than the estimate."

Therefore, from the definitions it follows that the *PBR* is calculated as:

$$PBR = N_{\text{MIN}} \frac{1}{2} R_{\text{MAX}} F_R \tag{1}$$

where:

N_{MIN} = the minimum population estimate of the stock,

$\frac{1}{2}R_{MAX}$ = one-half the maximum theoretical or estimated net productivity rate of the stock at a small population size,

F_R = a recovery factor between 0.1 and 1.

Note that the goal of the *PBR* is to allow each stock to reach or maintain its "optimum sustainable population" (*OSP*):

> "(9) The term 'optimum sustainable population' means, with respect to any population stock, the number of animals which will result in the maximum productivity of the population or the species, keeping in mind the carrying capacity of the habitat and the health of the ecosystem of which they form a constituent element."

To make that definition more specific, NMFS has defined *OSP* as a population level between carrying capacity and the population size at maximum net productivity (Federal Register, 21 December 1976, 41 FR 55536). Therefore, the specific goal of the *PBR* is to allow each stock to reach or maintain a population level above the maximum net productivity level (*MNPL*). This has long been the goal of the MMPA; the key difference instituted by the 1994 amendments is that management actions related to direct human-caused mortality no longer rely on detecting depletion, but on simply detecting a mortality level that will lead to depletion.

Although the MMPA specifies the three components of the *PBR*, it does not define them in quantitative terms. The purpose of this paper is to propose specific quantitative definitions for N_{MIN}, R_{MAX}, and F_R that can be used to calculate a mortality limit which can be used to evaluate the impact of known levels of human-caused mortality of marine mammals.

With perfect knowledge, a mortality limit of the product of N and R_{MNPL} would exactly maintain populations at *MNPL*. Thus, conceptually the *PBR* specifies the use of N_{MIN} to account for imprecision in the abundance estimate. Additionally, $\frac{1}{2}R_{MAX}$ is a conservative surrogate for R_{MNPL}, because $\frac{1}{2}R_{MAX}$ will always be less than or equal to R_{MNPL} if *MNPL* is greater than or equal to 50% of K (carrying capacity) (Fig. 1). Finally, F_R can be seen as both an additional factor to hasten the recovery of depleted populations and as a "safety" factor to account for additional uncertainties other than the precision of the abundance estimate. In statistical terms, using N_{MIN} addresses uncertainty due to imprecision which can be estimated. F_R, on the other hand, can be used to address potential biases caused by our ignorance of some important factors, such as stock boundaries.

Taylor (1993) used population simulations to compare the results of using two alternative definitions of N_{MIN}. She estimated PBR using mean abundance for N_{MIN} and using a lower, 2-tailed 95% confidence limit for N_{MIN}. Using the mean estimate of abundance for N_{MIN} (along with $F_R = 1.0$) resulted in many of the simulated populations being depleted (below *MNPL*) after 100 yr. In contrast, using the 95% lower confidence limit resulted in all populations being far above *MNPL* under the same conditions. Taylor (1993) also followed the structure used by the International Whaling Commission to test its Revised Management Plan (Donovan 1989) by performing "robustness" trials. In these trials, the performance of calculating the *PBR* in various ways was evaluated under simulations involving plausible flaws in the data or assumptions, such as substantial biases in the abundance or mortality estimates. In these robustness trials, a *PBR* calculated using the 95% lower confidence limit for N_{MIN} and an F_R of 0.5 also resulted in all simulated populations being far above *MNPL* after 100 yr.

It is worth considering whether other ways of estimating N_{MIN} are sufficient to maintain populations above *MNPL,* and whether other values of F_R are sufficient to account for potential bias or other problems with the data. The lower 95% confidence limit represents the 2.5th percentile of the sampling distribution of the abundance estimate, whereas the point estimate represents the 50th percentile. If the 2.5th percentile more than achieves the desired goal, but the 50th percentile does not, clearly some intermediate percentile could be found that would be just sufficient to result in a high probability that populations would be above *MNPL.* Similarly, various values of F_R could be tested to solve for a value that was just sufficient to account for "worst-case" scenarios of problems with the data or other information.

The intent of the proposed management scheme is to provide an appropriately conservative level for the *PBR* that will allow populations to recover to or remain above *MNPL* in spite of uncertainty, whether in the form of imprecise or biased information. R_{MAX} is unknown for most marine mammals, and only a moderate number of populations have available observed rates of increase. Gaining knowledge about the true value of R_{MAX} for any population of marine mammal is probably harder than estimating its abundance or human-caused mortality. I present a strategy that is based on assuming plausible default values for R_{MAX} for pinnipeds and for cetaceans (I will not consider what are appropriate values of R_{MAX} for other marine mammals). If population or species-specific information indicates that a value different from the default is appropriate, this specific value can and should be substituted for the default value. Thus, I proceed assuming a reasonable estimate for R_{MAX} is available (although significant bias in R_{MAX} will be addressed in the bias trials) and propose a scheme for estimating a mortality limit by ensuring that the product of N_{MIN} and F_R is less than the point estimate of abundance by a sufficient amount to achieve the management goal. The selection of an appropriate default R_{MAX} for cetaceans and for pinnipeds is discussed in the Appendix.

It is also worth considering how to set mortality limits for management objectives other than the specific U.S. MMPA goal of maintaining populations above *MNPL.* For example, one might be interested in a management goal of maintaining populations close to their pre-exploitation population level (*i.e.,* *K*). Another type of management goal might be to allow populations to grow at a rate close to what their population growth rate would be in the complete absence of human-caused mortality. This type of criterion might be useful for calculating a mortality limit that would promote the recovery of a population that is known to have declined to a very low fraction of its pre-exploitation size, such as 5%–20% of *K.* Therefore, I will briefly illustrate a method for calculating mortality limits to achieve these other management goals, again using Equation 1. However, for clarity, the product of such calculations will be referred to as a mortality limit (*ML*) rather than as a *PBR*, because the term *PBR* refers to a specific mortality limit intended to meet the objectives of the U.S. MMPA.

METHODS

Conservation Goals and Performance Criteria

Here I describe three specific conservation goals along with criteria designed to evaluate (by simulation) whether a mortality limit will achieve the desired goal. The first goal is that of the U.S. MMPA. I propose the second and third as other possible conservation goals.

MNPL goal—maintain populations above their maximum net productivity level (*MNPL*). This is the primary management goal of the U.S. MMPA. *PBR* is calculated using values of the two parameters N_{MIN} and F_R set according to these criteria:

(1) Base case criteria—find a value for N_{MIN} (as a percentile of a point estimate of abundance) such that (a) any population in the base case of an absence of significant biases in the data will be above *MNPL* with 95% probability after 100 yr (to measure long-term performance), under mortality equal to a *PBR* calculated with an F_R equal to 1.0, and (b) a population starting at *MNPL* will still be at or above *MNPL* in 20 yr (to measure short-term performance) with 95% probability.
(2) Bias criteria—find a value for F_R such that the above criteria (1(a) and 1(b)) are also met during bias trials in which the data are assumed to have plausible unknown problems, such as significant bias.

Carrying-capacity goal—allow a population to recover to a level close to its carrying capacity, or pre-exploitation population level.

Carrying-capacity criterion—find the value of F_R such that a population which then experiences that level of human-caused mortality will equilibrate above a specified fraction of its carrying capacity, with 95% probability. To distinguish this from a *PBR* calculated to meet the *MNPL* goal of the U.S. MMPA, a mortality limit calculated with this value of F_R will be called ML_K (mortality limit to achieve a population level close to K, the carrying-capacity).

Recovery-rate goal—allow a population known to be at a low level relative to its pre-exploitation level recover at a rate close to its maximum possible.

Recovery-rate criterion—find the value of F_R such that a population starting at just 5% of its pre-exploitation level will not be delayed by more than a specified percent in the time it takes to recover to its maximum net productivity level when it experiences that level of human-caused mortality (relative to the recovery-rate of a population with no human-caused mortality), with 95% probability. A mortality limit calculated with this value of F_R will be called ML_{Rec} (mortality limit to promote recovery).

Simulation Methods

Methods nearly identical to those of Taylor (1993) were used for the simulations. The underlying population dynamics model was a discrete form of the generalized logistic equation,

$$N_{t+1} = N_t + N_t R_{\text{MAX}}\left[1 - \left(\frac{N_t}{K}\right)^{\theta}\right] \tag{2}$$

where:

N_t = population size at time t,

R_{MAX} = the maximum net recruitment rate,

K = the pre-exploitation population size or carrying capacity,

θ = the shape parameter, which controls the amount of non-linearity in the density-dependent response of the net recruitment rate and thus sets the *MNPL* (see Fig. 1).

The procedure and sequence of each simulation were:

(1) The population was projected from year t to year $t + 1$ using Equation 2, with R_{MAX} equal to either 0.04 (typical of cetaceans) or 0.12 (typical of pinnipeds). In each simulation, $K = 10{,}000$, and $\theta = 1.0$, for a *MNPL* of $0.5K$, or 5,000.

(2) Every ith year (starting in year 1), an estimate of abundance was "surveyed" by randomly drawing from a log-normal distribution with a specified coefficient of variation CV(N).

(3) A *PBR* (or mortality limit) was then calculated from Equation 1, using the most recent survey.

(4) Incidental fisheries mortality was simulated by subtracting from the current population a Gaussian random deviate from a distribution with a mean equal to the *PBR* (or *ML*) and a coefficient of variation, CV(M), of 0.30.

(5) This sequence was repeated until the population was projected from year 0 to year 20, 100, or 200, depending upon the simulation. Each trajectory was initiated in year 0 at a population size equal to a specified fraction of K. The first survey occurred in year 1.

(6) For each trial, 2,000 trajectories were simulated, and the distribution of ending population sizes was stored. The mean and the 5th and 95th percentiles of this distribution were calculated. Thus, for example, if the lower percentile (representing the lower bound of a two-tailed 90% confidence limit) value was above *MNPL*, it could be concluded that more than 95% of the trajectories were above *MNPL*.

The sampling error of the survey was assumed to follow a log-normal distribution with a mean equal to the true population size, with a specified CV of either 0.2 or 0.8. Each abundance estimate, or "survey," was therefore generated by

Table 1. Specifications for the maximum population growth rate (R_{MAX}) and the coefficient of variation for each survey-based abundance estimate (CV(N)) for the four base case trials in the simulations.

Base cases	R_{MAX}	CV(N)
A. Cetacean, low CV	0.04	0.2
B. Cetacean, high CV	0.04	0.8
C. Pinniped, low CV	0.12	0.2
D. Pinniped, high CV	0.12	0.8

$$\hat{N}_t = \exp\left[\ln\left(\frac{N_t}{\sqrt{(1 + CV^2)}}\right) + x\sqrt{\ln(1 + CV^2)}\right] \tag{3}$$

where

x = a Gaussian random deviate with a mean of zero and a variance of 1.

N_{MIN} was calculated as the lower percentile of a log-normal distribution as

$$N_{MIN} = \frac{\hat{N}}{\exp(z\sqrt{\ln(1 + CV(N)^2)})} \tag{4}$$

where

z = a standard normal variate and thus equals 1.96 for the 2.5th percentile, 1.645 for the 5th, 1.282 for the 10th, 0.842 for the 20th, and so on.

MNPL Goal

Base case trials—A total of four "base cases" were considered (Table 1). To represent cetacean life history, two cases used an R_{MAX} of 0.04 for the *PBR* calculation (Eq. 1). One case used a CV(N) of 0.2 and the second used a value of 0.8. To represent pinniped life history, another two base cases used an R_{MAX} of 0.12 for the *PBR* calculation with the same combinations of CV(N). In all four base cases the "true" R_{MAX} in the population model (Eq. 2) was the same as the R_{MAX} used to calculate *PBR.*

Bias trials—A total of eight "bias trials" and the base case (trial 0) were considered (Table 2). Trials 1, 2, and 3 represented bias in the estimates of mortality, abundance, and R_{MAX}, respectively. Trials 4 and 5 represented situations where the variance of an estimate is severely underestimated. Trial 6 explored the result of surveying every eight years rather than every four years. Trial 7 had the true *MNPL* set to 0.45K rather than the assumed 0.5K. Trial 8 repeated trial 1 (bias in the estimate of mortality) but also had the true *MNPL* set to 0.7K rather than the assumed 0.5K. The magnitude of the assumed biases are given in Table 2. They were generally set to a level that was considered a plausible "worst-case scenario." However, deciding what level of unknown bias is plausible is an uncertain task. Some guidance can be gained

Table 2. Specifications for the bias trials for the simulation.

Trial	Description
0	Base case.
1	Estimated mortality equal to one-half the actual mortality.
2	Estimated N twice actual N.
3	Estimated R_{MAX} twice actual R_{MAX}. If estimated to be 0.04, actual R_{MAX} is set to 0.02. For estimated R_{MAX} of 0.12, actual R_{MAX} is set to 0.06.
4	Estimated abundance CV < actual CV (estimated CV of 0.2 actually 0.8, estimated CV of 0.8 actually 1.6).
5	Estimated mortality CV = one-quarter actual CV. CV(M) is set to 1.20 rather than 0.30.
6	Abundance estimated every 8 yr rather than every 4 yr.
7	True $MNPL$ equal to $0.45K$ ($\theta = 0.53$) rather than assumed $0.50K$ ($\theta = 1.0$).
8	Mortality bias as in trial 1 with true $MNPL$ equal to $0.70K$ ($\theta = 5.04$) rather than assumed $0.50K$ ($\theta = 1.0$).

from populations that have been studied more thoroughly than others. Justification for the plausibility of the specified magnitudes of bias is considered in the Appendix.

Carrying-Capacity Goal

The same four "base cases" were considered as above. The final population level after 200 yr (to allow time to equilibrate) was stored for simulated populations which started at $0.05K$ and experienced human-caused mortality at a level equal to ML_K, calculated with N_{MIN} equal to the 20th percentile for a range of values for F_R. It should be noted that the equilibrium level will be independent of the starting population level as long as the populations are projected for enough years, which was the case here.

Recovery-Rate Goal

The same four "base cases" were considered as above. First, a population was projected with no human-caused mortality from an initial population size of $0.05K$ to calculate how many years it took the population to reach $0.5K$. Then simulations which experienced human-caused mortality equal to ML_{Rec}, calculated with N_{MIN} equal to the 20th percentile and for a range of values for F_R, were performed, and again the year in which the population reached $0.5K$ was stored. For each simulation, the percent increase in time to recover to $0.5K$ was calculated.

Results

MNPL Goal

Base case trials—Using the best estimate of abundance (the 50th percentile) for N_{MIN} resulted in the majority of the trajectories ending up below 50% of

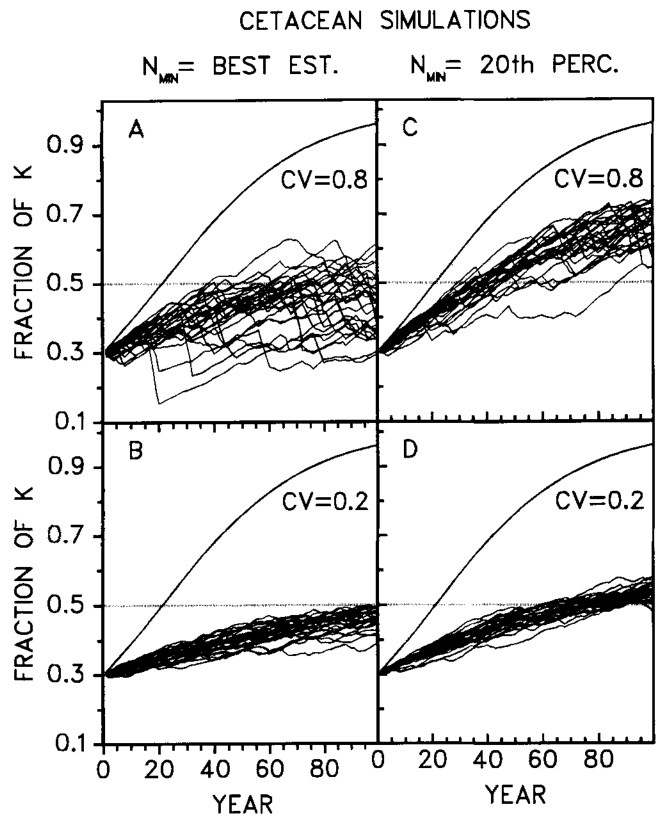

Figure 2. Simulated cetacean population trajectories (R_{MAX} = 0.04) with mean human-caused mortality equal to estimated *PBR*, showing 30 sample trajectories out of total of 2,000. Horizontal line represents maximum net productivity level (0.5*K*). Medium curved line represents a population trajectory with no human-caused mortality. The four panels differ in whether best estimate of abundance or 20th percentile of the abundance estimate was used for N_{MIN} and in whether abundance estimate has coefficient of variation (CV) of 0.2 or 0.8. (A) Using best estimate for N_{MIN} when CV = 0.8. (B) Using best estimate for N_{MIN} when CV = 0.2. (C) Using 20th percentile for N_{MIN} when CV = 0.8. (D) Using 20th percentile for N_{MIN} when CV = 0.2.

K, the *MNPL* (Fig. 2A, B; Fig. 3A, B). This replicated the results of Taylor (1993). In fact, in the pinniped simulations with poor precision of the abundance estimates (CV = 0.8), more than 5% of the trajectories went extinct (Fig. 3A; Fig. 4D). Using the 2.5th percentile (equivalent to the lower bound of a 2-tailed 95% confidence limit) for N_{MIN} resulted in all trajectories ending above *MNPL* for each case (Fig. 4), again replicating the results of Taylor (1993).

The percentile that just achieved the 100-yr performance criterion (95% of the trajectories above *MNPL* after starting at 0.3 of *K*) was close to the 20th percentile in all four base cases (Fig. 2C, D; Fig 3C, D; Fig. 4). A slightly

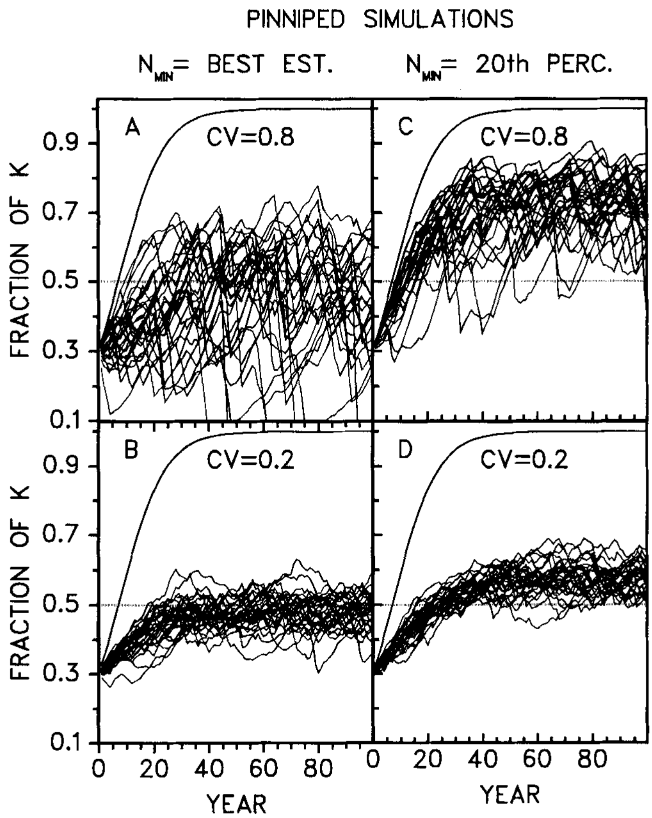

Figure 3. Simulated pinniped population trajectories ($R_{MAX} = 0.12$) with mean human-caused mortality equal to the estimated *PBR*, showing 30 sample trajectories out of a total of 2,000. Horizontal line represents maximum net productivity level (0.5*K*). Medium curved line represents population trajectory with no human-caused mortality. The four panels differ in whether best estimate of abundance or 20th percentile of abundance estimate was used for N_{MIN}, and in whether abundance estimate has coefficient of variation (CV) of 0.2 or 0.8. (A) Using best estimate for N_{MIN} when CV = 0.8. (B) Using best estimate for N_{MIN} when CV = 0.2. (C) Using 20th percentile for N_{MIN} when CV = 0.8. (D) Using 20th percentile for N_{MIN} when CV = 0.2.

higher value, the 25th percentile, was sufficient only for cetaceans with a high CV. Similar results were found for the 20-yr performance criterion (95% of the trajectories above *MNPL* 20 yr after starting at *MNPL*); the 20th percentile was sufficient or nearly sufficient in each case (Fig. 5). Therefore, using the 20th percentile for N_{MIN} achieved or nearly achieved both the 100- and 20-yr performance criteria.

Bias trials—After setting N_{MIN} equal to the 20th percentile of the abundance estimate, bias trial 1 (true mortality twice the estimated mortality) was run for a range of values of F_R. This type and magnitude of bias was considered a reasonable worst-case scenario, given the available information (Appendix).

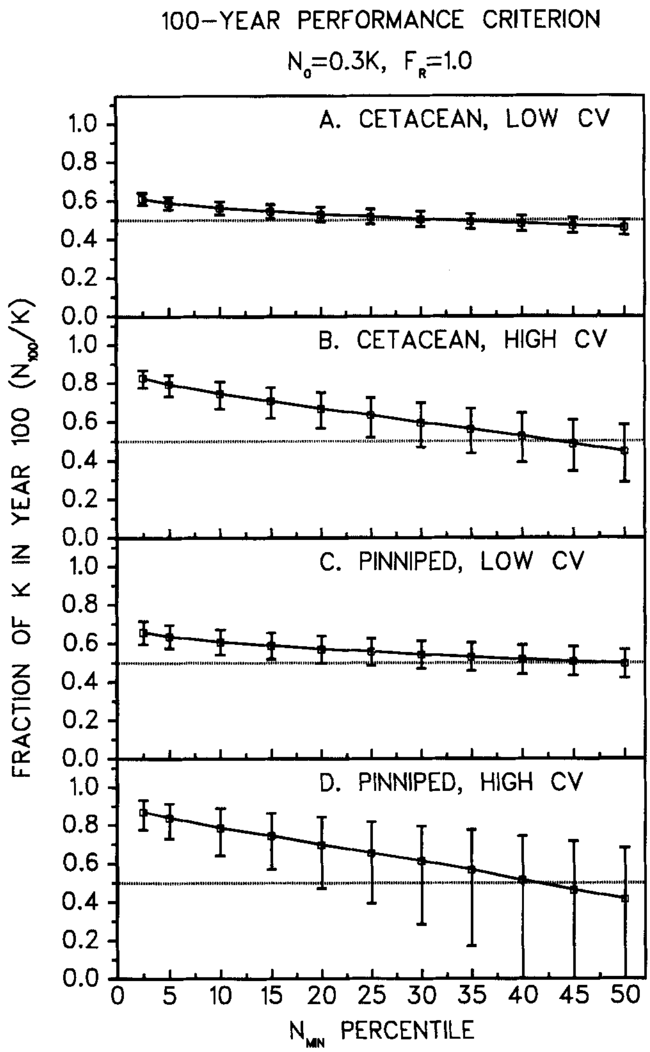

Figure 4. *MNPL* goal (100-yr performance criterion): population size after 100 yr *versus* percentile of abundance estimate used to calculate N_{MIN}, with F_R = 1.0 and initial population size equal to 0.3*K*. Boxes represent median value of simulations. Confidence limits capture 90% of simulations. Dotted line represents *MNPL* (0.5*K*). If lower confidence limit is above *MNPL*, simulation meets 100-yr performance criterion of 95% of trajectories ending above *MNPL*. (A) Cetacean (R_{MAX} = 0.04) with low CV (0.2). (B) Cetacean (R_{MAX} = 0.04) with high CV (0.8). (C) Pinniped (R_{MAX} = 0.12) with low CV (0.2). (D) Pinniped (R_{MAX} = 0.04) with high CV (0.8).

A value of 0.50 for F_R was sufficient or nearly sufficient for both pinnipeds and cetaceans to meet the 100-yr criterion, with 95% of the simulated trajectories above *MNPL* (Fig. 6). This is a consequence of the change in *PBR* being equivalent to the change in the mortality estimate due to the bias.

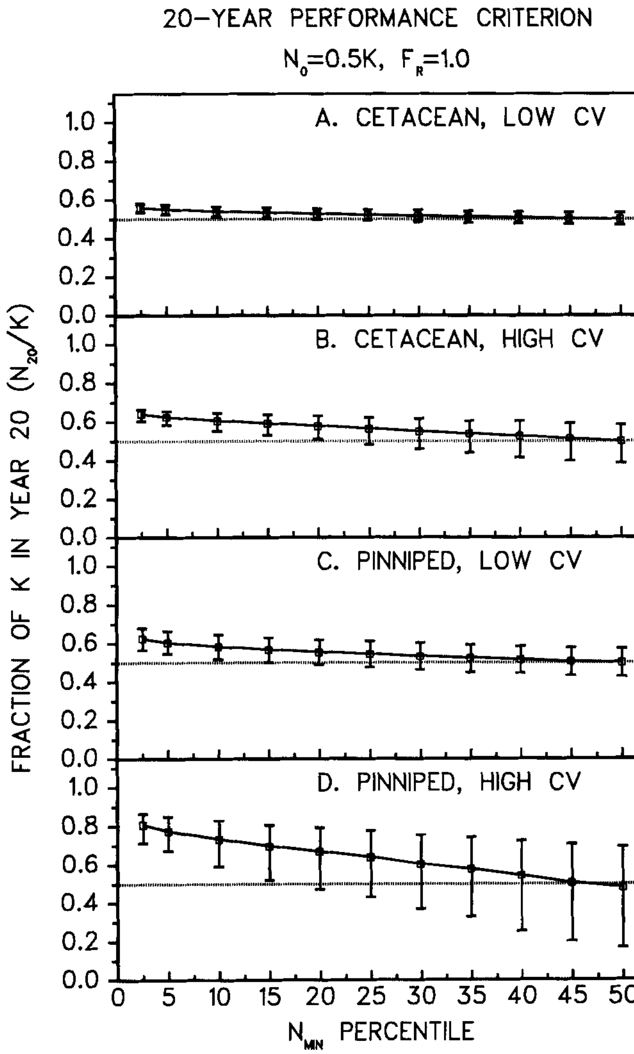

Figure 5. *MNPL* goal (20-yr performance criterion): population size after 20 yr versus percentile of abundance estimate used to calculate N_{MIN}, with F_R = 1.0 and initial population size equal to 0.5*K*. Boxes represent median value of simulations. confidence limits capture 90% of simulations. Dotted line represents *MNPL* (0.5*K*). If lower confidence limit above *MNPL*, simulation meets 20-yr performance criterion of 95% of trajectories ending above *MNPL*. (A) Cetacean (R_{MAX} = 0.04) with low CV (0.2). (B) Cetacean (R_{MAX} = 0.04) with high CV (0.8). (C) Pinniped (R_{MAX} = 0.12) with low CV (0.2). (D) Pinniped (R_{MAX} = 0.04) with high CV (0.8).

Setting F_R equal to 0.5 compensated for accidentally halving the mortality estimate and yielded the correct comparison between *PBR* and mortality.

The full bias trials confirmed that the combination of the 20th percentile for N_{MIN} and an F_R of 0.50 would meet or nearly meet the 100-yr criterion in all cases and trials (Fig. 7). Not surprisingly, bias trials 2 and 3 (overesti-

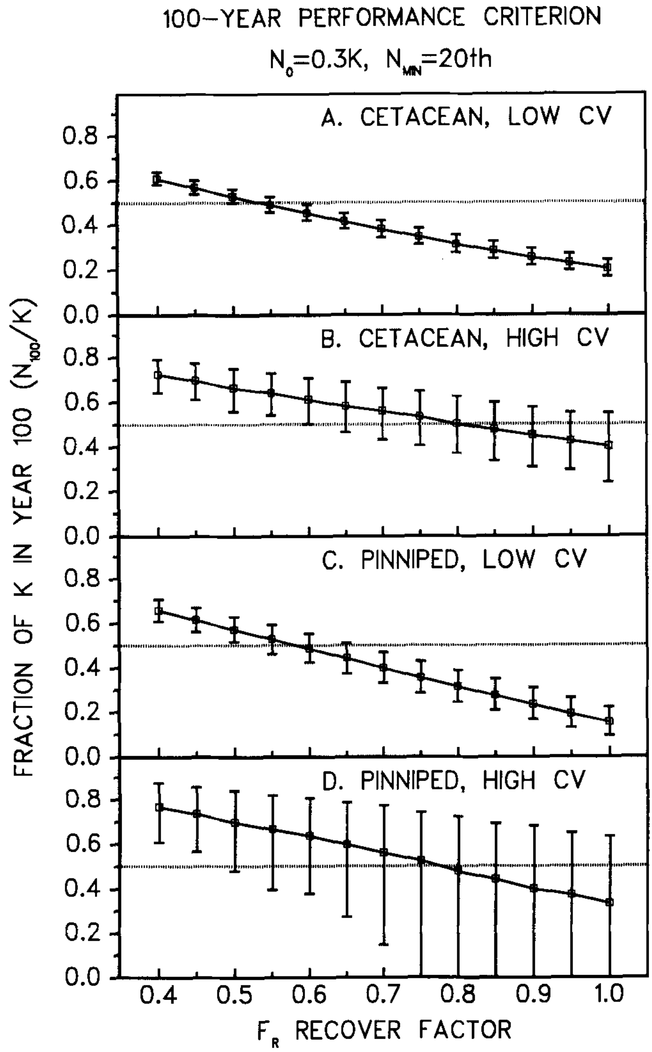

Figure 6. *MNPL* goal: bias trial 1 (true mortality twice estimated mortality), showing population size after 100 yr *versus* recovery factor (F_R) used to calculate *PBR*, with initial population size = 0.3*K*. Boxes represent median value of simulations. Confidence limits capture 90% of simulations. Dotted line represents *MNPL* (0.5*K*). If lower confidence limit is above *MNPL*, simulation meets 100-yr performance criterion of 95% of the trajectories ending above *MNPL*. (A) Cetacean (R_{MAX} = 0.04) with low CV (0.2). (B) Cetacean (R_{MAX} = 0.04) with high CV (0.8). (C) Pinniped (R_{MAX} = 0.12) with low CV (0.2). (D) Pinniped (R_{MAX} = 0.04) with high CV (0.8).

mating population size or R_{MAX} by a factor of 2) had similar results. Trials 2 and 3 both involved direct elements of the *PBR* equation and thus doubled the size of the *PBR*, whereas trial 1 effectively halved the mortality estimate. Bias trials 1, 2, and 3 had the greatest effect in terms of reducing the final population level after 100 yr relative to bias trial 0 (no bias).

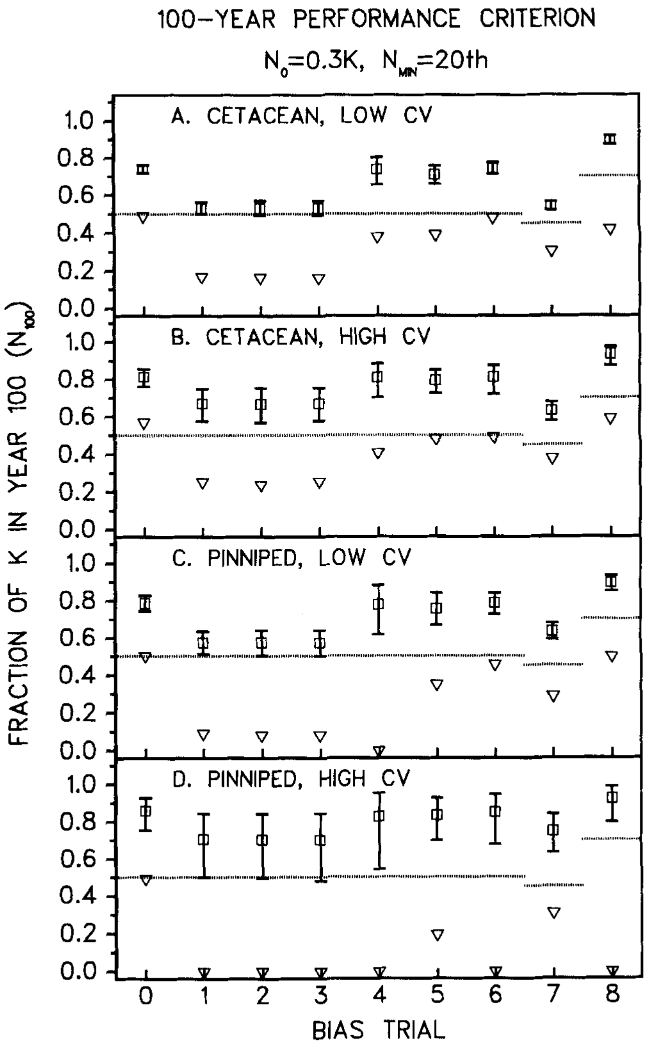

Figure 7. *MNPL* goal: population size after 100 yr for all bias trials, using 20th percentile for N_{MIN} and 0.5 for F_R, with initial population size = 0.3*K*. Boxes represent median value of simulations. Confidence limits capture 90% of simulations. Dotted line represents *MNPL*. If lower confidence limit is above *MNPL*, simulation meets 100-yr performance criterion of 95% of trajectories ending above *MNPL*. Triangles are lower confidence limits from simulations using F_R = 1.0 and thus represent effect of not accounting for unknown bias. (A) Cetacean (R_{MAX} = 0.04) with low CV (0.2). (B) Cetacean (R_{MAX} = 0.04) with high CV (0.8). (C) Pinniped (R_{MAX} = 0.12) with low CV (0.2). (D) Pinniped (R_{MAX} = 0.04) with high CV (0.8). Bias trials are (0) base case (no bias), (1) mortality, (2) abundance, (3) R_{MAX}, (4) abundance CV, (5) mortality CV, (6) survey frequency, (7) true *MNPL* = 0.45*K*, (8) mortality bias with true *MNPL* = 0.70*K*.

Severely underestimating the CV of the abundance estimate (trial 4) did not have as much effect in reducing the final population size except for the pinniped high-CV case. A value of 0.5 for F_R was sufficient to prevent depletion in that case and was more than sufficient in all the other cases. When the variance of the mortality estimates was severely underestimated (trial 5), there was less of an effect on the final population size, and an F_R of 0.5 was more than sufficient to prevent depletion. Doing abundance surveys every eight years instead of every four years (trial 6) had a strong effect only on the final population size of the pinniped, high-CV case, and again the value of 0.5 was sufficient to prevent depletion.

The effect on the final population size of an *MNPL* lower than the assumed $0.5K$ (trial 7) was moderately strong and was enough to cause depletion in each case (note that depletion here is defined as being below the different *MNPL* of $0.45K$). A value of 0.5 for F_R was more than sufficient to prevent depletion in most cases, but only by a small margin in the cetacean low-CV case. As expected, when the true *MNPL* was $0.7K$ (trial 8) in combination with biased mortality estimates, the population did relatively better than when the true *MNPL* was $0.5K$ (trial 1), although the effect of the bias in mortality was still enough to cause the populations to be depleted. Using F_R equal to 0.5 was then more than sufficient to prevent depletion.

In all cases the results from the bias trials for the 20-yr performance criterion were very similar to the results for the 100-yr criterion and thus are not shown. A recovery factor of 0.5 was just sufficient to meet the 20-yr performance criterion for trials 1–3 and more than sufficient for the other trials.

Carrying-Capacity Goal

The resulting distributions of population levels after 200 yr are shown for various values of F_R (Fig. 8). To achieve a goal of allowing a population to recover to at least a specific fraction of K, the lower confidence limit has to be above that level. For example, a limit of ML_K calculated with a value for F_R of 0.15 would be required for 95% of the simulations to be above $0.9K$ in all four cases. Alternatively a limit of ML_K calculated with a value for F_R of about 0.1 would be required for 95% of the simulations to be above $0.95K$ in all four cases.

Recovery-Rate Goal

The resulting distributions of percent increases in recovery time to *MNPL* are also shown for various values of F_R (Fig. 9). To achieve a goal of not delaying the time to recovery with 95% probability, the upper confidence limit has to be less than or equal to the specified percent increase in recovery time. For example, to not delay the time to recovery by more than 10%, the upper confidence limit has to be below the line shown in Fig. 9. Therefore, a limit of ML_{Rec} calculated with a value for F_R of 0.15 should accomplish

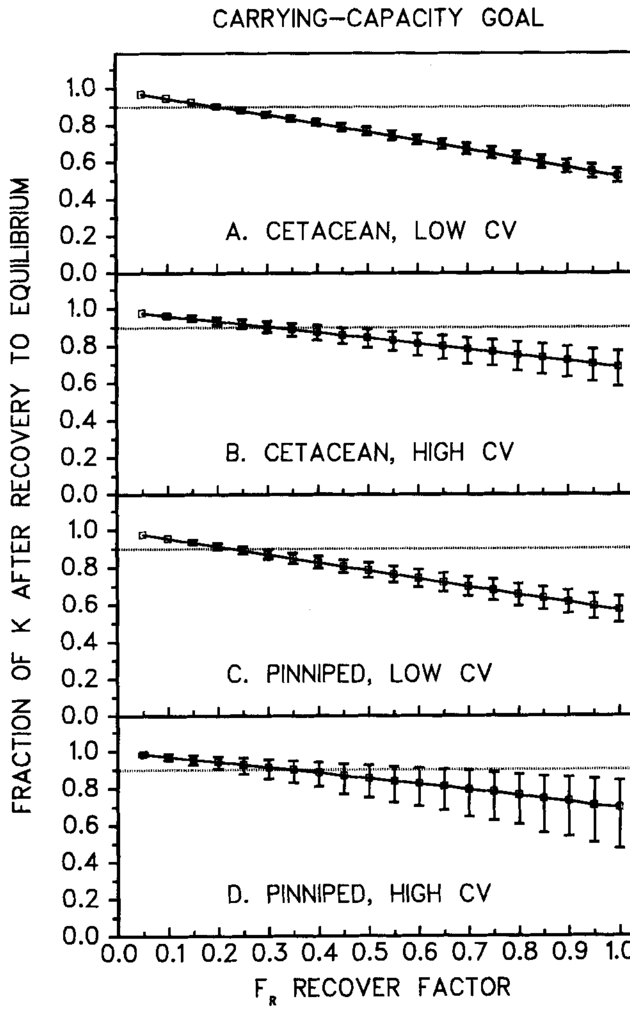

Figure 8. Carrying-capacity goal: population size after 200 yr *versus* value of recovery factor (F_R) used to calculate mortality limit ML_K, using 20th percentile for N_{MIN}. Initial population size = 0.05K but does not influence results as 200 yr is sufficient time for population trajectories to reach equilibrium. Boxes represent median value of simulations. Confidence limits capture 90% of the simulations. Dotted line represents example of possible conservation goal of maintaining populations at greater than specified fraction of K. If lower confidence limit is above line, 95% of trajectories would be at level greater than 0.9K. (A) Cetacean (R_{MAX} = 0.04) with low CV (0.2). (B) Cetacean (R_{MAX} = 0.04) with high CV (0.8). (C) Pinniped (R_{MAX} = 0.12) with low CV (0.2). (D) Pinniped (R_{MAX} = 0.04) with high CV (0.8).

this goal in all cases. Alternatively, a limit of ML_{Rec} calculated with a value for F_R of 0.25 would accomplish a goal of not delaying recovery by more than 20% for a cetacean population with a low CV (Fig. 9A), whereas a higher value of F_R would be sufficient in the other cases (Fig. 9B, C, D).

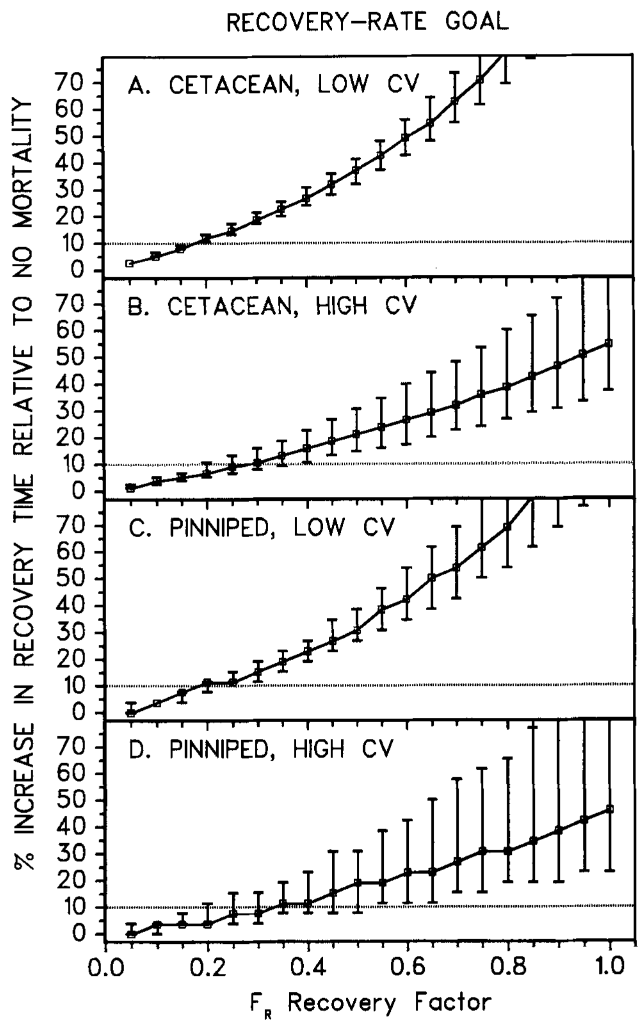

Figure 9. Recovery-rate goal: percent increase in time to recovery relative to population with no human-caused mortality, *versus* various values for recovery factor (F_R) used to calculate the mortality limit ML_{Rec}. Recovery is defined as achieving *MNPL,* although recovery to any specified population level will be delayed by approximately same percentage. Boxes represent median value of simulations. Confidence limits capture 90% of simulations. Dotted line represents 10% increase in recovery time. If upper confidence limit below 10% line, simulation meets example recovery-rate goal of 95% of trajectories not being delayed in their time to recovery by more than 10%. (A) Cetacean (R_{MAX}= 0.04) with low CV (0.2). (B) Cetacean (R_{MAX} = 0.04) with high CV (0.8). (C) Pinniped (R_{MAX} = 0.12) with low CV (0.2). (D) Pinniped (R_{MAX} = 0.04) with high CV (0.8).

DISCUSSION

MNPL Goal

Base-case trials—A sample of 30 of the simulation trajectories gives a visual representation of the performance of the chosen value of the 20th percentile for N_{MIN} (Fig. 2, 3; panels C and D). The desired properties of the management scheme are evident; depleted populations steadily recovered to a population level above *MNPL* and stayed there, in spite of uncertainty in the estimates of abundance and mortality. Additionally, motivation exists to improve the precision of the estimates of abundance, because for a given population level the *PBR* will be higher when the CV of the abundance estimate is lower (*e.g.,* in Fig. 1, lower panels, the expected *PBR* with a CV = 0.2 would be higher than the expected *PBR* with CV = 0.8). The *PBR* successfully allowed depleted populations to recover to above *MNPL* over 100 yr (the 100-yr criterion, Fig. 4) and also successfully maintained populations above *MNPL* over 20 yr (the 20-yr criterion, Fig. 5).

Although model simulations were used here to select specific values, one good characteristic of the *PBR*-based management approach is that all three components of the *PBR* have intuitive meaning by themselves and in how they are put together to calculate *PBR.* In other words, they have meaning apart from the specific population dynamics model used in the simulations. The *PBR* can be thought of as an appropriately conservative estimate of what the current net production of the population would be if it were currently at a true *MNPL* of 0.5*K.*

One half of R_{MAX} should be a conservative estimate of the current net production rate of a depleted population (*i.e.,* a depleted population should achieve more than $\frac{1}{2}R_{MAX}$ if there are no Allee effects), thus reserving part of the net production of the population for recovery. It will not be a conservative estimate if the population is not depleted. The 20th percentile of the abundance estimate represents a population level that should be smaller than the true population size and is based on the familiar concept of a lower confidence limit of the abundance estimate. Thus, current production is calculated from appropriately conservative values of the current production rate and the current population size. Using a recovery factor of less than 1.0, such as 0.5, provides a safety factor to account for levels of unknown bias or estimation problems that have been observed in some populations of marine mammals and would also account for less severe biases co-occurring, such as overestimating R_{MAX} while underestimating mortality.

It would be possible to perform simulations tailored to the specific information available for a particular stock. In other words, a *PBR* for each stock could be calculated from a unique simulation determined by the stock's specific estimates of abundance, mortality, and their associated CVs. However, a panel of scientists convened to review this issue recommended a simpler approach (Barlow *et al.* 1995*b*). That is, there is utility in having the *PBR* calculated from familiar quantities (such as a predetermined confidence limit) so that the process of calculating a mortality limit can be more transparent and intuitive to the casual observer rather than being a quantity that just emerges from a complex computer simulation.

Setting N_{MIN} equal to the 20th percentile of an abundance estimate maintained about 95% of the simulated populations above *MNPL* for all four base cases. It would be possible to calculate for each specific base case an exact percentile (that would be close to but different from the 20th percentile) that would meet the 100-yr performance criterion exactly for that particular base case. However, it is likely that a different percentile would result from meeting the 20-yr performance criterion exactly, and then it would be uncertain which percentile should be used. Additionally, as reasonable as the base-case simulations are, no one can be confident that they exactly represent the true dynamics of any real marine mammal population. Therefore, there is no strong reason to calculate an exact percentile for each case. Thus, the 20th percentile serves as a generic standard that can be expected to work reasonably well in a variety of real world situations.

Some examples illustrate the use of the *PBR*. Harbor porpoises (*Phocoena phocoena*) are killed incidentally in gillnet fisheries throughout their range. The Gulf of Maine population of harbor porpoises is impacted by the sink gillnet fishery. Abundance surveys in 1991 and 1992 led to a combined estimate of 47,200 (CV = 0.19) (Palka 1995). The 20th percentile of the abundance estimate is 40,297. Using the default R_{MAX} of 0.04 and a value of 0.5 for F_R means that the *PBR* is equal to $0.01N_{MIN}$, and is thus 403. Total fisheries mortality in 1993 was estimated to be 1,876, which is more than four times the *PBR* (Blaylock *et al.* 1995). In this case, the *PBR* calculation identified a population for which the mortality may not be sustainable.

Similarly, harbor porpoises in central California have been killed in the set gillnet fishery for Pacific halibut for many years, which may have caused the population to decline (Forney 1995). The most recent abundance estimate for this stock is 4,120 (CV = 0.31) from surveys from 1988 to 1993 (Barlow and Forney 1994), which results in an N_{MIN} of 3,431 and a *PBR* of 34. Fisheries mortality was greater than 100 per year for every year from 1979 to 1987, with a peak of 303 in 1984 (Barlow and Forney 1994). Fisheries mortality has decreased since the peak but was still equal to or greater than the *PBR* in every recent year through 1992. A substantial drop in fishing effort led to an estimated mortality in 1993 of only 11 animals. Thus, for this stock, human-caused mortality was greater than the *PBR* and may have caused a decline in the population, but the 1993 level of mortality was probably sustainable.

As a final example, harbor seals (*Phoca vitulina richardsi*) in Oregon and Washington coastal waters have been incidentally killed in several gillnet fisheries. In 1991–1992, the estimated mortality in the Washington and Oregon lower Columbia River drift gillnet fishery for salmon was an average of 213 harbor seals a year, with total mortality (including two other fisheries) estimated at 233 per year. The abundance of this population in 1992 was estimated to be 29,939 (CV = 0.062), which results in an N_{MIN} of 28,322 (Barlow *et al.* 1995*a*). A *PBR* calculated as the product of N_{MIN}, 0.06 (½ of the R_{MAX} of 0.12), and 0.5 (F_R) would be 849. The estimated human-caused mortality is well below this hypothetical conservative *PBR*[1], and therefore it can be concluded that this level of mortality is sustainable. Corroborating this conclusion is the evidence that this population is currently increasing in size (Barlow *et al.* 1995*a*).

Bias trials—The bias trials involve levels of bias that should be relevant to a variety of marine mammal populations, as most of the specified magnitudes of bias have been noted at least one time in real situations (Appendix). Past experiences with potential biases in estimates of mortality, abundance, and R_{MAX} (trials 1–3), as well as the definition of stock structure, lend justification to the concept of using a safety factor to guard against unknown biases when potential problems cannot be ruled out. Trials 4 and 5 indicate that biases in the estimated variances of mortality and abundance are less worrisome. In situations where it is known there is no bias in the parameters, and where the stock structure is accurately identified, a *PBR* calculated with an F_R of 1.0 should be a sufficient limit for human-caused mortality. However, the question remains as to when one will be sufficiently confident that no bias exists and that the stock structure is correctly identified. Only the most well-studied marine mammal populations will meet such high standards. Therefore, the default case should be to use a value of F_R less than 1.0, such as the value of 0.5 that was shown here to pass the specified bias trials. This will ensure a robust management procedure that will work for populations of unknown status, even under conditions of fairly severe bias in the collection of data. Populations meeting specified criteria regarding available information could have F_R increased from the default value. This potential would encourage the collection of better information when the effect of a certain level of human-caused mortality on a population is in question. One possible criterion for increasing F_R could be if a population increases while experiencing a known level of incidental mortality, which provides confirmation that such a level of mortality is sustainable. However, before such action is taken to raise the F_R value from the default value, reasonable assurance in the form of scientific justification should be provided to ensure that the estimates of abundance, mortality, and R_{MAX} are not severely biased and that the coefficients of variation of the abundance and mortality estimates are within the range used in these simulations (< 0.8 for the abundance estimate, < 0.30 for the mortality estimates).

The simulations were run assuming *MNPL* was 0.5*K*. If *MNPL* is actually higher than 0.5*K*, populations will achieve higher population levels than they would have with *MNPL* equal to 0.5*K*. For example, in bias trial 8, which is identical to trial 1 except for having an *MNPL* of 0.7*K* rather than 0.5*K*, the simulated trajectories reach both a greater population level and a greater level relative to *MNPL* (Fig. 7). This occurs because the *PBR* is calculated assuming a growth rate of $\frac{1}{2}R_{MAX}$ at 0.5*K*, but populations with an *MNPL* greater than

[1] Note that the actual *PBR* for this stock was 1,699; $F_R = 1.0$ was used because the population is significantly increasing (Barlow *et al.* 1995*a*).

$0.5K$ will actually be growing at a rate higher than $\frac{1}{2}R_{MAX}$ when they are at $0.5K$ (Fig. 1). The inability to precisely estimate *MNPL* for any marine mammal population, even some of the best studied (Ragen 1995), is part of the motivation for moving to a management scheme that does not require knowing what the *MNPL* actually is. The proposed management scheme is robust to higher values of *MNPL*. In such cases a population with human-caused mortality as great as the *PBR* would exceed the performance criteria specified here (*i.e.*, the *PBR* would be conservative relative to the goal of having 95% of the trials meet the short-term and 100-yr performance goals).

Bias trial 8 indicated by how much the population might exceed the performance criterion. Under the condition of true mortality twice the estimated mortality, with F_R equal to 1.0, it can be seen that populations with *MNPL* equal to $0.7K$ would still become depleted. The additional benefit to the population of the higher *MNPL* level was not enough to compensate for the biased mortality estimates. When F_R is set to 0.5, all of the simulated populations recover (as expected) to higher population levels than those of trial 1, where *MNPL* was equal to $0.5K$ (Fig. 7). Such populations exceed the performance criterion by a moderate to large amount, whereas when the true *MNPL* was $0.5K$, the populations just met the performance criterion (trial 1). This amount of potential extra conservatism seems a reasonable trade-off, *versus* the possibility of depletion given the complete lack of information regarding specific *MNPL* levels.

Note that in each bias trial only one parameter was assumed biased (except trial 8). In real situations, consideration needs to be given to the possibility of multiple biases.

The Carrying-Capacity and Recovery-Rate Goals

The goals of the U.S. MMPA are reasonable but, of course, are not the only goals which could be considered for managing the human-caused mortality of marine mammals. For example, one possible conservation goal could be to maintain populations at or near their pre-exploitation level (*i.e.*, their population level in the absence of human-caused mortality). Under the U.S. MMPA, a population previously unexploited would be allowed to decline to a level just above *MNPL*, which could be a level as low as 50% of *K*. However, such a decline would be unacceptable if one had the goal of maintaining populations close to their pre-exploitation levels. Conservation goals are rarely stated in specific quantitative terms. However, if a specific goal can be stated, such as maintaining populations at a level above 90% of *K*, then a limit of ML_K can be set by choosing the appropriate value for F_R from Figure 8.

The second type of alternative goal considers the population growth rate rather than the final population level; this might be most appropriate for managing the human-caused mortality of populations that are at a small fraction of their pre-exploitation level. Ensuring that the time to recovery is not substantially delayed is a way of ensuring that the population growth rate is not substantially reduced, thus promoting recovery. Like the use of the *PBR*, setting a mortality limit in this way allows a management scheme to work without requiring one to be able to estimate precisely the exact level of the population relative to its pre-exploitation size, as the limit ML_{Rec} is based on an abundance estimate and is calculated in the same way regardless of the current population level. In other words, this scheme can be applied to populations which are thought to be at a low level even if it is impossible to know precisely where they are relative to *K*.

The mortality limit ML_{Rec} may be useful for species given special protection status because they are at a low level. For example, in the U.S., most large whales were listed as "Endangered" under the U.S. Endangered Species Act because they were thought to have been reduced to low population levels by commercial whaling. Therefore, the U.S. in calculating *PBR*s chose to use a value of 0.1 for F_R for these species, based partly on the rationale that this would not cause more than a 10% increase in the time to recovery (Barlow *et al.* 1995*b*). Such a mortality limit should allow a large fraction of the net production of the population to go to population increase and eventual recovery and should thus have a relatively insignificant negative impact upon the population.

However, managing the human-caused mortality of endangered species involves some special considerations. A mortality level that is not thought to have much of an impact on the population growth rate would appear to be insignificant. However, for populations of extremely low abundance, any human-caused mortality may be significant. For such populations, the effect of human-caused mortality needs to be evaluated in the context of how much it might increase the risk of extinction for the population, which is beyond the scope of this paper. In other words, the goal of not delaying recovery time does not substitute for a proper population viability analysis (Gilpin and Soule 1986) that considers other factors, such as environmental and demographic stochasticity, that is most appropriate for evaluating the human-caused mortality of a small population that is at risk of extinction.

Additionally, situations where a population is declining for unknown reasons makes the evaluation of known human-caused mortality difficult. A mortality limit may still be useful in evaluating the role of various known sources of human-caused mortality. For example, if a declining population has an incidental fisheries mortality that is less than the *PBR*, one can then fairly reliably conclude that the fisheries mortality is not solely responsible for the decline. This allows managers to set research priorities; in this case they would need to investigate other possible causes of the decline besides the fisheries mortality.

Model Assumptions

The generalized logistic model used in these simulations is admittedly one that oversimplifies nature. However, it should accurately represent the main features of marine mammal population dynamics that are important to setting limits for human-caused mortality, with certain caveats discussed below.

The base trials assumed that *MNPL* was at least 0.5*K*. Eberhardt (1977) suggested that *MNPL* might be well above 0.5*K* for marine mammals, which corresponds to a convex non-linear response of the net recruitment rate to population size (*e.g.*, Fig. 1 with *MNPL* = 0.7*K*). Fowler (1981) used a model based on an evolutionary argument to infer that cetaceans would have an *MNPL* level well above 0.5*K*. Empirical evidence that is available for large, long-lived mammals has shown convex non-linear density dependence in life history parameters such as age-specific birth and mortality rates (Fowler *et al.* 1980; Fowler 1987, 1994), which would again indicate *MNPL* > 0.5*K*. Similarly, the data sets available for marine mammals, though fewer in number (Fowler 1984), are generally consistent with those found for large terrestrial mammals. Goodman (1980) showed that a linear density-dependent change in only the birth rate (which implies *MNPL* = 0.5*K*) would actually cause the population growth curve to be convex (*MNPL* > 0.5*K*). Taylor and DeMaster (1993) reviewed the available empirical data and concluded that (1) marine mammals show density-dependent responses, (2) these responses are not abrupt changes close to *K* (*i.e.*, knife-edge), and (3) these responses have not been shown to be concave, though the statistical power to detect concavity is low. Their analyses showed that combinations of even highly convex density-dependence in more than one life history parameter translates into a population level response where the inflection point of the growth curve (*i.e.*, *MNPL*) occurred at a population level that was less than 0.8*K*. Further, a concave population response could be produced only by the combination of linear responses in several life-history parameters. This, in combination with the lack of evidence for concave responses in life history parameters, led them to conclude that *MNPL* > 0.5*K* (Taylor and DeMaster 1993).

As shown and discussed above, the *PBR* scheme is robust to population dynamics which have a value for *MNPL* greater than 0.5*K*. Bias trial 7 showed that a value for F_R of 0.5 would be sufficient to make the scheme robust to values of *MNPL* as low as 0.45*K*. At some lower value for *MNPL* the scheme would no longer be robust, but there is little evidence to suggest such dynamics in large mammals. Such a low *MNPL* implies that individual animals feel the effects of the addition of another animal to the population much more strongly at very low densities than at high densities. In Figure 1 it can be seen that a value of less than 0.45*K* for *MNPL* would imply that a population can achieve a *per capita* growth rate of more than half its maximum possible value only when it is reduced to less than about 25% of its carrying capacity. Although such strongly concave dynamics in a single life-history parameter of a large mammal are not known to occur, it should be recognized that MacCall and Tatsukawa (1994) provided a theoretical mechanism for producing such dynamics from strong density-dependent habitat selection combined with certain types of habitat gradients (see the Appendix for further discussion of this point).

The generalized logistic model does not have what is referred to as the Allee effect, where at some point the net production rate declines as population size gets lower, rather than continuing to increase. Fowler and Baker (1991) concluded that the Allee effect was likely to be a common phenomenon in animal population dynamics, especially populations at a level less than $0.1K$. Therefore, the Allee effect is an important consideration for assessing the risk of extinction (Fowler and Baker 1991) but would likely not be of significance to the *MNPL* goal simulations performed here, as those simulations all start at $0.3K$ or higher. However, the Allee effect could influence the recovery time of populations reduced to lower levels and thus warrant further attention for calculations of ML_{Rec}.

The generalized logistic model also does not explicitly take into account the age and sex structures of the population. This should not make a difference in estimates of N_{MIN} or F_R as long as the human-caused mortality is relatively random with respect to age and sex. However, if the human-caused mortality is highly selective, it could be a cause for concern. Higher mortality of females relative to males would likely cause a population to decline to a lower level than if the mortality were random. Similarly, selective mortality of animals close to the age of sexual maturity would also have a greater impact, as these are the animals with the greatest reproductive value to the population. Where possible, data on the age and sex distributions of the animals killed should be collected. If such data indicate that the mortality is highly selective, a case-specific simulation could be used to calculate a *PBR* in a way similar to the approach used here, but using an age- and sex-structured model to account for selective mortality.

The model used is deterministic rather than stochastic, meaning that there is no variability in the population growth rate at a particular population size due to environmental variance. Simulations using a stochastic model would be possible, but specifying the amount of environmental variance to simulate for cetaceans may be difficult because such data are difficult to obtain. For pinnipeds, it is often possible to see environmental effects upon populations, such as large changes in the number of pups produced from one year to the next. The simulation results presented here may be relatively robust to environmental variance, as the *PBR* will be self-correcting in one sense; a sudden decline in a population due to unfavorable environmental conditions will be reflected in a lower subsequent abundance estimate and thus result in a lower *PBR*. However, it would still be useful to investigate the effects of stochastic dynamics through simulations which incorporated plausible levels of environmental variance.

Alternatives

There are other ways that N_{MIN} and F_R could be adjusted to meet the same performance criteria specified here. For example, F_R could be set to 1.0 and then the N_{MIN} percentile could be found that would have passed the bias trials. Alternatively, a point estimate of abundance could be used for N_{MIN}, and the value of F_R could be found that would have passed the bias trials. However, the two-part procedure suggested here has some desirable qualities. First, using a lower confidence limit for N_{MIN} is an intuitively reasonable method of accounting for the uncertainty of an abundance estimate. For management in the U.S., it also meets the intent of the 1994 amendments to the MMPA, which state that N_{MIN} "(A) is based on the best available scientific information on abundance, incorporating the precision and variability associated with such information; and (B) provides reasonable assurance that the stock size is equal to or greater than the estimate." Second, using a lower confidence limit encourages improving the precision of abundance estimates, as lower CVs result in higher *PBR*s. Third, separating the factors that account for precision (N_{MIN}) and other uncertainties such as bias (F_R) allows for flexibility in management. Finally, as discussed before, a *PBR* calculated this way has some biological meaning, as the product of N_{MIN} and R_{MAX} represents a conservative estimate of what the current net production would be if the population were at *MNPL,* and the recovery factor accounts for possible unknown biases and problems.

Another area that could be explored would be how to combine abundance estimates to improve precision. The simulations used here ignored previous abundance estimates once a new "survey" was performed. Use of previous estimates would involve a trade-off between improving precision by using more data and increasing potential bias from using abundance estimates made when the population was possibly at a different size. The performance of various methods of combining abundance estimates over a specified time period could easily be investigated, using the same simulation framework presented in this paper.

Conclusions

Adjusting the values of N_{MIN} and F_R to meet specific criteria should allow for a robust management procedure that will prevent the depletion of marine mammal populations by known human-caused mortality. This can be accomplished without being unnecessarily conservative or restrictive on the sources of human-caused mortality, such as commercial fisheries. If an estimate of human-caused mortality exceeds the calculated *PBR* for a population, it should serve as a warning that the mortality could lead to the depletion of the population.

It is important to note the distinction between estimating mortality to be greater than the *PBR versus* detecting a significant decline in abundance. Where mortality exceeds the *PBR,* it may be sufficient to cause a decline in abundance and subsequent depletion. This situation can be identified with only a single abundance estimate. This is not the same as directly detecting a significant decline in abundance, which generally takes many years of data (Gerrodette 1987). Initially, some populations with sustainable levels of human-caused mortality may, by chance alone, have estimated mortality greater than *PBR.* However, if the level of mortality is truly sustainable, subsequent estimates will show mortality to be less than or equal to the calculated *PBR.* The simulations performed here must be interpreted to mean that if mortality is consistently estimated to be greater than the *PBR* over many years, then the population will become depleted with a probability estimated to be > 0.05. Estimating incidental mortality in one year to be greater than the *PBR* calculated from a single abundance survey does not prove the mortality will lead to depletion; it identifies a population worthy of careful future monitoring and possibly indicates that mortality-mitigation efforts should be initiated.

Acknowledgments

Credit for developing the concept of a *PBR*-based management scheme is due mostly to Jay Barlow and Doug DeMaster. Additionally, they, along with Barbara Taylor, gave me much guidance in developing the concept of the simulation study presented here. The particular strategy used here for setting N_{MIN} and F_R evolved from discussions with Jay Barlow, Barbara Taylor, and Tim Gerrodette. I must also acknowledge that the discussions held at the *PBR* Workshop, 27–29 June 1994, greatly influenced the final form of this manuscript, and I thank all the workshop participants. The manuscript was greatly improved by thorough reviews from Jay Barlow, Douglas P. DeMaster, Barbara L. Taylor, William F. Perrin, and two anonymous reviewers. The author was supported during the initial part of this work by a National Research Council Associateship funded by the Southwest Fisheries Science Center, National Marine Fisheries Service, La Jolla, California.

APPENDIX

Plausibility of the Specified Bias Trials

The specified types and magnitudes of bias were chosen because they were thought to represent real possibilities. Justification for the selected levels of bias is presented here. Because the bias trials represent simulations under conditions of unknown bias, there is no definitive way to objectively determine what the magnitude of an unknown bias might be. However, it is possible to examine known biases to gain some insight into what plausible unknown biases might be.

Trial 1: Mortality Estimates

There are several ways in which estimates of incidental fisheries mortality can be biased. Usually, only a small fraction of all fishing trips are observed in a fishery, and mortality rates from those observed fishing trips are extrapolated to the total effort of the fishery. This standard method will give an unbiased estimate of marine mammal mortality only if the observed trips are representative of all trips. One way in which this assumption can be violated is if there are "observer effects" in which the behavior of the fishermen is different when they carry an observer aboard than when they do not. For example, a statistical analysis concluded that significant observer effects occurred in the eastern tropical Pacific tuna purse-seine fishery (Wahlen and Smith 1985). However, this fishery probably represents a special case in that the rate of marine mammal mortality is very much dependent upon the expertise of the crew and the amounts of time and energy expended to release dolphins from the net.

A more general source of potential bias from observer effects can occur if marine mammal mortality rates vary predictably depending upon when and where the fishermen fish. For example, harbor porpoise mortality rates in the Gulf of Maine sink gillnet fishery have been seen to vary by location and time of year, which has led to the implementation of time-area closures to attempt to reduce the mortality (NMFS 1994*a*). Where such variation in mortality rates exists (without time-area closures being implemented) the potential exists for fishing vessels with observers to stay away from areas where they have experienced high incidental takes of marine mammals in the past. This could lead to overall mortality being underestimated.

Mortality estimates for gillnet or other fisheries can also be biased because animals fall out of the gear while the gear is being hauled in and thus are not counted by an observer. Net fallout which could be observed from the vessel was found to be a potential problem in observing the Gulf of Maine sink gillnet fishery, where it was determined that many incidentally caught porpoises did not come aboard the vessel, and thus it was important for the observers to watch the net as it came out of the water (NMFS 1994*b*). Of course, in any gillnet fishery the possibility also exists that caught animals may fall out of the net or swim away entangled in a portion of the net before the net is retrieved and so may never be observed. Quantifying this kind of bias would be very difficult, as it would involve inspecting the net while it is still in the water in its fishing position just prior to being hauled in.

There are other potential sources of bias in mortality estimates that are common. Often, due to logistical or practical difficulties, it is not possible to place observers on vessels in a completely representative way. For example, it may be possible to place observers only on vessels in the larger ports, so vessels fishing out of smaller ports (and their mortality rates) may be under-represented. Also, fishing effort is often estimated using surrogate measures, such as the quantity of fish landed, and such conversions introduce the possibility of other kinds of bias. In conclusion, unless observer coverage approaches 100%, in many fisheries it will be difficult to exclude the possibility of bias in mortality estimates. It is plausible that mortality could be underestimated by one-half. For example, this could occur if mortality rates differed by a factor of 2 spatially, and if observed boats always went to known low-mortality locations.

Trial 2: Abundance Estimates

This trial used a twofold positive bias in abundance. Most estimates of abundance for cetaceans are from line-transect data. Most potential biases of line-transect data are negative, and sources of positive bias are limited. One known source for some species is attraction to vessels, which is often a problem with Dall's porpoise (*Phocoenoides dalli*), for example, and can introduce more than a twofold positive bias. Such a bias would be more than is accounted for by this bias trial, but it should be recognizable and not remain unknown (and thus be corrected for).

Another possible positive bias, especially for dolphins, comes from overestimating mean group size because of the easier detection of large groups. However, such a bias is unlikely to result in a greater than twofold overestimate of abundance. This type of bias is also identifiable and correctable.

Abundance might be overestimated by a factor of two very easily from incorrectly identifying the stock structure of the population in question, such as in a situation where two stocks with limited movement between them were considered one stock. Abundance would essentially be overestimated by a factor of 2 in a case where the stocks were of equal size and all human-caused mortality was in the region of just one stock. This is a plausible unknown bias because examples exist of just such scenarios. For example, the two stocks of harbor porpoise in California waters have estimated abundances of 4,120 for the central stock and 9,250 for the northern stock, but incidental fisheries mortality in the coastal set gillnet fishery occurred only within the range of the central stock (Barlow and Forney 1994). If the two stocks were treated as one stock, the lumped abundance would essentially overestimate, by a factor of more than 3, the estimated abundance of the population experiencing the mortality.

Trial 3: R_{MAX}

The *PBR* calculations assume that R_{MAX} is 0.04 for cetaceans and 0.12 for pinnipeds. Where species-specific information is available, it should be used rather than these defaults. However, it is difficult to estimate R_{MAX} because of the difficulty in estimating all of the life history parameters for marine mammals. In particular, survival rates are difficult to estimate, as to do so requires following the fate of individual animals within an increasing population over long periods of time. Alternatively, observed rates of increase may or may not serve as a good surrogate for R_{MAX}, depending on whether or not the population is at a low level relative to carrying capacity. Observed rates of increase should at least provide a lower bound for R_{MAX}. Therefore, a brief review of what data are available for some species may provide some guidance for setting default values when no data are available for a species. If the true value of R_{MAX} is higher than the default, then the *PBR* as calculated is too conservative. The issue here for the bias trial is what the appropriate value to use as a default is when no data are available. Most important is to choose a reasonable value for R_{MAX} for most species, while minimizing the possibility that this value is much higher than the true unknown value of any particular species. Such species could become depleted if their human-caused mortality were as high as a *PBR* calculated using the default value.

There are several estimates of rates of increase greater than 4% for mysticetes, especially southern hemisphere right whales (*Eubalaena australis*) (Best 1993). However, the northwest Atlantic population of right whales, *E. glacialis*, has been estimated to be growing at only 2.5% per year (Knowlton *et al.* 1994). Because that population is estimated to number only a few hundred animals, it should be growing at a maximum rate unless some form of depensation is taking place. The estimated net productivity (increase plus harvest) of gray whales, *Eschrichtius robustus*, was about 4% per year from 1968–1988 (Reilly 1992). An estimate of 3.4% per year was made for bowhead whales, *Balaena mysticetus* (Zeh *et al.* 1991). Although some mysticete populations apparently have an R_{MAX} greater than 4%, in unknown situations 4% is a reasonable default. Given the apparent observed rate of the northwest Atlantic right whale, 2% is a reasonable worst-case scenario.

Modeling of the life history of some odontocetes indicated that R_{MAX} could be as high as 0.06 if survival rates were very high (Reilly and Barlow 1986). However, such a high rate of increase has never actually been observed in an odontocete, although few observations of any kind exist. The rate of increase for a population of resident killer whales (*Orcinus orca*) has been estimated at 2.9% (Olesiuk et al. 1990*a*) and 2.5% (Brault and Caswell 1993) per year, but the maximum rate for this population could be higher. The eastern spinner dolphin (*Stenella longirostris orientalis*) was estimated to have an R_{MAX} of only 2%, although the 95% confidence limit on that estimate did not exclude 4% as a possible value (Wade 1994). In the same study the northeastern stock of offshore spotted dolphins (*Stenella attenuata*) was estimated to have an R_{MAX} of about 4% (Wade 1994). The lack of evidence of higher rates suggests that 4% is probably a suitable default value for odontocetes and that 2% represents a reasonable worst-case scenario. However, some caution is required, as so few data exist on observed rates of increase of odontocetes. Also, although several odontocete populations have apparently declined from human-caused mortality, none have been observed to recover. Although this may be due to the difficulty in monitoring odontocete populations, it also suggests that maximum rates of increase for some odontocetes could be even lower than 2%.

Some observed rates of increase are available for recovering phocid populations. The highest estimated rate of increase for the total northern elephant seal (*Mirounga angustirostris*) population is 8.3% per year (Cooper and Stewart 1983). Harbor seals (*Phoca vitulina*) in British Columbia increased at 12.5% per year from 1974 to 1988 (Olesiuk *et al.* 1990*b*). A preliminary estimate of the rate of increase of harbor seals in California was 9.7% per year from 1982 to 1992 (Barlow *et al.* 1995*a*). The Oregon and Washington coastal-waters stock of harbor seals increased 11% per year from 1977 to 1982 (Barlow *et al.* 1995*a*). The pup production of three undisturbed populations of grey seals (*Halichoerus grypus*) in the Outer Hebrides (1970–1976), Orkney (1964–1968), and the Farne Islands (1956–1971) increased at 6%–7% per year (Summers 1978); these populations were not at extremely low population sizes and they have likely increased at least since being partly protected in 1914, so the maximum growth rate for gray seals is possibly higher. The highest observed rate of increase at a breeding site for the Hawaiian monk seal (*Monachus schauinslandi*) is only 5%–6% per year (Gilmartin and Eberhardt 1995).

Several rates of increase are available for recovering otariid populations, especially in the Southern Hemisphere. Antarctic fur seal (*Arctocephalus gazella*) pup counts on South Georgia were estimated to have increased at 16.8% per year from 1958 to 1972 (Payne 1977), but a correction factor for undercounting was applied only to the last data point. An analysis of the uncorrected counts gives an estimate of 13.1% per year (York 1987). The total population of subantarctic fur seals (*Arctocephalus tropicalis*) increased 12.9% per year from 1951 to 1988 on Marion Island and 9.7% per year from 1982 to 1988 on Prince Edward Island, and the antarctic fur seal (*Arctocephalus gazella*) increased 10.9% per year from 1981 to 1988 on Marion Island (Wilkinson and Bester 1990).

However, for the Northern Hemisphere, York (1987) pointed out the great difference observed between *Arctocephalus* spp. and the northern fur seal (*Callorhinus ursinus*), which has been well studied and whose maximum observed rate of increase in pups was only 8% per year from 1911 to 1924 (Kenyon *et al.* 1954). A preliminary estimate of the net productivity rate of California sea lions (*Zalophus californianus*) from 1980 to 1994 was 11.7% per year (Barlow *et al.* 1995*a*).

In conclusion, 12% is a reasonable default value for R_{MAX} for both phocids and otariids. The information available regarding the monk seal suggests 6% may be a plausible worst-case scenario for phocids, although it is debatable how relevant the life history of monk seals is to other phocids. Six percent is likely a conservative worst-case scenario for otariids. The relatively low observed rate for the well-studied northern fur seal (8%) indicates that although many otariids have been observed to increase at rates of around 12% per year, it is not safe to assume that any otariid will necessarily increase at a rate that high.

Trial 4: CV of the Abundance Estimate

Although there is often much discussion of potential biases in abundance estimates, there has not been as much consideration given to potential biases in estimates of the variance of those abundance estimates. However, long-time series of abundance have occasionally resulted in more interannual variation in abundance estimates than expected from the estimated variance. For example, annual estimates of abundance for the southern stock of common dolphin (*Delphinus delphis*) in the eastern tropical Pacific showed a significant decline from 1986 to 1987 and then a significant increase to 1988 (Wade and Gerrodette 1992), changes which could not be due solely to mortality and reproduction of the population. The explanation was likely a low estimate in 1987 caused by a distributional shift of the population to the south, out of the study area, creating additional interannual variability not accounted for by the CV of the estimated abundance. Another example comes from the long series of abundance estimates available for gray whales, in which adjacent abundance estimates have non-overlapping confidence limits, indicating some component of the variance has not been accounted for (Reilly 1992).

Although this kind of bias is clearly possible, there is not much guidance for defining a worst-case scenario. The specified bias trials (CV actually 0.8 when estimated to be 0.2, and CV 1.6 when estimated to be 0.8) were not based on experience with actual situations. They were somewhat arbitrarily chosen to be magnitudes of bias greater than what one might imagine was reasonable.

Trial 5: CV of the Mortality Estimate

Bias trial 5 (CV of the mortality estimated to be 0.3 but actually 1.2) was similarly chosen in an arbitrary fashion, with perhaps less information available, indicating its potential to be a problem. However, it is possible to imagine situations which would lead to bias in the estimated variance of the mortality estimates. One example would be an observer effect that resulted in vessels fishing in areas with lower variability in their bycatch rates when an observer was on the vessel.

Trial 6: Survey Frequency

Although not strictly addressing a bias, it seemed appropriate to explore the consequences of doing surveys less frequently than was assumed during the simulations.

Violation of this assumption will be known, of course, so the implications of doing surveys less frequently than every eight years can be investigated, if necessary, at a later time.

Trial 7: MNPL *Less Than 0.5*K

As noted in the Discussion, Taylor and DeMaster (1993) reviewed the available empirical data and concluded that density-dependent responses in marine mammals have not been shown to be concave, although statistical power to detect this is low. Taylor and DeMaster (1993) also noted that a linear response in several life-history parameters simultaneously could generate a population-level response that was concave and thus had a maximum net productivity level of less than 0.5*K*, but there was likewise no known example of such a population. Concave dynamics have not often been suggested for marine mammals. Such dynamics imply that adding an individual to the population at a low population size has a greater effect on the other individuals in the population than does adding an individual at a high population size. For example, in the case used here, if R_{MAX} is 0.04 and *MNPL* is 0.45K, the *per capita* growth rate has already fallen to 0.02 (half the maximum rate assumed to exist at a very low population size) by the time the population is at only 0.27*K* (Fig. 1). In other words, the potential of the population to grow has been substantially reduced at a small fraction of its carrying capacity. If *MNPL* is equal to 0.5*K*, a linear decline in *per capita* growth rate results, which implies that adding an individual to the population has an effect independent of the population size, and thus the *per capita* growth rate declines to 0.02 at 0.5*K*. A more-than-linear decline is not seen in life-history parameters (Fowler 1987), and a decline more severe than implied by an *MNPL* of 0.45*K* seems unlikely given the available life-history data.

The exception to the above conclusion is the density-dependent habitat selection hypothesis of MacCall and Tatsukawa (1994). Under this hypothesis, selection can generate a population response that is concave even if local dynamics are convex. However, the hypothesis relies on strong habitat selection by the animals and on a constant gradient in habitat quality within the environment. For example, this assumes that there exists a small piece of habitat (such as 1% of the total habitat area) that is "best," and that any animals outside this best area will have a lower population growth rate irrespective of animal density. Furthermore, in applying this mechanism it is necessary to assume that if such best habitat is available, any animal not in such habitat will find it. MacCall and Tatsukawa (1994) recognized that it is unknown whether the assumptions of their model hold true for any whale population but cautioned that such a possibility would mean that local population dynamics would not provide an accurate account of overall population behavior.

Trial 8: MNPL *More than 0.5*K *with Biased Mortality Estimates*

It is thought that *MNPL* is somewhere between 0.50 and 0.85 of *K* for marine mammals (Eberhardt 1977, Fowler 1987). Although Taylor and DeMaster (1993) recognized that some range is plausible, they suggested that *MNPL* is probably not greater than 80%. Their reasoning was based on their analyses which indicated that non-linear dynamics in a single life-history parameter translate into more linear dynamics in the population response, if the other life-history parameters have a linear response themselves. Thus, for the population-level response to have an *MNPL* of 0.85*K*, either (1) all of the life-history parameters would have to have that extreme a non-linear response simultaneously, or (2) some of the single life-history parameters would have to have an even more extreme non-linear response, close to knife-edge, for which they concluded there was little evidence. The level of $0.7K$ used in this trial is therefore towards the high end of the probable range for marine mammals, but there is admittedly still much uncertainty in this conclusion.

ABSTRACT: The western North Pacific (WNP) population of gray whales *Eschrichtius robustus* is redlisted by the IUCN as Critically Endangered. As part of a long-term study on whales off Sakhalin Island, Russia, photo-catalog comparisons of gray whales in the western and eastern North Pacific (ENP) were undertaken to assess population mixing. These comparisons involved 2 approaches: (1) a systematic comparison of the WNP 'Sakhalin Catalog' to an ENP 'Pacific Northwest Catalog' that consisted of images from the northwest coast of North America and (2) a non-systematic comparison of the WNP 'Sakhalin Catalog' to an ENP 'Laguna San Ignacio Catalog' that consisted of images from central Baja California, Mexico. The Sakhalin to Pacific Northwest comparison consisted of 181 and 1064 whales, respectively, and resulted in 6 matches (3 males, 2 females, and 1 whale of unknown sex). All sightings of 'Sakhalin whales' in the Pacific Northwest occurred off southern Vancouver Island, British Columbia, Canada. The Sakhalin to Laguna San Ignacio comparison consisted of 181 and 2514 whales, respectively, and resulted in 4 matches (2 males and 2 females). As the Pacific Northwest and Laguna San Ignacio catalogs represent only a small fraction of the total estimated number of individuals in the ENP population (~19 000), it is likely that more WNP/ENP exchange has occurred than was detected by these photo-catalog comparisons. Although these matches provide new records of movements between the WNP and ENP, recent observations of gray whales off Japan and China suggest that not all gray whales identified in the WNP share a common wintering ground.

Once thought to be extinct, an endangered western North Pacific gray whale breaches off Sakhalin Island, Russia.

Pacific (WNP) and eastern North Pacific (ENP) populations (LeDuc et al. 2002, Lang 2010, Lang et al. 2011). The ENP population ranges from calving areas off Baja California, Mexico, to feeding areas in the Bering, Beaufort, and Chukchi Seas. The WNP population feeds in the Okhotsk Sea off Sakhalin Island, Russia, and in nearshore waters of the southeastern Kamchatka Peninsula (southwestern Bering Sea). Little is known about the current migratory routes and wintering areas of the WNP population, but historic evidence indicates that the coastal waters of eastern Russia, the Korean Peninsula, and Japan were part of the migratory route and that areas in the South China Sea were used as wintering grounds (see review by Weller et al. 2002).

Both populations were dramatically reduced by commercial whaling during the 19th and 20th centuries (Henderson 1984, Weller et al. 2002, Reeves et al. 2010). The ENP population was removed from the U.S. List of Endangered and Threatened Wildlife in 1994 and is currently estimated to number approximately 19 000 individuals (Laake et al. 2009). At the single species-level unit, gray whales are redlisted by the International Union for Conservation of Nature (IUCN) as being of Least Concern (Reilly et al. 2008). The WNP subpopulation, however, is redlisted by the IUCN as Critically Endangered (Reilly et al. 2008). The most recent assessment of the Sakhalin population, using a Bayesian individual-based stage-structured model, resulted in a median 1+ (non-calf) estimate of 130 individuals (90% Bayesian CI = 120–142) in 2008 (Cooke et al. 2008).

Research on gray whales in the WNP has been ongoing since 1995, predominantly on the primary feeding ground off northeastern Sakhalin Island (Weller et al. 1999, Bradford et al. 2008, Lang et al. 2011), and more recently off southeastern Kamchatka (Vertyankin et al. 2004, Tyurneva et al. 2010, Burdin et al. 2011). These studies monitor gray whales using photo-identification methods, as gray whales are individually identifiable based on unique, permanent pigmentation features (Darling 1984). Such monitoring on the Sakhalin feeding ground has documented (1) pronounced seasonal site fidelity and inter-annual return of known individuals, (2) consistent use of the area by adult females when pregnant, resting (i.e. when not pregnant or lactating), and accompanied by calves, and (3) annual return by many individuals that were first identified there as young-of-the-year (Weller et al. 1999, 2002, Bradford et al. 2008, Bradford 2011).

Whales associated with the Sakhalin feeding area can be absent for all or part of a given feeding season (Bradford et al. 2008), indicating that they probably use other areas during the summer and fall feeding period. Some of the whales identified feeding in the coastal waters off Sakhalin, including reproductive females and calves, have also been documented off the southern and eastern coast of Kamchatka (Tyurneva et al. 2010, Burdin et al. 2011). Further, whales observed off Sakhalin have been sighted off the northern Kuril Islands in the eastern Okhotsk Sea and Bering Island in the western Bering Sea (Weller et al. 2003). Finally, Lang (2010) reported that 2 adult individuals from the WNP, sampled off Sakhalin in 1998 and 2004, matched the microsatellite genotypes, mtDNA haplotypes, and sexes (1 male, 1 female) of 2 whales sampled off Santa Barbara, California, USA (Area 3 in Fig. 1) on 20 and 23 March 1995. The study by Lang (2010) was the first to suggest that some level of interchange might be occurring between the WNP and ENP.

While information regarding the summer feeding areas of gray whales in the WNP has become increasingly available in the past decade, current data from the historic migratory corridor(s) are limited and data from the presumed wintering area(s) are essentially unavailable. There have been only 13 known sightings or strandings in Japanese waters since 1990 (Nambu et al. 2010). Between 2005 and 2007, 4 female gray whales were fatally entrapped in set nets along the Pacific coast of Honshu, Japan. One of these females, entrapped in January 2007, was matched to earlier photographs of it as a calf (with its mother) while on the Sakhalin feeding ground in July and August 2006 (Weller et al. 2008). This match provided the most contemporary link between the summer feeding ground off Sakhalin and a winter location along the coast of Asia.

In an effort to obtain more information about the southern migration route(s) and wintering area(s) of gray whales in the WNP, a satellite telemetry project was undertaken in 2010 by a team of Russian and American scientists (Mate et al. 2011). While the objective of that study was to document gray whale movements in the WNP, the only whale tagged was tracked from the WNP to the ENP. The result of this telemetry study, together with the genetic matches reported by Lang (2010), provided the impetus for WNP/ENP photo-identification catalog comparisons, which we conducted to further assess population mixing.

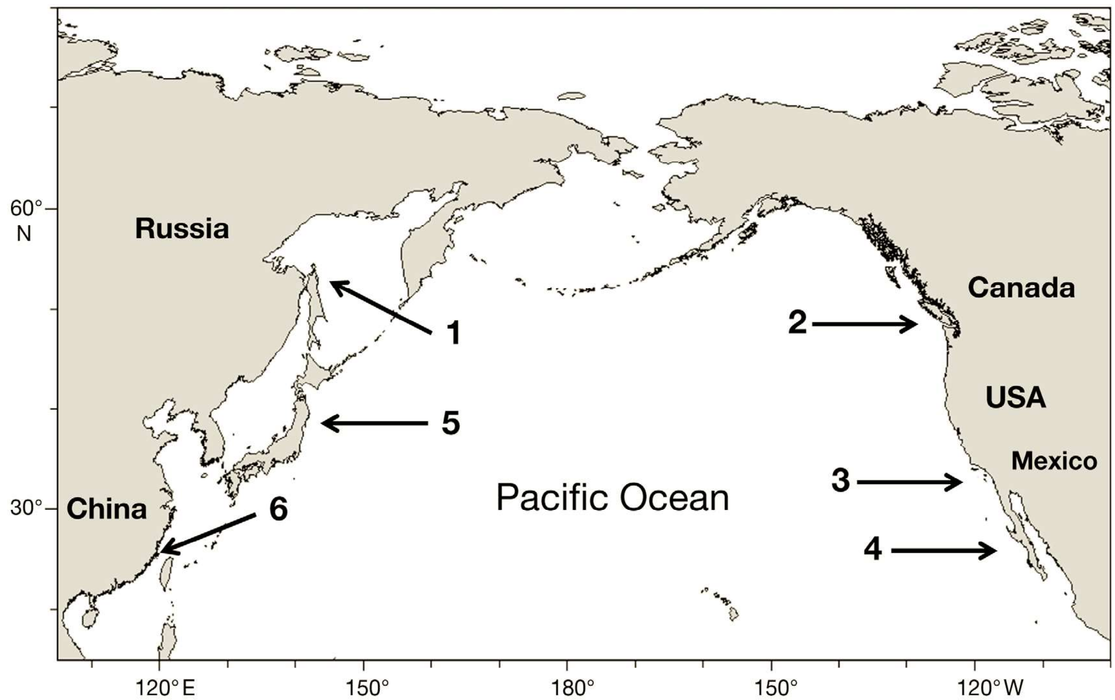

Fig. 1. *Eschrichtius robustus.* North Pacific Ocean, showing: (1) Western North Pacific (WNP) feeding ground off Sakhalin Island, (2) Eastern North Pacific (ENP) region off Vancouver Island where 6 photographic matches to Sakhalin individuals were found, (3) ENP region off California where 2 genetic matches were found (Lang 2010), (4) ENP region off Baja California where 4 photographic matches to Sakhalin individuals were found, (5) WNP region of Japan where a photographic match was found (Weller et al. 2008), and (6) WNP region of China where a gray whale stranded in November 2011 (Zhu 2012)

MATERIALS AND METHODS

Photo-identification images of 181 Sakhalin gray whales (the Sakhalin catalog, hereafter SAK catalog) collected off Sakhalin Island (Area 1 in Fig. 1) between 1994 and 2009 by a joint Russia-U.S. research program (Weller et al. 1999, 2002) were compared to a catalog of 1064 'Pacific Northwest gray whales' (hereafter, PNW catalog) identified by Cascadia Research Collective and collaborators working in U.S. and Canadian waters from California to Alaska (Area 2 in Fig. 1) primarily between 1998 and 2009 (Calambokidis et al. 2002, 2010). The PNW catalog focuses on gray whales that feed during summer and fall in coastal waters between northern California and the Gulf of Alaska, referred to as the Pacific Coast Feeding Group (PCFG), but also includes some migrating whales identified in the spring (March to May) during their northward passage to high-latitude feeding grounds.

Of the 181 whales in the SAK catalog, all were represented by a right-side dorsal flank image, and 179 were associated with a left-side dorsal flank image. Of the 1064 whales in the PNW catalog, 845 were represented by a right-side dorsal flank image, and 898 were associated with a left-side dorsal flank image. Each individual in the SAK catalog was compared in numerical order to all individuals in the PNW catalog as follows. First, the left-side dorsal flank of each individual in the SAK catalog was compared to the left-side dorsal flank of all individuals in the PNW catalog. This process was then repeated using the right-side dorsal flank and ventral aspect of the tail flukes. Comparisons were made by a single analyst (A.K.), but resulting matches were confirmed by 3 independent researchers skilled in gray whale photo-identification (including A.L.B. and J.C.).

Similarly, photo-identification images of 181 whales in the SAK catalog were compared to an online catalog of 2514 'Laguna San Ignacio gray whales' (hereafter, the LSI catalog) identified between 2006 and 2010 in Baja California, Mexico (Area 4 in Fig. 1). This assessment was not comprehensive or systematic, as was the case for the PNW catalog, because the LSI catalog represented a collection of 'annual working catalogs' rather than a single multi-year catalog of known individuals. Thus, the comparison to the SAK catalog reported herein was undertaken opportunistically. A single analyst (A.L.B.) conducted the appraisal, with identified matches confirmed by 2 additional observers (including D.W.W.).

RESULTS

The comparison of the SAK catalog to the PNW catalog resulted in a total of 6 confirmed matches of individuals, including 3 males, 2 females, and 1 whale of unknown sex (Table 1). None of these 6 whales is a known PCFG animal, and, to date, each one has only ever been photographed a single time during either April or May.

Remarkably, all 6 of the matches were from only 2 days of effort, with 3 whales identified on 2 May 2004 and 3 on 25 April 2008. The 3 whales identified on 2 May 2004 were together in a single group, while the 3 whales recorded on 25 April 2008 were in 2 separate groups but in close proximity. All of the sightings of Sakhalin whales in the Pacific Northwest occurred near Barkley Sound off the west coast of southern Vancouver Island, British Columbia, Canada.

Three of the 6 whales were first identified as calves (with their mothers) on the Sakhalin feeding ground during 1997 (no. RUS-U.S. 032/CRC 1045), 2003 (no. RUS-U.S. 119/CRC 1040), and 2004 (no. RUS-U.S. 135/CRC 1042; Table 1). Interestingly, a genetic analysis of paternity classified one of the matched males (no. RUS-U.S. 035/CRC 0809) as the putative father of 2, or possibly 4, calves identified off Sakhalin (Lang 2010). All 6 whales had sightings off Sakhalin prior to their respective sightings off Vancouver Island, and 5 (83%) had sightings off Sakhalin subsequent to their Vancouver sightings. Four whales were sighted off Vancouver Island and Sakhalin in the same year: 3 in 2004 and 1 in 2008. Of the 3 whales identified off Vancouver Island on 2 May 2004, 2 were resighted off Sakhalin on 31 July 2004, while the third was first resighted on 6 August 2004. Whale no. RUS-U.S. 032/CRC 1045 was sighted off Sakhalin in 2007 during July (29), August (4, 18, 25), and September (7, 8, 9), off southern Vancouver Island on 25 April 2008, and then back off Sakhalin on 19 July 2008. This whale is the same individual satellite-tracked from Sakhalin to the ENP in 2010/2011 (Mate et al. 2011).

The comparison of the SAK catalog to the LSI catalog resulted in a total of 4 confirmed matches of individuals, including 2 males and 2 females (Table 2). Three of these 4 whales were photographed in Laguna San Ignacio in only 1 year, while whale no. RUS-U.S. 052 was identified in both 2007 and 2010. All 4 whales had sightings off Sakhalin prior to their respective sightings in Laguna San Ignacio, and 3 (75%) had sightings off Sakhalin subsequent to their lagoon sightings. Two whales were sighted in Laguna San Ignacio and Sakhalin in the same year: one in 2008 (no. RUS-U.S. 063) and one in 2010 (no. RUS-U.S. 052).

One of the 4 whales (no. RUS-U.S. 020) was first identified as a calf on the Sakhalin feeding ground

[a]Same whale satellite-tagged in 2010 (Mate et al. 2011). First identified off Sakhalin as a calf in 1997. [b]Putative father of 2 (strict criterion) or 4 (relaxed criterion) Sakhalin calves (for definitions see Lang 2010). Years that these calves were first identified are: 1998, 2001, 2002, and 2003. [c]First identified off Sakhalin in 2003 as a calf. [d]First identified off Sakhalin in 2004 as a calf

during 1997 (Table 2) and photographically matched to the Commander Islands in June 2000 (Weller et al. 2003). A genetic analysis of paternity classified 1 of the matched males (no. RUS-U.S. 052) as the putative father of a calf identified in 1998 off Sakhalin (Lang 2010). Both of the matched females were identified as mothers with calves while in Laguna San Ignacio. Whale no. RUS-U.S. 042 was identified as a mother with a calf in 2009 but has never been seen with a calf off Sakhalin. Whale no. RUS-U.S. 063 was identified as a mother with a calf in 2008 and was also observed with a calf off Sakhalin (in 1998).

DISCUSSION

The photographic matches reported here provide new information that is of broad significance to understanding the migration patterns and mixing of gray whales in the North Pacific. The high number of matches made between the SAK and PNW catalogs is particularly intriguing given that the PNW catalog used for comparison focuses on PCFG whales and thus greatly underrepresents individuals that pass off the Pacific Northwest during the spring migration. Limited numbers of whales in the PNW catalog have been photographed during the spring off the coast of Vancouver Island where the 6 matched whales were observed (n = 26 for southern Vancouver Island; n = 48 for all of western Vancouver Island). Thus, 6 of the 74 (8.1%) whales identified off Vancouver Island in the PNW catalog were known Sakhalin individuals. Given that the PNW catalog contains only a small fraction (1064) of the estimated total number of individuals (~19000) in the ENP population, it is likely that more WNP/ENP exchange has occurred than was detected during this comparison.

The high match rate observed between the SAK and PNW catalogs suggests a spatio-temporal behavioral factor that makes Sakhalin whales more likely to have been identified in the small PNW spring sample. The fact that all the matches came from sightings made on only 2 days, mostly in the same groups and in localized areas, indicates that whales from the Sakhalin feeding ground associate, at least to some degree, even when utilizing migratory routes in the ENP. These 6 whales were sighted in an area where some whales tend to linger and feed during the northbound migration (Darling et al. 1998). Feeding whales are often found in more nearshore waters and over extended periods of time, potentially making them more likely to be photographed than animals rapidly migrating past the area (Darling et al. 1998, Calambokidis et al. 2010). The long distance and potential open water crossing required for transit from the ENP to the WNP may make it advantageous for whales to spend time feeding in the Pacific Northwest (e.g. Vancouver Island) prior to undertaking a westerly passage to Sakhalin.

The preliminary comparison of the SAK and LSI catalogs revealed 4 additional matches. Since the SAK to LSI catalog comparison was conducted in a non-comprehensive manner, relying on long-term familiarity with whales in the WNP catalog, it is probable that additional matches exist. Given the importance of conducting further comparisons to the wintering lagoons of Baja California, Mexico, a systematic and comprehensive comparison of the SAK catalog to a recently compiled multi-year catalog from LSI and Laguna Ojo de Liebre (Scammon's Lagoon) is presently underway (see IWC 2011).

When the 10 WNP/ENP photo-identification matches reported here are combined with the 2 genetic matches noted by Lang (2010), a total of 12 gray whales (6 males, 5 females and 1 whale of unknown sex) identified in the WNP off Sakhalin Island have been matched to 3 locations in the ENP (Vancouver Island, Southern California, Laguna San Ignacio), providing evidence that both sexes, in approximately equal numbers, move between the WNP and the ENP. Despite this level of mixing, significant mtDNA and nuclear genetic differences between whales utilizing the Sakhalin feeding ground and those summering in the ENP support the continued recognition of Sakhalin animals as a distinct genetic unit (Lang et al. 2011).

Adding to the complexity of mixing between the WNP and ENP are contemporary records of gray whales off Japan and, to a lesser degree, China. As previously mentioned, there have been only 13 records of gray whales in Japanese waters since 1990 (Nambu et al. 2010). One of these reports includes a whale first identified as a calf accompanied by her mother on the Sakhalin Island feeding ground in July and August 2006 that was later fatally entrapped in a set net off the Pacific coast of Honshu (Area 5 in Fig. 1) in January 2007 (Weller et al. 2008). While observations of gray whales in Japan have been made between November and August, most of these records are concentrated between March and May. This March to May period coincides with the sightings in the ENP of the 10 matched whales described here. Observations of gray whales in China are exceptionally rare. Only 24 sightings and/or strandings have been recorded since 1933, including observations of 2 mother–calf pairs (Wang 1984, Zhu 2002). However, a 13 m female gray whale stranded in the Taiwan Strait near the town of Baiqingxiang (Pingtan County), China (Area 6 in Fig. 1), in November 2011 (Zhu 2012). These findings, in combination, suggest that not all gray whales identified in the WNP share a common wintering ground.

The use of photo-identification methods, together with genetic and telemetry techniques, is essential to furthering our understanding of gray whale population structure. We recommend that other existing photo collections and tissue samples of gray whales in the WNP and ENP (e.g. those from Sakhalin, Kamchatka, Chukotka, Mexico, and Japan) be used to further examine gray whale movement patterns and population mixing within the Pacific. Ideally, a collaborative Pacific-wide study should be undertaken, similar in scope to those conducted for humpback whales in the Atlantic and Pacific (Smith et al. 1999, Calambokidis et al. 2008).

Acknowledgements. We thank all who have contributed photographs and data to the WNP and ENP catalogs. D. DeMaster and R. Wulff were instrumental in securing funding for this comparison. J. Cooke, G. Donovan, R. Reeves, and W. Perryman provided valuable insight and encouragement throughout this project. The IWC granted permission for use of photographic data from 2010. The National Marine Mammal Laboratory provided support for portions of the PNW photo-identification studies. The Protected Resources Division, Southwest Fisheries Science Center, National Marine Fisheries Service, National Oceanic and Atmospheric Administration provided support for the participation of R.L.B., A.R.L., and D.W.W.

NOAA Technical Memorandum NMFS

The National Oceanic and Atmospheric Administration (NOAA), organized in 1970, has evolved into an agency that establishes national policies and manages and conserves our oceanic, coastal, and atmospheric resources. An organizational element within NOAA, the Office of Fisheries is responsible for fisheries policy and the direction of the National Marine Fisheries Service (NMFS).

In addition to its formal publications, the NMFS uses the NOAA Technical Memorandum series to issue informal scientific and technical publications when complete formal review and editorial processing are not appropriate or feasible. Documents within this series, however, reflect sound professional work and may be referenced in the formal scientific and technical literature.

SWFSC Technical Memorandums

SWFSC Technical Memorandums are available online at the SWFSC web site (http://swfsc.noaa.gov). Copies are also available from the National Technical Information Service, 5285 Port Royal Road, Springfield, VA 22161 (http://www.ntis.gov).

Weller, D.W., Bettridge, S., Brownell, R.L., Jr., Laake, J.L., Moore, J.E., Rosel, P.E., Taylor, B.L and Wade, P.R. 2013. Report of the National Marine Fisheries Service gray whale stock identification workshop. U.S. Dep. Commer., NOAA Tech. Memo. NMFS-SWFSC-507

Executive Summary

The Marine Mammal Protection Act of 1972 (MMPA) requires that the National Marine Fisheries Service (NMFS) and the Fish and Wildlife Service develop stock assessment reports for all marine mammal stocks in waters under U.S. jurisdiction. NMFS considers stock structure as part of these assessments and has developed guidance for delineating separate population stocks under the MMPA. A single population stock of gray whales (*Eschrichtius robustus*), referred to as the eastern North Pacific (ENP) stock, is presently recognized in U.S. waters (Carretta *et al*. 2013). New information, however, suggests the possibility of recognizing two additional stocks of gray whales in U.S. waters: the Pacific Coast Feeding Group (PCFG) and the western North Pacific (WNP) stock. To evaluate the currently recognized and potentially emerging characterization of gray whale stock structure, NMFS established a scientific Task Force (TF). The overarching objective of this TF was to provide an objective scientific evaluation of gray whale stock structure as defined under the MMPA and implemented through the NMFS Guidelines for Assessing Marine Mammal Stocks (GAMMS; NMFS 2005). More specifically, the TF was convened to provide advice on the primary question – "*Is the PCFG a "population stock" under the MMPA and GAMMS guidelines"?* In addition, the TF was asked to provide advice on a question of developing importance – "*Is the WNP stock a "population stock" under the MMPA and GAMMS guidelines"?*

Both of these questions have immediate management implications, including: (1) how future NMFS stock assessment reports will address gray whale stock structure in the North Pacific, and (2) how to interpret any new information in the context of the Makah Indian Tribe's MMPA waiver request to resume hunting gray whales off Washington State, USA.

As the agency lead for gray whale science, the Southwest Fisheries Science Center convened a meeting of the aforementioned TF from 31 July to 2 August 2012. Using the best scientific information available at the time of the workshop, the TF worked to: (1) review new information relevant to gray whale stock structure, and (2) provide advice on revisions to stock structure so as to be available for management consideration. The TF conducted its work as an advisory rather than prescriptive body and therefore its conclusions should viewed as scientific advice based on review and discussion of the available science.

The implications of new data pertinent to stock structure, including considerable information related to the PCFG and WNP gray whales, were thoroughly reviewed during the workshop. Evaluating the new findings relevant to the status of the PCFG proved particularly complex. After review of results from photo-identification, genetics, tagging, and other studies within the context of the GAMMS guidelines (NMFS 2005) there remains a substantial level of uncertainty in the strength of the lines of evidence supporting demographic independence of the PCFG. Consequently, the TF was unable to provide definitive advice as to whether the PCFG is a population stock under the MMPA and the GAMMS guidelines. Members of the TF ranged in their opinions from strongly agreeing to strongly disagreeing about whether the PCFG should be recognized as a separate stock.

In the case of WNP gray whales, the work of the TF was more straightforward. The mitochondrial DNA and nuclear DNA genetic differentiation found between the WNP and ENP stocks provided convincing evidence that resulted in the TF providing unambiguous advice that the WNP stock should be recognized as a population stock pursuant to the GAMMS guidelines and the MMPA.

Additional research may narrow the uncertainty associated with the question of whether the PCFG should be recognized as a population stock. To work towards this objective, the TF recommended further investigation of recruitment into the PCFG. Presently, both the photo-identification and genetics data indicate that the levels of internal versus external recruitment are comparable, but these are not quantified well enough to determine if the population dynamics of the PCFG are more a consequence of births and deaths within the group (internal dynamics) rather than related to immigration and/or emigration (external dynamics). The TF offered a number of research recommendations, using the existing photo-identification and genetics datasets, that could provide increased resolution on the issue of recruitment and, in turn, the question of stock identification.

While the need for additional data collection was apparent, especially with regard to recruitment into the PCFG, the purpose of the workshop was for the TF to determine whether the *existing* best available science was sufficient to advise that the PCFG be recognized as a population stock under the language of the MMPA and GAMMS guidelines. Therefore, the advice of the TF offered in this report should be viewed as a contemporary "snapshot" taken from an emerging and ever-changing body of knowledge regarding the PCFG.

The TF emphasizes that the PCFG is relatively small in number and utilizes a largely different ecosystem from that of the main ENP stock. While the status of the PCFG as a population stock has yet to be resolved, continued research on these whales should be undertaken with particular attention dedicated to collecting data relevant to the question of stock identification.

1. Introductory Remarks

Dr. Lisa Ballance, Director of the Marine Mammal and Turtle Division at Southwest Fisheries Science Center (SWFSC), welcomed the workshop participants. She noted that this workshop represented a significant event, in that it: (1) brings agency scientists together to review research that continues to evolve and reveal unexpected patterns, (2) provides results that will be relevant to management activities for the National Marine Fisheries Service (NMFS), and (3) typifies the ideal model for how NMFS works, illustrating science addressing management actions and highlighting the collaboration between NMFS scientists, regional offices, and headquarters.

The technical and scientific expertise required on the Task Force (TF) was determined by SWFSC in consultation with the NMFS Northwest Regional Office (NWR) and the NMFS Office of Protected Resources (OPR). TF members were experts in their respective fields with ample experience and ability to bridge scientific and policy issues related to marine mammal stock structure. Members of the TF included the following eight NMFS scientists:

Dr. Shannon Bettridge	NMFS – Office of Protected Resources
Dr. Robert L. Brownell, Jr.	NMFS – Southwest Fisheries Science Center
Dr. Jeffrey L. Laake	NMFS – Alaska Fisheries Science Center
Dr. Jeffrey E. Moore	NMFS – Southwest Fisheries Science Center
Dr. Patricia E. Rosel	NMFS – Southeast Fisheries Science Center
Dr. Barbara L. Taylor	NMFS – Southwest Fisheries Science Center
Dr. Paul R. Wade	NMFS – Alaska Fisheries Science Center
Dr. David W. Weller (Chairman)	NMFS – Southwest Fisheries Science Center

In addition to the TF, a number of agency scientists and NMFS affiliates (e.g., post-docs, contractors, etc.) attended the workshop to observe and provide information. These participants included: Eric Archer (SWFSC), Lisa Ballance (SWFSC), Laurie Beale (NOAA General Counsel), Jim Carretta (SWFSC), Donna Darm (NWR), Kirsten Erickson (NOAA General Counsel - by phone), Jason Foreman (NOAA General Counsel), Annette Henry (SWFSC), Aimee Lang (SWFSC), Karen Martien (SWFSC), Sarah Mesnick (SWFSC), Phil Morin (SWFSC), Vicki Pease (SWFSC), Bill Perrin (SWFSC), Wayne Perryman (SWFSC) and Steve Stone (NWR). At the request of the TF, several of these participants provided valuable information to the workshop in the form of expert knowledge, presentations and/or written documents. Aimee Lang and Annette Henry generously agreed to serve as workshop rapporteurs.

The agenda for the workshop was circulated amongst the TF for input in advance of the meeting (Appendix 1). It was agreed, however, that the agenda would serve to guide the workshop proceedings but be viewed as flexible so as not to constrain discussion. Documents for the workshop were made available on a file sharing website. Appendix 2 provides a list of the workshop documents available for review and consideration by the TF in preparation for the workshop.

1.1 Workshop objectives

NMFS presently recognizes a single stock of gray whales (*Eschrichtius robustus*) in U.S. waters that is referred to as the eastern North Pacific (ENP) stock (Carretta *et al*. 2013). New information, however, suggests the possibility of recognizing two additional stocks of gray whales in U.S. waters, including: (1) the Pacific Coast Feeding Group (PCFG) - defined as whales observed between 1 June to 30 November within the region between northern California and northern Vancouver Island (from 41°N to 52°N) and photo-identified within this area during two or more years (see section 3.3), and (2) western North Pacific (WNP) gray whales - defined as whales observed feeding during summer and fall off Sakhalin Island, Russia, and other areas in the WNP (see section 3.2). The main objective of the TF was to provide scientific advice regarding gray whale stock structure using the definitions given in the GAMMS guidelines (NMFS 2005; see also Moore and Merrick 2011). More specifically, the TF was convened to provide advice on two questions: (1) *Is the PCFG a "population stock" under the MMPA and GAMMS guidelines?*, and (2) *Is the WNP stock a "population stock" under the MMPA and GAMMS guidelines?* Both of these questions have immediate management implications, including: (1) how future NMFS stock assessment reports (SAR) will address gray whale stock structure in the North Pacific, and (2) how to interpret any new information in the context of the Makah Indian Tribe's MMPA waiver request to resume hunting gray whales off Washington State, USA.

1.2 Workshop relationship to stock assessment reports

At the request of the TF, Carretta (SWFSC) summarized the relationship of the workshop to future gray whale stock assessment reports (SARs). The current eastern North Pacific gray whale SAR (Carretta *et al*. 2013) provides a summary of present knowledge but is expected to evolve based on the input received at this workshop as well as from input from the scientific review groups (SRG)[1], NWR and OPR. The TF expected that the outcome of the workshop would influence how the SAR is structured in the future, including how various data sources (i.e., genetics, movements, distribution) are evaluated for future stock designation. The workshop report will also serve as a useful SRG background document on gray whale stock structure.

1.3 Workshop relationship to Makah waiver request

Newly available information from genetic, photo-identification and tagging studies suggests that more than one stock of gray whales may occur in U.S. waters (Lang *et al*. 2010; Frasier *et al.* 2011; Lang *et al.* 2011a; Lang *et al*. 2011b; Mate *et al*. 2011; Calambokidis *et al.* 2012; Weller *et al*. 2012). With that in mind, the TF requested that Darm (NWR) present a summary of the Makah Indian Tribe's request to hunt gray whales off northwest Washington State, USA.

The Makah's right to hunt whales is secured by the 1855 Treaty of Neah Bay, where the Makah ceded lands to the U.S. government but reserved the right to hunt, fish, seal and whale. The Ninth Circuit Court of Appeals decision in 2004 (Anderson v. Evans) held that for the Makah to exercise their right to hunt whales they must comply with the requirements of the MMPA. In 2005, the Makah requested authorization from NOAA/NMFS, under the MMPA and the Whaling Convention Act, to resume limited hunting of gray whales for ceremonial and subsistence purposes in the coastal portion of their usual and accustomed (U&A) fishing grounds off the coast of Washington State (NMFS 2008). The spatial overlap of the Makah U&A with the summer distribution of PCFG whales has management implications. The proposal by the Makah Tribe includes time/area restrictions designed to reduce the probability of killing a PCFG whale and to focus the hunt on whales migrating to/from feeding areas to the north.

The NWR was assigned responsibility for evaluating the Tribe's request under the MMPA and National Environmental Policy Act (NEPA) process. Section 101(a) of the MMPA imposes a

[1] Pursuant to Sec. 117 of the MMPA, independent scientific review groups, representing Alaska, and the Pacific and Atlantic coasts, were established in 1994. These groups consist of individuals with expertise in marine mammal biology and ecology, population dynamics and modeling, commercial fishing technology and practices, and stocks taken under section 101(b).

moratorium on the take of all marine mammals, although the statute provides for certain exemptions allowing the take of marine mammals. Section 101(a)(3)(A) allows for a waiver of the take prohibition; this exemption applies to a specific stock and is only authorized to the extent provided for in the waiver. Determination of whether the waiver will be granted must be made based on the best scientific information, in consultation with the Marine Mammal Commission, and with due regard to the distribution, abundance, breeding habits, and movements of the stock in question. For the waiver to be granted there must also be a finding that the requested take is in accord with sound principles of resources protection and conservation as provided for in the MMPA.

Unlike most rulemaking by the agency, this determination will entail a formal rulemaking process in which the agency presents evidence before an administrative law judge (ALJ) to support the rule. This process may involve presenting evidence on the status of relevant stocks, including their optimum sustainable population level (OSP)[2], and whether the stocks are at or below that level (i.e., depleted).

Although the NWR made substantial progress in evaluating the waiver request during the past few years, this progress had been slowed by: (1) new information pertinent to the question of whether the PCFG is a separate stock, and (2) the potential implications of movements of whales between the WNP and ENP. Therefore, the advice of the TF will provide a collective "best professional judgment" useful to the ongoing evaluation of the waiver by the NWR.

In discussion, the TF asked Darm if there would be a potential need to get more than one waiver to the MMPA if it was determined that three stocks of gray whales occur in U.S. waters (i.e., ENP, PCFG and WNP stocks). In that case, Darm replied that there would be some possibility of needing to request multiple exemptions (waivers). However, the need for a waiver would be informed by the likelihood of take and obtaining a waiver for WNP gray whales (if the group is recognized as a stock) is highly unlikely given that they are listed as endangered under the Endangered Species Act (ESA) and as such, would be considered depleted under the MMPA.

2. Overview of MMPA Language, GAMMS Guidelines and Related Key Concepts

From the outset of the workshop, the TF concurred that it was important to review the existing language of the MMPA and GAMMS with regard to the definition of "population stock". In addition, it was also agreed important to discuss three key concepts inherent to defining a population stock, including: (1) "demographic independence", (2) "interbreed when mature", and (3) "functioning element of the ecosystem".

Under the MMPA, population stock (used interchangeably with "stock" and "population" hereafter) is the fundamental conservation unit. The MMPA (Sec. 3) defines population stock as: "*a group of marine mammals of the same species or smaller taxa in a common spatial arrangement, that interbreed when mature.*" The purposes and polices underlying the stated definition, as follows, are found in Sec. 2(2) and Sec. 2(6) of the MMPA:

[2] The maximum net productivity level is described in the National Marine Fisheries Service's definition of "optimum sustainable population" (OSP) (50 CFR 216.3) as the abundance level that results in the greatest net annual increment in population numbers or biomass resulting from additions to the population due to reproduction and/or growth less losses due to natural mortality. Under the U.S. Marine Mammal Protection Act, populations above MNPL are considered to be at OSP; populations below MNPL can be designated as 'depleted' and are afforded a greater level of protection.

(1) *"[marine mammal] species and population stocks should not be permitted to diminish beyond the point at which they cease to be a significant functioning element in the ecosystem of which they are a part, and, consistent with this major objective, they should not be permitted to diminish below their optimum sustainable population."*

(2) *"… the primary objective of their management should be to maintain the health and stability of the marine ecosystem."*

Acknowledging the above definitions and objectives of the MMPA, the TF then considered the related guidelines contained in the "Definition of Stock" section of the GAMMS guidelines (NMFS 2005):

(1) *"For the purposes of management under the MMPA, a stock is recognized as being a management unit that identifies a demographically isolated biological population."*

(2) *"Demographic isolation means that the population dynamics of the affected group is more a consequence of births and deaths within the group (internal dynamics) rather than immigration or emigration (external dynamics). Thus, the exchange of individuals between population stocks is not great enough to prevent the depletion of one of the populations as a result of increased mortality or lower birth rates."*

The TF noted that within the broader field of population biology, the term "isolation" generally implies little or no exchange (emigration or immigration of individuals) between stocks and is a criterion commonly used to distinguish taxonomic units higher than that of a population (e.g., species, subspecies). In contrast, the GAMMS guidelines and definition of stock clearly allow for the "*exchange of individuals between population stocks"* (NMFS 2005), a distinction more in line with use of the term "demographic independence" rather than "demographic isolation". The use of the term "independence" as opposed to "isolation" is potentially confusing and has been noted by a number of NMFS reviewers and workshops (Eagle *et al*. 2008). To avoid this confusion, Eagle *et al*. (2008) suggested that the term "demographic isolation" be replaced by "demographic independence".

Moore (SWFSC) provided the TF with an overview of the GAMMS III workshop, convened by NMFS in February 2011, which also noted the potential confusion over the use of "isolation" as opposed to "independence". The GAMMS III workshop recommended revising the SAR guidelines to reflect that the intent of the GAMMS II guidelines (NMFS 2005) was to base stock identification on demographic independence as noted in Eagle *et al.* (2008) and proposed that the term demographic isolation be replaced with "demographic independence" as follows:

(1) *"For the purposes of management under the MMPA, a stock is recognized as being a management unit that identifies a demographically independent biological population."*

(2) *"Demographic independence means that the population dynamics of the affected group is more a consequence of births and deaths within the group (internal dynamics) rather than immigration or emigration (external dynamics). Thus, the exchange of individuals between population stocks is not great enough to prevent the depletion of one of the populations as a result of increased mortality or lower birth rates."*

In other words, the participants at the GAMMS III workshop viewed this as a semantic issue where the term demographic independence is a better description for the current GAMMS guidelines definition than is the term demographic isolation.

2.1 Discussion of "demographic independence"

This interpretation of "isolation" differs substantively from how it is used within the GAMMS guidelines definition above, wherein allowance is made for some level of exchange of individuals between stocks. The TF concurred that in spite of using the term "isolation", the actual definitions under the current GAMMS guidelines (see above) are more consistent with MMPA objectives to protect population stocks than with the objective of protecting just subspecies and species.

Given that the draft GAMMS guideline revisions from the GAMMS III workshop have not yet been formally approved, the TF agreed to use the current GAMMS guidelines definition (NMFS 2005) for the purposes of their discussions and deliberations but noted that the actual definition used in the two versions (for demographic isolation and demographic independence) is essentially the same in that neither implies true "isolation" within the context of the MMPA.

2.2 Discussion of "interbreed when mature"

Bettridge (OPR) presented a brief overview of relevant language under the MMPA and GAMMS guidelines pertaining to NMFS interpretation of "interbreed when mature". She explained that the draft second revision to the SAR guidelines (from the GAMMS II workshop held in Seattle in 2003) included a definition of interbreed when mature. This term was interpreted to mean cases in which either:

(1) "*mating occurs primarily among members of the same demographically isolated group*"

or

(2) "*the group migrates seasonally to a breeding ground where its members breed with members of the same group as well as with members of other demographically distinct groups which have migrated to the same breeding ground from a different feeding ground."*

When comments were solicited on the draft GAMMS II guidelines (69 FR 67541, 18 November 2004), the Marine Mammal Commission (MMC) supported the aforementioned interpretations, but suggested that a more rigorous analysis was needed of how the revisions fit with the language of the MMPA. Additionally, the MMC stated that NMFS should develop criteria for applying the modified guidelines to determine when a population is demographically isolated to an extent that it is a discrete group that warrants recognition as a separate stock.

In its response to comments on this issue (70 FR 35397, 20 June 2005), NMFS stated that public comments were sufficient to raise questions about the proposed interpretation, and the agency removed the proposed text pertaining to "interbreed when mature" from the final GAMMS II guidelines.

Subsequent NMFS review and consultation with MMC staff and NOAA General Counsel suggest that the GAMMS II workshop definition of "interbreed when mature" is consistent with NMFS GAMMS guidelines and the review undertaken in Eagle *et al.* (2008, see below). In those forums NMFS has consistently interpreted a population stock not as one that is completely reproductively isolated but rather as something less restrictive.

Regarding the MMC request for scientific criteria for how much interbreeding would be consistent with the proposed GAMMS II guidelines definition, the TF noted that specific quantitative criteria would be impractical to apply consistently across all contexts of uncertain stock definition and that determining whether a population is demographically independent or an isolated unit would likely have to be conducted on a case-specific basis. Some TF members felt that the “interbreed when mature” component of the MMPA definition of stock should merely be viewed as a necessary but not sufficient criterion for defining a stock. In other words, individuals “in a common spatial arrangement” would not constitute a stock unless there is some interbreeding (satisfying the need criterion), but this would not preclude individuals of a stock from also breeding with members of other stocks.

For the purposes of the workshop, the TF agreed they would continue to interpret “interbreed when mature” consistent with “demographic independence” as suggested by Eagle *et al*. (2008) and GAMMS II (NMFS 2005), with the minor change of “isolation” being replaced with “independence”.

2.3 Discussion of “functioning element of the ecosystem”

Sec. 2 of the MMPA states that marine mammals are “resources of great international significance, esthetic and recreational as well as economic” and “that the primary objective of their management should be to maintain the health and stability of the marine ecosystem”. The TF therefore considered whether the functioning element of the ecosystem criteria is aesthetically or ecologically based (or both) but no clear resolution on how to best define functioning element of the ecosystem was reached by the TF.

The TF then focused its discussion on defining the ecosystem and appropriate scale of management with respect to gray whales. The TF agreed the matter was complex given the species’ seasonal use of different ecosystems. In general, the TF agreed that the Chukotka Peninsula/Bering Strait feeding areas were not part of the same ecosystem as that found off the Pacific Northwest and used by the PCFG. In discussion of this concept, it was noted by some TF members that even for the largest-scale classification system for marine ecosystems (Longhurst 1998, discussed in Moore and Merrick 2011), it could be argued that the PCFG is in a different ecosystem than other gray whales. Other TF members pointed out, however, that this was only true for part of the year, and that the interpretation was complicated because non-PCFG animals migrate through the area defined for PCFG whales and, in some cases, may feed there in a given year but not return in a subsequent year.

2.4 Additional information on the definition of “population” for marine mammals

In addition to applying the MMPA language and GAMMS guidelines definitions, the TF considered two documents relevant to the question of stock definition under the MMPA. In the first (Taylor 1997), simulation analyses were used to explore the potential consequences, in terms of the risk of violating MMPA ecosystem function objectives, of defining a population stock as a unit akin to an evolutionarily significant unit or reproductively isolated group. Briefly, this analysis considered scenarios in which a single reproductively isolated population was distributed as a network of discrete groups occupying distinct habitat areas throughout its range, with some level of dispersal between discrete groups. The major analytical finding was that, if allowable human caused mortality (HCM) for the entire population (i.e., sum of all discrete groups) were to act disproportionately on certain groups, those groups could be extirpated, depending on whether the amount of immigration from other groups was below a certain dispersal rate threshold (which varied with simulation conditions). In conclusion, to achieve MMPA objectives of maintaining marine mammals as “functioning elements of their ecosystem”, distinct groups should be managed as separate stocks if their connectivity to other groups via dispersal is low, although how low is context specific.

Taylor (1997) provides several examples (Figure 1) where localized removals lead to local extirpation which arguably violates the ecosystem goals of the MMPA. For all of the models tested, when dispersal fell below a few percentage of the population per year, recruitment into the population with HCM was insufficient to compensate for removal, and population levels declined below those sought by management objectives. Therefore, populations should be managed separately if dispersal between them is less than several percent per year.

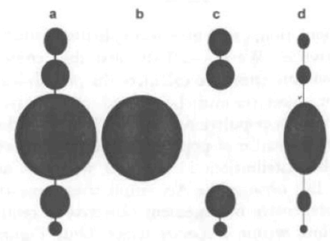

Figure 1. Distribution of pristine populations (a), versus potential distributions after 50% of the total abundance is removed (b–d). Width represents abundance; length represents distance.

Figure 1. Original figure from Taylor (1997).

Taylor (SWFSC) cautioned the TF, however, that it is impossible to have a "one number fits all" criterion and that a better approach would be to have an objective that states what is important in terms of maintaining the extent and connectivity of the range. There are some cases where it is obvious that a stock is no longer a functioning element of its ecosystem, such as example C in Figure 1 where the large central group is extirpated. Extirpation of the PCFG would be more analogous to removing one of the smaller groups outside of the main group (e.g., example B). Further discussion is needed to better define the intent of the MMPA with respect to maintaining marine mammals within different parts of their range.

The second document discussed by the TF, as pertains to the agency's definition of population stock, was the report of a 2006 workshop entitled "Conservation Units of Managed Fish, Threatened or Endangered Species, and Marine Mammals" (Eagle *et al.* 2008). This workshop was convened by NMFS with the objective of bringing together scientists, managers and policy advisers to discuss differences and recommend revisions to how NMFS defines units to conserve under three statutes – the MMPA, ESA and Magnuson-Stevens Act (MSA). The workshop sought to address two overarching questions: (1) why are conservation units different under the three statutes? and (2) is there a biological paradigm that can be used to explain the differences?

In brief, it was agreed by the participants of the 2006 workshop that the differences in how NMFS defines conservation units under the three statutes are appropriate given the differing objectives of the three laws. Under the ESA, major objectives are to prevent *species* extinction and preserve evolutionary potential. Thus, conservation units under this Act should be substantially reproductively isolated. Under the MMPA, objectives correspond to maintaining population and ecosystem goals. Therefore, conservation units align with demographically independent units (DIPs), which are demographically discrete from other populations but not necessarily genetically discrete due to a low but sufficient degree of interbreeding between them. Participants of the 2006 workshop concluded that while the GAMMS guidelines "…*clearly support the use of DIPs as stocks of marine mammals […] the MMPA does not indicate to what extent breeding should occur within a stock instead of among stocks*" and that future revisions to the GAMMS guidelines "*should, therefore, include a rationalization for recognizing DIPs as stocks in cases where males from one stock may breed with females from the same and other stocks*".

There was discussion amongst the TF regarding where to reasonably draw the line in defining small stocks, given that for some marine mammal species very small groups of animals could be considered DIPs. For example, individual pods of killer whales (*Orcinus orca*) could potentially be considered demographically independent. However, other TF members noted that the intent of the GAMMS guidelines was not to recognize very small population units – such as individual killer whale pods or a small group of animals occupying a small habitat fragment – as population stocks. It was similarly suggested that other criteria besides demographic independence, such as whether the unit can be considered a significant functioning element of the ecosystem, should also be considered in defining stocks. The TF understood that most biological "populations" and "stocks" do not exist as truly distinct groups, nor are individuals within the same population typically part of a truly panmictic group (Waples and Gaggiotti 2006). Rather, population differentiation occurs along a continuum, and placing discrete boundaries along this continuum for management purposes is a challenge. The TF acknowledged that marine mammal social structure can further complicate determining whether a unit should be considered demographically independent. In these areas of uncertainty, decisions will likely be case specific, and ultimately rely on scientific judgment and the factors identified for consideration in the MMPA and GAMMS guidelines.

The TF considered the report by Eagle *et al.* (2008) and the recommendations from that workshop as support for the NMFS interpretation of "interbreed when mature" as one that includes cases where individuals interbreed primarily within their stock but occasional interbreeding amongst stocks may occur and agreed to use such as the operational definition for the purposes of their work.

3. Overview of Eastern, Western and Pacific Coast Feeding Group Gray Whales

Like many species of baleen whales, gray whales exhibit seasonal movements between high-latitude summer feeding grounds and low- latitude wintering areas. The current distribution of this species is limited to the North Pacific, where a small western population (<150 individuals) and a much larger eastern population (~19,000 individuals) are recognized.(Reilly *et al.* 2008).

Lang (SWFSC) presented a brief overview of information on the biology of ENP, WNP, and PCFG gray whales. The purpose of this overview was not to discuss gray whale stock structure in detail but rather to provide a summary of relevant background information.

3.1 Eastern North Pacific (ENP) gray whales

During summer and fall most ENP whales feed in the Chukchi, Beaufort and northwestern Bering Seas (Figure 2). An exception is the relatively small number (100s) of whales that summer and feed along the Pacific coast between Kodiak Island, Alaska and northern California (Darling 1984; Calambokidis *et al.* 2002; 2012; Gosho *et al.* 2011). By late November, the southbound migration of the ENP stock is underway as whales begin to travel from summer feeding areas to winter calving areas off the west coast of Baja California, Mexico (Rugh *et al.* 2001; Swartz *et al.* 2006). The southbound migration is segregated by age, sex and reproductive condition (Rice and Wolman 1971). The northbound migration begins about mid-February and is also segregated by age, sex and reproductive condition.

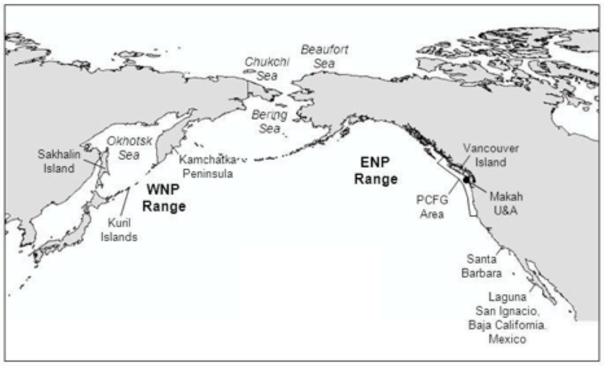

Figure 2. Geographic range of ENP, WNP and PCFG whales. In summer, WNP whales are typically found in feeding areas off the coasts of Sakhalin Island and the Kamchatka Peninsula, in Russia. Most ENP whales are typically found in summer north of St. Lawrence Island (in the northern Bering Sea), including the Bering Strait, the Chukotka Peninsula in Russia, the Chukchi Sea, and along the Beaufort Sea coast (north slope) of Alaska. Additional summer ENP feeding areas include Kodiak, AK, and areas between Southeast Alaska and Northern California. ENP whales migrate to the Baja Peninsula, Mexico in the autumn and return to feeding areas in the spring. The region used by the PCFG is defined to be the area between northern California and northern Vancouver Island (from 41°N to 52°N).

Gray whale breeding and calving are seasonal and closely synchronized with migratory timing. Sexual maturity is attained between 6 and 12 years of age (Rice 1990; Rice and Wolman 1971). Gestation is estimated to be 13 months, with calving beginning in late December and continuing to early February (Rice and Wolman 1971). Some calves are born during the southbound migration while others are born near or on the wintering grounds (Shelden *et al.* 2004). Females produce a single calf, on average, every 2 years (Jones 1990). Calves are weaned and become independent by six to eight months of age while on the summer feeding ground (Rice and Wolman 1971). Three primary calving lagoons in the ENP are utilized during winter, and some females are known to make repeated returns to specific lagoons (Jones 1990).

The abundance of the ENP population, which includes the PCFG, is presently estimated to be about 19,000 whales (Laake *et al.* 2012). The potential biological removal (PBR) level for the ENP stock of gray whales is calculated as the minimum (20^{th} percentile) estimate of population size, times one-half of the maximum theoretical net population growth rate (½ x 6.2% = 3.1%), times a recovery factor of 1.0 for a stock above its maximum net productivity level (MNPL) (Punt and Wade 2012). The minimum population estimate (N_{MIN}) for the ENP stock is calculated from Equation 1 from the PBR Guidelines (Wade and Angliss 1997): $N_{MIN} = N/\exp(0.842\times[\ln(1+[CV(N)]^2)]^{1/2})$. Using the 2006/07 abundance estimate of 19,126 and its associated CV of 0.071, N_{MIN} for this stock is 18,017. Therefore, PBR is 558 animals. A recent analysis conducted by Punt and Wade (2012) estimated a probability of 0.884 that the ENP gray whale stock is above its MNPL, which means there is a 0.884 probability that it is at its OSP as defined by the MMPA.

Genetic studies suggest some sub-structuring may occur on the wintering grounds, with significant differences in mitochondrial DNA (mtDNA) haplotype frequencies found between females (mothers with calves) utilizing two of the primary calving lagoons and females sampled in other areas (Goerlitz *et al.* 2003). Other research, employing both mtDNA and microsatellites, identified significant departure from panmixia between two of the lagoons using nuclear data, although no significant differences using mtDNA were observed (Alter *et al.* 2009). Significant mtDNA and nuclear (nDNA) genetic differences have been found between whales in the WNP and those in the ENP (LeDuc *et al*. 2002; Lang *et al.*, 2011b).

In discussion, the TF agreed that the information presented by Lang represented an up to date overview of the ENP population and had no follow up questions.

3.2 Western North Pacific (WNP) gray whales

Information on the distribution and migration patterns of gray whales in the WNP is incomplete. There is no doubt that the historical distribution of gray whales in the Okhotsk Sea once greatly exceeded what is found at present (Reeves *et al*. 2008). Today, the main feeding ground is in the Okhotsk Sea off the northeastern coast of Sakhalin Island, Russia (Figure 2) but some animals also occur off eastern Kamchatka and in other coastal waters of the northern Okhotsk Sea (Weller *et al.* 2002; Vertyankin *et al.* 2004; Tyurneva *et al.* 2010). Whales associated with the Sakhalin feeding area can be absent for all or part of a given feeding season (Bradford *et al*. 2008), indicating they probably use other areas during the summer and fall feeding period. For example, some whales observed off Sakhalin have been sighted off the northern Kuril Islands in the eastern Okhotsk Sea and Bering Island in the western Bering Sea (Weller *et al*. 2003).

The WNP migration route(s) and winter breeding ground(s) are poorly known (Weller *et al*. 2002; Weller and Brownell 2012). Information collected over the past century indicates that whales migrated along the coasts of Japan and South Korea (Andrews 1914; Mizue 1951; Omura 1984) to wintering areas somewhere in the South China Sea, possibly near Hainan Island (Wang 1984). At present, observations of gray whales off Japan are rare. Nambu *et al*. (2010) reported 13 known sighting or stranding records in Japanese waters between 1990 and 2007. Between 2005 and 2007, four female gray whales were fatally entrapped in set nets along the Pacific coast of Honshu, Japan. One of these females, entrapped in January 2007, was matched to earlier photographs of it as a calf (with its mother) while on the Sakhalin feeding ground in July and August 2006 (Weller *et al*. 2008). This match provided the most contemporary link between the summer feeding ground off Sakhalin and a winter location along the coast of Asia. More recently, in March 2012 a gray whale was sighted and photographed in Mikawa Bay (Aichi Prefecture), east of Ise Bay near Nagoya on the Pacific coast of Honshu (Japan Times, 3 May 2012).

Observations of gray whales in China are also exceptionally rare. Although 24 capture, sighting or stranding records exist since 1933 (Wang 1984; Zhu 2002), including observations of two mother-calf pairs, some of these (especially the sightings) have not been reported in sufficient detail to validate species identification. More recently, an 11.5 m female stranded live at Zhuanghe (Bohai Sea ca. 39˚N) in December 1996 (Zhao 1997) and a 13 m female gray whale was taken in fishing gear offshore of Baiqingxiang (Pingtan County), in the Taiwan Strait in November 2011 (Zhu 2012). The last known sighting of a gray whale off Korea was in 1977 (Park 1995).

The WNP gray whale population is redlisted by the IUCN as Critically Endangered. The most recent population assessment (for 2012), using a Bayesian individually-based stage- structured model, resulted in a median 1+ (non-calf) estimate of 155 individuals, with 95% CI = 142-165 (IUCN 2012). A collaborative Russia-U.S. research program on WNP gray whales summering off northeastern Sakhalin Island, Russia, has been ongoing since the mid-1990s. When data collected between 1994-2011 are combined, a catalog of 200 photo-identified individuals has been compiled. Beginning in 2002, photo-identification studies off Sakhalin have also been conducted by Russia scientists working with oil and gas companies (Tyurneva *et al*. 2010). This research largely corroborates the work of the Russia-U.S. team and in some cases collaborative analyses utilizing combined datasets have been conducted.

Recently, results from photo-identification (Urbán *et al.* 2012; Weller *et al.* 2012), genetic (Lang 2010; Lang *et al.* 2011b), and telemetry studies (Mate *et al.* 2011) have documented spatial and temporal overlap between WNP and ENP gray whales. Observations of such overlap include: (1) six whales photographically matched from Sakhalin Island to southern Vancouver Island, (2) two whales genetically matched from Sakhalin to Santa Barbara, California, (3) 13 whales photographically matched from Sakhalin Island to San Ignacio Lagoon, Mexico, and (4) 2 satellite tagged whales that migrated from Sakhalin Island to the west coast of North America. In combination, these studies have recorded a total of 23 gray whales observed in both the WNP and ENP. Despite this overlap, significant mtDNA and nDNA differences are found between whales in the WNP and those summering in the ENP (Lang *et al.* 2011b). Although it is clear that some whales feeding off Sakhalin Island during the summer/fall migrate to the west coast of North America during the winter/spring, past and present observations of gray whales in the WNP off Japan, Korea and China during the winter/spring suggest that not all gray whales in the WNP share a common wintering ground (Weller and Brownell 2012).

In discussion, the TF agreed that the occurrence of WNP gray whales in U.S. waters presented previously unexpected implications with respect to the SAR process and the Makah waiver request. More specifically, two questions were discussed at length, including: (1) given the occurrence of WNP gray whales in U.S. waters, is a WNP gray whale SAR required? and (2) given the potential occurrence of WNP gray whales in the proposed Makah hunt area, what are the implications regarding the existing wavier request?

TF members also noted that these new findings of gray whales moving between Sakhalin Island and the ENP had significance to our understanding of the status of gray whales in the WNP. That is, given that some of the whales sighted off Sakhalin appear to overwinter in the ENP, the number of animals remaining in the WNP year-round may be much smaller and of greater conservation concern than is currently recognized (Weller and Brownell 2012).

3.3 Pacific Coast Feeding Group (PCFG)

Gray whales using the Pacific Northwest area during summer and autumn include two components: (1) whales that return frequently and account for most of the sightings between 1 June and 30 November, and (2) whales that are sighted only in one year, tend to be seen for shorter time periods in that year, and are encountered in more limited areas. For the purposes of their work to evaluate the proposed Makah Indian Tribe gray whale hunt, the International Whaling Commission (IWC) defined PCFG gray whales as: whales observed between 1 June to 30 November within the region between northern California and northern Vancouver Island (from 41°N to 52°N) and photo-identified within this area during two or more years (IWC 2011; IWC 2012a). This same definition has been adopted in the analyses of Calambokidis *et al.* (2012). In this report, the TF defines "PCFG whales" following the IWC definition.

Recent research has provided new information on movements and habitat utilization of PCFG whales (for example Frasier *et al.* 2011; Lang *et al.* 2011a; Calambokidis *et al.* 2012). While PCFG whales are known to feed during summer and fall off the Pacific coast between northern California and southeastern Alaska, they also occasionally occur as far north as Kodiak (Gosho *et al.* 2011) and Barrow, Alaska (Calambokidis *et al.* 2012). The sighting from Barrow suggests that some PCFG whales (meaning whales seen in summer in the defined area used by the PCFG and in more than one year), at least occasionally occur in one of the most northern gray whale feeding areas in the ENP (Calambokidis *et al.* 2012). Similarly, of the 121 whales identified off Kodiak from 1998-2010, there have been 30 sightings of 17 individuals between June-November in areas extending from northern California to northern British Columbia (Table 9, Calambokidis *et al.* 2012). These observations indicate that at least some PCFG whales have used both the Kodiak feeding area in addition to the 41°N to 52°N area defined for the PCFG.

Satellite tagging studies between 3 September and 4 December 2009 off Oregon and California provide additional movement data for whales considered to be part of the PCFG (Mate *et al.* 2010). While duration of tag attachment differed between individuals, some whales remained in relatively small areas within the larger PCFG seasonal range while others traveled more widely. All six individuals whose tags continued to transmit through the southbound migration utilized the wintering area within and adjacent to Laguna Ojo de Liebre (Scammon´s lagoon). Three whales were tracked north from Ojo de Liebre and displayed the following movement patterns: (1) one whale traveled at least as far as Icy Bay, Alaska, and (2) two whales were tracked to coastal waters off Washington (Olympic Peninsula) and California (Cape Mendocino). In combination, satellite tag and photo-identification data suggest that the range of the PCFG may, at least for some individuals, exceed the pre-defined 41°N to 52°N boundaries that have been used in a number of PCFG-related analyses (e.g., abundance estimation).

Further support of the PCFG range extending beyond the pre-defined 41°N to 52°N boundaries comes from a study of six whales satellite tagged off the central west coast of Vancouver Island in March. This study was designed to determine northern migration routes in the greater Vancouver Island area (Ford *et al.* 2012). Three of the tagged whales had been previously sighted within the seasonal range used by PCFG whales (41°N to 52°N) and two had multi-year sighting histories there. These three whales moved north to between ~55°N to 57° N before their tags stopped transmitting. One of these whales was later observed in the seasonal range of the PCFG off southern Vancouver Island. These findings suggest that in the spring at least some PCFG whales may migrate northward, past the defined seasonal range used by the PCFG, along with the larger ENP stock before "circling back" to within the range of the PCFG summer feeding area.

It is unknown how long gray whales have used the PCFG area in summer and autumn; it may have been colonized as recently as the last century or during the Little Ice Age (~1540-1850) or other glacial periods when it was difficult or impossible for gray whales to feed further north. Records of gray whales feeding between northern California and Alaska during summer/fall date back to at least 1926 (Howell and Huey 1930), including reports of whales feeding on the southern feeding ground during the 1940s, 1950s, and 1960s (Gilmore 1960; Pike and MacAskie 1969; Rice and Wolman 1971). The consistent return of individuals to the southwestern coast of Vancouver Island, British Columbia, was first documented in the early 1970s (Hatler and Darling 1974).

A unique characteristic of PCFG whales is an apparent flexibility in their feeding habits. That is, whales summering in the seasonal range of the PCFG consume a varied diet including mysids, amphipods, crab larvae, and herring eggs/larvae. This is in contrast (generally speaking) to gray whales feeding in the arctic where they seem to be more focused on an amphipod food base (Nerini 1984). That being said, whales that utilize the seasonal range of the PCFG in only a single year (i.e., non-PCFG whales) must also be flexible, at least to some degree, in their feeding habits.

Abundance estimates of PCFG gray whales reported by Calambokidis *et al.* (2012) show a high rate of increase in the late 1990s and early 2000s, but have been relatively stable, albeit with some decline, since about 2003. No statistical analysis of trends in abundance is currently available for this population. The PCFG is estimated to contain about 200 individuals (Calambokidis *et al*. 2012). As stated in the 2012 gray whale SAR "because the PCFG appears to be a distinct feeding aggregation and may warrant consideration as a distinct stock in the future, a separate PBR was calculated" (Carretta *et al*. 2013). Calculation of a PBR for the PCFG allows NMFS to assess whether levels of HCM are likely to cause local depletion of this group. In keeping with that management objective, NMFS used the 2008 abundance estimate of 194 (SE = 17.0)[3] from Calambokidis *et al*. (2010) and the range of the PCFG (between 41°N to 52°N) as defined by the IWC to calculate a potential PBR for PCFG whales (Carretta *et al*. 2013). This calculation used the minimum population size (180 animals), times one half the maximum theoretical net population growth rate (½ x 6.2% = 3.1%), times a recovery factor of 0.5 (for a population of unknown status), resulting in a PBR of 2.8 animals (NMFS 2012). Further, a review of annual HCM in the PCFG between 2006 and 2010 was estimated and averaged 0.6 animals/year known deaths (Carretta *et al*. 2013).

In discussion, the TF asked Lang if there was any evidence that oceanographic changes have influenced the abundance or recruitment of whales into the PCFG. Lang replied that Calambokidis *et al.* (2012) reported a higher than usual "pulse" of animals recruited into the PCFG in the years following the 1999-2000 gray whale Unusual Mortality Event (UME). This UME has been theorized to be the result of limited food resources on the northern feeding grounds (see Gulland *et al.* 2005), and as such, this "pulse" of gray whale immigration[4] into the PCFG could potentially be considered a response to oceanographic changes. Given that the photo-identification effort on PCFG whales expanded greatly in 1998 (data from years prior to 1998 exist but not at the same level of effort), coinciding closely in time with the UME, it makes it impossible to resolve with certainty the occurrence or magnitude of the hypothesized pulse recruitment.

In response to the observations of PCFG whales in northern areas such as Kodiak and Barrow, Alaska, some members of the TF asked why the boundaries of the PCFG area defined by the IWC were not extended further north? The TF noted that the IWC definition was not intended to define the stock but rather to provide a conservative basis on which to evaluate the gray whale hunt proposed by the Makah Indian Tribe. With respect to low survey effort north of 52°N, the TF agreed that the PCFG could have a higher abundance than currently estimated and that this might affect a number of analyses including determination of annual sighting patterns of individual whales (e.g., a PCFG whale may have been present in a larger area but not photographed because it was located in an region not surveyed). The TF concurred that these issues are important to assignments of PCFG whales (i.e., those seen in two or more years between 41°N and 52°N) and highlighted the importance of expanding the spatial and temporal coverage of the photo-identification effort. In addition, further satellite tagging of known PCFG whales would also help to better define habitat use and delineate the seasonal feeding range.

Additional discussion was devoted to addressing the possibility that HCM (e.g., ship strikes and commercial fisheries bycatch) for whales in the PCFG area could be higher than for whales that migrate through the area. That is, PCFG whales spend more time near shore where ship traffic and fishing gear are concentrated. Despite this concern, little information is available on where

[3] This estimate will be updated in the 2013 SAR to include the now available 1999-2010 time series presented in Calambokidis *et al*. (2012).

[4] Immigration, as used here, means a permanent change of feeding ground fidelity and is considered interchangeable with "external recruitment".

HCM actually occurs. The TF asked Carretta how whales were classified as being PCFG in his analysis. He replied that the estimate was based on NMFS stranding data for the most recent 5-year period and included whales that stranded within the defined PCFG time period (1 June and 30 November) and range (41°N to 52°N). Carretta noted that his estimate of 0.6 animals/year, based on only the most current 5-year period (as per protocol of the SAR guidelines), is lower than the 20-year average of 1.5 animals/year reported elsewhere (IWC 2012a). The TF agreed that both of these estimates of HCM for the PCFG were likely to represent minimum estimates because there is no correction for incidents that go unobserved or unreported.

Related to the issue of HCM, the TF also discussed the results presented in Connor *et al.* (2011), which found that PCFG whales had higher rates of scarring than other gray whales. It was noted that crab pots are common off the Washington and Oregon coasts and as such may pose an increased threat in some parts of the PCFG range. Carretta noted that when looking through the HCM records, a fair number of southern California crab pot interactions were reported, which suggests that fisheries interactions of this nature could be a pervasive issue along the coast. The TF noted that PCFG animals could have more interactions (compared to non-PCFG whales) with crab pots and coastal fishing gear given their extended residency in nearshore areas. Therefore, the TF recommended that the existing photo-identification time series be used to examine scarring patterns of PCFG whales to possibly provide a better assessment of their interactions with fishing gear.

4. Population Dynamics of the Pacific Coast Feeding Group

Laake (AFSC) provided a summary of information regarding the PCFG (following the IWC definition) based on photo-identification research as described in Calambokidis *et al.* (2012). Photo-identification studies from 1998 to 2010 between northern California and northern British Columbia have categorized gray whales using that region during summer and autumn in two components: (1) whales that frequently return to the area, are seen in more than one year between 1 June and 30 November, and account for most of the sightings during that time period, and (2) whales that are sighted only in one year, tend to be seen for shorter time periods in that year, and are encountered in more limited areas.

4.1 Definition of Pacific Coast Feeding Group whales based on timing and area

Defining the PCFG involves analysis that spans both time and space. The temporal component of the PCFG range is better defined than the spatial component, but neither can be considered absolute. As mentioned previously, the IWC defines the PCFG as: gray whales observed between 1 June to 30 November within the region between northern California and northern Vancouver Island (from 41°N to 52°N) and photo-identified within this area during two or more years (IWC 2012a). The spatial boundaries of the PCFG range under the IWC definition were chosen for the following reasons: (1) samples used for the genetic analyses were taken from whales across this range, (2) the work of Calambokidis *et al.* (2012) showed movements of whales throughout the area (Figure 3), (3) only a small number of PCFG whales have been observed north or south of the area during the 1 June to 30 November time period, and (4) few if any whales are still migrating north through the 41°N to 52° N region from 1 June to 30 November. The temporal definition (1 June to 30 November) was based, in part, on the disparity in sighting rates across months. Whales observed after 1 June were more likely to be sighted (i.e., photographed) more than one time, in more than one year, and in more than one region (Figure 4).

In discussion, the TF asked whether the results presented in Figure 3 were effort-corrected. Laake explained that the proportions are only dependent on the effort in the region from the Makah U&A to Southern Vancouver Island (SVI) and not in the other areas. Variation in effort in areas outside of the Makah U&A-SVI region will change the sample size that could be detected in the Makah U&A-SVI but not the proportion of individuals resighted in the Makah U&A-SVI.

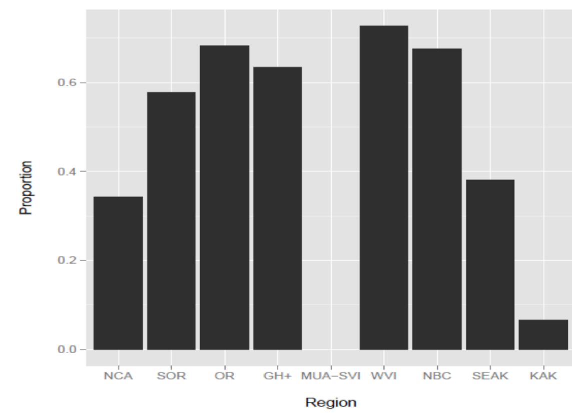

Figure 3. Proportion of whales sighted in the MUA-SVI region of whales seen in the identified areas. MUA and SVI were collapsed due to their proximity and high exchange rate. NCA = Northern California, SOR = Southern Oregon, OR = Central Oregon, GH+ = Gray's Harbor and surrounding coastal waters, MUA-SVI – Makah Usual and Accustomed Area to Southern Vancouver Island, WVI = West Vancouver Island, NBC = Northen Vancouver Island and coastal areas of British Columbia, SEAK = Southeast Alaska, KAK = Kodiak, Alaska.

The spatial range of PCFG whales was then discussed by the TF, including apparent gaps in survey coverage. Surveys in the seasonal range of the PCFG tend to focus on regions where gray whales have been seen and so the surveys are not randomly designed to cover the entire possible range. There is a large gap in survey effort north of 52° N (i.e., between northern Vancouver Island and Kodiak, Alaska). Because only a limited amount of gray whale survey effort has been undertaken in this region, it is unknown whether this area represents a true distributional gap. Even with this limitation, it is nevertheless possible to document observed movements of known individuals and estimate a related minimum range. Figure 5 presents the observed range of maximum distances between sighting locations for individual whales. Overall, approximately 40% of PCFG whales are known to have utilized areas spanning at least one degree of latitude. Further, there are documented movements of PCFG whales to Kodiak (Gosho *et al.* 2011) and Point Barrow, Alaska (Calambokidis *et al.* 2012), in years they were not seen in the PCFG area. Finally, information from tagging (see section above) also supports the idea that the range of some PCFG whales extends outside of the presently defined boundaries.

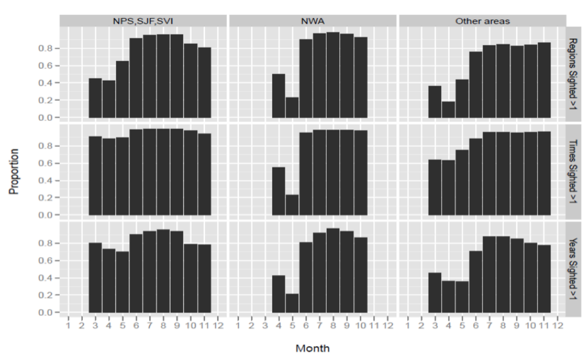

Figure 4. Proportion of whales sighted in more than one region (top), on more than one day (center) and in more than one year (bottom) as defined by the region and month they were seen. NPS = Northern Puget Sound, SJF = Strait of Juan de Fuca, SVI = Southern Vancouver Island, NWA = Northern Washington Coast.

It was noted by the TF that site fidelity of known reproductive mothers to the WNP Sakhalin Island feeding area is very strong (Weller *et al.* 2002). The TF therefore recommended that the existing PCFG photo-identification data be examined to see if moms/calves demonstrate higher levels of fidelity than other whales.

4.2 Pacific Coast Feeding Group abundance and survival

The photo-identification data collected annually in the seasonal range of PCFG whales (following the IWC definition) between 1998 and 2010 have been used to estimate abundance. In these analyses, the term "transient whale" was used to refer to whales seen in only one year and never seen again in any other year, and "non-transient whale" was used to refer to whales seen in at least two years, such that an estimate of the number of non-transient whales would be equivalent to an estimate of the number of whales defined to be in the area used by the PCFG. The total number of gray whales in the area used by the PCFG in summer would include both transient and non-transient whales, and is therefore higher than the number of defined PCFG whales in the area. In the following discussion of abundance estimates, whether an estimate is biased or not is relative to the true number of defined PCFG whales (not to the total number of gray whales in the area).

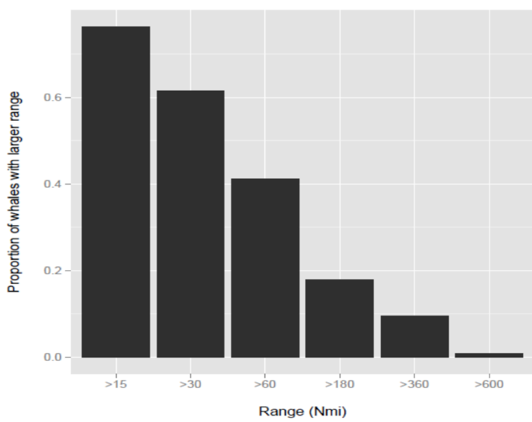

Figure 5. Distribution of maximum distance, in nautical miles, between photo-id locations for PCFG gray whales during 1 June – 30 November 1998-2010. The distance for 40% of the whales exceeded 1 degree latitude (60 nautical miles).

A number of different estimators were used including: (1) Lincoln-Peterson (LP), (2) Limited Lincoln-Peterson (LLP), and (3) Modified Jolly-Seber (JS1). The first two estimators constructed estimates from consecutive years of data. The LP estimator assumes a closed population and is unbiased if there are only losses or only gains. There are both losses and gains to the PCFG due to transient whales and therefore induces a positive bias. The LLP estimator removes the positive bias of the LP estimator by restricting the data to whales seen during the 2-year period but also in another year prior or after the 2-year period. This restriction eliminates whales that were transients in either of the years. The JS1 estimator is an open population model that estimates the abundance of non-transient whales. A fourth estimator, JS2, is an alternate JS modification that produced similar results except at the end of the time series (Calambokidis *et al*. 2012).

Calambokidis *et al.* (2012) considered the JS1 estimator to be the best suited for analysis of the PCFG (Figure 6). The Jolly Seber 1 (JS1) estimator assumes that any gray whale joining the PCFG is seen the first year it enters. The assumption is made to model the data adequately with the strong relationship between minimum tenure (time between first and last sighting in the year) and the probability it remains in the PCFG. The magnitude and trend of the LP abundance estimates do not match up well with the limited LP and the JS1 estimates; this is due to the fact that the LP

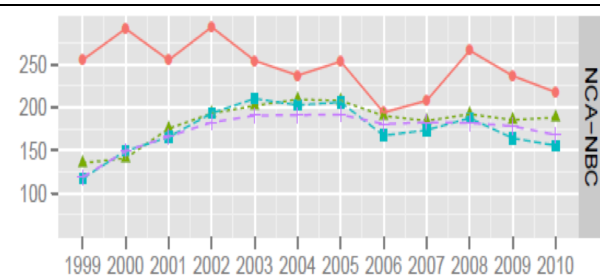

Figure 6. Estimates of the abundance of PCFG gray whales between northern California and northern British Columbia (NCA – NBC) using four different estimators based on photo-id data collected annually between 1998 and 2010. LP = Red Circle, JS1=Green Triangle, LLP=Blue Square, JS2=Purple Dotted Line

estimator was positively biased and the bias was greater at the beginning of the time series when there was more immigration and emigration into and out of the area used by the PCFG.

In discussion, the TF focused on whether the increase in the JS1 abundance estimates from 1999-2002 (Figure 6) was real or a reflection of the discovery of "new" whales that were present in the area used by the PCFG but not observed (i.e., photographed). Some of that discussion also focused on the related topic of recruitment described below. Laake responded that there were 13 whales not sighted in 1998 that were seen after 1998 (most of them were sighted in 1999) and were in the catalog for sightings prior to 1998. These results indicate that the assumption of JS1 (i.e., that any gray whale joining the PCFG is seen the first year it enters) was not met entirely. That being said, Laake argued that the bias was small or negligible after 1999 for the following reasons: (1) values from the JS1 estimator correspond closely to the value from the limited LP estimator which does not make the same assumption, (2) simulation results using similar values for capture probability estimated from the data showed a minimal amount of bias after 1999, and (3) the UME in 1999-2000 provides a plausible explanation for the coincident increase in PCFG abundance.

4.3 Pacific Coast Feeding Group IWC implementation review

Wade (AFSC) presented a brief overview of the status of the Implementation Review (IR) process conducted by the IWC. The IR includes trials based on three hypotheses: (1) Hypothesis P (Pulse) assumes that there is no bias in the PCFG abundance estimates (but dropping 1998) and that a pulse of immigration occurred in 1999 and 2000; (B) Hypothesis B (Bias) assumes a strong time-varying bias in the abundance estimate but no pulse of immigration; and (3) Hypothesis I (Intermediate) includes a moderate time-varying bias in the abundance estimates and a pulse of 10 immigrants into the PCFG in both 1999 and 2000. These hypotheses were evaluated because the model used in the IWC IR trials could not produce simulated abundance trajectories that fit the abundance estimates without incorporating a pulse or a bias into their model. For these trials the IWC Scientific Committee agreed that a sufficient fit to the data could be achieved with maximum annual immigration of up to six animals.

Wade noted that for the most part there was broad similarity between the population trajectories in the IWC trials and the population trajectories in the OSP determinations performed by Moore and Punt (pers. comm.), which only use Hypothesis P (a pulse of immigrants in 1999 and 2000, see related item below). The IWC implementation trials produce final statistics related to conservation status and catches.

There was some discussion about the need to evaluate trials that produced worrying conservation statistics and that it would be valuable to look at what the depletion level could be in those trials. Wade noted that the trials incorporating a low growth rate with little immigration or the trials in which the probability of taking a PCFG whale were doubled were the trials which do not do well with respect to conservation statistics such as final depletion level. Note that "final depletion level" is defined by the IWC to be the final population level as a percent of K. This is related to, but can be slightly different from, the U.S. MMPA definition of "depletion", which is defined to be a population level below the Maximum Net Productivity Level (MNPL). In U.S. MMPA depletion determinations, MNPL is generally assumed to either be a range from 50-70% of K, or a single value such as 50% or 60% of K. The only practical difference occurs when a range is used in MMPA determinations, where one calculates the probability a population is below MNPL over a range of percentages of K. If a single value is used for MNPL (e.g., 60%), than the IWC final depletion level is identical.

Some of the simulations conducted by the IWC with worrisome conservation performance (with respect to final depletion below 60%) are those using Maximum Sustained Yield Rate (MSYR) of 1% or 2%, implying a relatively low maximum population growth rate (Annex E, IWC 2012b). Note that the IWC Scientific Committee parameterizes population models with MSYR rather than Rmax (used in U.S. MMPA calculations). MSYR is the population growth rate at the Maximum Sustained Yield level, which is equivalent to MNPL if human-caused removals are unbiased with respect to age. Therefore, if MNPL is 50% of K, a population with an MSYR of 2% has an Rmax of 4%, and a population with an MSYR of 1% has an Rmax of 2%. Taylor noted that although she would have initially thought population growth rates that low were unlikely, after seeing some of the results presented she felt that relatively low population growth rates cannot be ruled out. She also noted that all trials in the table (which was a summary of trials that performed poorly with respect to conservation statistics) have annual immigration = 0 to 2, at the low end of the range considered. It appears that rates of annual immigration higher than 2 provide just enough of an offset to low MSYR rates of 1 or 2%.

The TF asked how the rescaled final depletion level was related to final depletion level in the IWC results. The rescaled final depletion statistic is used by IWC in trials whose specifications cause the population to decline even in the absence of catches. To evaluate those trials, the final population level for the trial (with catches) is compared to the final population level that would have been obtained in the absence of catches. That ratio is termed the rescaled final depletion, and represents the fraction of the population size that would have been obtained in the absence of catches. Since a low MSYR rate results in low population growth, the IWC found it is useful to compare depletion levels both with and without catches. The rescaled final depletion results for the PCFG only differ from the final depletion statistic for trials with a low value for MSYR, where the PCFG would decline and become depleted regardless of whether a hunt occurred due to the combination of a low population growth rate and bycatch.

4.4 Pacific Coast Feeding Group recruitment

Although new whales are identified each year in the range of the PCFG, about 50% of these individuals are seen in only one year and considered "transients" or "visitors" (Figure 7). Other whales are resighted in subsequent years and are considered "recruits" into the PCFG. Whales with a longer minimum tenure in the first year they were sighted have higher first year apparent survival and higher probability of return (i.e., do not permanently emigrate). This relationship might be expected given a hypothesis that whales are more likely to return if they find a suitable prey base during their first year in the seasonal range of the PCFG.

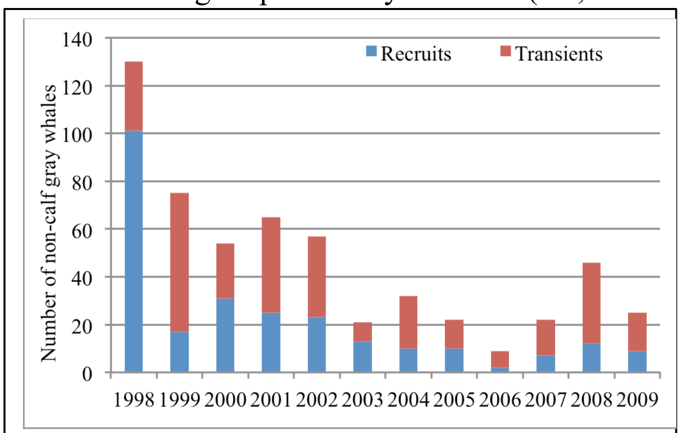

Figure 7. Number of "new" whales seen each year in the PCFG area that are transients (only seen in one year) and recruits (seen in more than one year).

Whales that recruited into the PCFG in 1999 or a subsequent year had lower first year apparent survival than whales that were first identified in 1998. Approximately 75% of the whales whose minimum tenure was 100 days or more in 1999 or later were resighted in a following year. For whales identified in 1998 (the first year of the study) whose minimum tenure was 100 days, nearly 100% were

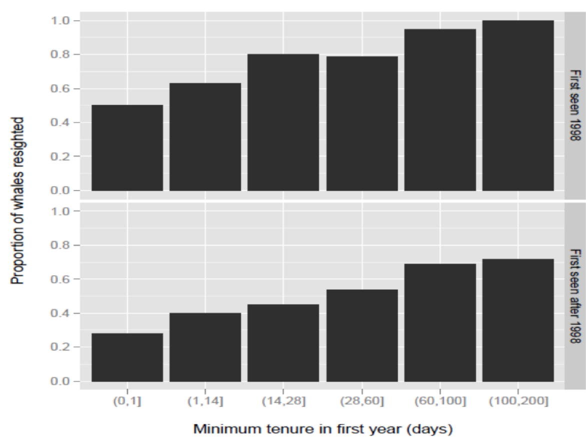

Figure 8. Relationship between minimum tenure in first year (# of days between first and last sighting plus 1) and the proportion resighted in at least one following year. The data series starts in 1998 so all whales are "new" so while the pattern is similar, the proportions are higher for 1998 because most whales are not truly new to the PCFG.

resighted in a following year (Figure 8). This suggests that some of the animals that recruited into the PCFG in 1999 or later may have subsequently emigrated out; this could explain why the abundance has declined somewhat in the later years (Figure 6). The high number of new whales identified in the seasonal range of the PCFG between 1999 and 2002 is hypothesized to have been in response to the 1999-2000 UME.

The TF discussed several alternative explanations for the relatively high numbers of recruits into the PCFG in the early part of the time series (1999-2002). For example, whether the increase in abundance during early years could be due to a "discovery" effect, such that it took a number of years for all the whales which were part of the PCFG to be photographed and "discovered". Alternatively, the heterogeneity in survey coverage over time and space could lead to some animals being considered "new" in a given year even if they had been utilizing areas with limited or no survey coverage in previous years. However, overall capture probabilities are high, suggesting it is unlikely a whale would be in the area for several years and not photographed. The TF concurred that on an annual basis, whales observed in the area used by the PCFG could be characterized as a collection of individuals whose residence patterns vary along a continuum such that some whales use the area for a single year (e.g., transients), some for a few years, and others on a consistent long-term basis.

By way of an analogy, Laake characterized the PCFG as a "leaky bucket", in that some whales are immigrating in while others are emigrating out. The "leaky bucket" phenomenon is not a random process, however, because a "core group" of whales appear to stay in the bucket over time. The dataset cannot discriminate between PCFG whales that die versus those that emigrate. Animals that recruit into the PCFG as non-calves may be more likely to emigrate out of the area than calves recruited to the PCFG in the year they were born. That is, calves of the year have been taught to feed on prey types common to the PCFG area (various swarming prey for instance) by their mothers and may obtain "local knowledge" that allows them to be successful long-term inhabitants of the PCFG area. To evaluate this, the TF recommended that the existing PCFG photo-identification time series be examined to see if moms/calves demonstrate higher degrees of fidelity than other whales.

In thinking about the "core group" of PCFG whales that return to the area on a consistent basis, the TF questioned if biopsy efforts in the area could be potentially biased towards these whales. If sampling efforts are unintentionally concentrating on the "core group" of PCFG whales, then the results of genetic comparisons may be driven by matrilineal fidelity of this "core group". In addition, the biopsy efforts are not spread evenly over time and space (more heterogeneity than the photo-identification survey efforts). If "core group" animals predominantly use the areas with high biopsy effort, then this potential bias could be magnified.

Some newly seen whales are calves with their mothers (Figure 9). As described in Calambokidis *et al.* (2012), much of the sighting effort occurs in August and later when many calves are likely to already be weaned and thereby more difficult to identify as a calf (versus a yearling). The TF noted that many of the whales identified as calves off Sakhalin Island in the WNP are not resighted for many years subsequent to their birth year but eventually they are again resighted in the area. This pattern suggests that young animals (1+ years old) may use other areas to feed during their first several years. Therefore, in the case of the PCFG, if a whale was not seen as a calf but returned in a later year it would appear to be an external rather than internal recruit. With that in mind, the TF recommended that the existing PCFG photo-identification time series be examined following a protocol developed by Bradford et al. (2011) that uses barnacle and pigmentation characteristics on young gray whales to reliably distinguish calves of the year from yearlings.

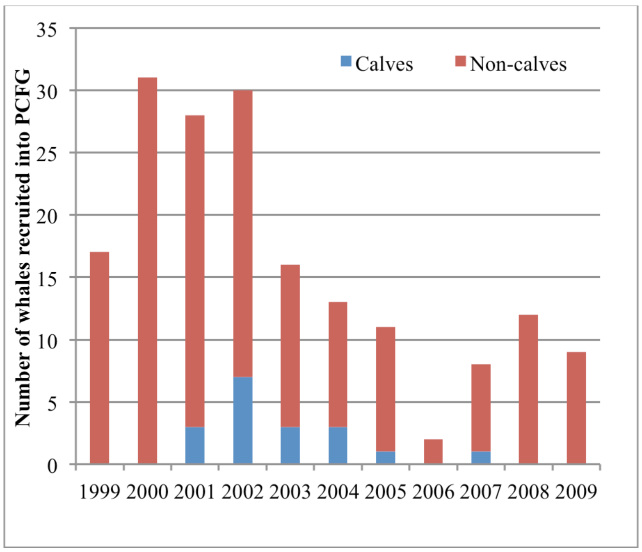

Figure 9. Number of whales first seen and recruited (seen in a following year) by year and calf and non-calf designation.

In summary, the TF discussion about the magnitude and source of recruitment into the PCFG focused on: (1) incomplete survey coverage of the entire seasonal range used by the PCFG and the potential for whales to be missed and then "recruited" in a subsequent year, (2) the proportion of "recruited" whales that were calves of mothers from the PCFG that may have been missed as a calf or misidentified as an external recruit, (3) the potential of the 1999/2000 UME to create a pulse of immigration into the PCFG, (4) to what degree gray whales recruited in 1999 or later were either emigrating back to the northern feeding areas or experiencing higher mortality, and (5) whether the biopsy sampling effort was prone to sample whales that spent more time in the range used by the PCFG.

All of these issues are relevant to assessing the amount of external recruitment into the PCFG and thereby especially pertinent to determining if it should be recognized as a population stock under the MMPA and GAMMS guidelines. That is, if the PCFG experiences little external recruitment then it would be considered demographically independent and should be recognized as a stock. If most of the recruitment into the PCFG were external, however, then it would not be considered demographically independent and would not be recognized as a stock. The TF concurred that the resolution of the existing photo-identification data in combination with uncertainly surrounding the accuracy of assigning whales as external or internal recruits prevent this question from being fully resolved. Increased genetic sampling in tandem with increased photo-id effort over both space and time may be the only way to better address this question.

4.5 Pacific Coast Feeding Group trend and optimum sustainable population determination

Moore presented an update on work he conducted in collaboration with Andre Punt (University of Washington) to determine if the PCFG, as a putative stock, is at OSP. The OSP assessment is based on the two-stock population model that has been developed as part of the IWC gray whale

Implementation Review (see section 4.3). Both assessments use the same definition for a PCFG whale. There are some differences, however, between the IWC model framework and the one used for the OSP assessment. First, in the OSP analysis, a Bayesian approach is used in which prior distributions are specified for input parameters and the time series of abundance estimates (for the ENP and PCFG) are used to the update priors and output posterior distributions. This contrasts with the IWC approach of generating outputs for many models each based on alternative fixed combinations of values for some parameters. Second, the IWC trials consider several hypotheses that attempt to explain the rapid increase in abundance estimates in the first few years of the time series; these include bias in the early abundance estimates, a pulse of immigration, and a combination of these two factors. In the OSP assessment, only the pulse immigration hypothesis is considered, based on work by Calambokidis *et al.* (2012) which suggested that the most recent abundance estimates should be fairly unbiased apart from the first estimate in 1998, which is not used in the OSP analysis.

At the time of the workshop, the OSP analysis considered two hypotheses pertaining to the regular annual immigration rate: one in which there is no immigration (PCFG is closed) and one in which the annual immigration rate is estimated, given a uniform prior distributed between 0 and 6 individuals per year. Different versions of the model allow the density-dependent (or inflection point) parameter θ to be estimated separately for each putative stock (PCFG vs. rest of the ENP) or to be constrained so that the two groups share a common θ. Outputs from both versions and immigration rate considerations (none vs. U[0, 6]) are similar in models run thus far. The primary parameter of interest in the OSP assessment is the probability that PCFG abundance is above MNPL (MSYL in IWC terms).

The analysis was not able to generate useful assessment results because, apart from the rapid population increase in the late 1990s attributed to an immigration pulse, the abundance time series is fairly flat and therefore not very informative for estimating *in situ* population growth parameters. The data have also not been informative for estimating population carrying capacity (K), a parameter necessary to determine whether current abundance is above MNPL. Posterior distributions for K have been strongly dependent on the upper bound used for the prior. Given that the abundance has been stable throughout most of the 2000s, it appears to be regulated at this level (of around 200 - 250 animals) by some factor, and thus it is somewhat puzzling that the data do not seem more informative with respect to estimating K. Moore suggested that annual levels of incidental take included in the model (about 2 animals per year) could be making it difficult to estimate whether the population is being regulated at K or some level below K, given that the data do not inform the estimates of MSYR (the population growth parameter in IWC models). For example, given annual bycatch mortality of 1%, a combination of being well below K and having a low MSYR may describe the data equally well as being close to K and having a high MSYR, since in both cases, the realized value for population growth would be low and potentially balanced by the additive mortality. It was also suggested that the population might be regulated at its current level as a result of emigration and bycatch offsetting the combination of immigration and *in situ* growth.

Moore and Punt were continuing to troubleshoot the problem by running alternative models that, for example, exclude incidental take from the model or constrain estimates of MSYR for the PCFG to be equal to those of the ENP. The goal of this troubleshooting is to explain why estimates of K and hence probability of being at OSP are elusive, which in turn may enable a decision as to whether an OSP assessment may be possible.

The TF thanked Moore and Punt for their work on this complicated matter and raised several points for clarification. It was asked where the estimates of incidental mortality for the model had come from. Moore reported that the bycatch estimate being used is based on a summary compiled at the 2011 IWC Aboriginal Whaling Management Procedure (AWMP) intersessional workshop (IWC 2012a). Carretta clarified that those estimates included data from over a 20-year period that tried to assign animals as being part of the PCFG (or not) based on time and space. Carretta also noted that the bycatch values used in the OSP analysis (as well as the SARs) account for only observed bycatch, which is likely to be an underestimate of actual bycatch.

It was also noted that emigration is a possible explanation for the difficulty in estimating K in spite of apparent PCFG population size stability. That is, all recruits are assumed in the model to have the same annual survival rate but as discussed above, whales that recruited into the PCFG in 1999 or later had lower first year survival than whales that were first identified in 1998. Not including this extra survival parameter may explain some of the lack of fit of the model to the abundance time series (plots show that the model underestimates abundance in the first half of the time series and overestimates abundance in the second half of the series).

The TF asked if the model assumed immigration was constant across years in the assessment given that in reality immigration into the PCFG is thought to vary across years. In the model, immigration to the PCFG occurs at a constant rate, with the number of immigrants being proportional to the northern stock (non-calf) abundance. The rate is equal to the estimated immigration parameter (*I*, specified with the uniform [0,6] prior) divided by 20,000. In other words, for recent abundance levels of the northern stock, annual immigration to the PCFG is approximately *I* individuals. Emigration from the PCFG group is similarly assumed to occur at a constant rate, specified by an additional survival parameter ($1 - S$), with the number of emigrants proportional to PCFG abundance. *S* is set so that when both stocks (northern and PCFG) are at carrying capacity, immigration and emigration to the PCFG is balanced, i.e., $IK_{\text{north}}/20000 = (1 - S)K_{\text{PCFG}}$.

Some members of the TF commented that based on this model it seems plausible that the pulse of immigration into the PCFG is larger than what the IWC is modeling or what the genetic simulations have modeled. If that were the case, then the estimates of regular annual immigration would be lower than estimated in the genetic simulations. In the light of this discussion, the TF noted that the genetic simulations should try pulses of 30 animals to see if that is consistent with the empirical genetic data. This line of thinking led to additional discussion as to how common pulse immigration events might be, and whether, for the purposes of the workshop and deliberations on internal versus external recruitment, the TF should be considering the pulse as part of the average level of immigration or if the pulse should be considered a one-time event and only annual immigration should be considered (in assessing how demographically independent the PCFG is).

It was further noted that if a UME event the size of the one in 1999-2000 had occurred previously, some record of it would be expected. Wade noted that it was due to this reasoning that they did not incorporate additional mortality events in the northern stock OSP analysis conducted by Punt and Wade (2012). Wade also noted, however, that there had been a drop in the northern stock abundance in earlier years of the time series but these were not accompanied by a record of increased strandings. The TF suggested that pulses could occur regularly on decadal time scales or as a result of a variety of other environmental or anthropogenic factors.

The TF discussed if the genetic data may reflect a sampling bias toward "core" PCFG animals. This follows other lines of evidence showing that there is a relationship between minimum tenure and probability of photographically capturing animals in the PCFG area (see section 4.4 above). If "core" PCFG whales are more approachable, then they are potentially more likely to be biopsied, meaning that these whales may be disproportionately selected for in the biopsy process.

Lang noted that she had looked at the current genetic sample set to see if the rare haplotypes found in the PCFG sample set came from animals that were sighted in 1999 or later, which might suggest that they were immigrants as the expectation would be that immigrants would be likely to bring in rare haplotypes. The results were mixed, with some rare haplotypes found in long-term PCFG whales while others were found in animals that came into the PCFG in 1999 or later.

This led to a discussion about what additional information might help the PCFG OSP assessment and improve inference generally about the level of internal versus external recruitment to the PCFG. The TF agreed that additional genetic sampling to improve estimates of immigration and residency times (emigration), and improved estimates of incidental mortality would be useful.

5. Probability of a Western North Pacific Gray Whale Being Taken by the Makah

Mixing of whales identified in the WNP and ENP has recently been reported (Weller *et al.* 2012). Lang (2010) reported that two adult individuals from the WNP, sampled off Sakhalin in 1998 and 2004, matched the microsatellite genotypes, mtDNA haplotypes, and sexes (one male, one female) of two whales sampled off Santa Barbara, California in March 1995. In 2010 and 2011, Mate and colleagues (Mate *et al.* 2011) satellite-tracked three whales from the WNP to the ENP (Mate *et al.* 2011; IWC 2012a; IWC 2012b). Finally, photographic matches between the WNP and ENP, including resightings between Sakhalin and Vancouver Island and Laguna San Ignacio, have further confirmed use of areas in the ENP by whales identified in the WNP (Urbán *et al.* 2012; Weller *et al.* 2012). Despite this level of mixing, significant mtDNA and nuclear genetic differences between whales in the WNP and ENP have been found (Lang *et al.* 2011b).

Observations of gray whales identified in the WNP migrating to areas off the coast of North America raise concern about placing the WNP population at potential risk of incurring mortality incidental to the ENP gray whale hunt proposed by the Makah Indian Tribe off northern Washington, USA (see IWC 2012a; IWC 2012b). Given the ongoing concern about conservation of the WNP population, in 2011 the Scientific Committee of the IWC emphasized the need to estimate the probability of a western gray whale being killed during aboriginal gray whale hunts (IWC 2012a). Additionally, NOAA is required by NEPA to prepare an Environmental Impact Statement (EIS) pertaining to the Makah's waiver request. The EIS will need to include an analysis of the likelihood of a western gray whale being killed during the proposed Makah gray whale hunt.

Moore summarized the work that he and Weller (SWFSC) have done to estimate the probability that a WNP whale might be taken during the proposed gray whale hunt (Moore and Weller 2013). Four alternative models were evaluated; these models made different assumptions about the proportion of WNP whales that would be available for the hunt or utilized different types of data to inform the probability of a WNP whale being taken. The probability of striking at least one WNP whale over the course of five years was estimated to range from 0.034 – 0.058 across different scenarios of the preferred model, with upper 95% CI estimates ranging from 0.107 –

0.170. This result may be compared to an estimate of PBR. If the recovery factor for calculating PBR is set to 0.1, and discounting the estimate for the proportion of the population that may be migrating through U.S. waters and the proportion of time (months out of a year) they are in U.S waters, then the 5-year PBR estimate is between 0.1 and 0.6 animals, depending on different assumptions about the amount of mixing between the WNP and ENP. Thus, if a WNP whale were to be struck during the 5-year period, PBR would be exceeded.

6. Status of Gray Whale Stocks as Defined by, MMPA, ESA and IUCN

At the request of the TF, Stone (NWR) provided a review of the status of ENP, WNP and PCFG gray whales under the MMPA, ESA, and the International Union for Conservation of Nature (IUCN) redlist.

(1) ENP – The ENP stock is not considered *"strategic/depleted"* under the MMPA and is listed as "*Least Concern*" by the IUCN. Gray whales in the ENP were delisted from the ESA in 1994. Although there have been two petitions (2001 and 2010) to relist the ENP stock under the ESA, both petitions were denied.

(2) WNP – The WNP stock is considered "*strategic/depleted*" under the MMPA and is redlisted as "*Critically Endangered*" by the IUCN. WNP whales are considered "*Endangered*" under the ESA, although there is no stand-alone SAR for WNP whales. Given that ENP whales were delisted in 1994, gray whales in the WNP would be considered a Distinct Population Segment (DPS) under the ESA. Use of the DPS terminology was not common at the time of the delisting and thus the listing documents do not describe the WNP as a DPS.

(3) PCFG - The PCFG does not have a formal status under the MMPA, IUCN nor ESA.

In addition to the above, the TF discussed the status of gray whale stocks as defined by the IWC. Under the IWC implementation review (IR) process, the IWC considers all plausible hypotheses of stock structure, and then determines which hypotheses have high or medium plausibility. Those stock hypotheses with high or medium plausibility are used to evaluate the management variants proposed by hunters. In the case of gray whales, the IWC traditionally considered only the hypothesis of a single ENP stock. New information presented to the IWC in 2010 (Frasier *et al.* 2011) suggesting that the PCFG could be a separate stock resulted in the IWC evaluating a two-stock hypothesis. Members of the TF reminded the group that the IWC does not have to decide if there are one or two gray whale stocks, but only if it is plausible that there is one stock and if it is plausible that there are two stocks (or three stocks). The objective of the IWC is to make sure that the stock or stocks are robust to the proposed hunt under all plausible scenarios. Thus, the IWC process is currently considering both stock hypotheses (1-stock and 2-stock). Future work by the IWC may need to incorporate a third stock (i.e., WNP) but for now the calculation of the probability of a WNP whale being killed during the Makah hunt (see section 5 above) is a stand-alone calculation.

7. Overview of Evidence Used in Recently Defined Population Stocks

Stone provided an overview of the lines of evidence used by NMFS to delineate stocks as inferred from the text of each SAR. It became clear during discussion of the summary that many of the SARs do not explicitly lay out the lines of evidence and justifications for originally delineating a stock but instead only present recent information. The killer whale SARs, for example, do not describe the acoustics data and other lines of evidence that were originally used to identify the stocks. There was general agreement that an updated summary, in spreadsheet form, would be useful as it could capture the history and provide a long-term record of how each stock was delineated, but this would not be a trivial task. In the end, the TF concurred that agency practices for delineating stocks were not based on a set standard but were more variable and fact-specific so as to use the best available information.

8. Review of Stock Definition Cases Relevant to the Pacific Coast Feeding Group

The TF reviewed several examples of stock delineations for other species exhibiting some similar characteristics to the PCFG. Similar characteristics included: (1) use of mtDNA as the sole genetic marker necessary for stock structure determination and (2) mixing with individuals from other stocks during parts of the year.

8.1 Atlantic harbor porpoises

Rosel (SEFSC) presented an overview of stock structure in Atlantic harbor porpoises (*Phocoena phocoena*) with a focus on the Gulf of Maine/Bay of Fundy stock. A single stock was designated in U.S. waters of the Northwest Atlantic based on published literature of Gaskin (1984) who hypothesized four populations in the Northwest Atlantic (three in Canadian waters and one in U.S. waters). While following Gaskin (1984), the first SAR for U.S. Gulf of Maine/Bay of Fundy harbor porpoises stated "*Presently there is insufficient evidence to accept or reject this hypothesis*" (Blaylock *et al*. 1995). In subsequent years, mtDNA evidence supported four stocks in the Northwest Atlantic, including the Gulf of Maine stock, but nuclear microsatellite data did not (Rosel *et al.* 1999). Organopollutant levels (Westgate *et al.* 1997, Westgate and Tolley 1999) and life history characteristics (Read and Hohn 1995) also differed between the Gulf of Maine/Bay of Fundy and other populations in the Northwest Atlantic. The weight of evidence supported delineation of the Gulf of Maine/Bay of Fundy stock and the lack of nDNA differentiation between this stock and others in the Northwest Atlantic was taken to indicate female philopatry coupled with male-mediated gene flow. Microsatellite data indicated that porpoises from the Gulf of Maine/Bay of Fundy probably overlap in winter in the mid-Atlantic with porpoises from other regions of the Northwest Atlantic (Hiltunen 2006), but this is outside the breeding season.

8.2 Alaska harbor seals

Taylor summarized the history of recognizing stocks of harbor seals in Alaska. Harbor seals (*Phoca vitulina*) are continuously distributed throughout Alaskan waters, but mtDNA indicates that genetic differentiation among sampled sites increases with increasing geographic distance (O'Corry-Crowe *et al.* 2003). The continuous distribution implies that there will be movement of animals across stock boundaries drawn on a map, but if no stock boundaries are designated, there is the risk of local depletion and loss of portions of the species' range. The first SARs for Alaska harbor seals comprised three stocks- Bering Sea, Gulf of Alaska and Southeast Alaska (Hill and DeMaster 1998). In 2011, the three stocks were changed to twelve (Allen and Angliss 2012). MtDNA, satellite telemetry, trend and distributional data were used to delineate these 12 stocks. At that time, nDNA data were not available and mtDNA analyses were considered sufficient to meet the criteria of demographic independence under the GAMMS guidelines.

8.3 Humpback whales

Lang presented a review of humpback whale (*Megaptera novaeangliae*) stocks, with a focus on the North Atlantic. There are multiple humpback whale feeding grounds in the Northwest Atlantic, but individuals from these different feeding grounds share one breeding ground in the

West Indies. Humpback whales throughout the Northwest Atlantic were originally classified as a single stock (Waring *et al.* 1999). However, genetic studies have revealed small but significant differences in mtDNA between animals sampled on different feeding grounds (Palsbøll *et al.* 2001) and photo-identification studies have documented strong site fidelity of individuals to the Gulf of Maine feeding area (Clapham *et al.* 1993). The 2000 SAR recognized whales utilizing the Gulf of Maine feeding area as a separate stock (Waring *et al.* 2000). Although this SAR covers only Gulf of Maine whales, individuals from other feeding areas have been identified in U.S. mid-Atlantic waters (Barco *et al.* 2002).

The stock structure of humpback whales in the Pacific is complex (Baker *et al.* 2008; Calambokidis *et al.* 2008) and differs from the western North Atlantic with respect to the "interbreed when mature" criteria. That is, humpback whales from different feeding grounds in the NW Atlantic have the opportunity to interbreed with each other in a single breeding area, while in the North Pacific not all animals have the opportunity to interbreed with each other because there are multiple breeding areas. There is some similarity between North Pacific humpbacks and those in the central and eastern North Atlantic, in that whales on the Norway and Iceland feeding areas may breed in different areas (Palsbøll *et al.* 1997; Stevick *et al.* 1998; Wenzel *et al.* 2009). Three humpback whale stocks are currently recognized in the North Pacific, based on three feeding areas (Allen and Angliss 2012; Carretta *et al.* 2013). The SAR for the Central North Pacific stock includes calculations of PBR for three different feeding areas (Allen and Angliss 2012), as is done for the PCFG in the current SAR (Carretta *et al*. 2013).

9. Review of Gray Whale Genetic Research on Population Structure

Lang provided a chronological summary of genetic research performed on North Pacific gray whales. Steeves *et al*. (2001) used mtDNA control region sequence data to compare 16 samples collected in summer in Clayoquot Sound, British Columbia, representing the PCFG, to 41 samples collected elsewhere in the ENP. Some haplotypes were shared between the two groups and no significant differentiation was found between them. Additional genetic analysis utilizing an extended set of samples (n=45) collected from whales within the seasonal range of the PCFG indicated that the genetic diversity and the number of mtDNA haplotypes identified among these samples were inconsistent with measures that would be expected (based on simulations) if recruitment into the group were exclusively internal (Ramakrishnan *et al*. 2001). Alternative scenarios, such as limited dispersal of whales from other areas into the PCFG, were not explored. LeDuc *et al*. (2002) examined mtDNA control region differences between ENP and WNP gray whales. The ENP sample consisted primarily of stranded animals along the migratory route with some samples from Chukotka, Russia (no distinctions between PCFG and non-PCFG whales were made). The WNP samples were collected off the northeastern coast of Sakhalin Island, Russia. Seven of the 36 identified haplotypes were shared between the two regions and significant genetic differentiation was found. In addition, haplotypic diversity of the WNP sample was lower than that seen for the ENP samples.

Within the ENP, Goerlitz *et al*. (2003) made comparisons between two wintering lagoons and between females sampled in wintering lagoons and those sampled outside the lagoons (in Clayoquot Sound and along the migration route- *i.e.,* "non-lagoon females"). They found small but significant differences in mtDNA data between Laguna San Ignacio cows (females with calves) and non-lagoon females and between Laguna Ojo de Libre cows and non-lagoon females but not when cows from the two lagoons were compared. Alter *et al*. (2009) compared both mitochondrial and nuclear microsatellite markers across three wintering lagoons and found small but significant differences between only one of the three pairwise comparisons using the microsatellite data set only. Similar to Goerlitz *et al.* (2003), they did not find significant differentiation between Laguna San Ignacio and Laguna Ojo de Libre at mitochondrial or nuclear DNA.

More recently, Frasier *et al*. (2011) examined mtDNA differences between whales sampled in Clayoquot Sound, British Columbia (representing the PCFG) and a more carefully constructed data set of ENP whales from LeDuc *et al.* (2002) in which known PCFG whales were specifically removed. They found significant genetic differentiation between the two sample sets and high levels of haplotype diversity in the PCFG sample, comparable to samples thought to represent the larger ENP population. Using this dataset, Frasier *et al.* (2011) also performed a likelihood ratio test using Theta (Θ) as a proxy for effective population size to examine whether the two sample sets come from the same population. The likelihood ratio test indicated that Θ for the PCFG did not equal Θ for the ENP and the authors concluded that the two groups were demographically independent.

D'Intino *et al*. (2012) made a comparison of whales sampled off Vancouver Island and representing the PCFG to whales sampled at the calving lagoon at San Ignacio. Using 15 microsatellite loci, they found no evidence for population differentiation between these two areas and concluded that the two sampled groups come from the same interbreeding population and that maternally-directed site fidelity to different feeding areas leads to genetic differentiation at mtDNA among feeding areas. Lang *et al*. (2011a) expanded on this result and compared whales sighted over two or more years within the PCFG seasonal range to animals sampled on the feeding ground(s) north of the Aleutians using both mtDNA and nuclear microsatellite markers. Significant differentiation was seen for the mtDNA data but not the microsatellite data, supporting the conclusion of Frasier *et al.* (2011) that structure is present among different feeding areas and this structure may be directed by matrilineal fidelity[5] to feeding grounds. Of note, when all samples collected on the PCFG seasonal range (including those collected from animals seen in only one year) were utilized in the mtDNA analyses, no significant differences were detected in the comparison to samples collected from whales off Chukotka. When all samples collected on the PCFG seasonal range were compared to all samples collected north of the Aleutians, the mtDNA F_{ST} comparison detected a significant difference although the χ^2 test did not.

Finally, Lang *et al.* (2011b) re-examined differences between ENP and WNP gray whales, expanding on the previous study of LeDuc *et al.* (2002) by using larger sample sizes, better characterized sampling and both mtDNA and nuclear microsatellite data. Comparisons of whales sampled off Sakhalin Island with whales feeding north of the Aleutians (i.e., ENP whales) and with the PCFG demonstrated significant differentiation at both nuclear and mtDNA markers. The extent of mtDNA differentiation between ENP strata (PCFG and whales feeding north of the Aleutians) and Sakhalin Island was higher than that observed in comparisons within ENP strata. As with previous studies, significant differentiation among ENP feeding areas was not seen in the microsatellite data. The Sakhalin stratum again displayed reduced haplotype diversity compared to the ENP strata. The authors conclude that the mtDNA data support demographic

---

[5] Matrilineal fidelity as used here means the learned behavior of a calf (male or female) returning to the feeding ground of its mother.

independence for ENP and WNP gray whales. However, in examining the microsatellite genotypes, Lang *et al.* (2011b) found two individuals biopsied at the Sakhalin feeding ground and off the coast of southern California. These matches, in combination with recent photo-identification and telemetry data (Mate *et al.* 2011; Urbán *et al*. 2012; Weller *et al.* 2012), suggest that some animals summering off Sakhalin overwinter in the ENP in at least some years. Given that recent records document gray whales in the waters off Japan and China during winter and spring (see review in Weller and Brownell 2012) these results suggest that population structure in gray whales may be more complex than previously believed, such that not all of the animals that feed off Sakhalin share a common wintering ground, or that some animals may switch between wintering grounds.

In discussion, TF members suggested some further avenues for exploration including examining whether any microsatellite loci were out of Hardy-Weinberg equilibrium (HWE) for the Sakhalin samples, which might be an indication of mixing of multiple breeding populations on that feeding ground. It was noted that at the 2012 IWC Scientific Committee meeting a paper evaluating the use of HWE tests to look at mixing of stocks was presented and it might be worthwhile to see if the approaches in this paper could be applied to the Sakhalin dataset (IWC 2012b). There was also discussion regarding what proportion of mixing would have to take place before it would be detected by a relatively weak test like HWE.

9.1 Genetic modeling of immigration rates

Lang presented an overview of recent work utilizing a simulation-based approach to evaluate the plausible level of immigration (i.e., a permanent change of feeding ground fidelity, used interchangeably with external recruitment) that might be occurring into the PCFG. While the empirical studies summarized above have shown significant differences in mtDNA between the PCFG and other ENP gray whale feeding areas, suggesting that matrilineal fidelity is important in structuring feeding ground use, other evidence (some from genetics, mostly from photo-id) suggests that some immigration into the PCFG may be occurring. Lang and Martien (2012) used simulations to examine how much immigration into the PCFG could occur to produce results consistent with the empirical genetic (mtDNA) analyses. The results suggested that the plausible range of immigration is >1 and <10 animals/year on top of a two-year pulse of immigration (of 20 animals each year in 2000 and 2001). Annual immigration of 4 animals (with the 2 year pulse of immigration) produced simulated results that were most consistent with the empirical data. If the PCFG had been founded more recently or the abundance of the PCFG is greater than used in the simulations, it is plausible that no annual immigration could be occurring (still assuming the occurrence of a 2-year pulse of immigration).

In discussion of these results, the TF noted several important caveats to the approach used by Lang and Martien (2012), including: (1) the results may be overly precise because so many model parameters are set, and (2) the simulated abundance trajectories do not match well with the mark-recapture estimates (Calambokidis *et al*. 2012) when immigration is 4 immigrants/yr or more. The simulated population trajectories assumed that the PCFG split from the larger ENP population in 1930. Task Force members thought that the 1930 split might be unrealistic, as oceanographic conditions during the Little Ice Age (and earlier) would have limited access to the northern feeding ground(s) and thus may have caused some gray whales to utilize more southern waters for feeding. Lang commented that there were plans to model a split of the PCFG from the larger ENP in the Little Ice Age, but that this work is not yet complete. She also noted that there were many possible histories and it would be difficult to encompass all of them.

10. Discussion of Makah Documents Concerning the Pacific Coast Feeding Group

Weller introduced three documents drafted by or on behalf of the Makah Indian Tribe regarding the PCFG. These documents were provided to the TF in advance of the meeting for review and consideration. In combination, these three documents provided important summary information on the PCFG, including reviews of what is known about the history of the PCFG and summaries of the current status of the group.

The 2011 Makah document (Makah 2011) was drafted by the Tribe and their attorneys and provided to the Pacific and Alaska SRGs as a background paper to help inform their respective reviews of the draft 2012 gray whale SAR (NMFS 2012). This document provides the Makah perspective on whether the PCFG should be recognized as a stock and was therefore deemed important for the TF to review and consider. Information provided in Scordino *et al*. (2011) is largely the same as that presented in the Makah 2011 document.

The 2012 Makah document (Makah 2012) contains comments from the Makah Tribe and their attorneys on the 2012 draft gray whale SAR (NMFS 2012). This document was considered important for the TF to review. In response to the Tribe's request for government-to-government consultation, the SWFSC met with representatives from the Makah Tribe and their attorneys in person to review comments provided in the 2012 document. These comments, where appropriate, were incorporated as changes to the draft text of the SAR (NMFS 2012).

10.1 Discussion of genetics sections of Makah documents

In discussion of these documents, the TF agreed that it was most important to focus on the Makah comments and perspective regarding genetics research on the PCFG. Rosel agreed to lead the TF through the genetics sections of the Makah documents that called into question the strength of the genetic data presented with respect to demographic independence of the PCFG. These points were summarized as: (1) the samples used to represent the overall ENP stock may not be a random sample of the entire stock but could come from different and unknown feeding grounds. This calls into question what the PCFG is being compared to in the genetic analyses, (2) sample sizes from many locations are small relative to overall population size (i.e., relative to the size of the larger ENP population) and to the total level of genetic diversity and that this could cause misleading results, (3) many population comparisons of gray whales have yielded significant but low-level differences in haplotype frequencies; if this is considered sufficient evidence to classify the PCFG as a stock then every group of gray whales utilizing a particular feeding area should be considered a stock, and (4) the genetics results do not support reproductive isolation of the PCFG.

The first two points were related to sampling effects. In discussion, some members of the TF noted that it is not necessarily the sample size that is potentially problematic but rather if related animals are grouped together and multiple biopsies are taken from that "group" then the effective sample size is much smaller. It was further noted that small sample sizes may add variability, but it would only be a problem if there were additional (unrecognized) structure in the samples. From a genetic standpoint, many analyses rely on haplotype frequencies, but if a good sample relative to the genetic diversity of the group is not obtained then the genetic diversity may not be well characterized, especially if there are many rare haplotypes. Since haplotype frequency data also go into analyses for F_{ST} and Chi-square, then poor frequency estimates due to small sample size could affect the accuracy of the genetic differentiation results as well. Lang noted that there is some evidence from North Atlantic humpbacks that the migration to the West Indies is segregated according to feeding ground origin (Stevick *et al.* 2003).

The TF noted, however, that the recent PCFG genetic analyses show high diversity indicating that sampled animals have different haplotypes and are thus not related (maternally). The TF asked if the question at hand is whether gray whales have feeding aggregations or whether the group that migrates north of the Aleutians is different from the group that does not migrate north of the Aleutians. Lang noted that the original intent of the project was to compare samples collected from different feeding areas north of the Aleutians to the area used by the PCFG but in the end sample sizes were insufficient for areas other than Chukotka. Nevertheless, although there could be multiple feeding aggregations north of the Aleutians, one of the comparisons conducted by Lang *et al.* (2011a) used only samples collected off Chukotka to try to avoid including unrecognized structure.

The TF recognized the continuing need for additional data to be collected, but for the purposes of the workshop the focus was whether the lines of evidence from existing genetic analyses are strong enough to counter lines of evidence that put the demographic independence of the PCFG into question. The primary question in the short-term is what can be done with the information that is currently available.

The TF noted that Frasier *et al.* (2011) compared animals from the PCFG with a sample set primarily derived from stranded animals along the U.S. west coast during migration. They agreed that these samples might not be a random representation of the larger ENP, as was also pointed out in the Makah documents.

Overall, the TF felt it was important to recognize that the current research questions being addressed center around feeding-ground-based groups of animals. The genetics work has already shown that when the PCFG is compared to a sample set from northern feeding area (Chukotka) animals or to the Sakhalin animals (also a feeding area) differences have been found (Lang *et al.* 2011b). That is, the PCFG has been shown to be different from two other well-characterized feeding grounds.

While interpretation of the currently available genetic results as relevant to the PCFG has lead to debate amongst different groups, the TF concurred that it represents the best available science. In discussion, some members of the TF agreed that although more progress on this issue could be made over the next few years if resources were available for more intensive sampling, they did not think that the current interpretation of results would change much. That is, even if 1% of the 19,000 or so animals going through Unimak Pass were sampled, a mtDNA difference with the PCFG (as already observed) would remain. So far the PCFG has been compared to samples from feeding areas and from the migratory route and both comparisons detected a genetic difference. It was agreed that the critical issue for additional research to address was better determining the levels of internal versus external recruitment in the PCFG.

At this point the TF returned to discussing the remaining points raised by the Makah documents. The third point was that since multiple genetic comparisons have found low but significant differences, every group of gray whales should be considered a stock. The TF concurred and noted that there is nothing wrong with incrementally adding stocks as new evidence is uncovered, and that decisions have to be made based on the best available science.

The final point discussed was that the genetics results do not support reproductive isolation of the PCFG. The TF agreed in general that the pattern and timing of migration provide ample opportunity for breeding between PCFG whales and other ENP whales. Little is known about gray whale social and mating systems, however, and presently unrecognized mechanisms facilitating selective breeding could exist. If a form of selective breeding does exist, then it could be a long time before nDNA differences appear. A suggested approach to resolving this question is to look at the relatedness of animals in the PCFG. Despite this, the TF agreed that it is most likely that PCFG animals are interbreeding with animals coming from other areas.

11. Research Recommendations

The TF agreed that the following set of recommendations represent key research needs that could help provide additional insight regarding if the PCFG should be recognized as a population stock under the MMPA and GAMMS guidelines.

Given the limited photo-identification and biopsy effort north of 52°N but knowing that at least some observations of PCFG whales in northern feeding areas (e.g., Kodiak and Barrow, Alaska) have been recorded, the TF highlighted the importance of expanding the spatial and temporal coverage of the photo-identification and biopsy effort. In addition, the TF also recommended that further satellite tagging of known PCFG whales be conducted to better delineate habitat use and define the summer/fall feeding area boundaries.

The TF noted that PCFG animals might more regularly interact (compared to non-PCFG whales) with crab pots given their extended residency in coastal waters. Therefore, the TF recommended that the existing photo-identification time series be used to examine scarring patterns of PCFG whales to better understand the incidence of interactions with fishing gear.

Since much of the photo-identification sighting effort occurs in August and later, when many calves are likely to already be weaned and thereby more difficult to identify as a calf (versus a yearling), the TF recommended that the existing PCFG photo-identification time series be examined following a protocol developed by Bradford *et al*. (2011). This photo-based method uses barnacle and pigmentation characteristics on young gray whales to reliably distinguish calves of the year from yearlings.

Knowing that several lines of evidence demonstrate a relationship between minimum tenure and the probability of photographically capturing animals in the 42°N-52N° PCFG area, the TF recommended that the existing PCFG photo-identification time series be examined to see if moms/calves demonstrate higher degrees of fidelity than other whales.

Although photo-identification studies of the PCFG by Calambokidis and colleagues have been ongoing for over a decade, a relatively high number of "new" animals (not previously sighted in the area) are identified each year and subsequently show consistent return to the area (Calambokidis *et al*. 2012). These "new" animals could represent calves born into the group (i.e., internal recruitment) and not identified in their first year, or they could represent animals that traditionally feed in northern areas but now show fidelity to the seasonal range of the PCFG (i.e., external recruits). To better address this question, the TF recommended that relatedness analysis, in which microsatellite genotypes are used to identify animals that represent putative mother-offspring pairs, be used to assess the proportion of internal recruitment occurring within the PCFG. A sufficient understanding of recruitment to make a stock definition determination could potentially be achieved with a concerted effort to sample known mothers and recruits and determine their relatedness.

Related to the recommendation above, some TF members felt that it was plausible that the pulse of immigration into the PCFG could be larger than what the genetic simulations have modeled. If so, then the estimates of annual immigration into the PCFG could be lower than that estimated in the genetic simulations. With this in mind, the TF recommended that the genetic simulations should try pulses of 30 animals and see if that is consistent with the empirical genetic data.

12. Structured Decision-Making Process

At the request of the TF, Bettridge provided an overview of the FEMAT-style structured decision-making process[6]. In some NMFS status reviews, Biological Review Teams (BRTs) formed pursuant to the ESA have adopted formal methods to express plausibility for use in guiding its analysis of DPSs and in assessing the risks to the population(s). These formal methods are important in a setting where quantitative measures of uncertainty derived from the empirical data are unavailable. This point allocation method is often referred to as the "FEMAT" method because it is a variation of a method used by scientific teams evaluating options under the Northwest Forest Plan (Forest Ecosystem Management Assessment Team). In this approach, for example, each expert is asked to distribute plausibility points among the choices/scenarios for a given decision, reflecting his or her opinion of how likely that choice or option correctly reflected the population status. If the expert is certain of a particular option, or feels it is the only plausible scenario, he or she could assign all points to that option. An expert with less certainty about which option best reflected reality or best reflected the population's status could split the points among two or more options. This method has been used in all status review updates for anadromous Pacific salmonids since 1999, as well as in reviews of Southern Resident killer whales, West Coast rockfishes, Pacific herring (*Clupea pallasii*), Pacific groundfish, North American green sturgeon (*Acipenser medirostris*), black abalone (*Haliotis cracherodii*), Hawaii false killer whale (*Pseudorca crassidens*), and humpback whales.

In the humpback whale status review, BRT members distributed 100 likelihood points among the defined scenarios or options, reflecting their expert opinion of the relative likelihood that the status of a specific DPS falls into each of three risk categories. Then the team discussed how they had allocated points and subsequently had a chance to revise their scores. Scorer identity was known.

In the Hawaii false killer whale status review, BRT members distributed 10 points between the arguments for and against each factor. Team members agreed to view resulting scores with names associated to facilitate discussion and assure that linguistic uncertainty was not responsible for any disparate votes. The BRT discussed the scores and, in some cases, adjusted scores when prior articulation of the arguments had been unclear.

After presentation of the structured decision-making approach, Bettridge asked the TF the following questions: (1) Does the TF want to use this approach? (2) If so, how many points will each member allocate among scenarios? (3) Does the TF wish to disclose names, or keep scores anonymous? (4) Does the TF wish to allow for rescoring after discussion? The TF members agreed to employ the structured decision-making approach, allocating 100 points per person. The

[6] The TF agreed that Bettridge, as leader of the decision-making process, should refrain from allocating points on the decision questions.

group agreed to disclose names with scores for the purposes of internal discussion and possible rescoring but to retain anonymity in the final report.

The TF further agreed that they needed to carefully formulate the questions to be addressed and clearly understand what it means to put likelihood points in one category or another so as to provide the necessary advice for management-related issues such as: (1) how future NMFS stock assessment reports will be drafted with regard to gray whale stock structure in the North Pacific and (2) how to interpret any new information in the context of the Makah Indian Tribe MMPA waiver request to resume hunting gray whales off Washington State, USA.

Some TF members with experience using this approach in other situations found that when one or a few members allocated points very differently it was often due to misunderstanding of the question or what the answers implied. Therefore, it was agreed that the questions and the categories of answers should be as clear as possible to make the process both efficient and transparent.

12.1 Question formulation

In keeping with the objectives stated above for developing questions, the TF dedicated significant time during day 2 of the workshop agreeing on questions to be considered during the decision-making process. A key objective of this exercise was to focus on existing lines of evidence to help create the questions while at the same time being mindful of the existing definitions of the terms (e.g., demographic independence, interbreed when mature, functioning element of the ecosystem) contained in the MMPA and GAMMS guidelines. For instance, a simple example of this might be; "*evidence of demographic independence is when the number of internal recruits is greater than the number of external recruits*". In general, this philosophy of creating questions was adopted by the TF and maintained during its deliberations.

After considerable work, the TF agreed to 11 questions. Overnight, TF members privately completed their point allocations for each of the questions. Point allocations were tallied and ready for discussion on the final day of the workshop. Allocating points in this manner allowed individual TF members to express their level of certainty on each of the questions, such that placement of all points in a single category indicated relative certainty in the lines of evidence discussed during the workshop. The TF agreed to view resulting scores with names associated to facilitate discussion and assure that linguistic uncertainty was not responsible for any disparate votes. The TF discussed the scores and, in some cases, members adjusted them when prior articulation of the lines of evidence had been unclear. The final 11 questions and likelihood point allocations for each of the TF members (anonymous, labeled A – G), as well as the proportional distribution of points overall, are provided below.

Question 1.	Overall	A	B	C	D	E	F	G
	Does the ecosystem occupied by the PCFG when they are feeding differ from the ecosystems occupied by other ENP gray whales?							
Strongly Agree	53	100	0	80	100	90	0	0
Somewhat Agree	47	0	100	20	0	10	100	100
Neutral	0	0	0	0	0	0	0	0
Somewhat Disagree	0	0	0	0	0	0	0	0
Strongly Disagree	0	0	0	0	0	0	0	0

Question 2.	Overall	A	B	C	D	E	F	G
	If gray whales in the ENP continued to be managed as a single stock, would the future abundance of PCFG gray whales be maintained above 60% of their current abundance if annual HCM in the PCFG was 5?							
Strongly Agree	38	0	95	0	0	20	50	100
Somewhat Agree	23	20	5	5	0	80	50	0
Neutral	25	50	0	25	100	0	0	0
Somewhat Disagree	14	30	0	70	0	0	0	0
Strongly Disagree	0	0	0	0	0	0	0	0

Question 3.	Overall	A	B	C	D	E	F	G
	If gray whales in the ENP continued to be managed as a single stock, would the future abundance of PCFG gray whales be maintained above 60% of their current abundance if annual HCM in the PCFG was 10?							
Strongly Agree	10	0	50	0	0	0	0	20
Somewhat Agree	24	10	50	0	0	25	30	50
Neutral	21	40	0	0	0	25	50	30
Somewhat Disagree	17	40	0	10	0	50	20	0
Strongly Disagree	29	10	0	90	100	0	0	0

Question 4.	Overall	A	B	C	D	E	F	G
	If gray whales in the ENP continued to be managed as a single stock, would the future abundance of PCFG gray whales be maintained above 60% of their current abundance if annual HCM in the PCFG was 20?							
Strongly Agree	0	0	0	0	0	0	0	0
Somewhat Agree	4	0	25	0	0	0	0	0
Neutral	7	0	50	0	0	0	0	0
Somewhat Disagree	22	10	25	0	0	50	50	20
Strongly Disagree	67	90	0	100	100	50	50	80

Question 5.	Overall	A	B	C	D	E	F	G
	Given the lack of significant differences found in nuclear markers between PCFG whales and other eastern Pacific whales, how would you allot points to:							
There is complete random mating within the eastern NP	63	70	70	70	50	80	60	40
There could be some non-random mating within PCFG whales that is either too recent or at too low a level to be detected given current sample sizes and marker numbers	37	30	30	30	50	20	40	60
PCFG whales breed primarily with each other	0	0	0	0	0	0	0	0

Question 6.	Overall	A	B	C	D	E	F	G
	Based on the genetic data and simulations, how would you allot points to:							
Nearly all recruitment into the PCFG area results from external recruitment (immigration)	0	0	0	0	0	0	0	NA
Most recruitment into the PCFG area results from external recruitment	21	20	30	20	0	20	33	NA
Recruitment is about equal between internal (births) and external (immigration) recruitment	56	60	50	60	100	30	34	NA
Most recruitment into the PCFG area results from internal recruitment	24	20	20	20	0	50	33	NA

Question 7.	Overall	A	B	C	D	E	F	G
	Based on the photo-identification data, how would you allot points to:							
Nearly all recruitment into the PCFG area results from external recruitment (immigration)	0	0	0	0	0	0	0	0
Most recruitment into the PCFG area results from external recruitment	38	30	55	50	0	30	50	50
Recruitment is about equal between internal (births) and external (immigration) recruitment	48	40	35	35	100	50	35	40
Most recruitment into the PCFG area results from internal recruitment	14	30	10	15	0	20	15	10
Nearly all recruitment into the PCFG area results from internal recruitment	0	0	0	0	0	0	0	0

Question 8.	Overall	A	B	C	D	E	F	G
	Do the genetic and photo-identification data indicate that the PCFG is a demographically independent population?							
Strongly Agree	0	0	0	0	0	0	0	0
Somewhat Agree	35	25	10	80	100	30	0	0
Neutral	21	50	30	10	0	40	20	0
Somewhat Disagree	25	25	50	10	0	30	40	20
Strongly Disagree	19	0	10	0	0	0	40	80

Question 9.	Overall	A	B	C	D	E	F	G
	Given all lines of evidence, is the PCFG a "population stock" under the agency's interpretation of the MMPA?							
Strongly Agree	14	0	0	0	100	0	0	0
Somewhat Agree	22	25	10	80	0	30	10	0
Neutral	21	50	30	10	0	40	20	0
Somewhat Disagree	24	25	50	10	0	30	35	20
Strongly Disagree	18	0	10	0	0	0	35	80

Question 10.	Overall	A	B	C	D	E	F	G
	Given that some whales identified in the WNP migrate through U.S. waters to Mexico, should a separate SAR be developed for the WNP?							
Yes	79	100	70	100	100	50	80	50
No	21	0	30	0	0	50	20	50

Question 11.	Overall	A	B	C	D	E	F	G
	Given the differences found in mtDNA and nDNA between Sakhalin Island (WNP) and ENP gray whales, is there a "population stock" within the WNP under the agency's interpretation of the MMPA?							
Strongly Agree	100	100	100	100	100	100	100	100
Somewhat Agree	0	0	0	0	0	0	0	0
Neutral	0	0	0	0	0	0	0	0
Somewhat Disagree	0	0	0	0	0	0	0	0
Strongly Disagree	0	0	0	0	0	0	0	0

12.2 Question outcomes and discussion

The outcomes of each question above are discussed below and follow the convention of using "percentage of total points" to describe the results. For example, in Question 1 the "strongly agree" category was allotted 53% of the total available TF points (370 points allotted/700 total points = 53%).

Question 1

The TF expressed general agreement, by allocating 100% of the their combined points to the categories "somewhat agree" (47%) and "strongly agree" (53%) that PCFG whales seasonally feed in a unique ecosystem that differs from other gray whale feeding areas in the Pacific. Therefore, the TF concurred that it is reasonable to consider that if the PCFG no longer existed and the region was not reoccupied via immigration, summer feeding gray whales would no longer be a functioning element of the coastal Pacific Northwest ecosystem. Although such a circumstance is plausible, keeping all other things equal (e.g., habitat, prey availability), the current lines of evidence from photo-identification studies suggest it is unlikely that the level of annual immigration into the PCFG in the past decade would cease. Thus, the likelihood of gray whales not being found in the PCFG area seems low. However, the time it might take for "recolonization" of the PCFG via immigration is undetermined and thereby puts into question whether this scenario would meet the MMPA objectives of maintaining stocks not only for ecological purposes but also for aesthetic, recreational and economic reasons.

Questions 2, 3 and 4
These three questions were meant to address the MMPA objective of maintaining population stocks as significant functioning elements in the ecosystem of which they are part, and that population stocks should not be permitted to decline below OSP. GAMMS II state that where mortality is greater than a PBR level calculated from the abundance for the region where human caused mortality (HCM) occurs, serious consideration should be given to identifying an appropriate management unit in the region. While estimates of PBR and HCM for a putative PCFG stock have been generated (Carretta *et al*. 2013), there is uncertainty about both estimates, especially with respect to: (1) whether HCM (e.g., ship strikes and fisheries bycatch) for whales in the PCFG area is indeed higher than for whales that migrate through the area, and (2) where HCM actually occurs. In response to these questions, the TF expressed increasing concern about the ability of the PCFG to be maintained above 60%[7] of its current abundance once HCM exceeded 5 whales per year.

The point allocation in Question 2 indicates that the TF overall tended to agree that the future abundance of PCFG gray whales would be maintained above 60% of their current abundance if annual HCM in the PCFG was 5. However, the relatively equal distribution of likelihood points in all categories except "strongly agree" indicates a high level of uncertainty among the TF.

For Question 3, points were allocated more broadly across categories, indicating a higher level of uncertainty among TF members as to whether the PCFG could sustain levels of HCM at 10 whales per year.

There was increased consensus among the TF for Question 4 in that none of them responded "strongly agree". Overall, the TF concurred that it somewhat (22%) or strongly disagreed (67%) that the future abundance of PCFG gray whales would be maintained above 60% of their current abundance if annual HCM in the PCFG was 20.

Question 5
The TF found no evidence to suggest that PCFG whales breed primarily with each other. While there was general agreement (63%) that the lack of significant differences found in nuclear DNA markers between PCFG whales and other ENP whales suggests random interbreeding among all ENP whales, the allotment of 37% of the total points to the intermediate category suggests TF members thought it was possible that some breeding segregation may exist based on migratory timing (see Lang *et al*. 2011) but there is no direct evidence presently available to support or further test this theory.

Question 6
The TF found no evidence in the results from genetics studies to suggest that nearly all recruitment into the PCFG area results from external recruitment (immigration). Based on the genetic data and simulations discussed during the workshop, the highest average TF response (56%) indicates that TF members believe recruitment is most likely about equal between internal (births) and external (immigration) recruitment. That being said, the remaining 45% of the total points were split between most recruitment into the PCFG area resulting from either internal or

---

[7] The management goal of the MMPA is to prevent populations from "depletion". NMFS considers a population depleted if it fall below its Maximum Net Productivity Level (MNPL). For marine mammals, this level is thought to be between 50% and 85% of carrying capacity and is more likely to be in the lower portion of that range (Taylor and DeMaster 1993). Therefore, populations are considered depleted by the U.S. government if they are directly estimated to be below their MNPL, or if they are estimated to be below 50%-70% of a historic population size which it thought to represent carrying capacity (Gerrodette and DeMaster 1990).

external recruitment, indicating some overall uncertainty among members regarding the presently available lines of evidence about recruitment in the PCFG. It should be noted that one member of the TF refrained from assigning any points to this question, so these results represent 6 of 7 TF members actively involved in the point assignment process.

Question 7

Based on the photo-identification data, the TF found no evidence to suggest that nearly all recruitment was either external or internal, but rather some combination of the two. As with the genetics evidence, the highest average TF response (48%) indicates that the TF felt recruitment from internal (births) and external (immigration) sources are comparable. That being said, 38% of the total points were allocated to most recruitment into the PCFG area resulting from external recruitment. Therefore, a majority of the total points were allocated to either recruitment being about equal between internal (births) and external (immigration) recruitment (48%) or most recruitment into the PCFG area results from external recruitment (38%). As was also true with the genetic lines of evidence, these results from the TF suggest a fairly high level of uncertainty regarding recruitment into the PCFG.

Question 8

Based on the genetic and photo-identification data, the TF did not strongly agree that the PCFG is a demographically independent population. Although the highest average TF response (35%) was “somewhat agree” that the PCFG is a demographically independent population, the combined categories of “somewhat disagree” and “strongly disagree” elicited 44% of the total points allocated. Overall, these results from the TF suggest a high level of uncertainty regarding recruitment in the PCFG.

Question 9

Given all lines of evidence, the point allocation of the TF reflects broad uncertainty as to whether the PCFG should be regarded as a population stock under the MMPA and GAMMS guidelines. Perhaps more than all of the other questions considered, Question 9 reflects the highest degree of uncertainty. For instance, the “strongly agree” (14%) and somewhat agree (22%) categories are almost perfectly counter-balanced by the “somewhat disagree”(24%) and “strongly disagree” (18%) categories. An additional level of uncertainty is indicated by the “neutral” category (21%). Given these results, it seems clear that TF was unable to reach a definitive response with respect to the PCFG being a population stock. That is, members of the TF ranged in their opinions from strongly agree to strongly disagree as to whether the PCFG should be considered a separate stock.

Given that this question represents the primary purpose of the workshop, the following two sections provide insight into the deliberations of the TF with regard to arguments for and against the PCFG being a demographically independent unit.

❖ *Arguments for the PCFG being a demographically independent unit*

The return of individual whales to specific feeding areas for as long as the PCFG has been studied (30+ years) strongly suggests that site fidelity is key to maintaining gray whales as a functioning element of this ecosystem. There was agreement that this ecosystem differs from other feeding ecosystems occupied by gray whales. Gray whales are unique among the great whales in being found in only a single ocean basin. Within this ocean basin the PCFG is the only feeding group that does not rely on the dynamics of a sub-arctic ecosystem. As such, the PCFG deserves the protections afforded by being an MMPA stock because the ecosystem role of these animals is unique and also because it provides gray whales, as a species, the flexibility they may need given potential challenges in a changing sub-arctic ecosystem.

Although there is evidence of recruitment from other feeding aggregations, there is also evidence of direct internal recruitment because calves have been shown to return to the PCFG area and reside there. Furthermore, because photographic efforts take place after most claves would be weaned, the recruits into the population not first seen as calves are actually of unknown origin and cannot be definitively assigned as external recruits.

PCFG whales show a low but significant level of genetic differentiation at the mtDNA control region when compared to samples collected in Chukotka [representative of the ENP population and sampled at a single feeding location in the Bering Sea], and when compared to a set of samples collected primarily from animals that stranded along the west coast of the U.S. [representative of a broader sampling of the ENP population]. The significant differences found when the mtDNA haplotype data from the PCFG is compared with that of groups representing the larger ENP population provide indirect evidence of internal recruitment and matrilineally-directed site fidelity to feeding grounds. The level of differentiation is on par with levels identified among humpback whales feeding in different areas of the western North Atlantic (Palsbøll *et al*. 2001) as well as humpback whales using different breeding grounds in the Southern Hemisphere (Rosenbaum *et al*. 2009), suggesting that the PCFG exhibits demographic independence similar to what has been inferred for other large whales. Within the western North Atlantic, humpback whales feeding in the Gulf of Maine are managed as a separate stock despite the fact that they share a common breeding ground with humpbacks feeding in other areas. Although evidence for nuclear DNA differentiation between PCFG whales and other areas has not been found, nuclear genetic differentiation has not always been required for stock delimitation. Pacific harbor seal stocks were delimited on mtDNA differentiation alone (nuclear data were not available at the time), while the Gulf of Maine/Bay of Fundy stock of harbor porpoises was delimited based on significant differentiation at mtDNA, contaminant loads, and life history differences, and despite a lack of differentiation at nuclear markers.

❖ ***Arguments against the PCFG being a demographically independent unit***

The evidence that external recruitment is not a rare event is quite strong. The genetic data have numerous rare haplotypes that are not consistent with a small, closed population. Indeed, simulations are not consistent with a closed population. A sizable number of individuals seen in the main feeding season are identified as transients, which is consistent with an on-going level of the main ENP population investigating this new habitat but then moving on. Further, when all samples collected in summer in the PCFG area are used there is not a significant difference found in mtDNA frequencies compared to all samples collected north of the Aleutian Islands. The number of recruits into the PCFG has been estimated, through genetic data, to be 4 to as high as 8 individuals per year. Photo-identification data suggest similarly high numbers of non-calf recruits per year (8-11). These numbers exceed the estimated number of internal recruits and, given that PCFG numbers appear to be relatively stable, an addition of 4 or more external recruits per year cannot be considered trivial. These external recruitment rates suggest the PCFG is not demographically independent from the larger ENP population.

Furthermore, unlike other large whale populations, the annual coastal migration of the vast majority of ENP gray whales brings most individuals into contact with the habitat used by the PCFG. Should there be increased removals from this area, the continual visitation to this area by a large number of gray whales would make it likely that external recruitment would increase to fill any voids. The apparent pulse recruitment in 1999-2000 when conditions in the sub-arctic feeding areas resulted in a large mortality event shows that gray whales can adapt to a new habitat when conditions dictate. Using data collected since 2002 (post-pulse recruitment event), an average of 29.3 new whales have been identified in summer in the area used by the PCFG, with 18.5 animals that are not seen in later years and 10.8 whales that are seen in later years. Given that an average of 18.5 new whales (at least, as this does not account for new whales not photographed) visit the PCFG area each summer but do not return, this suggests that something on the order of 10% of the whales that occur in the PCFG area each summer are transients that otherwise feed north of the Aleutians, and serve as a substantial and continuous source of potential recruitment into the PCFG.

To date, there is no evidence for nDNA differentiation between Chukotka and PCFG whales based on 8 microsatellite loci or between the PCFG and one Mexican calving lagoon based on 15 loci. These results may be interpreted as female directed site fidelity to the PCFG area coupled with random mating between PCFG and ENP whales on the breeding ground. Lack of nuclear differentiation diminishes support for demographic independence.

All lines of evidence (photo-identification and genetics) are consistent with ongoing external recruitment that could be at a magnitude that is not trivial to the persistence of the feeding aggregation (more than a percent or two per year). Uncertainty in the number of recruits per year and exactly who those recruits are (PCFG calves misidentified as recruits, true recruits of adults, temporary immigrants who do not stay more than a few years and may not even be contributing to the gene pool) creates significant uncertainty as to whether internal recruitment exceeds external recruitment. Given the high level of mtDNA haplotypic diversity, the precision of F_{ST} estimates is also uncertain. Taken together, the available evidence is weak for concluding the PCFG is demographically independent.

Question 10
Given that some whales identified in the WNP have been observed to migrate through U.S. waters to Mexico, in combination with the 1994 amendments to the MMPA requiring that SARs be published for all stocks of marine mammals in U.S. waters, the TF agreed to a high degree (79%) that a separate SAR should be developed in the future for the WNP stock of gray whales.

Question 11
Based on the differences found in mtDNA and nDNA between Sakhalin Island (WNP) and ENP gray whales, the TF unanimously (100%) agreed that it qualifies as a population stock under the MMPA and GAMMS guidelines.

13. Concluding Remarks

The implications of new data pertinent to stock structure, including considerable information related to the PCFG and WNP gray whales, were thoroughly reviewed during the workshop. Evaluating the new findings relevant to the status of the PCFG proved particularly complex. After review of results from photo-identification, genetics, tagging, and other studies within the context of the GAMMS guidelines there remains a substantial level of uncertainty in the strength of the lines of evidence supporting demographic independence of the PCFG. Consequently, the TF was unable to provide definitive advice as to whether the PCFG is a population stock under the MMPA and the GAMMS guidelines. Members of the TF ranged in their opinions from strongly agreeing to strongly disagreeing about whether the PCFG should be recognized as a separate stock.

In the case of WNP gray whales, the work of the TF was more straightforward. The mitochondrial DNA and nuclear DNA genetic differentiation found between the WNP and ENP stocks provided convincing evidence that resulted in the TF providing unambiguous advice that the WNP stock should be recognized as a population stock pursuant to the GAMMS guidelines and the MMPA.

Additional research may narrow the uncertainty associated with the question of whether the PCFG should be recognized as a population stock. To work towards this objective, the TF recommended further investigation of recruitment into the PCFG. Presently, both the photo-identification and genetics data indicate that the levels of internal versus external recruitment are comparable, but these are not quantified well enough to determine if the population dynamics of the PCFG are more a consequence of births and deaths within the group (internal dynamics) rather than related to immigration and/or emigration (external dynamics). The TF offered a number of research recommendations, using the existing photo-identification and genetics datasets, that could provide increased resolution on the issue of recruitment and, in turn, the question of stock identification.

While the need for additional data collection was apparent, especially with regard to recruitment into the PCFG, the purpose of the workshop was for the TF to determine whether the *existing* best available science was sufficient to advise that the PCFG be recognized as a population stock under the language of the MMPA and GAMMS guidelines. Therefore, the advice of the TF offered in this report should be viewed as a contemporary "snapshot" taken from an emerging and ever-changing body of knowledge regarding the PCFG.

The TF emphasizes that the PCFG is relatively small in number and utilizes a largely different ecosystem from that of the main ENP stock. While the status of the PCFG as a population stock has yet to be resolved, continued research on these whales should be undertaken with particular attention dedicated to collecting data relevant to the question of stock identification.

14. Acknowledgements

The Task Force appreciates the dedication and hard work of Aimee Lang and Annette Henry. Their contributions to the workshop and related report were indispensable. We also thank Lisa Ballance, Donna Darm, Jeremy Rusin, and Wayne Perryman for their advice and support in bringing the workshop to fruition. Jim Carretta and Steve Stone provided astute summaries of information that greatly benefitted the work of the Task Force. Cisco Werner and Kristen Koch provided encouragement for the workshop to be held and made available the facilities of the Southwest Fisheries Science Center. Barb Taylor kindly hosted a wonderful social gathering at her home.

16. Appendix 1 – Workshop Agenda

GRAY WHALE STOCK IDENTIFICATION WORKSHOP AGENDA

Southwest Fisheries Science Center
La Jolla, California
31 July-2 August 2012

Day 1 (31 July 2012)

8:30-8:45
1. Introductory Items
1.1 Convenor's opening remarks (Ballance)
1.2 Arrangements for the meeting (Henry)
1.3 Appointment of chair, task force and rapporteurs
1.4 Adoption of agenda
1.5 Documents available

8:45-9:15
2. Workshop Objectives
2.1 Provide scientific advice on gray whale stock structure (Weller)
2.2 Workshop relationship to stock assessment reports (Carretta/Bettridge)
2.2.1 Confirm current stock structure
2.2.2 Assess new information on putative or prospective stocks
2.2.3 Provide advice on necessary changes to stock structure
2.3 Workshop relationship to Makah waiver request (Darm/Stone)
2.3.1 History
2.3.2 Key considerations
2.3.3 Current status of waiver request
2.3.4 Need to know information

9:15-10:30
3. Working Group on Stock Identification (Bettridge and Moore)
3.1 Overview of MMPA language and GAMMS guidelines pertaining to stock definition (Moore)
3.1.1 Existing GAMMS language
3.1.2 Proposed GAMMS revisions from the GAMMS III workshop
3.2 Overview of recent history pertaining to NMFS interpretation of "interbreed when mature" (Bettridge/Beale)
3.2.1 Draft GAMMS II language pertaining to "interbreed when mature"
3.2.2 Status of current legal analysis of NMFS proposed definition
3.3 Additional relevant history concerning definition of "population" for marine mammals (e.g., Taylor 1997, excerpts from Eagle *et al.* 2008) (Moore/ Taylor)

BREAK 10:30-10:45

10:45-12:00
3.4 Current status of gray whale SAR development (Bettridge)
3.5 Discuss key concepts: interbreed when mature, population, demographic independence, functioning element of ecosystem
3.6 Proposed TF voting protocol and process: examples from FEMAT and the ESA (humpback whale BRT, false killer whale BRT) (Bettridge)

3.7. Proposed questions to be voted on by the Task Force

12:00-12:45
4. Working Group on Other Information (Weller and Brownell)
4.1 Overview of gray whale "population stocks" (Lang)
4.1.1 Eastern North Pacific Stock
4.1.2 Western North Pacific Stock
4.1.2.1 Genetic lines of evidence as being a stock
4.1.2.2 Movements of whales between the WNP and ENP
4.2 Brief overview of the Pacific Coast Feeding Group (PCFG) putative stock (Lang)
4.2.1 History
4.2.2 Range
4.2.3 Abundance
4.2.4 Diet
4.2.5 Movements (tagging, photo-ID)
4.2.6 Incidental Take (Carretta)
4.2.7 Emerging issues and areas of uncertainty
4.2.7.1 Probability of a WNP Being Taken by the Makah (Moore)
4.3 Status of the ENP, WNP and PCFG as stocks (NMFS/MMPA/ESA/IWC) (Stone)
4.4 Proposed questions to be voted on by the Task Force

LUNCH 12:45-1:30

13:30-14:15
5. Working Group on Genetic Population Structure (Taylor and Rosel)
5.1 Broad overview of evidence used in recently defined stocks (Stone)
5.2 Review of stock definition cases relevant to the PCFG case
5.2.1 Atlantic harbor porpoises (Rosel)
5.2.2 Alaska harbor seals (Taylor)
5.2.3 Humpback whales (Lang)

14:15-15:00
5.3 Review of gray whale genetic research relating to population structure (Lang)
5.3.1 Summary of early work (LeDuc, Ramakrishnan, Alter breeding lagoon)
5.3.2 Summary of recent work
5.3.2.1 Frasier and D'Intino
5.3.2.2 Lang – empirical genetics
5.3.2.3 Lang – modeling genetics
5.4 Proposed questions to be voted on by the Task Force

BREAK 15:00-15:30

15:30-17:00

6. Discussion of Documents Drafted by the Makah Tribe and Other General Matters (Task Force)
6.1 Makah Tribe documents (Weller)
6.1.1 Introduce GWLJ33: "Is the Pacific feeding group of gray whales a "population stock" within the meaning of the Marine Mammal Protection Act?"
6.1.2 Introduce GWLJ32: "Comments on Draft 2012 Stock Assessment Report for eastern North Pacific stock of gray whales"
6.1.3 Introduce GWLJ34: "What is the PCFG? A review of available information"
6.1.4 Discuss genetics sections of Makah Tribe document GWLJ33 (Taylor/Rosel)
6.2 General discussion of Day 1 information

Day 2 (1 August 2012)

9:00-10:30
7. Working Group on Population Abundance and Trends (Laake and Wade)
7.1 Photo-identification and population dynamics of the PCFG (Laake)
- 7.1.1 Definition of PCFG whales based on timing/area
- 7.1.2 Movements of know PCFG whales (photo-identification and telemetry)
- 7.1.3 Abundance/survival estimates
- 7.1.4 Trends (Wade)
- 7.1.5 Recruitment
- 7.1.6 PCFG Trend/OSP (Moore)
- 7.1.7 Discuss photo-identification and telemetry sections of Makah Tribe document GWLJ33 (Laake/Wade)

7.2 Proposed questions to be voted on by the Task Force

BREAK 10:30-11:00

11:00-12:30
8. Review and Agree on Workshop Questions for Voting

LUNCH 12:30-13:30

13:30-15:30
9. Description of Vote Procedure (Bettridge)
10. TF Voting on Workshop Questions (TF Only)

Overnight
11. Compile and Tally Votes (Lang/Henry)

Day 3 (2 August 2012)

9:00-12:00
12. Review of Vote Outcomes (Lang/Henry)
13. Discussion of Vote Outcomes
14. Revision of Questions for voting if Necessary
15. Revote if Necessary

LUNCH 12:00-13:30

13:30-16:30
16. Review of Revote Results if Necessary (Lang/Henry)
17. Other Business
18. Workplan for Workshop Report Completion
19. Adjourn

17. Appendix 2 - Workshop Document List

GWLJ01

Moore, J. E., and Merrick, R., eds. *Guidelines for Assessing Marine Mammal Stocks: Report of the GAMMS III Workshop, February 15 – 18, 2011, La Jolla, California*. Dept. of Commerce, NOAA Technical Memorandum NMFS-OPR-47.
