DECLARATION OF JOHN R. BRANDON

I, John R. Brandon, Ph.D., declare as follows:

1. I am a biometrician specializing in population dynamics modeling, statistical analysis, management strategy evaluation, and survey design and am employed by ICF International, Inc. I am under contract with the Tribe's legal counsel to provide expert testimony and testimony based on my personal knowledge of the International Whaling Commission's review of aboriginal subsistence whale hunts and the Tribe's proposed hunt. My work address is ICF International, 201 Mission Street, Suite 1500, San Francisco, CA 94105.

2. For purposes of this hearing, I prepared and hereby incorporate the attached report and supporting exhibits as my written direct testimony.

3. The attached report includes: (1) expert opinions developed through my education, experience, research, and knowledge of population dynamics modeling and management strategy evaluation involving marine mammal populations; and (2) testimony based on my personal knowledge of the proceedings of the International Whaling Commission regarding aboriginal subsistence hunts in general and the Tribe's proposed hunt in particular. My qualifications to testify as an expert are described in further detail at the beginning of the attached report.

4. The attached report provides factual and scientific information supporting

NMFS's proposed waiver and regulations that would, in addition to tribal management measures, govern a ceremonial and subsistence hunt of gray whales from the Eastern North Pacific stock under the Tribe's treaty-reserved right.

5. I have reviewed NMFS's published issues for the hearing, *i.e.*, the "Issues that May be Involved in the Hearing," 84 Fed. Reg. 13639, 13641-43 (Apr. 5, 2019). As I describe in the attached report, I believe there is additional scientific information available that supports the proposed waiver and regulations. In general, as NMFS's proposed issues of fact relate to my testimony, I agree with the issues presented and support the waiver and regulations NMFS has proposed. The Makah Tribe has prepared and is submitting today a document entitled Makah Tribe's Position Regarding NMFS's Proposed Issues of Fact. The document identifies my position as to the issues presented by NMFS (or in some cases, that I have no comment) and I hereby adopt and incorporate those positions as a part of my written direct testimony.

6. The attached report provides support for additional issues of fact for the hearing. The Makah Tribe has prepared and is submitting today a document entitled Makah Tribe's Proposed Issues of Fact. The document identifies additional issues of fact for the hearing based on my attached report and I hereby adopt and incorporate those issues as part of my written direct testimony.

I declare, under penalty of perjury under the laws of the United States, that the foregoing (and the attached report) is true and correct to the best of my knowledge, information and belief.

John R. Brandon, Ph.D.

Dated: May 16, 2019

Testimony of John R. Brandon, PhD

TABLE OF CONTENTS

Bio:

I earned my PhD at the University of Washington, School of Aquatic and Fisheries Sciences. My dissertation was completed under the tutelage of my major professor, Dr. André E. Punt. Our research developed a mathematical modeling framework for population dynamics of large whales given future uncertainties linked to climate change and environmental variability in critical habitat. This allowed us to evaluate the performance of catch control limits relative to management objectives for aboriginal subsistence whaling of bowhead and gray whales, taking into account scientific uncertainties through the use of computational statistics (e.g. Brandon 2009 (Ex. M-0504); Brandon and Punt 2013 (Ex. M-0505)). The methods we employed are also known in fisheries science as Management Strategy Evaluation (see Section 1.2 for an overview of this approach).

I have been an Invited Participant to the Scientific Committee of the International Whaling Commission (IWC or Commission) since 2006. Much of my research in that capacity has involved serving on the working groups and subcommittees that provide management recommendations for catch limits of aboriginal subsistence whaling both in and outside the United States.

In 2010, I was contracted as a Population Dynamics and Statistical Consultant for the Makah Tribe. I have worked in this capacity periodically since then, on projects related to aboriginal subsistence catch quotas for gray whales as they pertain to the Makah Tribe, including research relevant to the IWC and as an expert witness in these proceedings.

At the 2018 IWC Scientific Committee meeting, I served as the Co-Chair of the Standing Working Group on the Aboriginal Whaling Management Procedure. This working group is responsible for: (1) designing and evaluating catch limit control rules relative to the conservation management objectives of the IWC for aboriginal subsistence whaling; and (2) providing scientific recommendations to the Commission based on such evaluations. Since the working group was established two decades ago by the Commission, it has developed rigorous scientific frameworks for quantitatively evaluating aboriginal subsistence whaling hunt management plans as requested by signatory nations of the IWC, including the United States.

My recent marine mammal research has focused on computer simulation performance testing of algorithms that extend the current status quo approach adopted for the Potential Biological Removal (PBR) management scheme under the Marine Mammal Protection Act (MMPA), while still satisfying the

MMPA’s statutory requirements and conservation management objectives (Ex. M-0506 (Brandon et al. 2017); Ex. M-0553 (Punt et al. 2018)).

I am currently a staff biometrician for the Fish and Aquatics Science Team at ICF International, Inc. My research for ICF involves quantitative survey design work, population dynamics modeling, and statistical data analyses for studies of state and federally listed species of fish in California.

(PCFG) Pacific Coast Feeding Group

(SLA) Strike Limit Algorithm

(WNP) Western North Pacific stock of gray whales

Introduction and Outline:

Legal counsel for the Makah Indian Tribe asked me to provide expert witness testimony in this proceeding, and my written testimony is divided into five sections.

The first three sections address the three currently identified gray whale management units in the North Pacific Ocean: (1) the Eastern North Pacific (ENP) stock; (2) the Pacific Coast Feeding Group (PCFG) and; (3) the Western North Pacific (WNP) stock. These sections provide a review of approaches taken to date regarding population dynamics modeling and assessments of conservation risk with respect to human caused mortality of whales within each management unit. Additionally, these sections provide background information and a comparison of the conservation management objectives of the IWC and the MMPA and how they overlap. They also include a comparison of the IWC's scientific approach to evaluating proposed aboriginal subsistence whaling hunt plans and the PBR management strategy under the MMPA.

The fourth section addresses the current hunt plan proposed by the National Marine Fisheries Service (NMFS) for Makah whaling. The IWC Scientific Committee evaluated NMFS's proposed hunt plan at its 2018 meeting (Ex. M-0532 (IWC 2018b)). The results of that evaluation demonstrate that the NMFS hunt plan, which is more restrictive than the previous Makah hunt plan in several respects (including additional provisions aimed at minimizing the conservation risk to WNP gray whales), meets the IWC's conservation management objectives for ENP, PCFG and WNP gray whales. This is an important result because, as I explain in the first three sections, a hunt plan that meets the IWC's management objectives will also meet the MMPA's conservation objective of maintaining a stock at its optimum sustainable population (OSP) or reaching that abundance level if the stock is below it.

The fifth and final section addresses several public comments that were submitted in response to NMFS's 2015 Draft Environmental Impact Statement (DEIS) on Makah whaling (NMFS 2015).

1. Eastern North Pacific Gray Whales

1.1. MMPA Management Objectives; ENP Abundance Relative to the Optimum Sustainable Population Level; Potential Biological Removal Level

The MMPA, 16 U.S.C. § 1361(6), states the primary objective of management of marine mammals should be to maintain the health and stability of the marine ecosystem and that, whenever consistent with that objective, it should be the goal to obtain an optimum sustainable population (OSP) keeping in mind the carrying capacity of the environment. As defined by the MMPA, 16 U.S.C. § 1362(9):

> *The term "optimum sustainable population" means, with respect to any population stock, the number of animals which will result in the maximum productivity of the population or the species, keeping in mind the carrying capacity of the habitat and the health of the ecosystem of which they form a constituent element.*

Because the definition of optimum sustainable population incorporates consideration of the carrying capacity of the habitat and the health of the ecosystem, it seems apparent that a management strategy that is designed to obtain an optimum sustainable population will satisfy the MMPA's primary objective of maintaining the health and stability of the marine ecosystem. Thus, it is not surprising the MMPA management strategies (e.g. PBR, as discussed in more detail below) focus on obtaining an optimum sustainable population.

The definition of OSP relies on the concept of the "… maximum productivity of the population or species…." This concept also draws on the definition of the net productivity rate under the MMPA, 16 U.S.C. § 1362(26):

> *The term "net productivity rate" means the annual per capita rate of increase in a stock resulting from additions due to reproduction, less losses due to mortality.*

The maximum net productivity of a population will occur when its abundance is below the carrying capacity of the ecosystem; as the population increases in abundance and approaches its carrying capacity, its net productivity will decline. Thus, for regulatory purposes, NMFS has defined OSP as a range of population sizes between the population level resulting in the maximum net productivity at the lower bound and carrying capacity at the upper bound (50 CFR 216.3):

> *Optimum Sustainable Population is a population size which falls within a range from the population level of a given species or stock which is the largest supportable within the ecosystem to the*

population level that results in maximum net productivity. Maximum net productivity is the greatest net annual increment in population numbers or biomass resulting from additions to the population due to reproduction and/or growth less losses due to natural mortality.

The "population level" of a species or stock, relative to the carrying capacity of its environment, at which the maximum net productivity rate is assumed to occur, is also referred to as the "maximum net productivity level" or MNPL (Ex. M-0559 (Wade 1998); Ex. M-0551 (Punt and Wade 2010)). There is no statutory definition of carrying capacity in the MMPA. Stock assessment models of ENP gray whales assume that, carrying capacity is the largest population size that the ecosystem can support, on average, through time (e.g. Punt and Wade 2010). This assumption is consistent with the regulatory definition for the upper bound of OSP (50 CFR 216.3).

MNPL is generally thought to occur between 50% and 85% of carrying capacity, but it is difficult to estimate, given the limited data typically available for marine mammal stocks (e.g. Taylor and DeMaster, 1993 (Ex. M-0558)). Stocks for which an estimate of status, relative to MNPL, has been developed tend to have long time series of abundance and human caused mortality estimates available[1]. For ENP gray whales, data are available in sufficient quantity and quality to estimate with confidence that their abundance, following recovery from historical whaling, is above MNPL (Ex. M-0551 (Punt and Wade 2010)).

Available information for the ENP stock of gray whales includes the time series of abundance estimates from the southbound migration off Central California, which spans the last 50 years (Ex. M-0537 (Laake et al. 2012); Durban et al. 2015 (Ex. M-0516), 2017 (Ex. M-0517). Additionally, annual estimates of human caused mortalities are available, including decades of catch estimates from historical commercial whaling (e.g. Reeves et al. 2010 (Ex. M-0554)). The magnitude of historical catches provides information on the population level, relative to carrying capacity, at the nadir of abundance in the early 1900s following commercial whaling. Given these sources of

[1] The ability to estimate stock status relative to MNPL is not solely a function of the number of abundance and mortality estimates available. It also depends on such factors as the precision of abundance estimates – and in the case of recovering stocks, how far below carrying capacity a stock has been depleted prior to monitoring, the rate of recovery from depletion, *etc*. The exact number of years of monitoring data necessary to estimate stock status relative to MNPL is therefore case specific. In general, however, an estimate of a recovering marine mammal stock's status relative to MNPL requires monitoring data spanning multiple decades.

information, including the lengthy time series of abundance estimates, it is possible to model the population dynamics of ENP gray whales during recovery from commercial whaling (i.e. from the early 1900's to present), and hence assess this stock's status relative to OSP. In the most recent assessment that addresses OSP directly, Punt and Wade (2010) (Ex. M-0551) estimate there is an 88% probability that the ENP stock is at its OSP level, and that the population size is near the carrying capacity of its environment.

Further, the two most recent estimates of abundance, from southbound migrations, indicate the size of the population has increased by approximately 22% since 2010 (Ex. M-0517 (Durban et al. 2017)). The recent increase in abundance is consistent with recruitment from a sustained period of high calf production that has been ongoing since 2011 (Ex. M-0545 (Perryman et al. 2017)).

Given the difficulty in determining OSP for most marine mammal stocks — because of the lack of data such as that available for ENP gray whales — PBR was introduced in the 1994 amendments to the MMPA. Although this section of my testimony does not focus on PBR in detail, a brief introduction at this stage is nevertheless relevant in the broader context of the OSP management objective under the MMPA.

PBR was developed as a reference level for NMFS to assess whether the OSP conservation management objective would be expected to be achieved given estimates of incidental mortality in commercial fisheries. The PBR level is defined in the MMPA, 16 U.S.C. § 1362(20), as:

> *the maximum number of animals, not including natural mortalities, that may be removed from a marine mammal stock while allowing that stock to reach or maintain its optimum sustainable population. The potential biological removal level is the product of the following factors:*
>
> > *(A) The minimum population estimate of the stock.*
> >
> > *(B) One-half the maximum theoretical or estimated net productivity rate of the stock at a small population size.*
> >
> > *(C) A recovery factor of between 0.1 and 1.0.*

It is worth noting that PBR was established to determine the number of animals that could be removed from a stock while allowing the stock "to reach or maintain" its OSP level. Thus, PBR is a management tool that is designed to achieve the MMPA's statutory objective of obtaining OSP, whether or not a stock's current status relative to OSP can be calculated based on current information. For ENP gray whales, a recent value of PBR was calculated to be 624 whales (Ex. M-0514 (Carretta et al. 2017)).

Sections 1.2.1 and 2.2 of my testimony provide a more detailed discussion of how PBR has been applied in practice. Specifically, I will discuss how that application compares to the approach used to evaluate catch limits for aboriginal subsistence whaling by the IWC. And more generally, I will discuss how the conservation management objectives of the IWC mirror the OSP management objective of the MMPA.

1.2. Management of Aboriginal Subsistence Whaling for ENP Gray Whales

1.2.1. IWC Management objectives; Comparison to OSP and PBR

The IWC establishes aboriginal subsistence whaling catch limits for whale stocks under its jurisdiction, including the ENP gray whale stock (Ex. M-0530 (IWC 2016)). In 2012, the IWC approved a 6-year block catch limit covering 2013 through 2018 for ENP gray whales based on information submitted by the United States and Russian Federation regarding the needs of aboriginal subsistence whaling communities in those countries (the Makah in the United States and Chukotka Natives in Russia; Ex. M-0526 (IWC 2013a)). In 2018, the IWC approved a 7-year block catch limit covering 2019 through 2025.

The IWC Scientific Committee has interpreted the management objectives for aboriginal subsistence whaling, as established by the Commission, into three principles in order to provide management advice (Ex. M-0521 (IWC 1995)):

> *(1) Ensure that the risks of extinction to individual stocks are not seriously increased by subsistence whaling;*
>
> *(2) Enable aboriginal people to harvest whales in perpetuity at levels appropriate to their cultural and nutritional requirements, subject to the other objectives; and*
>
> *(3) Maintain the status of stocks at or above the level giving the highest net recruitment and to ensure that stocks below that level are moved towards it, so far as the environment permits.*

Highest priority is given to the first objective: to ensure that aboriginal subsistence whaling does not increase the risk of extinction to individual stocks (*id.*). However, under the third objective, the abundance level resulting in the "highest" or "maximum" net recruitment is a key reference population level for management of aboriginal subsistence whaling under the IWC's conservation management objectives and can be compared to MNPL (the maximum net productivity level) under the MMPA. The IWC uses a different term than the MMPA for this population level. Instead of MNPL, the IWC refers to it as the "maximum sustainable yield level" or MSYL (e.g., Punt 1999 (Ex. M-0546); Punt and Wade 2012 (Ex. M-0552).

Under identical assumptions regarding the mathematics of population dynamics, MNPL and MSYL are equivalent. As an illustrative example, in the most recent assessment of the population status of the ENP gray whale stock under the MMPA, Punt and Wade (2010) (Ex. M-0551) present estimates of abundance relative to MNPL. Based on the same analyses, Punt and Wade (2012) (Ex. M-0552) present these numerical estimates in the peer-reviewed scientific publication of the IWC. For the IWC audience, the numbers are presented in terms relative to MSYL, rather than MNPL. The numbers are identical in both reports — only the nomenclature differs. For consistency, I will refer to this reference level, shared by MMPA and IWC conservation management objectives, in terms of MNPL.

MNPL serves as the reference population level for the third IWC conservation management objective for aboriginal subsistence whaling, as well as for the OSP management objective under the MMPA. As noted above, under Section 1.1, in the MMPA, OSP is defined in terms of the number of animals that will result in the "maximum productivity" of a population. And, in NMFS's regulations, MNPL is the abundance level at the lower bound of the range considered to satisfy the OSP management objective of the MMPA (50 CFR 216.3). Therefore, the MMPA and IWC conservation management objectives are effectively identical in this respect and can be jointly summarized as: limiting the extent of human caused mortality such that the goal of maintaining or recovering stocks to population levels at or above MNPL will be achieved.

Under the MMPA, this shared conservation management objective is expressed in the statutory definition of Potential Biological Removal (provided in Section 1.1 above) as well as in the statutory and regulatory definitions of OSP. As explained above, PBR was developed to assess whether or not incidental mortality levels (e.g. bycatch) in commercial fisheries are sufficiently small to allow a "stock to reach or maintain its optimum sustainable population" level [MMPA, 16 U.S.C. § 1362(20)[2]].

As also explained above, PBR is defined in the MMPA as the product of three terms: (1) The minimum population estimate of the stock (N_{MIN}); (2) One-half the maximum theoretical or estimated net productivity (growth) rate of the stock at small population size ($0.5 * R_{MAX}$); and (3) A recovery factor (F_R) of between 0.1 and 1.0. Although the MMPA prescribes the general formula for

[2] In other words, if a stock is below MNPL (below OSP), mortality from commercial fisheries bycatch or other human activity that is at or below the PBR level should not prevent the stock from recovering to a population level that is at or above MNPL (*i.e.*, OSP). Likewise, if a stock is above MNPL (at OSP), mortality at or below the PBR should not result in a decline below MNPL (below OSP).

calculating PBR,[3] it does not specify detailed quantitative definitions of the terms used in the formula (Ex. M-0559 (Wade 1998)). For example, the term "minimum population estimate" (N_{MIN}), is only qualitatively defined under the MMPA, 16 U.S.C. § 1362(27):

> *The term 'minimum population estimate' means an estimate of the number of animals in a stock that – (A) is based on the best available scientific information on abundance, incorporating the precision and variability associated with such information; and (B) provides reasonable assurance that the stock size is equal to or greater than the estimate.*

Wade (1998) (Ex. M-0559) used computer simulations to provide quantitative specifications for the constituent terms of PBR. For example, the simulations were used to "tune" the N_{MIN} parameter as a function of an abundance estimate and its precision, such that the resulting PBR value would be sufficiently precautionary to meet the OSP management objective with 95% confidence. Through these simulations, Wade (1998) found that using the 20th percentile (the lower 60% log-normal confidence limit) of abundance estimates provided a sufficiently precautionary quantitative specification for N_{MIN}. The values currently in use for R_{MAX} and F_R were also evaluated through the simulations, and the simulations were designed to be generic enough that the resulting quantitative specifications for PBR could be applied across a range of stocks with confidence that the OSP management objective would be met.

The IWC also uses computer simulations to evaluate proposed hunt plans and catch limits for aboriginal subsistence whaling (e.g. Punt and Donovan 2007 (Ex. M-0549)). Those evaluations, including proposed hunt plans and catch limits for gray whales, follow the same general approach used to determine the quantitative specifications currently adopted for PBR. The technical details of these two approaches are not identical, however, and I discuss the differences between simulation testing of PBR and aboriginal subsistence whaling catch limits in more detail under Section 2. Nevertheless, like the simulations used to derive the quantitative specifications for PBR, the IWC evaluations are also based on simulating the performance of proposed catch limits and management strategies relative to their ability to allow stocks to reach or maintain a population level at or above MNPL (i.e. OSP). In other words, the IWC evaluations of aboriginal subsistence whaling catch limits are both consistent with meeting the OSP conservation management objective under the MMPA and, likewise, they employ the same general scientific methods used to develop the quantitative specifications for the current PBR formula. In the next section, I provide background on the computer simulation

[3] $PBR = N_{MIN} * 0.5 * R_{MAX} * F_R$

approach used to evaluate PBR under the MMPA, and aboriginal subsistence whaling catch limits under the IWC.

1.2.2. IWC Management Strategy Evaluation of Aboriginal Subsistence Hunt Plans

IWC catch limits for aboriginal subsistence whale hunts, including those for gray whales, follow the recommendations of the IWC's Scientific Committee. The Scientific Committee's recommendations for ENP gray whale catch limits are based on the approach known in fisheries science as "Management Strategy Evaluation" (MSE). The MSE approach was also used when evaluating the PBR management scheme as currently implemented and its ability to meet the OSP management objective of the MMPA (Ex. M-0559 (Wade 1998)).[4] MSE is also regularly employed to provide management advice for commercial finfish and shellfish fisheries in the United States and abroad (Ex. M-0548 (Punt et al. 2016)).

A management strategy in this context relates to specifications for the data to be collected and how those data are used to inform a set of rules for calculating limits on human caused mortality. MSE provides a scientific means to assess the expected performance of management strategies relative to management objectives, like maintaining stocks at or above MNPL (Ex. M-0549 (Punt and Donovan 2007); Ex. M-0548 (Punt et al. 2016)). Computer simulation is used to perform experimental stress tests to determine if a management strategy can be expected to satisfy management objectives, even if the current assessment of a stock's status is not accurate (e.g. under a scenario where data are subject to bias). In this regard, MSE is consistent with the "precautionary principle" (Holt and Talbot 1978) (Ex. M-0520), in that management strategies are evaluated relative to whether they are robust to scientific uncertainties (Ex. M-0509 (Butterworth 2007)).

MSE involves several steps: (i) developing a model of the system, which represents the "truth" for the purposes of simulation (the "operating model"); (ii) specifying the range of uncertainties to be considered and thereby which "trials" will be undertaken to test a candidate management strategy; (iii) defining performance metrics that quantify the management objectives; (iv) conducting projections of each candidate management strategy across the set of trials to evaluate performance relative to management objectives; and (v) providing the results in the form of scientific recommendations to decision makers (Ex. M-0548 (Punt et al. 2016)).

MSE has been used extensively to evaluate the ability of proposed management strategies related to commercial and aboriginal subsistence whaling in terms of their abilities to satisfy the management objectives of the IWC for these two separate categories of whaling (Ex. M-0549 (Punt and

[4] A comparison of the MSE approaches used for PBR and ASW is discussed in more detail under Section 2.

Donovan 2007)). In addition to ENP gray whales, MSE has also been used to evaluate aboriginal subsistence whaling catch limits for the Bering-Chukchi-Beaufort seas (BCB) stock of bowhead whales in Alaska and Russia (e.g. IWC 2002) (Ex. M-0522), as well as for aboriginal subsistence hunts of humpback, fin, minke, and bowhead whales off Greenland (Ex. M-0532 (IWC 2018b)). Although the Scientific Committee of the IWC only just recently completed MSEs for the Greenlandic aboriginal subsistence hunts, the catch limits that have been implemented for ENP gray whales and the BCB bowhead whales have a long track record of sustainability. The first MSEs for BCB bowhead and ENP gray whales were completed in 2002 and 2004, respectively. Since their implementation nearly two decades ago, the resulting catch limits for these stocks have proven to meet conservation management objectives for population growth and recovery while also satisfying aboriginal subsistence need (e.g., Carretta et al. 2017 (Ex. M-0514); Muto et al. 2017 (Ex. M-0543)).

An important component of the MSE process in the IWC is known as an "Implementation Review". After the initial MSE and "Implementation" of a catch limit for an aboriginal subsistence hunt, the IWC requires regular Implementation Reviews. The purpose of these reviews is to consider any new information that has become available since the previous Implementation Review (or the initial MSE). As such, regular Implementation Reviews provide the Scientific Committee the opportunity to review any new information on the relevant stock and evaluate whether it warrants a change in the management advice to the IWC. The goal of an Implementation Review is to determine if any of the new information indicates that the current state of nature[5] is outside the bounds of plausibility considered to date (Ex. M-0549 (Punt and Donovan 2007); IWC 2013b, p. 170-171 (Ex. M-0527)).

These reviews are scheduled on a regular basis, often coinciding with IWC's consideration of a request to renew a block catch limit. Currently the default interval is every six years, but Implementation Reviews may be called at any time if new information is presented that warrants a re-evaluation of the current management strategy (e.g. introducing additional trials and simulation testing for existing catch control rules to take into account previously unevaluated scenarios). This is a form of adaptive management and serves a similar purpose as the regular updating and review of Stock Assessment Reports (SARs) under the MMPA, including updating the comparison of estimates of human caused mortality relative to PBR. An

[5] A "state of nature" represents such factors as natural mortality, reproductive rates, and stock structure. MSE involves developing multiple versions of an operating model, which reflect alternative plausible hypotheses about the 'true' state of nature. In particular, new information has become available over the last decade that indicates the state of nature of gray whale stock structure may be more complicated than previously hypothesized. This is discussed below in terms of the Implementation Review with a focus on the PCFG, as well as the recent evaluation based on the Rangewide modeling, which incorporated new information on WNP gray whales,

Implementation Review, however, is typically a much more data- and modeling-intensive review than the domestic SAR process.

Catch control rules for aboriginal subsistence whaling under the IWC, in combination with data collection schemes, are known as "Strike[6] Limit Algorithms" (SLAs). The *Gray Whale SLA*, which has been used to set aboriginal subsistence whaling catch limits for ENP gray whales, was subject to an MSE under the IWC prior to its initial implementation (Ex. M-0523 (IWC 2005)). During a subsequent Implementation Review, which was completed in 2010[7], there was no change in management recommendations with respect to the *Gray Whale SLA* being the most appropriate tool for calculating catch limits for ENP gray whales (Ex. M-0524 (IWC 2011)). The 2013-2018 IWC catch limit for the ENP stock of gray whales, which was based on the joint request by the Russian Federation on behalf of the Chukotka Natives and the United States on behalf of the Makah Tribe, was set over a six-year block, with a catch limit of 744 whales over the block period and no more than 140 whales in any given year. In 2018, the IWC approved a catch limit for the ENP stock of gray whales for a seven-year block.[8] The new catch limit was for 980 whales over the block period and no more than 140 whales in any given year. These limits reflect the demonstrated subsistence need of the Chukotkan and Makah communities. For comparison, as noted above, the recent value of PBR for this stock in any given year is 624 whales, more than four times the IWC's annual catch limit (Ex. M-0514 (Carretta et al. 2017)).

The average subsistence harvest of gray whales by Chukotka Natives in the years 2000 – 2015 was 125 whales per year.[9] As discussed above, the most recent assessment of the population's status relative to OSP (Punt and Wade 2010 (Ex. M-0551); 2012 (Ex. M-0552)) and current trends in estimates of abundance (Durban et al. 2017 (Ex. M-0517)) indicate that the IWC catch limits for ENP gray whales have been sufficiently conservative to maintain ENP gray whales above MNPL, i.e., at their OSP level. Furthermore, the Scientific Committee has recently evaluated aboriginal subsistence whaling

---

[6] The Scientific Committee's evaluation of a hunt's impact focuses on strikes and typically makes the precautionary assumption that every strike results in a kill, regardless of whether or not the whale is landed, i.e., a "catch." This is another example of how MSE, as applied by the IWC, is consistent with the 'precautionary principle.'

[7] Information was presented during the 2010 ENP gray whale Implementation Review that resulted in the Scientific Committee immediately calling for a subsequent Implementation Review, but only after it reiterated that its management advice on the *Gray Whale SLA* was still appropriate for ENP gray whale catch limits. The subsequent Implementation Review focused on the Makah hunt and the PCFG and is discussed in Section 2 below.

[8] The 7-year length is only for 2019-2025; subsequent catch limit blocks will revert to 6 years (Ex. M-0534 (IWC 2018d (Chair's Report, Annex P)); Ex. M-0535 (IWC 2018e (IWC/67/01 Rev 01) pp. 4, 10)).

[9] Source: https://iwc.int/table_aboriginal

catch limits for ENP gray whales under the assumption that this stock would be subject to combined catches by Makah and Chukotkan whaling; as discussed below, those evaluations indicate that the management of catch limits that have been proposed for Makah whaling pose no concern with respect to maintaining ENP gray whales above MNPL (IWC 2014a (Ex. M-0531); 2018b (Ex. M-0532)).

2. The Pacific Coast Feeding Group Gray Whales

2.1. Lack of Data to Determine Optimum Sustainable Population Level

The second currently identified management unit of gray whales in the North Pacific Ocean is the Pacific Coast Feeding Group (PCFG). However, unlike ENP gray whales, NMFS does not consider the PCFG to be a stock under the MMPA. Rather, NMFS considers the PCFG to be a feeding group of ENP gray whales (Ex. M-0561 (Weller et al. 2013)).

Unlike the available data for the greater ENP stock of gray whales, the available data for the PCFG is not sufficiently informative to determine whether the abundance of this feeding group is above or below MNPL, i.e., to determine whether it is at an OSP level (Ex. M-0550 (Punt and Moore 2013)). As noted by Punt and Moore (2013), because the PCFG is not a 'closed'-population (i.e. immigration and emigration occur), estimates of its status relative to MNPL are confounded by uncertainty in factors like bycatch mortality and annual rates of immigration into the PCFG from the greater ENP stock.

I am not aware of another example where a formal quantitative OSP status determination has been attempted (much less successfully estimated relative to MNPL) for a non-stock feeding group of marine mammals in the United States or elsewhere. I believe this would be unusual, if not unprecedented.

Most large whale stocks, and most marine mammal stocks in general, have an undetermined status relative to MNPL due to insufficient data in this regard. NMFS publishes stock assessment reports (SARs) for three regions: Alaska, the Atlantic and Gulf of Mexico, and the U.S. Pacific (including Hawaii but not Alaska). Of the 87 marine mammal stocks that have been assessed in the U.S. Pacific region, a formal quantitative OSP determination of stock status relative to MNPL has only been attempted for a handful (e.g. Carretta et al. 2017 (Ex. M-0514)). Harbor seals in Oregon (Brown et al. 2005) (Ex. M-0508) and Washington (Jeffries et al. 2003) (Ex. M-0536) previously were assessed to be at OSP but those determinations are considered outdated under NMFS's Guidelines for Assessing Marine Mammal Stocks because the most recent abundance estimates are more than eight years old (Ex. M-0544 (NMFS 2016); Carretta et al. 2017)). The northern California/southern Oregon stock of harbor porpoise has undergone a formal OSP status determination, and it is currently considered to be at OSP (Carretta et al. 2017). And most recently in the U.S. Pacific region, a first OSP status determination has been conducted for California Sea lions (Ex. M-0538 (Laake et al. 2018)). Nevertheless, including ENP gray whales, these examples add up to only five stocks representing only six percent of stocks in the U.S. Pacific region having an available quantitative estimate of stock status relative to MNPL. I am not aware of any stocks in either the Alaska or Atlantic and Gulf of Mexico regions that have an OSP status determination presented in the SARs that is based on a quantitative analysis (e.g. fitting a population dynamics model to available data, in order to estimate the abundance level as a fraction of carrying capacity, as has been done for ENP gray whales).

2.2 Managing Stocks to Achieve OSP Management Objectives: Generic and Case-Specific MSEs

The challenge of assessing stock status relative to MNPL, i.e., of assessing whether a stock is at its OSP level, was one of the motivating factors in developing the PBR management scheme more than two decades ago (Ex. M-0558 (Taylor and DeMaster 1993)). It takes much less data to calculate PBR than it does to estimate a stock's status relative to MNPL. Nevertheless, through the use of MSE, PBR has been shown to be a relatively simple and straightforward approach to calculating levels of human caused mortality that are consistent with the OSP management objective of the MMPA (Ex. M-0559 (Wade 1998)). Similar considerations led the IWC to start evaluating candidate management strategies for whaling based on principles analogous to those that precipitated the development of PBR (Ex. M-0549 (Punt and Donovan 2007)). Although PBR and SLAs for aboriginal subsistence whaling share common underpinnings, there are also some important differences. In this section I explain and compare these approaches.

PBR was developed with the goal of being generically applicable to all marine mammal stocks found in the U.S. Exclusive Economic Zone. As context, after PBR was introduced in the 1994 amendments to the MMPA, the first set of marine mammal SARs included about 165 stocks.[10] At the time of the 2014 SARs, the number of stocks identified had increased to 248 (Ex. M-0557 (Simmons 2016)). The quantity and quality of data available for each stock is also variable (Ex. M-0514 (Carretta et al. 2017); Ex. M-0519 (Hayes et al. 2017); Ex. M-0543 (Muto et al. 2017)). Developing case-specific MSEs for all of these stocks, or even the subset of stocks with frequent interactions with

[10] Source: https://www.fisheries.noaa.gov/national/marine-mammal-protection/marine-mammal-stock-assessments

commercial fisheries, currently appears to be an unrealistic proposition given the limited available agency resources.

The quantitative implementation of PBR was developed as an approach that is not data intensive compared to the estimation of a stock's status relative to MNPL (i.e. an OSP status determination); PBR only requires a minimally sufficient amount of information necessary to provide an assessment of incidental human caused mortality relative to the OSP management objective of the MMPA. For example, the current default values (e.g. for N_{MIN}) were evaluated based on calculating PBR from only the single most recent abundance estimate (Ex. M-0559 (Wade 1998)). An OSP status determination requires many more years (often decades worth) of abundance estimates.

The development of PBR is consistent with a mortality reference level being applied to stocks with limited time-series abundance estimates and estimates of incidental levels of human caused mortality. As noted above, PBR can be calculated given only a single recent estimate of abundance (Ex. M-0554 (NMFS 2016)). The lowest common denominator for assessment of bycatch relative to the MMPA conservation management objectives under the PBR management scheme is therefore two data points: a single recent estimate of abundance to calculate PBR, and, for comparison, a single recent estimate of human caused mortality (NMFS 2016). However, in order for approaches such as PBR to achieve conservation management objectives across a wide spectrum of data availability scenarios (e.g. including higher degrees of uncertainty common for data-limited stocks), such approaches may need to be more precautionary than case-specific MSEs that have been applied to aboriginal subsistence whaling for more data-rich stocks (Ex. M-0549 (Punt and Donovan 2007)).

Aboriginal subsistence whaling catch limits under the IWC, in contrast to PBR, have been evaluated using case-specific approaches. This allows, for example, the full time-series of available abundance and human caused mortality data (including any information on age- and sex-structure of human caused mortality) to be incorporated when estimating the parameters of the operating model, and forms the quantitative basis to simulate future abundance trajectories in the MSE. Likewise, case-specific approaches allow for underlying spatial and temporal patterns in abundance to be modeled for feeding groups (where stock structure might be uncertain), as has been the case for ENP gray whales and the PCFG.

The approach taken for aboriginal subsistence whaling also allows for case-specific trials to be tailored such that uncertainties for the affected stock (or stocks) can be evaluated. For example, during the 2010 – 2013 IWC

Implementation Review for ENP gray whales with an emphasis on the PCFG, scientific uncertainties in the availability rates of the PCFG to the Makah hunt were evaluated (i.e. the performance of the 2005 hunt plan[11] was evaluated under trials which assumed the availability of PCFG whales to the hunt would be twice that estimated from available photo-identification data). This was shown to be an important consideration in the performance of the hunt plan relative to conservation objectives. Based on the results of the MSE, the IWC Scientific Committee's management recommendations included a research provision for future monitoring of the proportion of PCFG whales in the area of the Makah hunt (Ex. M-0528 (IWC 2014a)). One benefit of the case-specific approach is that an evaluation of the management strategy extends beyond the performance of the rules controlling catch limits. It also allows for a means of assessing whether case-specific data collection strategies are sufficient to meet management objectives and if they are not, to recommend modifications.

Case-specific MSEs, like those used by the IWC in evaluating the effect of proposed catch limits on the PCFG, may result in different mortality limits than PBR. Under certain circumstances, human caused mortality limits can be greater than PBR, while still meeting the MNPL management objective. Brandon et al. (2017) (Ex. M-0506) demonstrate an example along these lines: if multiple imprecise estimates of abundance are averaged to calculate N_{MIN}, a higher value than the 20^{th} percentile for N_{MIN} could be used in calculating PBR. Hence a larger mortality limit could be allowed in such cases, while still meeting the OSP management objective relative to MNPL. The reverse can also be true; for example, if reproductive females are particularly vulnerable to human caused mortality, PBR as evaluated would not be sufficiently conservative, unless an additional adjustment is made to decrease the recovery factor (F_R) value (Ex. M-0544 (NMFS 2016); Brandon et al. 2017)).

Given these and other factors, catch limits evaluated based on case-specific MSEs for aboriginal subsistence whaling might be above or below the corresponding value calculated for PBR. Nevertheless, if a case-specific management strategy for aboriginal subsistence whaling is evaluated to meet the conservation management objectives of the IWC, it will also meet the OSP objective of the MMPA because of the shared MNPL performance criteria. This holds true even if, in combination with estimates of incidental human caused mortality levels, case-specific aboriginal subsistence whaling catch limits exceed PBR to some degree.

[11] The "2005 hunt plan" or "Makah hunt plan" refers to the catch limit rules proposed in the Makah Tribe's 2005 application for a waiver of the MMPA's take moratorium.

2.3. IWC Evaluation of the Impacts of the 2005 Makah Hunt Plan on the PCFG

2.3.1 The 2010-2013 Implementation Review

The main focus of the IWC Scientific Committee's research during the 2010—2013 Implementation Review involved extending the previous case-specific ENP gray whale MSE (i.e. that used to evaluate the *Gray Whale SLA*; IWC 2005 (Ex. M-0523)) to also model the effects of the 2005 Makah hunt plan on PCFG gray whales. Although most ENP gray whales utilize summer feeding grounds in the Bering, Beaufort and Chukchi Seas, some utilize more southerly summer feeding grounds. At the Scientific Committee's 2010 meeting, an analysis of genetics data was presented, which compared samples between gray whales on a southern feeding ground (Clayoquot Sound) off British Columbia, with samples from wintering areas, including nursery lagoons around Baja California, Mexico (Ex. M-0518 (Frasier et al. 2010)). Based on that analysis, which showed a small but statistically significant genetic difference in the samples compared, the Scientific Committee agreed that a precautionary strategy would be to develop an updated operating model that incorporated the hypothesis of stock structure within the ENP population in order to evaluate the impact of aboriginal subsistence whaling catch limits that might be allocated between Russia and the United States on the PCFG. (Ex. M-0524 (IWC 2011, pp. 17–20)). The modeling framework that was developed for this Implementation Review assumed there were two stocks in the greater ENP population: the larger 'Northern' feeding group and the smaller, more southerly PCFG. The PCFG was assumed to be composed of individuals observed to have some defined level of seasonal fidelity to feeding areas between Northern California and Northern British Columbia (Ex. M-0527 (IWC 2013b)).

The Makah hunt plan was incorporated in this MSE based on the specifications of the Makah's 2005 application for a waiver of the MMPA's take moratorium (Ex. M-0527 (IWC 2013b)). Specifically, the IWC gray whale Implementation Review conducted from 2010 to 2013 focused on evaluating whether the proposed Makah hunt plan was sustainable in terms of meeting conservation management objectives for the PCFG, under the assumption that the PCFG was a separate stock (*id.*). The Scientific Committee made no formal statement as to whether the PCFG should be considered a separate stock by the IWC. Rather, the Scientific Committee agreed that the most precautionary strategy would be to proceed by evaluating the catch limits under the assumption that the PCFG was a separate stock.

The Implementation Review process involved multiple meetings of the full Scientific Committee, as well as intersessional meetings of smaller working groups composed of domestic and international scientists with expertise in gray whale ecology, biology, genetics and population dynamics modeling, including applied mathematicians and statisticians. In particular, the Standing Working Group on the Aboriginal Whaling Management Procedure ("AWMP") is responsible for developing case-specific MSEs, which form the basis for Implementation Reviews of aboriginal subsistence whaling. The AWMP Standing Working Group, and the other working groups and subcommittees of the Scientific Committee, convene prior to the annual meeting of the full Scientific Committee. During this annual meeting, the AWMP Standing Working Group considers, among other research, the progress of intersessional working groups tasked with developing MSEs in preparation for an Implementation Review. Any resulting recommendations of the AWMP Standing Working Group are reported to the full Scientific Committee, which convenes after the completion of the working group and subcommittee meetings. If the full Scientific Committee reaches agreement on any of its working group or subcommittee recommendations, including catch limits, these are provided as recommendations to the Commission in the annual report of the Scientific Committee.

Much of the Scientific Committee's deliberations during the 2010-2013 gray whale Implementation Review revolved around how best to model information relevant to the available time series of abundance estimates resulting from photo-identification sampling efforts focused on PCFG whales (Ex. M-0527 (IWC 2013b); Ex. M-0510 (Calambokidis et al. 2010)). At the time, the Implementation Review with a focus on the PCFG involved the most extensive and detailed MSE developed for providing management advice on aboriginal subsistence whaling catch limits for gray whales. The number of data inputs compared to the MSE used during the initial implementation of the *Gray Whale SLA* had doubled. The number of modeling scenarios representing uncertainties had likewise expanded compared to the previous Implementation Review, which had assumed only a single stock. In total, there were 119 trials[12] representing various uncertainties in: available photo-identification data; population demographics, including hypotheses regarding internal and external recruitment rates for the PCFG; availability rates of the PCFG to whaling by the Makah; struck and lost rates; intrinsic rates of population growth; episodic mortality events, and other factors (see Tables 3 and 4 in IWC 2013b, p. 139).

2.3.2 IWC performance criteria

---

[12] For comparison, the MSE for PBR considered nine base-case bias trials with respect to the MNPL objective under the MMPA (Ex. M-0559 (Wade 1998, Table 2, p. 11)).

A key MSE performance metric that has formed the basis of the current PBR management scheme, as well as the IWC's MSEs for ENP gray whales (including the 2010-2013 Implementation Review with a focus on the PCFG), is that there should be 95% certainty that abundance will be above MNPL after 100 years. For each trial[13] in these MSEs, a set of simulated population trajectories results in a range of final abundance levels at the end of the projection period. The range of projected final abundance levels results from future uncertainties (abundance estimates, catches, etc.) being modeled probabilistically. The lower 5th percentile of the resulting range of abundance is compared with the MNPL management goal, to determine whether the candidate management strategy is able to satisfy the performance criteria with 95% certainty and meet the conservation management objective, given the assumptions underlying a given trial (Ex. M-0559 (Wade 1998); Ex. M-0527 (IWC 2013b)).

Additional performance metrics have also been considered for aboriginal subsistence whaling under the IWC: metrics for subsistence need satisfaction have been taken into account, as well as trends in abundance at the end of the projection period. These metrics have been used to evaluate the performance of management strategies relative to the first two management objectives of the IWC for aboriginal subsistence whaling (IWC objectives 1 and 2, above). During the 2010-2013 ENP gray whale Implementation Review, all three types of performance metrics were considered. The conservation performance metrics (not increasing extinction risk, and moving to or maintaining stocks above MNPL) were generally given a higher priority than subsistence need satisfaction during that Implementation Review. This is consistent with the priorities of the IWC management objectives for aboriginal subsistence whaling (IWC 1995 (Ex. M-0521); 2013b (Ex. M-0527)).

The following table provides a summary of the conservation performance metrics mentioned in the preceding paragraph. These performance metrics (also called performance statistics) are also described in more detail under Section 4.4:

Table 1.

Performance metrics used by the IWC to evaluate the conservation risks of gray whale aboriginal subsistence hunt plans and catch limits.

Performance Metric	What it shows	Why it was used

[13] Trials are described in further detail under Sections 1.2.2 and 4.1.

Final Depletion	Abundance relative to carrying capacity at the end of the projection period.	Evaluate whether hunt would allow stocks to reach or exceed MNPL, i.e. to reach or maintain OSP.
Relative Depletion	Abundance relative to carrying capacity, with whaling, at end of the projection period divided by the expected abundance relative to carrying capacity, with no whaling, at the end of the projection period.	Evaluate whether hunt plan would increase the risk of extinction by comparing population levels expected with and without whaling.
Relative Increase	Whether abundance will increase or decrease under hunting.	Evaluate whether hunt plan would allow population levels below MNPL to be recovering towards OSP.

2.3.3 Conclusions of the 2010-2013 Implementation Review with a focus on the PCFG

The Implementation Review with a focus on the PCFG eventually spanned three years and was completed when the Scientific Committee was able to reach full agreement on management advice in 2013 (IWC 2013b (Ex. M-0527), 2014a (Ex. M-0528)). The Scientific Committee agreed that the proposed 2005 Makah hunt plan met the conservation management objectives of the IWC for aboriginal subsistence whaling, i.e. the proposed Makah hunt plan would not increase extinction risk or result in a PCFG abundance level below MNPL after 100 years. Because of the overlap between the IWC's conservation management objectives and those of the MMPA, the Scientific Committee's conclusion provides compelling evidence that the 2005 hunt plan also met the MMPA's conservation objectives for the PCFG.

The Scientific Committee's evaluation also demonstrated, however, that the 2005 Makah hunt plan was sensitive to potential bias in the estimates of availability of PCFG whales to the hunt. The Scientific Committee's conclusion was therefore conditioned on a research provision, which requires a continuation of the annual photo-identification surveys in order to monitor the relative probability of the Makah hunt encountering a PCFG whale (IWC 2013a (Ex. M-0526), 2014a (Ex. M-0528)).

A related factor that complicated the IWC evaluation of the 2005 Makah hunt plan stemmed from a proposed catch limit rule regarding whether or not a struck and lost whale would be presumed to be a PCFG whale. The Makah hunt plan, as then proposed, would have allowed whaling to occur during the migratory period: Dec. 1st – May 31st. Acknowledging that PCFG whales are more likely to be encountered closer to the summer feeding season, NMFS proposed that any whale struck and lost during the month of May would have to count towards the PCFG mortality limit in the plan (based on a PBR calculation); however, if a whale was struck and lost during any other month (Dec – Apr) it would not count towards the PCFG limit (i.e. that whale would be assumed to be an individual from the 'Northern' feeding group on migration; IWC 2013b (Ex. M-0527)).

A difficulty with the proposed catch limit rules that were evaluated during the 2010—2013 Implementation Review arose from the fact that there were insufficient data *a priori* to inform when Makah whaling effort might be expected to occur by month. Therefore, it was not possible to predict the proportion of strikes that might occur during the proposed Dec–Apr *vs.* May split (i.e. there was an outstanding question regarding what proportion of struck and lost whales might be assumed to be PCFG and therefore count towards the PBR-based limit under the proposed rule). In order to take this uncertainty into account, the Tribe proposed evaluating two variants of the hunt plan. Each variant represented an extreme case as to when the hunt might occur with respect to the assumption of whether or not struck and lost whales would be assumed to be from the PCFG (Ex. M-0527 (IWC 2013b); Ex. M-0507 (Brandon and Scordino 2013)).

The two variants of the proposed 2005 Makah hunt plan therefore bracketed the range of possible strikes by month. At one end of the extreme, Variant 1 was tantamount to assuming all hunting (up to 7 strikes) would occur during Dec-Apr, when struck and lost whales would not be assumed to be individuals from the PCFG. At the other end of the extreme, Variant 2 assumed all hunting would occur during May, and every struck and lost whale would be assumed to be PCFG. At the 2012 Scientific Committee meeting it was noted that that neither of these variants modeled the Makah hunt exactly as it had been proposed because the plan did not specify month-by-month use of available strikes (Ex. M-0526 (IWC 2013a)). Brandon and Scordino (2013) (Ex. M-0507) demonstrated, and the Scientific Committee subsequently agreed, that the IWC's evaluation of the 2005 Makah hunt plan (as modified to add the struck and lost presumption) is not sensitive to the month-by-month distribution of available strikes; ultimately, this issue did not change the IWC's conclusion that the 2005 hunt plan met the conservation management objectives of the IWC (Ex. M-0528 (IWC 2014a)).

3. Western North Pacific Gray Whales

During the course of the 2010-2013 IWC Gray Whale Implementation Review with a focus on the PCFG, new evidence was presented demonstrating that at least some gray whales considered to be a part of the WNP stock migrate to the eastern North Pacific as far south as the wintering grounds in Mexico (e.g., Mate et al. 2011 (Ex. M-0540)). Although putative WNP gray whales that feed off Sakhalin Island have not been observed to date in the portion of Makah's Usual and Accustomed fishing grounds where the hunt will take place (Makah U&A), they have been observed in the Pacific Northwest off Vancouver Island, Canada (Ex. M-0560 (Weller et al. 2012)). These observations have raised conservation concerns that WNP gray whales, listed as endangered by NMFS under the Endangered Species Act (ESA), could be vulnerable to Makah whaling.

3.1 Estimate of the Probability of a Take in the Makah Hunt

The conservation risk of the Makah hunt plan for WNP gray whales was not evaluated during the 2010-2013 Gray Whale Implementation Review. Instead, given the focus of that Implementation Review on the PCFG, a full evaluation of the conservation risk to WNP gray whales was deferred to a later date, when a set of workshops to review the rangewide population structure and status of North Pacific gray whales would be completed (Ex. M-0529 (IWC 2014b, p. 191)). However, given the available evidence at the time, the Scientific Committee also emphasized the need to estimate the probability of a WNP gray whale being taken by Makah whaling (Ex. M-0525 (IWC 2012, p. 137)).

To address this need and also to inform the analyses for NMFS's DEIS for proposed Makah whaling, Moore and Weller (2013) (Ex. M-0541) developed a modeling framework to estimate the probability of taking a WNP gray whale in the Makah hunt proposed in 2005. They considered multiple models while noting their preference for one model in particular:

> *"We consider Model 2B the most plausible of all models because model set 2 makes use of all available information and 2B contains fewer assumptions than 2A."*
>
> - Moore and Weller (2013, p. ii, also pp. 7, 11)

The resulting estimate was based on several factors, including: (i) the relative abundance of ENP and WNP gray whales (as of 2007 and 2012, respectively); (ii) the proportion of non-PCFG (migrant) whales recorded in the photo-identification catalogue in the Makah U&A during the proposed hunting season; and (iii) the maximum number of non-PCFG gray whales that could be taken, as allowed under the proposed 2005 hunt plan. Additionally, probabilities were estimated for the expected number of unsuccessful strikes (a strike that either misses or fails to penetrate a whale) as well as non-lethal approaches (pursuit, but no attempt to strike a whale). The analyses included a range of uncertainties across these factors and calculated probabilities using Bayesian inference, which allowed for the integration of the various sources of uncertainty in the estimation process. Moore and Weller (2013, p. 11) stated that the "[e]stimates from our analysis are considered precautionary" and the results "offer a conservative initial step in assessing the potential risk of WNP gray whales incurring mortality incidental to the proposed hunt . . . "

Moore and Weller (2013) (Ex. M-0541) presented the results of all models considered, including versions A and B for two of the models (Moore and Weller 2013, pp. 8-10). Based on the results of the preferred model (2B), they estimated that the probability of striking a WNP whale during a given take event was 0.2%.[14] In one season under the 2005 hunt plan, the probability of striking at WNP whale was between 0.7% and 1.2% (based on a range of 3 to 7 strikes). Over a 5-year period, the probability of a strike ranged from 3.6% to 5.8%. The analysis also provided the expected number of struck WNP whales under the various scenarios (*i.e.*, over 1 or 5 years). Here, the results were 0.01 in one year and between 0.04 and 0.06 over five years of hunting. In the 2014 stock assessment report for WNP gray whales, NMFS translated the single-year strike probability (there, reported as a range of 0.006 to 0.012) to a more tangible number, stating that it "corresponds to an expectation of ≥ 1 WNP whale strike in one of every 83 to 167 years (Ex. M-0513 (Carretta et al. 2015, p. 185)). Based on the model results, Moore and Weller (2013, p. 8) concluded that the probability of striking a WNP gray whale over a 5 year period under the 2005 Makah hunt plan was "relatively low but non-trivial."

Moore and Weller (2018) (Ex. M-0542) subsequently presented updated estimates of the probability of a WNP gray whale being struck in a Makah hunt.[15] The reported median probabilities of striking at WNP whale in a single interaction, over one year, and over a 10-year waiver period, are 0.4%, 1.2% and 5.7%, respectively (Moore and Weller 2018, p 5). The point estimate for the expected number of WNP strikes if all 15 available strikes are used in the even year (migration season) hunts over the 10-year waiver period is 0.06 WNP whales. Using the same translation of the single-year strike probability as NMFS's 2014 stock assessment report, the 2018 results would correspond

---

[14] All modeling results presented here are median values. Moore and Weller (2013) also reported the upper 95th percentile value. They noted that for model sets 1 and 2, median parameter estimates were higher for version A than B, although upper 95th percentile estimates were similar.

[15] Moore and Weller informally updated their analysis for the 2015 DEIS. There, they took "into account modified assumptions/data values regarding hunt duration and the number of approaches, strikes, and attempted strikes (NMFS 2015, p 3-93). The DEIS indicates that Moore and Weller "rel[ied] on the same [2013] model but reflect the updated data."

to an expectation of ≥ 1 WNP whale strike once in 83 even-year hunts (or once every 166 years given the alternating season structure of the hunt).

These new estimates are based upon updated photo-identification and abundance data. The estimates are also updated to reflect the hunt plan and catch limits proposed by NMFS in 2018. Importantly, instead of being based on the previously preferred 'Model 2B' they are now based on 'Model 2A', which is the more conservative of the two, *i.e.*, it is more precautionary with respect to the probability of encountering a WNP gray whale in the Makah U&A.[16]

The difference between Model 2A and 2B essentially boils down to an assumption regarding the proportion of non-PCFG whales during the migration season that could be WNP gray whales. Model 2A assumes that, on a per-capita basis (i.e. taking into account the different population sizes), non-PCFG whales in the Makah U&A are as likely to be WNP gray whales as they are to be ENP gray whales (in essence, assuming that all WNP gray whales migrate through the Makah U&A). Model 2B does not make that assumption. Instead Model 2B incorporates more uncertainty about the per-capita likelihood by integrating over a range of probabilities for this variable. The difference between the two modeling approaches, and the rationale for presenting updated estimates based on Model 2A, is described by Moore and Weller (2018) (Ex. M-0542):

> *"Moore and Weller (2013) considered four models in their analysis but they based final inferences on what they termed Model 2B. Here, we use Model 2A instead. Models 2A and 2B are similar. The difference is that for Model 2A, the conditional probability of a non-PCFG whale being a WNP (rather than ENP) whale is simply based on the ratio of WNP:ENP population size. This is an intuitive estimator, though it does rely on the assumption that WNP and ENP animals migrating together are using the same migration corridors and behaving similarly. For Model 2B, this assumption is relaxed and we allow for broader uncertainty by stating that the conditional probability varies uniformly from zero (if the WNP whales do not migrate through the Makah area at all) to some maximum value that is based on (but not equivalent to) the ratio of WNP:ENP population size. However, it is difficult to define the maximum value, and allowing a lower probability of zero is not precautionary and arguably should not be considered without supporting evidence."*

[16] Unlike Moore and Weller (2013), Moore and Weller (2018) do not present the results of all models used in their analysis.

- Moore and Weller (2018, p. 4)

Although Moore and Weller's (2018) analysis using a conservative selection of the available models demonstrates there is a very low probability of striking a WNP gray whale, it is important to emphasize that whatever the merits of the probability analysis, this approach cannot assess the central and far more complex issue in evaluating the impacts of the proposed hunt, namely what are the expected population level consequences (for WNP or PCFG whales). In the next section, I detail how the Scientific Committee of the IWC addressed this issue comprehensively and more definitively through a series of annual workshops and related meetings culminating in 2018. In that more comprehensive effort, the Scientific Committee of the IWC found that Makah whaling under the current proposed hunt plan would meet the conservation management objectives of the IWC, and, consequently, the OSP management objective of the MMPA.

3.2 IWC Rangewide Review

As noted above, the 2010—2013 IWC gray whale Implementation Review with a focus on the PCFG did not attempt to evaluate the population level consequences of the proposed 2005 Makah hunt plan on WNP gray whales (Ex. M-0529 (IWC 2014b, p. 191)). Instead, the Scientific Committee requested the probability analysis ultimately performed by Moore and Weller and deferred the population level evaluation until it could complete a rangewide review of relevant information for North Pacific gray whales as a whole (Ex. M-0525 (IWC 2012, p. 137)). To this end, following the 2010 – 2013 Implementation Review with a focus on the PCFG, the Scientific Committee conducted five workshops during 2014–2018 (e.g. IWC 2018a (Ex. M-0531)).

These IWC "rangewide workshops" originated from the need to carefully consider the conservation implications of satellite tagging, genetic, and photo-identification data that demonstrated at least some whales from the putative WNP gray whale stock migrate to the eastern North Pacific (Ex. M-0540 (Mate et al. 2011); Ex. M-0560 (Weller et al. 2012)). The potential conservation risks for WNP gray whales in the eastern North Pacific are not limited to Makah whaling; risk in this context also includes sources of incidental human caused mortality between Alaska and Mexico, e.g. entanglements and ship-strikes (e.g. Scordino et al. 2014 (Ex. M-0555).

A related motivating factor behind the IWC rangewide review was the recognition that the previously established idea that there are two separate populations of gray whales (ENP and WNP) with non-overlapping ranges in the North Pacific was in need of re-evaluation (e.g. Bickham et al. 2013 (Ex. M-0503)). Thus, because it had become evident by 2013 that gray whale stock structure was more complicated and the scientific understanding of such more uncertain than had been realized just a few years earlier, the Scientific Committee undertook the most comprehensive review of North Pacific gray whales to date (e.g. IWC 2018a (Ex. M-0531)).

The annual workshops involved the participation of scientific experts from range states across the North Pacific (e.g. South Korea, Japan, Russia, the United States, Canada and Mexico). They served as an expert review to synthesize available information relevant to stock structure and conservation risks. The information reviewed included (but was not limited to): genetics; population dynamics; and incidental human caused mortality levels, across the entire North Pacific gray whale range.

An important goal of the IWC rangewide review process was to synthesize relevant information in order to develop a set of stock structure hypotheses that include plausible alternative scenarios representing underlying spatial-temporal mixing patterns across stocks. For example, one stock structure hypothesis developed during the IWC rangewide review involves a scenario where gray whales found off Sakhalin Island are a mixed stock feeding aggregation. Under this hypothesis, the feeding aggregation off Sakhalin is composed of members of two stocks: the ENP stock, some of whose members feed off Sakhalin and migrate back to the eastern North Pacific after the feeding season (this hypothetical ENP group has been termed the ‘Western Feeding Group’, or WFG); and a ‘Western Breeding Stock’ (WBS) that migrates south of Japan after the feeding season and interbreeds in the western North Pacific. Other stock structure hypotheses were developed as well, including a scenario where gray whales in the western North Pacific are at present composed solely of WFG whales (i.e., whales from the ENP stock) and the WBS was extirpated at some point in the past (Ex. M-0531 (IWC 2018a)).

The IWC rangewide review is important because the resulting set of stock structure hypotheses for WNP gray whales provide a basis for developing an updated operating model, which can be used for evaluating hunt plans for Makah whaling (along with the hunt in Russia by Chukotka Natives). The stock structure hypotheses also provide a context for evaluation of the risk of a “WNP” strike—for instance, if the whales from Sakhalin Island are actually a feeding group of ENP whales (the WFG), the hunt poses no risk to the western breeding stock of WNP whales. The five-year IWC rangewide review process has culminated in agreement between international experts on the specifications for this rangewide multi-stock modeling framework. The resulting framework represents the best available science in terms of an approach for quantitatively evaluating management plans and mitigating conservation risks for WNP and ENP gray whales, including the PCFG. In the next section I discuss some aspects of the new hunt plan that NMFS proposed in 2018 for Makah whaling, how the IWC rangewide modeling framework was applied to evaluate that hunt plan, and what the results of that evaluation indicate in terms of the hunt plan's expected performance under the statutory OSP objective of the MMPA.

4. Evaluation of the 2018 Proposed Hunt Plan

4.1. Description of the 2018 Proposed Hunt Plan

The hunt plan proposed by NMFS in 2018 differs from the 2005 hunt plan in several important respects: allowable strike and landing limits have been reduced by approximately one-half (see Table 2); an alternating season structure is used; a limit on the number of PCFG females that can be taken in the hunt is introduced; and the confirmed striking of a WNP gray whale will result in a suspension of the hunt. An additional new component of the 2018 hunt plan is a requirement that a mathematical projection based on the time series of PCFG abundance estimates indicate that PCFG abundance is above a threshold limit (i.e. a point estimate of 192 or an N_{MIN} value of 171[17]) for hunting to occur in any year. These threshold limits also apply to the most recently available abundance estimate from photo-identification data, noting abundance estimates are typically not available until a year or two after the end of a survey season. Also, NMFS is seeking to authorize the hunt for only ten years. A comparison of the strike and landing limits for the hunt plans is provided in Table 2 below.

Table 2.

Comparison of 10-year ENP gray whale strike and landing limits for the 2005 and 2018 hunt plans proposed for Makah aboriginal subsistence whaling.

	Hunt Plan	
Limits over 10 years[18]	2005	2018
Strikes	70	25
Struck and Lost	30	25[19]

[17] N_{MIN} is the 20th percentile of the projected or empirically estimated abundance.

[18] No ten-year sunset was proposed in the 2005 hunt plan.

[19] Unlike the hunt plan proposed in 2005, the 2018 hunt plan does not have separate limits for 'strikes' and 'struck and lost' whales; thus, the limit on 'strikes' is, in effect, the limit on 'struck on lost' whales.

Landings	40	20
PCFG Strikes	Determined by PBR[20]	16
PCFG Female Strikes	NA[21]	8
Plan sunsets after 10 years?	No	Yes

The 2005 hunt plan was proposed before WNP gray whales were known to migrate to the eastern North Pacific. In that context, the focus of the 2005 plan was to minimize the conservation risk of Makah whaling to PCFG whales. As such, proposed whaling effort in the 2005 plan was restricted to the migration season (Dec – May). During the migration season, the vulnerability of PCFG whales to the hunt is lower than during the feeding season, because large numbers of whales from the greater ENP stock are available to the whalers. The mixture dilutes the conservation risk to the PCFG during the migration season. The migration around (and potentially through) the Makah hunt area is now known, however, to also include WNP gray whales.

The presence of WNP gray whales in the eastern North Pacific adds a new dimension to any risk assessment for Makah whaling. Further, there is a competing seasonal risk factor between WNP and PCFG whales. All else being equal, whaling during the migration season increases the risk to WNP whales while decreasing the risk to PCFG whales. The conservation risk is reversed for whaling in the summer feeding season, when WNP whales are known to be feeding in the western North Pacific, and PCFG whales are likely to be present in the Makah U&A.

The 2018 hunt plan includes management measures to reduce the likelihood of Makah whalers encountering a WNP gray whale. These measures reduce the overall number of strikes and shift all whaling effort away from the migration season in half of the years to limit the exposure of WNP gray whales. Whaling effort would be required to alternate annually between the feeding and migration seasons. During even numbered years, whaling would be

[20] As proposed and subsequently evaluated by the IWC (2013b) (Ex. M-0527), the 2005 hunt plan uses a PBR calculation to determine the allowable limit on PCFG strikes, where PBR is the product of: (i) $0.5 * R_{MAX} = 0.0235$; (ii) $F_R = 1.0$, and; (iii) N_{MIN} = the lower 20th percentile of a subset of the PCFG abundance estimate from Oregon to Southern Vancouver Island. Only whales struck and lost in May, and those whales struck during Dec—Apr (either lost or landed) that are subsequently matched to an individual in the PCFG photo-identification catalogue, counted against the PCFG limit under the 2005 hunt plan.

[21] "NA" stands for "Not Applicable", i.e. the PCFG strike limit is independent of sex under the hunt plan proposed in 2005.

restricted to the migration period (from the previous December to May). In odd numbered years whaling would be restricted to a subset of the feeding season (from July to October). No hunting would be allowed in June or November to give time for late northbound WNP migrants to pass through the hunt area and for early southbound WNP migrants to enter the hunt area without risk of being struck in a hunt. In effect, the 2018 plan's alternating season framework is a hedge – spreading the whaling effort across seasons – given the competing seasonal risks for WNP and PCFG gray whales. The reduction of annual strikes during the migration season (3 strikes maximum) compared to the 2005 hunt (7 strikes maximum) also serves to reduce the likelihood of whalers encountering or killing a WNP gray whale. The strike limit proposed in the 2018 hunt plan during the summer feeding season is two; however only one strike is allowed if the first whale is landed. As mentioned above, hunting in any year is only allowed if projected PCFG abundance stays at or above recent levels[22] in order to limit the impacts of the hunt on PCFG whales.

4.2. Request for IWC Review of the 2018 Proposed Hunt Plan

The new hunt plan proposal was presented by NMFS at the March 2018 IWC rangewide review workshop (Appendix 1 of IWC 2018a (Ex. M-0531)), and a request was made on behalf of the United States government for the Scientific Committee to evaluate the plan and determine if it would meet the conservation objectives of the IWC. As I described above, the conservation objectives of the IWC mirror the conservation objectives of the MMPA (Section 1.2.1 above).

At the same IWC rangewide workshop, a final set of operating model specifications (e.g. stock structure hypotheses) and trials were agreed upon in order to evaluate the new hunt plan. The specifications for the rangewide operating model, as well as factors identified as key scientific uncertainties in the evaluation trial structure (e.g. levels of cryptic incidental human caused mortality), had been under development and review by the Scientific Committee since the first annual rangewide workshop in 2014 (Ex. M-0531 (IWC 2018a)). In addition to modeling the spatial distribution, population dynamics, and sources of human caused mortality for gray whales across the North Pacific, the rangewide modeling included updated estimates of abundance and human caused mortality for WNP, ENP and PCFG whales (IWC 2018a). In total, 54 trials, incorporating multiple stock structure hypotheses were selected for the evaluation. Additionally, it was agreed a variant of the 2005 hunt plan would also be subject to performance testing using the same

[22] "Recent levels" pertains to the relatively stable period in abundance estimates since 2002.

rangewide operating model and trial structure for comparative purposes.

While the evaluation of the hunt plan using the model developed in the rangewide review was not a formal Implementation Review, the process shared many of the same elements. For example, the modeling and evaluation framework were developed through the course of a multi-year review of available information[23]. Additionally, the steps taken in developing the evaluation process (e.g. alternative stock structure hypotheses) were presented in annual workshop reports to the broader Scientific Committee for feedback during 2014-2018 (e.g. IWC 2018a (Ex. M-0531)). The next Implementation Review for gray whales is scheduled for 2020 (a one year delay from the normal interval). The results of the evaluation based on the rangewide modeling will almost certainly form the basis for providing management advice during the next Implementation Review. In essence the rangewide evaluation had all the technical rigor of an Implementation Review, without the formal title.

4.3. Trial Structure for Evaluating Makah Hunt Plans Under the IWC Rangewide Model

Incorporating WNP gray whales (and alternative plausible stock structure hypotheses) in the IWC rangewide evaluation framework for the proposed hunt was a critical and necessary development accomplished through the last five years of the rangewide review process. That was not, however, the only important revision that has been introduced to the current evaluation framework and trial structure. During the 2010-2013 Implementation Review with a focus on the PCFG, the hunt plan proposed in 2005 was evaluated under the base case assumption that there was no negative bias (or at least that any such bias was negligible) in reported numbers for incidental human caused mortality and prorated serious injuries in the United States and Canada. In other words, incidental human caused mortality levels were assumed to be equal to observed counts of "serious injury and mortality" by NMFS (Ex. M-0527 (IWC 2013b); Ex. M-0514 (Carretta et al. 2017)). Although the previous evaluation did include a trial where 'true' incidental human caused mortality was modeled to be twice as large as recorded numbers (*id.*), new information was published subsequently that indicated the previous assumptions regarding this correction factor may have been optimistic (Ex. M-0552 (Punt and Wade 2012); Ex. M-0512 (Carretta et al. 2016)). In addition, an effort to

[23] Compared to the 2012 – 2013 Implementation Review focused on the PCFG, the rangewide review developed a more sophisticated operating model in order to take into account the complexities of alternative stock structure hypotheses that include WNP gray whales.

compile a record of human caused mortalities in other countries within the gray whale range was completed and peer-reviewed by the Scientific Committee (Ex. M-0556 (Scordino et al. 2017)).

Taking this new information into account, the rangewide evaluation framework assumed a base case multiplicative correction factor of four times the number of reported incidental human caused mortalities throughout the gray whale range (Ex. M-0556 (Scordino et al. 2017); Ex. M-0531 (IWC 2018a)). This updated correction factor is founded on a published analysis of observed versus expected carcass recovery rates for the California coastal population of bottlenose dolphins (Ex. M-0512 (Carretta et al. 2016)). Furthermore, based on a comparison between: (i) an estimate from population dynamics modeling of the number of gray whales that died during the 1999-2000 mortality event; and (ii) the reported number of gray whale carcasses observed stranded between Mexico and Alaska during that event, Punt and Wade (2012) (Ex. M-0552) estimate that only 4 – 13% of gray whales that die each year, over that geographical range, are actually observed as stranded. Therefore, in addition to the base case assumption for incidental mortality (four-times observed), additional trials were introduced in the rangewide evaluation framework that assume incidental human caused mortality levels are 10 and 20 times higher than observed (IWC 2018a).

Another important aspect of available data on incidental human caused mortality includes the nature of fisheries effort as it pertains to uncertainties in historical estimates of mortality due to fisheries bycatch. Certain fisheries are known to have higher rates of gray whale bycatch due to factors like gear type and operational effort overlapping with the gray whale migration. Unfortunately, for some fisheries that are known to have relatively high interaction rates with gray whales, available time series of systematic observer effort are incomplete, e.g. reliable data on gray whale bycatch are unavailable prior to the early 1980s for the set-net fishery targeting halibut off California (Ex. M-0531 (IWC 2018a)).

The IWC rangewide review included a dedicated effort to reconstruct relevant historical fishing effort as it relates to spatial and temporal patterns of gray whale bycatch underlying the trial structure used for evaluation. This research involved the collaboration of scientists with expertise in pertinent fisheries bycatch data and provided a basis for bycatch rates to be extrapolated back in time over years for which observer data are incomplete (Ex. M-0556 (Scordino et al. 2017); Ex. M-0531 (IWC 2018a)). To the best of my knowledge, this research initiative has resulted in the most complete reconstruction to date of incidental human caused mortality of gray whales. Reconstructing historical bycatch rates vis-à-vis trends in fisheries' effort through time is important in the context of the IWC evaluation process because of the magnitude of bycatch multipliers used to develop trials for this factor as discussed above, i.e. if such mortality is not accurately modeled, the results of the evaluation may be biased. To guard against such an outcome, the rangewide model included several sensitivity tests with respect to how the commercial fishing effort data was incorporated in the reconstructed record of incidental human caused mortality (IWC 2018a).

In general, the strategy for developing the IWC rangewide trials involved first identifying a set of factors representing scientific uncertainties relevant to conservation risk (e.g. cryptic mortality). Base-case levels assumed for key factors were then expanded, forming a list of values (i.e. multiple levels may be assumed for each factor). Examples of key factors include, cryptic mortality [levels of 4 (base-case value), 10 or 20 times observed mortality, in addition to a level where zero cryptic mortality was assumed], and annual immigration rates into the PCFG [levels of zero, one, two (base-case value) or four whales immigrating into the PCFG per year, which 'recruit' into the feeding group]. The IWC rangewide evaluation considered a total of 21 factors in the set of trials, including other key factors such as various stock structure hypotheses and values for intrinsic[24] growth rates for each stock (Ex. M-0531 (IWC 2018a, Table 5, p. 16)).

The value for each factor that was considered most plausible in an expert review usually was adopted as the 'base-case' level (*id*.) but in some cases a value that was more conservative than the most plausible value was selected. The majority of base-case values were determined from empirical data. For example, the base-case level for PCFG availability to Makah whalers during the migration season is based on estimates from photo-identification data. Likewise, as mentioned above, the base case value for the level of cryptic mortality assumes that total incidental human caused mortality is four times that observed based on the carcass recovery study of coastal bottlenose dolphins (Ex. M-0512 (Carretta et al. 2016)). And the probability of encountering a WNP gray whale was based on the analyses of Moore and Weller (2013) (Ex. M-0541).

An example where the selected value was less than the most plausible value to ensure the model was conservative was the adoption of the immigration rate of two whales per year into the PCFG, even though simulations of genetic diversity were found to be most consistent with four

[24] "Intrinsic" in this context means the growth rate of a stock, in terms of its life history (birth rates, natural mortality rates, etc.), independent of extrinsic factors that would result in changes of abundance (e.g. incidental human caused mortality, immigration, or aboriginal subsistence whaling)

immigrants per year (Ex. M-0539 (Lang and Martien 2012); Ex. M-0531 (IWC 2018a, Table 5, p. 16)). Multiple levels were often added for key factors for evaluation, until the range of values for each spanned the bounds of agreed plausibility. The probability analyses of Moore and Weller (2013) (Ex. M-0541) was included.

The final set of trials was then developed by “crossing” various levels between factors, resulting in a set of trials that aimed to cover the plausible parameter space, not just for a single factor but across all key factors (Ex. M-0531 (IWC 2018a, Table 6, p. 17)). As a simplified example of crossing levels between factors, consider just two factors, cryptic mortality and the immigration rate into the PCFG; crossing the base case value of PCFG immigration with all four levels of cryptic mortality would result in four potential trials represented by the various combinations across levels (2 immigrants per year with no mortality correction factor; 2 immigrants per year with a mortality correction factor of four, etc.). Each of the factors in this example has four levels (as listed above), hence fully crossing all levels across just these two factors would result in 16 combinations or 16 potential trials if all other factors were held constant. This, in turn, would represent a subset of the global parameter space, which can be thought of as a larger grid containing the full set of potential combinations resulting from crossing all levels across all factors.

The cost of running the entire global set of potential trials would have been exorbitant and ultimately prohibitive in terms of computational time (running a single trial may take many days to complete). Fortunately, there are areas of the global parameter space that, while plausible, are not necessarily informative with respect to evaluating the performance of a hunt plan in terms of its ability to satisfy conservation management objectives. Take for example a single factor like the intrinsic growth rate of the PCFG. This factor included three[25] levels in the IWC rangewide evaluation: 2%, 4.5% (base-case value), and 5.5% growth per year, as measured at MNPL. The majority of trials in the final set involve the base-case value, consistent with the treatment of other factors, with four trials run as “sensitivity tests” under the lower and upper values for intrinsic PCFG growth rate. The bottom end of the range for this parameter-value was determined during the 2010-2013 Implementation Review to have lower plausibility than the base-case value given empirical data and observed rates of increase (Ex. M-0527 (IWC 2013b, p. 142)). The upper value, on the other hand, is not necessarily as informative as the base-

[25] A fourth level was also included, which involved estimating the value of this parameter from available abundance data, but I am ignoring that level here, for the purposes of illustrating a larger point.

case value, because if the performance of a hunt plan satisfies conservation management objectives under scenarios with 4.5% intrinsic growth rate, its performance will be satisfactory under scenarios with a higher level of productivity and resilience (i.e. under a value of 5.5% intrinsic growth rate). Based on considerations such as these, the Scientific Committee agreed on a final set of trials for the rangewide evaluation, such that a balance was struck between covering relevant and plausible parameter space in terms of informing the evaluation of conservation risk while also limiting the extent of redundancy between trials (Ex. M-0531 (IWC 2018a, Table 6, p. 17)).

4.4. Performance Statistics for Evaluating Makah Hunt Plans Under the IWC Rangewide Model

In evaluating NMFS's 2018 proposal for the Makah hunt, several additional performance statistics were considered in addition to the 100-year MNPL management objective. These included the 'relative depletion' and 'relative increase' statistics discussed above (see Table 1).

Depletion is a key element in both of these statistics. In this context depletion refers to abundance as a fraction of carrying capacity, so that a stock that has a depletion level of 40% is at 40% of its carrying capacity, a stock that has a depletion level of 60% is at 60% of its carrying capacity, and so on. Stocks with depletion levels at a high percentage of carrying capacity are less depleted, and vice-versa (depletion levels at lower percentages of carrying capacity are more depleted). Thus, the lower the percentage, the more depleted a stock is said to be. MNPL is commonly assumed to represent a depletion level of 50-60% of carrying capacity (e.g. Punt and Wade 2010 (Ex. M-0551); Wade 1998 (Ex. M-0559)).

Relative depletion provides a comparison of how much whaling contributes to the depletion of stock or feeding group relative to the expected level of depletion without whaling. This performance statistic is informative for trials with high levels of incidental human caused mortality, like those in the IWC rangewide evaluation in which incidental human caused mortality is assumed to be 10 or 20 times the observed value. Under the assumptions of such trials, future abundance could be well below carrying capacity (and other reference levels like MNPL) even in the absence of whaling. Relative depletion is therefore a useful performance statistic because it controls for extrinsic factors, which might otherwise bias the interpretation of simulation results, and allows the effects of whaling and non-whaling factors to be separated during the performance evaluation.

Relative depletion also provides a metric for evaluating a hunt plan's responsiveness under scenarios where the stock has become highly depleted (at a small fraction of carrying capacity) or is declining for some reason in the future. In such cases a hunt plan would be expected to respond by reducing or stopping catches such that the risk of extinction is not being increased. The relative depletion statistic has also been employed in the evaluation of other aboriginal subsistence hunt plans (e.g. West Greenland humpback whales; IWC 2014b (Ex. M-0529)).

It is widely accepted that no hunt plan can be expected to meet conservation objectives under the most difficult of hypotheticals, and the relative depletion statistic ensures that the performance of a hunt plan relative to the first conservation objective of the IWC, i.e. "risks of extinction to individual stocks are not seriously increased by subsistence whaling," is met (Ex. M-0521 (IWC 1995); Section 1.2.1)). That is not to imply that a hunt plan would be considered to have met the IWC's conservation objectives if it satisfies this objective alone. For the remaining IWC conservation objectives, including those that mirror the OSP objective under the MMPA, hunt plans are evaluated by the IWC given the additional performance metrics that I describe below.

The relative increase statistic measures the expected future depletion of a stock with hunting divided by that prior to the implementation of a hunt plan. A value of this statistic equal to 1.0 would indicate the future status of a stock would be unchanged by whaling. Values greater than 1.0 would indicate a population would grow under whaling while values less than 1.0 would indicate it would decline under whaling. This performance statistic is important in evaluating how well a candidate hunt plan is expected to perform relative to a component of the third conservation management objective of the IWC for aboriginal subsistence whaling, *i.e.*, to "…ensure that stocks below that level (*i.e. MNPL*) are moved towards that level, so long as the environment permits" (Ex. M-0521 (IWC 1995); Section 1.2.1; words in italics are mine). In cases where the status of a stock or feeding group may be below MNPL, or where its status is uncertain prior to the onset of aboriginal subsistence whaling (e.g. the PCFG; Punt and Moore 2013 (Ex. M-0550)), this performance statistic is useful in evaluating whether a candidate hunt plan will allow stocks (or feeding aggregations) below MNPL to recover to MNPL in the future with whaling. In terms of the MMPA, relative depletion measures how well a candidate hunt plan is expected to perform under the management objective of "allowing a stock to *reach* or maintain its optimum sustainable population" [MMPA, 16 U.S.C. § 1362 (20), italics added].

4.5. Results of Evaluating Hunt Plans for Makah Whaling Under the IWC Rangewide Model

As noted above, in addition to simulating the performance of the 2018 hunt plan, a variant of the hunt plan proposed in 2005 was also subjected to performance testing under the IWC rangewide model and set of trials. The evaluation results for the older hunt plan did not enter into deliberations during the 2018 Scientific Committee meeting, which instead focused on the 2018 plan, but a preliminary inspection of the results by the AWMP Standing Working Group confirmed that the new hunt plan is more conservative than the 2005 plan[26]. In particular, one illustrative example of the performance of the two hunt plans stands out in comparison. Recall, that the during the 2010-2013 Implementation Review, the performance of the 2005 hunt plan was found to be sensitive to the availability of PCFG whales, which led to the IWC's affirmative management recommendation being provisional on the continuation of photo-identification studies in the future in order to monitor the proportion of PCFG whales available to the hunt. A trial was included during the 5th IWC Rangewide workshop that assumes 100% of whales available to Makah whaling are from the PCFG. The assumption that 100% of all whales taken by the Makah hunt will be removed from the PCFG represents a 'worst-case' scenario, for conservation risk to the PCFG under this factor.

Not surprisingly, given the 2005 hunt plan's demonstrated sensitivity to the availability factor in the 2010-2013 Implementation Review (previously only evaluated at up to 60% PCFG availability), the 2005 hunt plan did not meet the MNPL management objective for the 100% PCFG availability trial under the rangewide evaluation framework. The 2018 hunt plan, on the other hand, was able to satisfy the MNPL management objective under this trial for the PCFG. This is an illustrative example in terms of conservation performance between the two hunt plans. It indicates the 2018 hunt plan is more robust to scientific uncertainties in terms of being expected to meet management objectives over a wider range of hypothetical scenarios, including certain worst-case scenarios. Qualitatively at least, this is not a particularly surprising result given the 2018 plan's more conservative catch limits compared to the 2005 hunt plan (Table 2). Quantitatively, and perhaps more importantly, this result demonstrates that the 2018 hunt plan is not sensitive to a key factor identified in the Scientific Committee's evaluation of the 2005 hunt plan. For completeness, it should also be noted that both hunt plans as evaluated under the IWC rangewide model, met the MNPL/OSP objective for WNP and ENP gray whales under this trial (i.e., 100% PCFG availability).

The evaluation of the 2018 hunt plan was completed under the rangewide

---

[26] This is based on my personal observations of the Scientific Committee's discussion while co-chairing the AWMP Standing Working Group meetings during the 2018 Scientific Committee meeting.

modelling framework at the 2018 Scientific Committee meeting (Ex. M-0533 (IWC 2018c)). The evaluation considered the performance of the hunt plan over a set of gray whale stock structure hypotheses and trials developed by international experts during the course of the five years of research, analysis, and modeling at the IWC Rangewide Workshops. This represents the first and only management strategy evaluation to evaluate a gray whale hunt plan for the Makah taking into account population level consequences of expected removal levels on the WNP stock.

In the final analysis of the 2018 hunt plan, there were 106 trials across the alternative stock structure hypotheses. The results across the vast majority of trials were found to meet the MNPL conservation management objective. In other words, across the vast majority of trials, all three management units (ENP, PCFG, and WNP) would be above (or allowed to reach) MNPL under the 2018 hunt plan after 100 years. [27]

For the PCFG and western feeding group (WFG) a total of four trials across stock structure hypotheses did not meet the final depletion (MNPL) or the relative increase conservation management objectives, i.e. the abundance of the affected group of whales was below MNPL (OSP) and was not increasing towards that level at the end of the projection period. These trials assumed levels of cryptic mortality that were 10 or 20 times observed, and/or little to no immigration into the PCFG. Three of the four trials were for the PCFG. For the PCFG trials, the relative depletion statistic ranged from 81 to 92 percent. The WNP trial, which assumed cryptic incidental mortality was 20 times observed, had a relative depletion statistic of 99 percent. As described above, the relative depletion statistic is the projected population size with removals from whaling, divided by the projected population size with no whaling. The high relative depletion statistics for these trials is consistent with scenarios in which aboriginal subsistence whaling is not seriously increasing the risk of extinction (the primary conservation management objective of the IWC for aboriginal subsistence whaling). In other words, the high values for relative depletion indicate that it is not removals from whaling that result in smaller population sizes for these trials, but rather it is the assumptions about little to no immigration into the PCFG and high levels of cryptic mortality. In its final evaluation, the AWMP concluded that these trials "corresponded with scenarios that were considered to have low plausibility (e.g. bycatch mortality of ~20 PCFG whales per year)" (Ex. M-0532 (IWC 2018b)).

[27] 100 years is a standard projection period for evaluating mortality limits in this type of simulation modeling. It was the length of time used for the base case management strategy evaluations of PBR as well (Ex. M-0559 (Wade 1998)).

Ultimately, after reviewing the AWMP's evaluation of the performance metrics (including those that correspond with the OSP management objective under the MMPA), the full Scientific Committee agreed with the AWMP's assessment that the 2018 hunt plan meets the IWC's conservation objectives for all affected gray whales:

> *"the performance of the management plan for Makah whaling was adequate to meet the Commission's conservation objectives for the Pacific Coast Feeding Group, Western Feeding Group and Northern Feeding Group [of] gray whales in the context of the proposed Makah hunt."* (Ex. M-0533 (IWC 2018c, Report of the Scientific Committee, p. 16))

As discussed above (section 2.3.2), the criteria used to evaluate the performance of the 2018 hunt plan were based on quantitative metrics for the conservation management objectives of the IWC. The evaluation framework included a wide range of available information about North Pacific gray whales and took into account important uncertainties (e.g. in stock structure). In taking into account various sources of uncertainty, conservative assumptions for parameter values were made with respect to conservation risk. Further, the Scientific Committee is composed of leading international and domestic scientists in both gray whale ecology and MSE for aboriginal subsistence whaling hunt plans. For these reasons, it is my opinion that the results of the Scientific Committee evaluation represent the best available science with respect to the potential impacts of the 2018 hunt plan on gray whales.

As I also explained above (section 1.2.1), the quantitative metrics and the IWC's conservation management objectives used to evaluative the 2018 hunt plan mirror those under the MMPA (e.g. OSP). However, in important respects the IWC's evaluation was more conservative than what is required under the MMPA. For example, if a waiver were granted under the MMPA, it would cover a ten-year period, whereas the IWC evaluation focused on the conservation risk of the hunt plan over a 100-year timeframe (as was done with PBR). The evaluation of the hunt plan over a longer time period is conservative, because the aggregate removals over 100 years would be larger than for a 10-year waiver period. It is therefore my opinion, based on the Scientific Committee's evaluation and the conclusions of the world's leading experts therein, that if a waiver were granted to implement the current (2018) version of the hunt management plan for Makah whaling, this plan would meet the OSP statutory objective of the MMPA for WNP, ENP and PCFG gray whales.

5. Response to Selected Public Comments

I have also been requested by legal counsel for the Makah Indian Tribe to respond to four public comments that were provided to NMFS regarding the 2015 DEIS.

First, with regard to WNP gray whales, in a public comment letter to Steve Stone of NMFS, the Animal Welfare Institute (July 31, 2015; hereafter "AWI" (Ex. M-0502)) states:

> *… the analysis by Moore and Weller examined only the numerical probability of being affected by the hunt based on the total number of WNP gray whales and the proportion of the population known to have emigrated to the ENP gray whale range. They didn't consider any variable linked to time spent in the ENP range or, more specifically, in the Makah U&A. This is not a trivial concern since the more time a WNP gray whale spends in the hunting area, particularly during the time when a hunt is permitted, the greater the probability of an approach, pursuit, strike attempt, or strike.*
>
> *Even NMFS notes that "Sakhalin whales were seen in an area of the ENP (i.e., Vancouver Island) where some whales tend to linger and feed during the northbound migration," and that "the long distance and potential open water crossing required for transit from the ENP to the WNP may make it more advantageous for whales to spend time feeding in the Pacific Northwest prior to undertaking a westerly passage to Sakhalin." DEIS at 3-89 (citing Darling et al. 1998 and Weller et al. 2012).*
>
> - AWI (2015 p. 61)

As noted by AWI, the amount of time WNP gray whales might spend in the Makah U&A is an important factor in evaluating the conservation risk of the proposed hunt. I also agree that the quotation from the DEIS (citing Darling et al. 1998 (Ex. M-0515) and Weller et al. 2012 (Ex. M-0560)) represents a plausible scenario for WNP gray whale movements through the eastern North Pacific (i.e. WNP gray whales might make a "pit stop" to feed). The fact that the six WNP gray whales sighted off Vancouver Island were in an area where gray whales have been observed feeding (Barkley Sound; *id*.) supports this line of reasoning, but only to a point. When considering this comment, it is important to focus first on available data from the area of the Makah hunt (the ocean portion of the Makah U&A).

Moore and Weller (2018) (Ex. M-0542) present available photo-identification survey effort for gray whales in the Makah U&A during 1996 – 2012. Survey data from the Makah U&A provides the most direct line of evidence (*i.e.*, the best available scientific information) on the availability of WNP gray whales in the hunting area. As noted by Moore and Weller (2018, p. 3), with respect to the available survey data in the Makah U&A, "none of the 181 whale-days[28] observed included WNP gray whales." Moore and Weller (2013) (Ex. M-0541) note that WNP gray whales have a high fidelity to their feeding grounds off Sakhalin Island, and therefore, in their assessment, the absence of WNP sightings in the Makah U&A is likely not due to false negative identification errors (i.e. the absence of WNP whales in the Makah U&A photo-identification catalogue is likely not due to missing a match with the Sakhalin catalogue).

It is possible that the amount of survey effort in the Makah U&A has not been sufficient to detect WNP gray whales there. Some WNP gray whales may have been missed. Nevertheless, the conservation concern stated by AWI rests on the premise that WNP gray whales might spend longer periods of time in the hunt area than is considered by the analyses of Moore and Weller (2013 (Ex. M-0541), 2018 (Ex. M-0542)). Under this scenario, not only would the risk posed by hunting during the migration season be increased, but the likelihood of WNP gray whales having been sighted during the surveys in this area would also be increased. Simply put, there is no evidence from the Makah U&A sightings data to support AWI's hypothesis that WNP gray whales spend a disproportionate amount of time in the Makah U&A, whether feeding or otherwise. Next I will respond to three comments related to the PCFG.

First, regarding the PCFG and the Implementation Review conducted during 2010—2013 (IWC 2013a (Ex. M-0526), 2014a (Ex. M-0528)), AWI notes, with respect to the IWC evaluation of the variants of the hunt plan proposed in 2005 for Makah whaling:

> *Although both variants were deemed acceptable, neither corresponded exactly to the hunt proposal submitted by the Makah Tribe to the IWC; therefore, the Scientific Committee expressed concern that the actual conservation outcome of the proposed hunt was not tested. DEIS at 3-160. More specifically, the "aspect of the proposed hunt that had not been evaluated was the*

[28] "Whale days" represent an individual whale being sighted on a given day, "e.g., multiple sightings of the same individual on the same day count as just 1 whale-day, but the same individual seen the next day would count as a second whale-day" (quoting Moore and Weller, 2013, p 3) (Ex. M-0541).

interaction between the actual number of strikes per month during the hunting season (December through May) and the assumption of whether a struck and lost whale belongs to the PCFG." id.

- AWI (2015 p. 65) (Ex. M-0502)

I will keep my response here brief. My testimony above, under Section 2.5 covers this topic in detail. To summarize, Brandon and Scordino (2013) (Ex. M-0507) responded to the Scientific Committee's concern by demonstrating that the conclusions from the IWC evaluation of the 2005 hunt plan were not sensitive to the specific timing of allowable strikes. The Scientific Committee accepted and agreed with our analysis, and this marked the completion of the Implementation Review with a focus on the PCFG (Ex. M-0528 (IWC 2014a)). Moreover, in light of the fact that a new hunt plan has been proposed and the IWC has recently completed an evaluation of that plan based on the rangewide modeling, this concern is moot.

Second, with respect to the PCFG's status relative to OSP, AWI states:

"… NMFS reports that the PCFG abundance trend appears to be flat at the current rate of recruitment. DEIS at 4-84, 4-100 (See Figure 637). Noting that Punt (2015) ***found*** *that PCFG whales are at 50 percent of K, the long-term stability of this population should be cause for concern, since the population should be increasing in size toward the region's carrying capacity."*

- AWI (2015 p. 75) (Ex. M-0502)

My reply to this comment is two-fold: First, although the trend in PCFG abundance may have appeared (at the time) to be flat given the available estimates when the 2015 DEIS was written, more recent estimates suggest this is no longer the case (Fig. 1 below; data from Calambokidis et al. 2017 (Ex. M-0511)). In particular, over the five most recent abundance estimates available, the number of PCFG whales is estimated to have increased from 205, in 2011, to 243, in 2015 (an 18.5% increase, with an average 4.6% annual rate of increase during those years). Over the longer-term, the abundance of the PCFG is estimated to have approximately doubled between 1998 and 2015 (Calambokidis et al. 2017; Fig. 1).

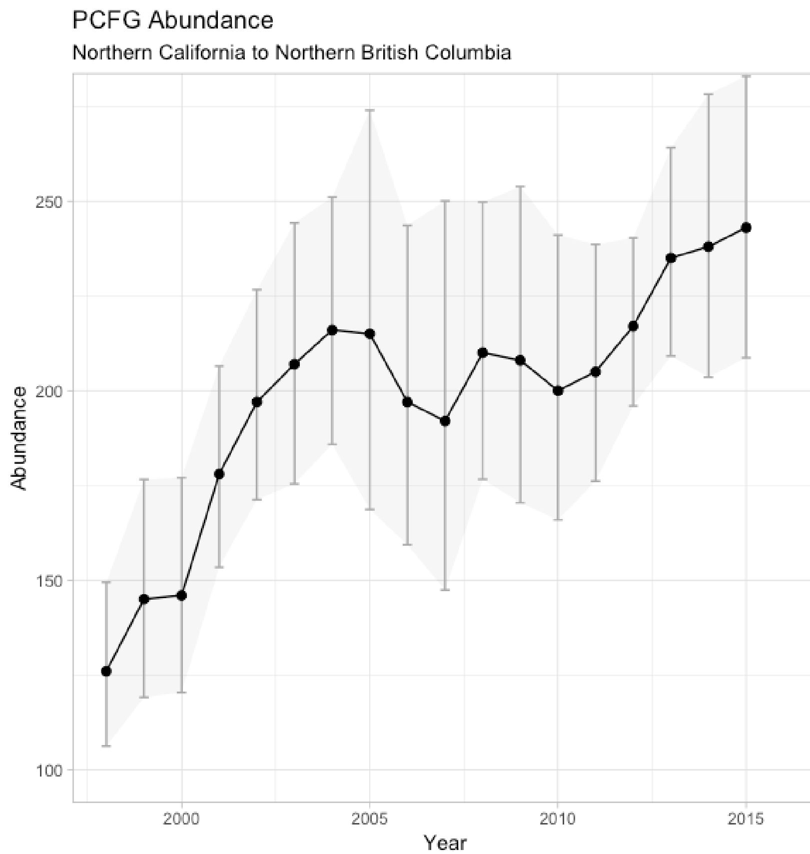

FIG 1. Abundance estimates for the PCFG between Northern California and Northern British Columbia: 1998—2015. Estimates are from Calambokidis et al. (2017) and are shown with point-wise 95% confidence intervals (vertical gray error bars).

Third, AWI cites the results of Punt (2015) (Ex. M-0547) out of context. Punt (2015) did not "find" that PCFG whales were at 50% of carrying capacity. Rather, Punt (2015) discussed various "data inputs" to inform the scientific working group at the IWC rangewide modeling workshops. Punt (2015) simply listed numerous caveats with respect to preliminary data inputs at the time, so that the working group of experts would have this list to consider when providing feedback on the modeling and data inputs:

"Several of the data inputs are preliminary. Specifically, it is necessary to finalize the catch series, update the survey estimates of abundance to include the variance covariance matrices for the abundance estimates for the Sakhalin feeding ground and the recent surveys off California. The mixing proportions should be updated to reflect photo-identification data and other catches of

known stock animals off Asia. The underlying data on mixing should be reanalysed to provide appropriate values for standard errors."

—Punt (2015, p. 7)

AWI also seemingly ignores Punt and Moore (2013) (Ex. M-0550), which adopted the population dynamics modeling framework developed under the IWC during the 2010-2013 Implementation Review with a focus on the PCFG, but focused instead more formally on the question of whether or not the PCFG was above or below MNPL (i.e., whether it was at OSP). After this focused investigation aimed towards a quantitative OSP Status Determination, Punt and Moore (2013) were unable to estimate the status of the PCFG relative to OSP with any statistical confidence, concluding, *"Ultimately it was not possible to draw a definitive conclusion as to whether the PCFG is within OSP"* (Punt and Moore 2013, p. 1).

There has been no subsequent peer-reviewed attempt to quantitatively estimate PCFG abundance relative to OSP, and this question may remain unresolved without substantial new information, including among other things a better understanding of internal vs. external recruitment rates into this feeding group (Ex. M-0550 (Punt and Moore 2013, p. 13)).

Nevertheless, the IWC evaluation frameworks are designed to propagate uncertainty in estimates across many such variables (including, but not limited to uncertainty around present abundance relative to MNPL). These uncertainties are incorporated through the simulations of future projected population dynamics under proposed catch limit rules and data collection schemes and, in the case of the rangewide review, under alternative stock structure hypotheses. The IWC evaluation aims less to answer the question of whether a stock is currently above MNPL (and hence, at OSP), but rather, given a proposed hunt plan (and uncertainties in stock status etc.), whether proposed catch limits would meet the conservation management objective of maintaining stocks above their MNPL (OSP) levels or ensuring that stocks below MNPL are allowed to recover to this management target over a wide range of uncertainties.

As an example, during the 2010—2013 Implementation Review with a focus on the PCFG, the IWC did not attempt to assess whether the PCFG was *currently* above MNPL (*i.e.*, at OSP). Instead, the IWC evaluated whether proposed Makah hunt's catch limits would allow the PCFG to reach or maintain its MNPL (OSP) level in the future. This is precisely the philosophy that went into the simulation testing that resulted in the current PBR management scheme (Ex. M-0559 (Wade 1998)). The PBR management scheme does not require a determination of whether or not a stock is at (or below) OSP. In fact, it was developed in part to provide management guidance without the need to determine a stock's status relative to OSP, which, as noted above, has rarely been accomplished. Instead, PBR is used to determine whether future removals from human caused mortalities would allow the stock to achieve or maintain the OSP management objective 100 years in the future.

It should also be noted that the IWC rangewide evaluation of the 2018 proposed hunt plan for Makah whaling (IWC 2018a) (Ex. M-0531) has since addressed the concerns raised by AWI based on Punt (2015) (Ex. M-0547). Ultimately, that process – through the continuation of IWC Rangewide Workshops in 2014 through 2018 – has resulted in agreement by the Scientific Committee, including experts on evaluating aboriginal subsistence whaling hunt plans, that NMFS's proposed 2018 hunt plan for Makah whaling will meet the IWC's conservation management objectives, including the MNPL (*i.e.*, OSP) goal shared with the MMPA (Ex. M-0533 (IWC 2018c); Section 4.5)).

The last comment I have been requested to respond to involves an argument presented by AWI with respect to the PBR calculation for the PCFG:

> *Interestingly, when the PCFG, OR-SVI, and Makah U&A PBRs are compared to the PBR for the California/Oregon/Washington stock of sperm whales or the ENP stock of blue whales, those populations are much larger than any of the groups of PCFG gray whales, but their PBR is either half (for the sperm whale) or just slightly higher (for the blue whale) compared to the PBR for PCFG whales.*
>
> —AWI (2015, p. 56) (Ex. M-0502)

Under the NMFS Guidelines for Assessing Marine Mammal Stocks (NMFS 2016) (Ex. M-0544), the default recovery factor (F_R) should be 0.1 for stocks that are listed as endangered under the Endangered Species Act (e.g., the aforementioned sperm and blue whale stocks). The PCFG, however, is not considered a stock under the MMPA by NMFS (Weller et al. 2013) (Ex. M-0561), nor is it listed under the ESA. Therefore, as it stands, the notion of PBR for the PCFG is ill-defined at best, and at worst it is illogically suited for comparison to PBR for recognized populations listed under the ESA with well-defined PBR values. Finally, as discussed above (sections 2 and 4), the IWC's case-specific MSEs for the 2005 and 2018 hunt plans proposed for Makah whaling have confirmed that they meet the IWC's conservation objectives for PCFG whales, including the OSP objective shared with the MMPA. For the reasons I discussed in section 2.2, those evaluations are a more reliable assessment of the conservation implications of Makah whaling than a comparison of PBR values between the PCFG and entirely different, ESA-listed stocks.

John R. Brandon, PhD
Biometrician

John is a staff biometrician at ICF International, Inc., where he provides survey design, population dynamics modeling and statistical support to the Fish and Aquatic Science Team. Prior to joining ICF, he was an independent consultant. His clients from independent consulting include: A National Science Foundation fisheries research center initiative; The International Whaling Commission; and The Makah Tribal Council. His independent consulting work has involved evaluating the performance of alternative management strategies using mathematical modeling, simulation, and computational statistics. Previously, he worked as a staff biostatistician for LGL and Greeneridge Sciences, Inc., leading the development of survey designs based on statistical power analyses, as well as post-survey data analyses and reporting for monitoring and mitigation studies.

Academic Degrees

PhD. School of Aquatic and Fisheries Sciences (SAFS), University of Washington (UW), 2003-2009, Dissertation Title: '*Quantifying Uncertainty and Incorporating Environmental Stochasticity in Stock Assessments of Marine Mammals.*'

B.Sc. Biology, Ecology and Evolution (Provost's Honors), University of California San Diego (UCSD), 1994-1998: Minors in Meteorology and Ocean Sciences (Scripps Institute of Oceanography), and Biological Anthropology.

Professional Positions

Biometrician, ICF International, Inc. Fish and Aquatic Science Team, 2019 – Present

Management Strategy and Software Development Consultant to the International Whaling Commission, 2017 – 2018

Population Dynamics and Statistical Consultant to The Makah Tribe, Neah Bay, WA, 2010 – 2013 and 2015—present

Management Strategy Consultant to the U.S. National Science Foundation's Science Center for Marine Fisheries Initiative, 2014 – Present

Biostatistician/Fisheries Scientist, LGL and Greeneridge Sciences, Inc., 2009 – 2015

Population Dynamics Modeling and Statistical Consultant to the Palumbi Lab, Stanford University, CA, 2011

Invited Participant to the Scientific Committee of the International Whaling Commission and 2018 Co-Chair of the Aboriginal Whaling Management Procedures Sub-Committee, 2006 – Present

PhD Student and Research / Teaching Assistant, SAFS, UW, Seattle, WA, 2003 – 2009

Protected Species Observer (Field Scientist), Various Monitoring and Mitigation Surveys, 1999 – 2012

Research Scientist, National Marine Fisheries Science Service, Seattle, WA and La Jolla, CA 1998 – 2003

Teaching Assistant (Undergrad), UCSD, La Jolla, CA 1997 – 1998

Mr. Steve Stone
National Marine Fisheries Service
West Coast Region,
1201 NE Lloyd Blvd., Suite 1100,
Portland, OR 97232.

Dear Mr. Stone:

On behalf of the Animal Welfare Institute, Cetacean Society International, International Marine Mammal Project of Earth Island Institute, Origami Whales Project, Whale and Dolphin Conservation, and the Whaleman Foundation (hereafter "Coalition"), I submit the following comments on the Draft Environmental Impact Statement (DEIS) on the Makah Tribe Request to Hunt Gray Whales (80 Federal Register 14,912 (March 20, 2015)). The Coalition notes with appreciation the decision by the National Marine Fisheries Service ("NMFS") to extend the deadline for public comments on this important issue (80 Federal Register 30,676 (May 29, 2015)). However, the Coalition concludes that NMFS cannot issue the requested MMPA waiver to the Makah Tribe, for reasons detailed below.

The Animal Welfare Institute (AWI) is one of the nation's oldest animal advocacy organizations. Since its founding in 1951, AWI has sought to alleviate the suffering inflicted on animals by people. AWI and the Society for Animal Protection Legislation (AWI's legislative companion organization until a 2004 merger), played a role in the passage of the Marine Mammal Protection Act (MMPA) and the Endangered Species Act (ESA), among other key environmental and animal protection statutes. AWI staff members attend meetings of the International Whaling Commission (IWC) to preserve the ban on commercial whaling, and we work to protect all marine life against the proliferation of human-generated ocean noise, including that from active sonar and seismic air guns. For decades, AWI has been opposed to the Makah Tribe resuming its hunt of gray whales, and for the reasons stated herein, we remain strongly opposed to this day. Other Coalition organizations have also been engaged in campaigns to protect marine mammals, many regularly attend IWC meetings, and all strongly oppose any resumption of whaling by the Makah Tribe.

It is troubling that, after two lawsuits, several environmental analyses, and decades of controversy that NMFS continues to endeavor to permit the Makah Tribe to resume the hunting of gray whales after a nearly 90-year hiatus in whaling. Indeed, with the exception of a single whale killed "legally" in 1999 and a second illegal kill in 2007, the Makah Tribe has not engaged in whaling since the 1920s. Even that date may not accurately reflect when the Makah largely ceased whaling which, based on evidence provided in past Makah needs statements, started to wane in the middle of the 19th century.

Despite this significant gap in whaling and without any apparent concern for international whaling standards or federal law, NMFS continues to commit valuable time and financial resources to this issue, seemingly because of a treaty right that may have been abrogated and its federal trust responsibility to the Makah Tribe.

Furthermore, other overarching concerns with the proposed hunt include the potential conservation implications to Eastern North Pacific (ENP), including Pacific Coast Feeding Group (PCFG), and Western North Pacific (WNP) gray whales by adding intentional take to the litany of threats to these animals. This is especially true for PCFG and WNP gray whales that, at present, number only a total of approximately 209 and 140 animals, respectively, with even smaller numbers in the PCFG regions considered in the DEIS (e.g., the Oregon-Southern Vancouver Island (OR-SVI) and Makah Usual and Accustomed hunting grounds (Makah U&A)). For the larger ENP population of gray whales, considering the significant changes occurring in the Arctic due to climate change and the unknown consequences of such ecosystem-wide alterations on gray whales, now is not the time to allow the Makah to hunt whales.

Such threats, of course, are not limited to the Arctic, as the gray whale has one of the longest migrations of any species on the globe and, throughout that journey, they face an increasing barrage of both anthropogenic and natural threats. Adding to such threats by authorizing a hunt is biologically reckless and unwise. Combine these threats with the hunt's risk to public safety and the basic fact that the chances of an instantaneous death of a swimming gray whale hunted from a moving boat on a rolling ocean are nil, particularly with the cold harpoon proposed by the Makah Tribe, and the evidence against granting the MMPA waiver and authorizing a hunt is insurmountable.

Based on these and other facts and as explained in detail throughout this comment letter, such efforts, including the current National Environmental Policy Act (NEPA) decision-making process, must end, the Tribe's MMPA waiver application must be denied, the United States must advise the International Whaling Commission (IWC) that its 2012 Aboriginal Subsistence Whaling (ASW) quota for gray whales is no longer valid, and it must cease attempting to secure the IWC's allocation of ASW quotas for the Makah Tribe.

For these and other reasons articulated in this letter, the Coalition strongly supports Alternative 1: the No Action Alternative. This is the only alternative that would comply with both international convention standards and US law. It also represents the most precautionary approach available which, in this case, is mandatory considering the critically endangered status of WNP gray whales, the small numbers of PCFG gray whales, and the myriad (and increasing) threats to ENP gray whales (and to the WNP and PCFG whales) throughout their range. This is not to suggest that the Makah Tribe cannot "use" gray whales, but such use must not involve the intentional lethal take of a single whale. Indeed, as described in this comment letter, there are alternatives NMFS failed to adequately consider in the DEIS that would substantially benefit all Makah tribal members while also facilitating the "use" of gray whales in a humane, non-lethal manner that would create jobs, generate revenue, attract tourists to Neah Bay, and provide a platform for the Makah to promote and celebrate their history, culture, and traditions.

While the Coalition strongly opposes whaling by the Makah Tribe, it does respect the Makah's whaling culture, traditions, and history. Contrary to claims made by the Tribe, however, no compelling evidence has been offered in the DEIS or elsewhere to prove that the Makah Tribe needs to kill whales to sustain its culture, to enhance its efforts at cultural revitalization, or to continue to engage in the ceremonies, rituals, dances, or songs celebrating its whaling heritage. For that matter, the DEIS contains evidence to suggest that such traditions have not been continually practiced as the Makah Tribe or its representatives have consistently claimed. Nevertheless, to the extent the tribe, including individual tribal families, need to engage in such traditions, even if they have only recently been resurrected, the annual Makah Days celebration provides the perfect venue for the Makah Tribe to embrace its cultural and historical links to whaling through dance, song, and ceremonies without any need to kill a whale. Similarly, throughout the year, whether whaling traditions are family-specific, secret, or available to celebrate with the entire tribe and/or non-tribal members, there is no reason why these traditions cannot be practiced at family or community events without requiring the resumption of whaling.

Ultimately, however, the Coalition's overarching concern is for the welfare of the whales – as well as the humans – who would or could be adversely impacted as a result of the proposed hunt. More specifically, it is concerned about: the impact of the hunt on gray whales, including WNP and PCFG gray whales; the hunt's legality; the cruelty inherent to whaling; public safety; the precedent that would be set if the hunt proceeds; and cumulative (and increasing) anthropogenic impacts to gray whales and their habitat.

While the Coalition commends NMFS for its 2008 decision to terminate a previous NEPA decision-making process based on new scientific information relevant to PCFG and WNP whales that became available, the present DEIS is replete with deficiencies. In general, those deficiencies include the failure to:

- Demonstrate how allowing the Makah to hunt whales is consistent with US law and international convention standards relevant to ASW;
- Consider a reasonable and feasible range of alternatives;
- Fully disclose all relevant information and provide a clear, consistent, and accurate analysis of the environmental consequences of the no action alternative and action alternatives on, among other variables, gray whales, tourism, economics, the social environment, and public health;
- Accurately assess the precedential effects of granting an MMPA waiver to the Tribe;
- Define or provide meaningful, quantifiable, and measurable impact thresholds to permit the public to distinguish between the direct and indirect impacts of the no action and action alternatives;
- Adequately evaluate the cumulative impacts of the analyzed alternatives in regard to other past, present, and reasonably foreseeable actions undertaken by federal, state/provincial, municipal, or private parties.

Furthermore, before proceeding with this decision-making process, it is imperative that NMFS render a determination as to whether PCFG whales constitute a population stock under the MMPA. Given the implications of such a determination to gray whales and the Makah Tribe's hunt proposal, continuing to delay this determination is improper. Even if making this determination requires additional scientific study of PCFG whales, this should be undertaken expeditiously so that a stock determination can be made as a prerequisite for the continuation of the present planning process.

There are two fundamental legal arguments that demonstrate why the MMPA waiver cannot be granted. These arguments are addressed below.

<u>NMFS cannot issue a MMPA waiver to the Makah Tribe:</u>

The MMPA sets forth general criteria to use in determining if a waiver to the MMPA's take prohibitions should be granted. Specifically, the Secretary, in consideration of the "distribution, abundance, breeding habits, and times and lines of migratory movements of such marine mammals" is authorized to determine "when, to what extent, if at all, and by what means it is compatible with this chapter to" issue a waiver to allow the taking of a marine mammal. 16 U.S.C. § 1371(a)(3)(A). In addition, the Secretary "must be assured that the taking of such marine mammals is in accord with sound principles of resource protection and conservation as provided in the purposes and policies of this chapter." *Id.* To be compatible with the MMPA and in accord with sound principles of resource protection and conservation, such a finding must ensure, at a minimum, that the marine mammals in question are not "permitted to diminish beyond the point at which they cease to be a significant functioning element in the ecosystem of which they are a part and, consistent with this major objective, they should not be permitted to diminish below their optimum sustainable population."[1] *Id.* at § 1361(2).

If NMFS grants an MMPA waiver, it also must promulgate regulations to govern the number, location, and manner of the permitted take as well as permits to formally authorize the take. In promulgating such regulations, the Secretary is allowed to consider all factors that may affect the extent to which such animals may be taken. This includes existing and future levels of marine mammal species and population stocks, international treaty and agreement obligations, and marine ecosystem and related environmental considerations, 16 U.S.C. § 103(b)(1-3), but does not require it to consider any treaty obligations with Native American tribes.

Based on the best available scientific evidence, including the myriad studies cited in the DEIS, it is not possible for NMFS to make the required determination for ENP gray whales. In this case, however, the decision to be made is not limited to ENP gray whales, despite the fact that the Makah's waiver application covers that particular population of gray whales. Because the MMPA's waiver language is applicable to "marine mammals" and is not limited to species or population stocks, since ENP, PCFG, and WNP gray whales can all share a common range (both geographically and temporally), and given that it is impossible to distinguish between ENP, PCFG, and WNP gray whales by observation alone, any MMPA waiver determination for ENP gray whales also must be made for WNP and PCFG whales. Indeed, it would be illogical and illegal for NMFS to issue an MMPA waiver to the Makah Tribe to allow the take, including lethal take, of ENP gray whales if by doing so it would cause WNP or PCFG gray whales to "cease to be a significant functioning element in the ecosystem of which they are a part" or if it could diminish WNP or PCFG gray whales below their "optimum sustainable population." This dilemma is similar to that addressed in *Kokechik Fishermen's Ass'n v. Secretary of Commerce* (839 F.2d 795 (D.C. Cir. 1988)), where the court ruled the issuance of an incidental take permit by NMFS was deemed to be "contrary to the requirements of the MMPA in that it allowed incidental taking of various species of protected marine mammals without first ascertaining as to each such species whether or not the population of that species was at the OSP level."

For the WNP gray whales, the current population estimate is 140 animals. Although the International Union for Conservation of Nature (IUCN) designates this subpopulation's demographic trend as increasing (Reilly et al. 2008), it remains classified as critically endangered. While our knowledge of this population of gray whales is increasing, much remains

[1] Optimum sustainable population or OSP is defined as "the number of animals which will result in the maximum productivity of the population or species, keeping in mind the carrying capacity of the habitat and the health of the ecosystem in which they form a constituent element." 16 U.S.C. §§ 1362(9) and 3-51/52. NMFS further defines this term in regulations implementing the MMPA to mean "a population size which falls within a range from the population level of a given species or stock which is the largest supportable within the ecosystem to the population level that results in the maximum net productivity level." 50 CFR § 216.3 and DEIS at 3-51/52.

unknown, including a complete understanding of migratory patterns. Based on tagging data, DNA analysis from biopsy samples, and photographic identification, 27 WNP gray whales (19 percent of the entire known population) have migrated from Russia, across the Bering Sea, and to the west coast of the United States and Mexico over the past several years. While all 27 WNP gray whales returned to Russia in the spring/summer, it is not known whether they bred with any ENP gray whales, whether any ENP gray whales have migrated to Russia, the total number of WNP gray whales that have emigrated to the ENP range, and whether any WNP whales have remained with the ENP gray whales in the Arctic or within the PCFG.

More importantly, in regard to the MMPA waiver criteria, the carrying capacity of the WNP habitat has not been determined and, consequently, the population's OSP is unknown. According to Punt (2015) the WNP population (which he separates into an Asian and Sakhalin stocks) is approximately 10 percent of their carrying capacities. Consequently, notwithstanding the ongoing need for more information about the migratory patterns and reproductive habits of WNP gray whales, without knowledge of carrying capacity or OSP, the Secretary cannot ensure that the issuance of a waiver to the Makah Tribe to permit the take of ENP gray whales will not diminish WNP gray whales below their OSP. Indeed, as mentioned repeatedly in the DEIS, while Moore and Weller (2013) report that there is only a seven percent chance for a single WNP gray whale being struck by the Makah over six years (under the Makah Tribe's proposal), it cautions that "loss of a single whale, particularly if it were a reproductive female, would be a conservation concern." Moreover, if Moore and Weller underestimated the risk to WNP gray whales from a Makah whale hunt, then the adverse conservation implications of a Makah hunt would be more severe.

Similarly, for PCFG whales, no one has determined the carrying capacity for these whales within the PCFG region or any of its sub-regions and, therefore, its OSP is also unknown. This was confirmed by Punt and Moore (2013), who determined "it was not possible to draw a definitive conclusion as to whether the PCFG is within OSP." DEIS at 3-156. More recently, Punt (2015) found the PCFG "sub-stock" is approximately at 50 percent of its carrying capacity. Even if NMFS determines that it need not consider PCFG whales in making a waiver decision for ENP whales (since PCFG whales have not yet been designated a stock), since NMFS has itself reported that the PCFG may qualify as a stock in the future and considering the precautionary principle, for the purpose of the waiver determination, NMFS should treat the PCFG gray whales as a stock.

Based on the foregoing analysis, and recognizing that with the exception of a handful of PCFG whales that may be known to Makah tribal biologists or other officials based on easily distinguishable markings, it is impossible to differentiate WNP, ENP, and PCFG gray whales through observation alone within the Makah U&A, NMFS must select the no action alternative. Alternatively, if NMFS does allow this process to proceed, the Secretary must not issue the requested waiver at this time. In the future, after further research begins to elucidate answers to many of the remaining questions about stock structure, demographics, reproductive characteristics, genetics, migratory patterns, and behaviors, this waiver request could be revisited but, at present, the waiver application must be denied.

The current NEPA process is invalid and must be terminated because the Makah Tribe cannot qualify for an ASW quota:

The DEIS designates a purpose and need for action for both the Makah Tribe and NMFS. For the Makah Tribe, its purpose is "to resume its traditional hunting of gray whales under its treaty right" while its need "is to exercise its treaty whaling rights to provide a traditional subsistence resource to the community and to sustain and revitalize the ceremonial, cultural, and social aspects of its whaling traditions." DEIS at 1-27. For NMFS, its purpose is "to implement the laws and treaties that apply to the Tribe's request, including the Treaty of Neah Bay, MMPA, and WCA," while its need is "to implement its federal trust responsibilities to the Makah Tribe with respect to the Tribe's reserved whaling rights under the Treaty of Neah Bay." *Id.*

The Coalition does not dispute that the Treaty of Neah Bay includes language recognizing the Makah Tribe's whaling right, but, as explained below, this treaty language may have been abrogated by the passage of the MMPA and the Makah Tribe cannot qualify for an ASW quota under the Whaling Convention Act (WCA) or IWC standards and, therefore, is not able to engage in whaling.

Given that the United States recognizes the legal authority of the IWC to regulate whaling, including ASW, if the Makah Tribe cannot qualify for an ASW quota (as is made clear below), then the United States should not request a quota, no quota should be approved, and, no quota can be allocated to the Makah. Therefore, as explained previously, since the Makah Tribe cannot satisfy the "continuing traditional dependence on whaling and the use of whales" language in the definition of "aboriginal subsistence whaling" and cannot demonstrate either a subsistence or nutritional need for whales or their products, it does not satisfy the basic criteria to obtain an IWC-approved quota (and any previously approved quotas should not be considered valid).

Since the Makah Tribe not qualify for an ASW quota from the IWC, its purpose and need (and the purpose and need proffered by NMFS) cannot be met without violating US law or an international treaty and are, therefore, invalid. In turn, without a legitimate purpose and need, the DEIS is unnecessary and the current decision-making process should be terminated.

If NMFS must select an alternative that satisfies its own or the Makah Tribe's purpose and need (additional discussion of this issue is below), then the overall outcome of this NEPA process has been predetermined in that the Makah will be granted a waiver and will be allowed to kill whales because that is the only option available given the purpose and need statements. Under this scenario, the only question is when, where, how, and how many whales the Makah Tribe will be allowed to kill. Consequently, any interested stakeholder that supports the no action alternative, regardless of the quality or substantive content of their comments, is wasting its time because NMFS will claim that it cannot select the No Action Alternative since it would not meet its or the Makah Tribe's purpose and need. Not only is there nothing in the NEPA statute or its implementing regulations that support this approach, but this effectively undermines the intent of NEPA and the importance of public participation in the NEPA process.

Consequently, to ensure that the decision-making process is meaningful for everyone, NMFS must eliminate the Makah Tribe's stated purpose and need for action and restate its purpose and need so that the no action alternative is a legally viable option at the conclusion of this process. In regard to the Makah Tribe's purpose and need, it is irrelevant what the Makah want, since this DEIS is being used by NMFS to assist in its decision-making process. Indeed, it is unusual for any DEIS to include dual purposes and needs – one set from the applicant and one set from the agency.

For NMFS, if it were to restate its purpose to be "to determine if the Makah Tribe's interest in resuming whaling under the Treaty of Neah Bay qualifies for a waiver of the moratorium on the take of marine mammals under the Marine Mammal Protection Act and is consistent with other federal laws," and its purpose to be "to determine if the Makah Tribe's whaling proposal is consistent with all federal laws," then the no action alternative is relevant. If this were the purpose and need stated in the DEIS, NMFS could decide that despite the treaty language, whaling by the Makah Tribe is not consistent with the MMPA, WCA, or other relevant federal laws and that, therefore, a waiver would not be granted, and thereby the No Action Alternative would be a legally viable selection.

Additional comments:

The remainder of this comment letter will provide additional evidence and analysis to support the deficiencies identified above, while also documenting other inadequacies in the analysis. The analysis will largely be based on the relevant international conventions and US statutes and regulations that govern ASW.

International Convention for the Regulation of Whaling, IWC Schedule, and Whaling Convention Act

As a result of the overexploitation resulting in the near extinction of the gray whale, "the United States signed in 1946 the International Convention for the Regulation of Whaling (Convention or ICRW) in order 'to provide for the proper conservation of whale stocks and thus make possible the orderly development of the whaling industry....'".[2] The ICRW does not explicitly permit Aboriginal Subsistence Whaling (ASW), but exceptions to restrictions on commercial whaling were incorporated into predecessor treaties to the ICRW and have been a part of the whaling regime since the Convention was approved.

The Convention enacted a schedule of whaling regulations (Schedule) and established the IWC, to be comprised of one member from each signatory country. The ICRW "granted the IWC the power to amend the Schedule by 'adopting regulations with respect to the conservation and utilization of whale resources,' including quotas for the maximum number of whales to be taken in any one season.[3] In 1982, the IWC voted to place a moratorium on commercial whaling, which is still in place today. Even those ASW hunts where the products are actively sold (e.g., Greenland), are not considered to be commercial whaling; although the sale of certain ASW products has been used to question if these hunts qualify as ASW. The Schedule provides regulations with which IWC Contracting Governments must comply in regard to whaling and the conservation of whale stocks. Under the auspices of the ICRW, ASW "is permitted, but such whaling must conform to quotas issued by the IWC for various whale stocks."[4]

The WCA (16 U.S.C. 916 et seq.), enacted in 1949, is the legal instrument in the United States that implements the ICRW domestically. The WCA prohibits whaling in violation of the ICRW, the Schedule, or any whaling regulation adopted by the Secretary of Commerce. *See id.* § 916c. The WCA also tasks the National Oceanic and Atmospheric Administration ("NOAA") and the National Marine Fisheries Service ("NMFS"), within the Department of Commerce, with promulgating regulations to implement the provisions of the WCA. *See id.* § 916 et seq.; 50 C.F.R. § 230.1 (1998). As the DEIS states, under the WCA, NMFS must regulate whaling in accordance with the ICRW and IWC regulations. DEIS at 1-26.

For the purposed of this comment letter, the most relevant portion of the Schedule is paragraph 13 and, specifically, subparagraph (b)(2), which pertains to Eastern North Pacific gray whales. That language defines when, where, and how ENP gray whales can be killed by aboriginal subsistence whalers. The current text provides that:

> 2) The taking of gray whales from the Eastern stock in the North Pacific is permitted, but only by aborigines or a Contracting Government on behalf of aborigines, and <u>then only when the meat and products of such whales are to be used exclusively for local consumption by the aborigines</u>. (emphasis added)

[3] Metcalf v. Daley, Id., citing 62 Stat. 1718-19.
[4] *Anderson v. Evans*, 371 F.3d 475, 483 (2002).

> (i) For the years 2013, 2014, 2015, 2016, 2017 and 2018, the number of gray whales taken in accordance with this sub-paragraph shall not exceed 744, provided that the number of gray whales taken in any one of the years 2013, 2014, 2015, 2016, 2017 and 2018 shall not exceed 140.

The WCA requires the United States to comply with the ICRW and the Schedule. The only time when such compliance is not required is if the United States were to file an objection to a Schedule amendment agreed to by the IWC. In the context of ASW, the WCA prohibits the United States from, for example, self-allocating ASW quotas in the event the IWC does not approve such quotas.[5] Furthermore, as made clear by Wold and Kearney (2015) (Attachment 1), even if the WCA allowed the United States to self-allocate ASW quotas, the historic pattern and practice within the IWC, which the United States has repeatedly endorsed, is for ASW countries to obtain approval from the IWC for their ASW quotas based on their documented need and concurrence from the IWC's Scientific Committee that the quotas are sustainable.

There are a number of definitions relevant to ASW used or agreed to by the IWC, contained in the ICRW or Schedule, historically used by the IWC, or included in the WCA. The most relevant definitions are provided below.

A 1981 Ad Hoc Technical Working Group on Development of Management Principles and Guidelines for Subsistence Catches of Whales by Indigenous People defined "aboriginal subsistence whaling" as "whaling for purposes of local aboriginal consumption carried out by or on behalf of aboriginal, indigenous, or native people who share strong community, familial, social, and cultural ties related to a continuing traditional dependence on whaling and the use of whales." The same Working Group defined "local aboriginal consumption" to mean the "traditional uses of whale products by local aboriginal, indigenous, or native communities in meeting their nutritional, subsistence, and cultural requirements."

While the IWC has never formally adopted these definitions, they have consistently been applied by the IWC since 1981 and consequently, based on historical use, are relevant to this analysis. In addition, the United States recites these definitions in the DEIS (DEIS at 1-23) and has done so in all previous NEPA analyses relevant to both the Makah and Alaska Eskimo Whaling Commission ASW hunts. Taken together, these definitions make clear that, to qualify as ASW, any aboriginal group has to demonstrate a "nutritional, subsistence, <u>and</u> cultural" (emphasis added) need for whale products and that they have a "continuing traditional dependence on whaling and the use of whales."

[5] The United States has wrongly suggested that it has the authority to self-allocate ASW quotas (see e.g., 2013 Bowhead Whale Final EIS, page 7, footnote 9).

The Schedule defines "strike" to mean "to penetrate with a weapon used for whaling" and "take" to mean "to flag, buoy or make fast to a whale catcher." Schedule at 1(C). Neither of these terms are defined in the WCA. Conversely, while the term "whaling" is not defined in the ICRW or Schedule, it is defined in the WCA to mean "the scouting for, hunting, killing, taking, towing, holding onto, and flensing of whales, and the possession, treatment, or processing of whales or of whale products."

Makah whaling is inconsistent with the criteria for ASW contained in the ICRW, its associated Schedule, and the WCA:

When these definitions noted above are considered together, it becomes clear that the Makah Tribe does not and never has qualified for an ASW quota from the IWC. Nevertheless, the United States successfully obtained an ASW quota for gray whales to be allocated to the Makah Tribe in 1997. At that meeting, contrary to the description of the debate in the DEIS, nearly all of the IWC Contracting Government delegates that intervened during the discussion of the gray whale ASW quota opposed any ASW quota for the Makah Tribe, stating the tribe did not qualify. Ultimately, the delegates agreed to allow the quota to be used by aboriginal groups "whose traditional subsistence and cultural needs have been recognized."[6] However, in reality the only reason the quota was secured is because the request was made jointly with the Russian Federation, which was seeking a gray whale quota to allocate to its Chukotkan natives who, unlike the Makah, do qualify for an ASW quota.[7]

The primary concerns with the IWC's approval of a gray whale quota for the United States to allocate to the Makah were that the Makah could not satisfy the "continuing traditional dependence on whaling and the use of whales" and that they did not have a "nutritional need." Regarding the first standard, Contracting Governments and many observers argued that, at that time, the approximately 70-year hiatus in Makah whaling simply could not be squared with the requirement that ASW had to be based on a "continuing traditional dependence on whaling and the use of whales." Even NMFS concedes in the DEIS that the Makah whale hunt is different

---

[6] After agreement was reached, the United States declared in a press release that it was able to successfully obtain a quota for the Makah Tribe. Australia, in its own press release, strongly disagreed with the United States, claiming that while a gray whale ASW quota was approved, the needs of the Makah had not been recognized by the IWC, and that the IWC was the only entity that had the authority to recognize such needs even though this was not explicitly identified in the language agreed to by the delegates. At the IWC's 2004 meeting, the "whose traditional subsistence and cultural needs have been recognized" text was removed entirely from the Schedule at the request of the Russian Federation.

[7] Prior to the 1997 IWC meeting, neither the United States nor any other ASW country had ever requested a joint ASW quota for a single stock of whales, revealing that contrary to recent claims of a requirement to bundle quota requests for a single stock, the ICRW and Schedule permit ASW countries to separately seek ASW quotas for the same stock.

than other aboriginal subsistence hunts because of "the Tribe's 70-80 year hiatus in whaling." DEIS at 4-268.

Despite the United States' success in obtaining the 1997 quota for the Makah Tribe and subsequent renewal of the quota in 2002, 2007, and 2012, the Makah Tribe's needs statement never satisfied the IWC criteria for ASW that the United States established through its efforts to secure a bowhead whale quota for Alaskan Natives. The Coalition, therefore, asserts that the IWC never should have approved the quota.

Notwithstanding IWC approval, the quota is inconsistent with the WCA, because the Makah Tribe's reported dependence on "whaling and the use of whales" over that 70-year (now nearly 90-year) period does not constitute "whaling" as defined by the WCA. As indicated above, "whaling" as defined in the WCA, means "the scouting for, hunting, killing, taking, towing, holding onto, and flensing of whales, and the possession, treatment, or processing of whales or of whale products."[8] In its needs statements submitted to the IWC (and in their defense of the quota at past IWC meetings), the Makah (and the US Government) have argued that the tribe satisfies the "continuing traditional dependence" language for ASW based on their traditional rituals, ceremonies, songs, dances, and stories that celebrate whales and whaling and their use of whales as culturally important symbols of their whaling traditions; practices that the Makah claim have continued despite the hiatus in whaling. Regardless of whether this claim is true or not (see page 91 for a discussion of such claims), the celebration of whales and whaling through ceremonies, songs, dances, and other rituals does not satisfy the definition of "whaling" in the WCA.

Furthermore, independent of the definition of "whaling" in the WCA, even under the Makah Tribe's definition of "whaling," the Tribe would not be able to meet the "continuing traditional dependence on whaling …" criteria to qualify for an IWC-approved ASW quota. For example, in both its 2001 Management Plan for Makah Treaty Gray Whale Hunting for the Years 1998-2002 and its 2013 Makah Whaling Ordinance (see Appendices A and B of the DEIS), the Makah define "whaling" to mean "the scouting for, hunting, striking, killing, or landing of a whale." The definition clearly does not encompass traditions, rituals, dances, songs, ceremonies, or other spiritual activities that the Makah have claimed they have continued to practice during the Tribe's hiatus in whaling.

As to the portion of the criteria that refers to the "use of whales," that requirement is in addition to a "continuing traditional dependence on whaling." Hence, even if the Makah Tribe could demonstrate a "continuing traditional dependence on … the use of whales," without

[8] Since "whaling" includes the act of "towing" the whale to shore, when other tribes joined with the Makah to assist it in towing the whale killed in 1999 to shore (see DEIS at 1-38, 3-312) they violated the WCA since only the Makah Tribe was authorized to conduct whaling.

being able to satisfy the whaling standard, the Makah cannot and do not qualify for a gray whale quota. In terms of the Makah Tribe's use of whales, while is it unknown how many drift, stranded, or entangled whales the Makah may have used since the late 1920s (when the Makah Tribe ceased whaling), in the past two decades the available evidence suggests the Makah have only used three gray whales; the one killed in the 1999 hunt, one drift whale, and two gray whales that died after being entangled in fishing nets.

Based on the foregoing discussion, it is astonishing that the United States has engaged in over 20 years of scientific study, environmental planning, international outreach, and decision-making, and has expended considerable time and resources attempting to defend its Makah whaling decisions in court, when the tribe clearly and indisputably cannot meet the basic criteria to secure an ASW quota. This inconsistency with the "continuing traditional dependence" language in the definition of ASW has been raised repeatedly by several members of the Coalition (and other organizations) in response to previous environmental analyses, but has been ignored by NMFS, as it has never offered, and fails to offer in this DEIS, any explanation as to how the Makah satisfy this definition. Instead, by forcing this square peg into the round hole of what qualifies for an ASW quota, the United States has undermined the entire ASW process within the IWC, and in the process created a new category of ASW whaling that is based on alleged cultural needs only.

1. <u>The Makah Tribe does not have a subsistence or nutritional need to whale:</u>

The second standard that must be met in order to qualify for an ASW quota as contained in the definition of "local aboriginal consumption" is that there must be a demonstrable cultural, subsistence, and nutritional need. The use of the conjunction "and" in this definition makes clear that all three needs (i.e., cultural, subsistence, and nutritional) must be met for an ASW quota to be approved. In this case, the Makah cannot demonstrate either a "subsistence" or "nutritional" need for gray whales and, consequently do not satisfy the definition of "local aboriginal consumption" and, therefore, do not quality for an ASW quota.

As an initial matter, the Makah Tribe's request for a waiver of the MMPA and the DEIS both specify that the Makah Tribe seeks to resume whaling to satisfy its ceremonial and subsistence needs (see e.g., DEIS at ES1, 1-1). In neither document is it suggested that the Makah Tribe's interest in killing gray whales is based on any nutritional need. There is information about the alleged nutritional benefit of marine mammal products, including whale meat, blubber, and oil, in the DEIS and in past Makah needs statements, including the 2002 statement appended to the DEIS, but the tribe's request for a waiver is explicitly not based on any claimed nutritional need.

The terms "subsistence" and "nutritional" are not defined in the ICRW, the Schedule, or the WCA. The terms "subsistence" and "subsistence use" are defined in regulations implementing the MMPA (50 CFR § 216.3), with the former definition applicable only to Alaskan natives, while the latter is limited to the use of fur seals. The dictionary definition of "subsistence" and "nutritional" (obtained from http://www.merriam-webster.com/) are:

> Subsistence: a)(1) real being; (2) the condition of remaining in existence; b) an essential characteristic quality of something that exists; and c) the character possessed by whatever is logically conceivable or, if used in the context of a means of subsisting then: a) the minimum (as of food and shelter) necessary to support life; and b) a source or means of obtaining the necessities of life.
>
> Nutrition: the act or process of nourishing or being nourished; *specifically*: the sum of the processes by which an animal or plant takes in and utilizes food substances.

The definition of "subsistence" in the MMPA, suggests that "subsistence" refers to the use of marine mammals to meet food, clothing, shelter, heating, transportation and other needs, while the term "nutrition" is specific to the use of marine mammals as food or for nourishment. Neither term refers to any ritualistic, ceremonial, spiritual, or other uses of whales, as those uses are clearly intended to be encompassed within the term "cultural."

Despite the Makah Tribe's claim that they have a subsistence and nutritional need for whale meat and other products, information from its own needs statements, as well as evidence contained in the DEIS, provide ample evidence that the Makah do not have a legitimate subsistence or nutritional need for whale meat and other products. That evidence is summarized in detail in another section of this letter that critiques the analysis of environmental consequences in the DEIS. Indeed, even without compiling and summarizing this evidence, the fact that the Makah Tribe has largely gone without whale products for nearly 90 years should be ample proof of the lack of a subsistence or nutritional need.

Based on the foregoing evidence and analysis, the Makah Tribe does not have and cannot demonstrate a legitimate subsistence or nutritional need for whales or whale products. Considering the definition of "whaling" under the WCA in the context of the requirement of a "continuing traditional dependence on whaling…," the existing ASW quota that the United States obtained on behalf of the Makah (which extends until 2018) is invalid, illegal, and should not be allocated if the Makah are allowed to whale before 2018. Furthermore, absent an amendment to the WCA, should the United States attempt to seek a renewed gray whale quota at the 2018 IWC meeting, it will be acting in violation of the WCA. Similarly, unless the United States can conclusively demonstrate that the Makah Tribe has a legitimate subsistence and nutritional need, it should not seek a quota renewal at the 2018 IWC meeting.

2. The Makah Tribe, if allowed to whale, has to limit consumption of any edible whale products to tribal members on the reservation:

Should the Makah be allowed to whale in the future, the terms of any waiver issued under the MMPA or any associated regulations or permits must require that any edible portions of any whale taken be "used exclusively for local consumption by the aborigines." IWC Schedule at 13(b)(2), DEIS at 1-22.

The DEIS contains references that indicate that if the Makah Tribe is allowed to whale, NMFS would allow the tribal members to "share whale products from any hunt within the borders of the United States with relatives of participants of the harvest, others in the local community (relatives and non-relatives), (and) persons in locations other than the local community with whom local residents share familial, social, cultural, or economic ties." DEIS at 1-24 (emphasis added). While Makah tribal members would not be allowed to sell any edible whale products, NMFS indicates that the distribution of whale products to qualified people in the United States is consistent with the working definition of "subsistence use." *Id*. That definition, which was created at a 1979 meeting of a Cultural Anthropology Panel convened as part of a larger meeting about the Alaska Eskimo bowhead hunt, specifies that "subsistence use" includes:

- The personal consumption of whale products for food, fuel, shelter, clothing, tools, or transportation by participants in the whale harvest.
- The barter, trade, or sharing of whale products in their harvested form with relatives of the participants in the harvest, with others in the local community, or with persons in locations other than the local community with whom local residents share familial, social, cultural, or economic ties. A generalized currency is involved in this barter and trade, but the predominant portion of the products from each whale are ordinarily directly consumed or utilized in their harvested form within the local community.
- The making and selling of handicraft articles from whale products when the whale is harvested for the purposes defined in (1) and (2) above.

This definition was eventually adopted, by consensus, at the IWC's 2004 annual meeting.

NMFS, however, is ignoring the explicit language in the Schedule relevant to ENP gray whales. That language, which trumps any of the IWC approved or adopted definitions, makes clear that the take of gray whales is allowed "only when the meat and products of such whales are to be used exclusively for local consumption by the aborigines." This same limitation is included in Schedule paragraph (b)(1) pertaining to the take of bowhead whales from the Bering-Chukchi-Beaufort Sea stock. For ASW hunting by Greenlandic natives, the relevant language allows for the use of whale products in Greenland "exclusively for local consumption" (Schedule, paragraph 13(b)(3)) while, for aboriginal whalers in Saint Vincent and the Grenadines, whale products can be used "exclusively for local consumption in St. Vincent and the Grenadines" (Schedule, paragraph 13(b)(4)). Consequently, it is the "by the aborigines" language that requires that any whale products obtained by the Makah Tribe to be used exclusively by them, while "local consumption" has to mean on the reservation, particularly since the Makah's alleged need for whale products is based on what is needed by tribal members living in Neah Bay.

If, despite this analysis, NMFS continues to believe the Makah Tribe, if allowed to whale, can share whale products with tribal and non-tribal members outside the reservation, it must, through regulations or permits, significantly restrict such sharing of edible whale products since the "familial, social, cultural or economic ties" language in the definition of subsistence use is so broad that it could allow sharing of such products with an unlimited number of people throughout the entire United States. Indeed, contrary to NMFS's willingness to allow the Makah Tribe to share whale products throughout the country, the Makah's 2005 waiver application requested that it be allowed to kill five gray whales each calendar year (or 20 in five years). Makah Waiver Application at 1. The selection of five whales was not random but, rather, was based on the number of Makah Tribe's ancestral villages. As noted in the DEIS, "the Tribe anticipated harvesting only one or two whales initially, but included five as the maximum extent of the yearly harvest, if it determined that it could use additional whales effectively and allocate them to each of five ancestral villages. DEIS at 1-30 (citing Makah Tribal Council 1995). This would suggest that the Makah Tribe had no intention of sharing whale products beyond its local area (i.e., the five ancestral villages).

Marine Mammal Protection Act

The MMPA (16 U.S.C. 1361 et seq.) is the nation's preeminent law for the protection of marine mammals. In passing this law, Congress found that "certain species and population stocks of marine mammals are, or may be, in danger of extinction or depletion as a result of man's activities." *Id.* at § 1361(1). In addition, Congress determined that "such species and population stocks should not be permitted to diminish beyond the point at which they cease to be a significant functioning element in the ecosystem of which they are a part, and, consistent with this major objective, they should not be permitted to diminish below their optimum sustainable population." *Id*. at § 1361(2) (see also DEIS at 1-13, 1-18). Congress further found that "marine mammals have proven themselves to be resources of great international significance, esthetic and recreational as well as economic, and … they should be protected and encouraged to develop to the greatest extent feasible commensurate with sound policies of resource management and that the primary objective of their management should be to maintain the health and stability of the marine ecosystem." *Id.* at § 1361(6). The goal is to "obtain an optimum sustainable population ("OSP") keeping in mind the carrying capacity of the habitat." *Id.*

To achieve such conservation objectives, the MMPA established a moratorium on the take of marine mammals. Under the MMPA, a marine mammal is defined as "any mammal which (A) is morphologically adapted to the marine environment (including sea otters and members of the orders Sirenia, Pinnipedia and Cetacea), or (B) primarily inhabits the marine environment (such as the polar bear); and, … includes any part of any such marine mammal, including its raw, dressed, or dyed fur or skin." *Id.* at § 1362(6). The law defines "take" to mean "to harass, hunt, capture, or kill, or attempt to harass, hunt, capture, or kill any marine mammal." *Id*. at § 1362(13).

Take, under some circumstances, can be allowed under the MMPA if the requisite permits are obtained from the agency. In allowing take, the drafters of the MMPA "endeavored to build… a conservative bias" in favor of marine mammals. H.R. REP. NO. 92-707, at 24 (1971), *reprinted in* U.S.C.C.A.N. 4144, 4148.

> In every case, the burden is placed upon those seeking permits to show that the taking should be allowed and will not work to the disadvantage of the species or stock of animals involved. If that burden is not carried-- and it is by no means a light burden-- the permit may not be issued. The effect of this set of requirements is to insist that the management of the animal populations be carried out with the interests of the animals as the prime consideration.

H.R. REP. NO. 92-707 at 18, *reprinted in* U.S.C.C.A.N. 4144, 4151.

When NMFS issues a permit, it needs to satisfy the criteria of section 104 and be consistent with MMPA purposes, as demonstrated by the applicant. MMPA § 1374(d)(3). A permit must also comply with regulations promulgated under section 103, be "consistent with the purposes and policies" of the MMPA, and "not be to the disadvantage of those species and stocks." Id. § 1373(a). A permit will disadvantage a marine mammal stock and cannot be issued if it causes it to fall below OSP or include takes from a stock already below OSP.[9]

One of the exceptions to the moratorium against the take of marine mammals is for "any Indian, Aleut, or Eskimo who resides in Alaska and who dwells on the coast of the North Pacific Ocean or the Arctic Ocean if such taking … (is) (1) … for subsistence purposes; or (is) (2) … done for purposes of creating and selling authentic native articles of handicrafts and clothing; and (3) in each case, is not accomplished in a wasteful manner. 16 U.S.C. § 1371(b)(1-3).

1. <u>Abrogation of the Makah Tribe's treaty right to whale:</u>

[9] See *Committee for Humane Legislation, Inc. v. Richardson*, 414 F. Supp. 297, 302 (D.D.C. 1976), aff'd, 540 F.2d 1141 (D.C. Cir. 1976); see also, Kokechik Fishermen's Ass'n v. Secretary of Commerce, 839 F.2d 795 (D.C. Cir. 1988).

Considering the MMPA's broad moratorium on take and the fact that Congress did not include the Makah Tribe or any other United States coastal tribe with a history of whaling or, as is the case for the Makah, a treaty right explicitly recognizing the tribe's whaling right, the MMPA exception language is ample and indisputable evidence that the Makah's treaty right was abrogated by the MMPA. Supreme Court precedent supports this position.[10]

Indeed, given the significance of the MMPA, the myriad interests[11] engaged in lobbying for or against the legislation, and the vast number of politicians, aides, and experts involved in both drafting the bill and in achieving its adoption, it is inconceivable that no one, particularly the Makah Tribe, advised Congress of the tribe's treaty language or of its tradition of whaling. Alternatively, if such communications never occurred, this demonstrates that no one, particularly the Makah Tribe, cared enough or was sufficiently concerned about its treaty language to bring it to the attention of Congress at that time. Abrogation of said treaty language is, therefore, inferred as a result of Congress not being asked to recognize or preserve the Makah's interest in whaling when promulgating the MMPA.

While the abrogation claim was raised in both *Metcalf v. Daley* (214 F.3d 1135 (9th Cir. 2000)) and *Anderson v. Evans* (314 F.3d 1006 (9th Cir. 2002) (rehearing en banc denied and opinion amended 350 F.3d 815 (9th Cir. 2003)), the courts have not ruled on that claim. Consequently, while it is inevitable that a court will eventually have to render a decision on the abrogation claim, NMFS should have, but failed to, discuss the issue in the DEIS. NMFS is well aware of this argument and, therefore, in its summary of the relevant laws applicable to Makah whaling, should have explained the relevant case law on treaty abrogation and made clear the reasons why it believes the MMPA did not abrogate the Makah's treaty language regarding whaling. It should include such a discussion in a revised analysis.

2. <u>The Makah MMPA waiver application:</u>

In this case, because of the MMPA's moratorium on take of marine mammals, the Makah Tribe is seeking a waiver to that prohibition as directed by the court in *Anderson v. Evans*. While the Makah Tribe does not agree with the ruling in *Anderson* and believes that its "treaty right" trumps the MMPA, it elected to pursue a waiver. In its 2005 application, the Makah include several elements or provisions that warrant additional scrutiny or are worth noting for the purpose of this comment letter.

[10] *See U.S. v. Dion*, 476 U.S. 734 (1986), which held that the Bald and Golden Eagle Protection Act abrogated the rights of the members of the Yankton Sioux Tribe under the 1858 treaty to hunt bald or golden eagles on the Yankton Reservation.

[11] These interests included Native American Tribes and organizations, states, industry, and non-governmental organizations.

Treaty of Neah Bay:

While the Makah attempt to address the specific criteria contained in the MMPA, which must be met to obtain a waiver (discussed in more detail below), it also relies on its "treaty right" to justify a waiver. Yet the Treaty is not the end all, be all; rather, it is limited by the MMPA.

The Treaty of Neah Bay was one of the Stevens Treaties, negotiated by Isaac Stevens, the Governor of Washington Territory, with leaders of the Northwest Tribes that occupied what is now the State of Washington. These treaties guaranteed signatory tribes "the right of taking fish at usual and accustomed grounds and stations … in common with all citizens of the Territory." The Treaty of Neah Bay explicitly references whaling: "the right of taking fish and of whaling or sealing at usual and accustomed grounds and stations is further secured to said Indians in common with all citizens of the United States." See Treaty of Neah Bay at Article 4.

In its repeated references to the treaty language in the DEIS, NMFS fails to include the "in common with" language. While the courts have interpreted that language, the layperson who may read the treaty will likely be confused by this language, which suggests the Makah Tribe can only engage in whaling if other United States citizens are also able to engage in the same activity. In 1855 that was the case, but today, US citizens are prohibited from intentionally killing any marine mammals. NMFS needs to provide additional discussion of judicial interpretations of this treaty language to ensure that all stakeholders have a common understanding of the meaning of the "in common with" language and, more broadly, the limitations inherent to the Makah's treaty right. The Coalition provides its understanding of the treaty language and the limitations on the treaty here.

Generally, the courts have interpreted the phrase "in common with" to establish "a cotenancy, in which neither party may 'permit the subject matter of [the treaty] to be destroyed.'" *Anderson v. Evans*, 314 F.3d 1006 (9th Cir. 2002) (quoting *United States v. Washington*, 520 F.2d 676, 685 (9th Cir. 1975)). *See also United States v. Washington,* 761 F.2d 1404, 1408 (9th Cir.1985) (recognizing that "in common with" has been interpreted to give rise to cotenancy-type relationships).

The treaties guarantee tribes the right to harvest an equal portion of the available resource, not just an equal opportunity to do so with non-Indians. *Washington v. Washington State Commercial Passenger Fishing Vessel Ass'n*, 443 U.S. 658, 679 (1979) (holding that the Stevens treaties guarantee tribes the "right to take a share of each run of fish that passes through tribal fishing areas"). That right is subject to federal and state regulation, provided that the regulation is *nondiscriminatory*. *See Puyallup Tribe v. Dept. of Game of Wash.*, 391 U.S. 392, 398 (1968). The treaties do not guarantee an absolute right to fish or hunt; a state may limit the total treaty and non-treaty fish catch, for example, if regulation becomes necessary for the preservation of the species, is tailored to the conservation of that species, and is nondiscriminatory in its treatment of the Indians. *See Puyallup Tribe, Inc. v. Dept. of Game of State of Wash*., 433 U.S. 165, 176 (1977) (holding that state fishing regulation applies on-reservation because "[t]he police power of the State is adequate to prevent the steelhead from following the fate of the passenger pigeon"); *United States v. Oregon*, 657 F.2d 1009, 1016–1017 (1981) (affirming a total ban on tribal harvest of spring chinook salmon).

Because tribal treaty rights to hunt and fish can be regulated for the preservation of a resource, the question is not what the treaty guarantees, but rather what the applicable statute/regulation requires and whether it is non-discriminatory. The *Anderson* court accordingly found the MMPA applied to the Makah because the Makah can be regulated "in common with all citizens."

Limitations and legal implications of the MMPA waiver request:

The waiver request is limited to ENP gray whales only. It does not cover WNP gray whales, nor would it cover PCFG whales if NMFS determined – as it should – that PCFG whales should be designated as a separate stock (an issue that is further discussed below). Since the waiver, if issued, would not cover WNP gray whales, this raises questions about the legal implications for the Makah if it were to take a WNP gray whale. It is worth noting here that different provisions of the MMPA are applicable to "marine mammals" while others are applicable to marine mammal "species" or "population stocks." For example, the moratorium, waiver, take prohibitions, and permit language apply broadly to "marine mammals," (see 16 U.S.C. 1371(a); *Id.* at 1371(a)(3)(A); *Id.* at 1372; *Id.* at 1374), while the MMPA sections on depleted species and issuance of regulations refer to marine mammal "species" or "population stocks" (see *Id*. at 1362(1)(A); *Id*. at 1373). These differences may have implications for the Makah's MMPA waiver request.

While the likelihood of the Makah actually striking and killing a WNP gray whale may be remote according to NMFS (citing to Moore and Weller 2013), since take under the MMPA is broadly defined to include "to harass, hunt, capture, or kill, or attempt to harass, hunt, capture, or kill any marine mammal," if allowed to whale, the Makah may take a WNP gray whale. Moreover, the MMPA's moratorium covers all takes, regardless of the likelihood of such take. Consequently, absent a separate waiver or any other legal authorization permitting the take of an endangered WNP gray whale, the Makah Tribe will be subject to prosecution under the ESA and MMPA.

The MMPA does provide for the incidental take of marine mammals listed under the Endangered Species Act through the acquisition of an "incidental harassment authorization" (IHA) or a "letter of authorization" (LOA) (for incidental take). If the Makah are granted a waiver to the MMPA and NMFS then determines that any "take" of WNP gray whale is incidental to the Makah's whaling operations, then the Makah would have to obtain an IHA or LOA. In this case, given that the duration of any waiver, if granted, would be valid for at least 10 years (see Alternative 6) and since the Makah would likely take and could potentially seriously injure or kill a WNP gray whale, more than one LOA would be applicable.

NMFS provides no explanation as to the legal implications of the Makah's waiver request being limited to ENP gray whales, nor does it discuss the applicability, or lack thereof, of its incidental take standards to the Makah Tribe's whaling plans. In order to obtain such an authorization, a request must be made by the applicant (in this case the Makah Tribe), NMFS must evaluate the impacts of the application pursuant to NEPA, it must publish a notice seeking public comment on the requested authorization, and then must decide whether the authorization should be granted under the relevant criteria contained in the MMPA. Since the existing DEIS does not address the issuance of any such authorization, the authorization process either must be pursued separately from the current DEIS decision-making process (presumably with a decision on a "letter of authorization" made prior to the completion of the present NEPA process) or NMFS must explain why the incidental harassment provisions of the MMPA are not applicable in this case.

Conversely, if the Makah Tribe is granted a waiver to hunt ENP whales and NMFS determines that any take, including serious injury or killing of a WNP whale, constitutes intentional take (since the purpose of the hunt is to kill a whale and because ENP, PCFG, or WNP whales cannot be distinguished by observation alone), then the issuance of a waiver will permit illegal take in violation of the MMPA's moratorium. If such take is considered to be intentional, the only way it can be permitted is if the Makah's waiver application is amended to include WNP gray whales.

Lack of accurate and complete analysis of impacts on Pacific Coast Feeding Group whales within the Oregon-Southern Vancouver Island region:

The Makah Tribe has requested, consistent with the recommendation in Calambokidis et al. (2004), that the primary area of emphasis for the impact of its proposed whale hunt on the PCFG of ENP gray whales be restricted to the OR-SVI region of the PCFG range. The OR-SVI region is larger than the Makah U&A but smaller than the full seasonal range of PCFG whales, which is from Northern California to Southeast Alaska. NMFS has included in the DEIS analysis of the impact of the Makah's proposed hunt (Alternative 2) and the other action alternatives (Alternatives 3-6) on PCFG whales within the OR-SVI region but, as discussed in more detail below, its analysis of the impacts on PCFG whales in the OR-SVI region is deficient. Moreover, despite the Makah Tribe's request to focus the analysis on OR-SVI PCFG gray whales and the *Anderson* court's emphasis on the need to consider impacts in the local area (e.g., the Makah

U&A), NMFS's analysis of Alternatives 3-6 calculated the PBR level using the larger PCFG population estimate instead of using the estimates for the OR-SVI and Makah U&A regions.

Additional limited waiver request:

Embedded within the Makah Tribe's request for a waiver of the MMPA's prohibition on taking marine mammals is a second request for "a limited waiver from the MMPA's prohibition on the sale of marine mammal products for the purpose of selling such traditional handicrafts." Makah Waiver Application at 3. No additional information about this second waiver request, including any explanation as to scope of the "limited waiver," is contained in the waiver application or in the DEIS. Since this additional waiver request clearly applies to the Tribe's interest in the sale of authentic native handicrafts manufactured from the non-edible byproducts of killed gray whales, it is imperative that additional information about this second waiver request and its implications be made available so that the public has a chance, as the law requires, to participate in the decision-making process inherent to the second waiver request.

3. NMFS must determine if PCFG whales are a separate stock under the MMPA:

Although the prohibition on taking contained in the MMPA is for "marine mammals," 16 U.S.C. 1372, the authorization of take is restricted to marine mammal "species" and "population stocks" 16 U.S.C. 1373. The MMPA defines the term "population stock" or "stock" as "a group of marine mammals of the same species or smaller taxa in a common spatial arrangement, that interbreed when mature." Unlike the Endangered Species Act, which permits the listing of "Distinct Population Segments," the MMPA does not provide protections for anything other than species or population stocks.

PCFG gray whales are not currently designated as a population stock or stock. The IWC's Scientific Committee, however, has determined that it is "plausible that the PCFG may be a demographically distinct feeding group,"[12] DEIS at 1-5, 3-157, while NMFS repeatedly reports in the DEIS that the PCFG "seems to be a distinct feeding aggregation and may warrant consideration as a distinct stock in the future" *Id.*

If the PCFG were designated as a stock, this would have significant implications for the PCFG and the Makah Tribe's whaling proposal. Among other things, a stock designation would permit the PCFG to be potentially designated as "depleted" under the MMPA if the current population size was below the optimum sustainable population (OSP) size (which has historically been interpreted by NMFS as 60 percent of the stock's carrying capacity). If designated as

[12] As explained in the DEIS, "although the IWC has not formally identified the PCFG as a stock, the Scientific Committee (IWC 2012a) noted that its implementation review of eastern North Pacific gray whales (with an emphasis on the PCFG) was "based on treating PCFG as a separate management stock" (which may not be equivalent to a stock as defined under the MMPA)." DEIS at 1-5.

"depleted," the Secretary would be barred from issuing any permit to allow take. While this bar could be overcome with an MMPA waiver, if the PCFG were designated as a stock, the current Makah waiver application would not cover PCFG whales. Instead, as explained above for WNP whales, the Makah could be prosecuted under the MMPA for illegally taking (intentionally or incidentally) a PCFG whale. The Makah would have to seek an LOA to permit incidental harassment and take, including serious injury and mortality, or it would have to amend its waiver application to include PCFG whales.

Considering the implications of the decision on whether PCFG whales are a stock, NMFS must suspend the current decision-making process and make a stock determination before continuing with the current analysis. Indeed, since the DEIS must provide the substantive evidence to support any decision made under the MMPA, NMFS must make a stock determination for PCFG whales as part of this decision-making process.[13] If NMFS determines, after providing an opportunity for public participation, that PCFG whales are a stock, this development would likely require a reassessment of the Makah's waiver request and, at a minimum, preparation of a supplemental DEIS. Conversely, it would be nonsensical to complete this MMPA waiver and NEPA process and then to conclude that the PCFG is a stock, as that could then require a full reevaluation of previous decisions with implications to the Makah Tribe, other interested stakeholders, and the gray whales.

The best available scientific information provides ample support for the designation of PCFG whales as a stock. While neither the MMPA nor its implementing regulations provide direction on how to determine if a group of marine mammals of the same species constitute a stock, NMFS has guidelines that it utilizes to make such determinations.

To determine if a group of marine mammals represent a stock, NMFS relies on its Guidelines for Assessing Marine Mammal Stocks (NMFS 2005 or GAMMS II). The original guidelines were developed in June 1994 and were finalized in 1995 to aid NMFS in preparing Stock Assessment Reports (SAR). Immediately thereafter minor revisions to the guidelines were proposed and a new version of the guidelines was published in 1997. NMFS (2005) represents the current version of the guidelines. However, based on a workshop held in 2011 to review the guidelines (referred to below as the GAMMS III workshop), NMFS published a Federal Register notice in 2012 soliciting public comment on proposed amendments to the guidelines. To date, NMFS has not finalized those amendments which, for the purpose of this analysis, will be referred to as GAMMS III Revisions 2011.[14]

[13] At a minimum, if NMFS makes a preliminary determination to issue an MMPA waiver to the Makah Tribe it must make a stock determination for PCFG whales before the administrative law judge hearing in order to meet the requirements of the MMPA.
[14] The revisions are available at http://www.nmfs.noaa.gov/pr/pdfs/sars/gamms3_appendix4.pdf

The MMPA defines "population stock" as "a group of marine mammals of the same species or smaller taxa in a common spatial arrangement that interbreed when mature." NMFS (2005). In interpreting this definition, NMFS considers the objectives of the MMPA, including maintaining the health and stability of the marine ecosystem and that "…species and population stocks of marine mammals…should not be permitted to diminish beyond the point at which they cease to be a significant functioning element in the ecosystem of which they are a part, and consistent with this major objective, they should not be permitted to diminish below their optimum sustainable population." *Id.*

In the 2005 GAMMS report, a stock is deemed a management unit if it constitutes a "demographically isolated biological population." NMFS has interpreted this concept to be synonymous with "demographically independent biological population" in subsequent applications of the guidelines since the "demographically independent" better reflects the intent of both the MMPA and those who prepared the GAMMS II report.[15] Furthermore in Weller et al. (2013), the use of demographic independence in defining a stock was articulated as follows:

> The GAMMS III workshop recommended revising the SAR guidelines to reflect that the intent of the GAMMS II guidelines (NMFS 2005) was to base stock identification on demographic independence as noted in Eagle et al. (2008) and proposed that the term demographic isolation be replaced with "demographic independence" as follows:
>
> > (1) "For the purposes of management under the MMPA, a stock is recognized as being a management unit that identifies a demographically independent biological population."
> >
> > (2) "Demographic independence means that the population dynamics of the affected group is more a consequence of births and deaths within the group (internal dynamics) rather than immigration or emigration (external dynamics). Thus, the exchange of individuals between population stocks is not great enough to prevent the depletion of one of the populations as a result of increased mortality or lower birth rates."
>
> In other words, the participants at the GAMMS III workshop viewed this as a semantic issue where the term demographic independence is a better description for the current GAMMS guidelines definition than is the term demographic isolation.

Further, Weller et al. (2013) explained that:

[15] Pers. comm. with Shannon Bettridge, NOAA/NMFS (July 29, 2015)

> "This interpretation of "isolation" differs substantively from how it is used within the GAMMS guidelines definition above, wherein allowance is made for some level of exchange of individuals between stocks. The TF (Task Force) concurred that in spite of using the term "isolation," the actual definitions under the current GAMMS guidelines … are more consistent with MMPA objectives to protect population stocks than with the objective of protecting just subspecies and species.
>
> Given that the draft GAMMS guideline revisions from the GAMMS III workshop have not yet been formally approved, the TF agreed to use the current GAMMS guidelines definition (NMFS 2005) for the purposes of their discussions and deliberations but noted that the actual definition used in the two versions (for demographic isolation and demographic independence) is essentially the same in that neither implies true "isolation" within the context of the MMPA.

Consequently, for the purpose of defining a stock, NMFS uses the concept of "demographic independence" instead of "demographic isolation." Simply stated, the definition of "demographic independence" is a situation where "the population dynamics of the affected group is more a consequence of births and deaths within the group (internal dynamics) rather than immigration or emigration (external dynamics)." GAMMS Revisions 2011.

A variety of information can be used to identify a stock. This can include information about the prospective stocks such as: distribution and movements; population trends; differences in morphology, life history, genetics, parasites, and oceanographic habitats; and contaminant and natural isotope loads. (NMFS 2005). A comparison of population trends of the same species occupying different areas can also be used to assess potential stock status, since different trends would suggest that the stocks are not "strongly linked demographically." *Id*. Similarly, morphological or genetic differences in animals from different regions are evidence that these populations are demographically independent.

In examining recruitment dynamics in a prospective stock, a failure to detect differences in immigration or emigration rates does not mean that a population is not demographically independent. In some cases, while dispersal rates may be sufficient to "homogenize morphological or genetic differences detectable between putative populations," they may not be sufficient to deliver enough recruits from an unexploited source to an adjacent exploited sink population which could cause the sink population to no longer be a functioning element of its ecosystem. *Id*.

As an example, NMFS (2005) notes that it is common to have human-caused mortality restricted to a portion of a species' range. Depending on the magnitude of such concentrated mortality, it could lead to population fragmentation, a reduction in range, or even the loss of undetected populations. This would only be mitigated by high immigration rates from adjacent areas. If such immigration rates are unknown or are insufficient to mitigate the level of mortality, the affected group of whales may not remain a functioning element of its ecosystem or it may diminish below OSP.

If there is inadequate information about stock structure and fisheries mortality is greater than a PBR calculated from the abundance just within the oceanographic region where the human-caused mortality occurs, managers should seriously consider dividing a species into stocks within designated and defensible management units. *Id*. Such management units could be designated in "distinct oceanographic regions, semi-isolated habitat areas, and areas of higher density of the species that are separated by relatively lower density areas." *Id*. Such areas have often been found to represent true biological stocks where sufficient information is available or when such evidence is known.

Notably, in trans-boundary situations, if a stock's range spans international boundaries or the boundary of the US Exclusive Economic Zone (EEZ), an international management agreement for the species is recommended. Until such an agreement is adopted, if a stock is migratory, the fraction of time in US waters should be noted, and the PBR for US fisheries should be apportioned from the total PBR based on this fraction.[16]

In regard to PCFG gray whales, compelling evidence exists that there is a genetic substructure within the ENP population (DEIS at 3-59, 3-94). For example Lang et al. (2011), based on samples taken from PCFG gray whales and ENP gray whales on the northern feeding grounds, demonstrated small but statistically significant mitochondrial DNA differences demonstrating site fidelity to the southern feeding area. DEIS at 3-60. Although no significant differences in microsatellites (from nuclear DNA) were seen between whales from the different areas, Lang et al. concluded that these results indicate "that structure is present among gray whales using different feeding areas, matrilineal fidelity plays a role in creating such structure, and individuals from different feeding areas may interbreed." *Id*. In a more recently published paper, Lang et al. (2014; Attachment 2) states that their "findings support recognition of the PCFG of gray whales as demographically independent based on the significant differences in mtDNA between the PCFG and whales feeding further north."[17] Frasier et al. (2011) also concluded that PCFG gray whales likely mate with ENP whales but their findings that there were significant differences in mtDNA haplotype distribution and in estimates of long-term effective

[16] This raises a question as to whether, in calculating a PBR for the OR-SVI PCFG whales that PBR should be lowered based on the proportion of OR-SVI gray whales in Canada.
[17] Furthermore, Lang et al. (2014) notes that "although uncertainty remains, our results indicate that it is plausible that the PCFG represents a demographically independent group and suggest that caution should be used when evaluating the potential impacts of the proposed Makah harvest on this group of animals."

population size between PCFG and ENP whales were a result "of maternally directed site fidelity of whales to different feeding grounds." DEIS at 3-125 (see also Lang et al. 2011).

The existing data appears to be equivocal on the recruitment mechanism for PCFG whales. Studies that have found significant differences in mtDNA haplotype frequencies between PCFG whales and whales sampled in the northern areas suggest that the "use of some feeding areas is being influenced by internal recruitment (matrilineal fidelity)." DEIS at 3-127, 3-130. However, Ramarkrishnan et al. (2001), based on an analysis of samples collected from whales within the PCFG range found that the genetic diversity and number of mtDNA haplotypes "were greater than expected if recruitment into PCFG were exclusively internal," DEIS at 3-124, suggesting that there may be some external recruitment into the PCFG gray whale population via immigration. DEIS at 3-127. As explained in GAMMS II, however, a lack of conclusive evidence as to the immigration or emigration rates or mechanisms does not disqualify a feeding aggregation of whales from being designated as a stock.

Based on this and other evidence, a 2012 NMFS task force concluded that there "remains a substantial level of uncertainty in the strength of the lines of evidence supporting demographic independence of the PCFG." DEIS at 3-129. Evidence in favor of demographic independence includes the fact that PCFG gray whales are the "only feeding group that does not rely on dynamics of a subarctic ecosystem" and that "this uniqueness may provide important flexibility to the species as a whole given potential challenges in a changing sub-arctic ecosystem." *Id.* Other supporting evidence includes the persistent return of individual whales to specific feeding areas which "strongly suggests that site fidelity is key to maintaining gray whales as a functioning element of this ecosystem," (DEIS at 3-129), and that data documenting "internal calf recruitment … may actually be an underestimate because of survey limitations." DEIS at 130.

For those who question whether PCFG whales exhibit demographic independence, they point to evidence demonstrating ongoing external recruitment into the PCFG, although it is conceded that there is "considerable uncertainty as to whether external recruitment exceeds internal recruitment." DEIS at 3-130. In addition, they claim that genetic analyses using mtDNA and nuclear DNA have not shown a significant difference between the PCFG and larger ENP population when, in fact, mtDNA analyses have demonstrated such differences. While nuclear DNA analyses have not revealed similar results, this does not disqualify a group of whale from being designated as a stock. External recruitment of ENP whales migrating through the PCFG range is also used to question a stock determination even though the mere fact that such external recruitment may occur does not disqualify PCFG whales from being designated a stock. Indeed, as noted in NMFS (2005), if the population dynamics of the affected group is more a consequence of births and deaths within the group (internal dynamics) rather than of immigration or emigration (external dynamics), the group can qualify for a stock designation.

Other evidence that supports the designation of the PCFG as a stock includes:

- Since Punt (2015; Attachment 3) determined that PCFG population is at 50 percent of its carrying capacity and given that NMFS reports that at current rates of recruitment, PCFG abundance trends appear to be flat, DEIS at 4-100, 4-84, if external recruitment was the primary mechanism for PCFG whales then population numbers should be increasing. This could suggest that internal recruitment is a more important mechanism for maintaining PCFG numbers and, therefore, would support a stock designation. In addition, if PCFG gray whales were designated as a stock then, at 50 percent of carrying capacity, they would not be at OSP and any intentional take by the Makah would be prohibited.
- If the Makah are allowed to whale, particularly under Alternative 2, the killing of up to six ENP gray whales (which may include PCFG whales) each year would constitute the largest source of reported human-caused mortality for gray whales in US waters. As it is not clear that such concentrated mortality (i.e., in the Makah U&A) would be replaced or how such recruitment is likely to occur, the PCFG gray whales in these smaller regions may no longer be a functioning element in the ecosystem, which would violate the MMPA. Furthermore, for the Makah U&A, the potential mortality of gray whales, including PCFG whales, could be well above the PBR for this region.
- The potential for PCFG whales to be a buffer for the species against adverse impacts attributable to climate change in the Arctic cannot be ignored in making this determination. Given that the evidence demonstrates maternally-driven recruitment into the PCFG and noting the high site-fidelity of some PCFG whales to particular regions, simply assuming that ENP whales will fill PCFG vacant niches is risky given the potential importance of PCFG whales. Moreover, if the PCFG represents an ecological/population buffer against the impact of climate change induced changes in the Arctic, then the removal of any PCFG may prevent full development of the buffer. NMFS should err on the side of caution to designate PCFG as a stock to provide protection and to ensure that they continue to serve their role as a functioning element of the ecosystem as required by the MMPA.
- While the apparent stability of the PCFG population is a concern if it is well under K, the stability of this feeding aggregation is nonetheless noteworthy and suggests that the aggregation is exploiting important habitat and should be protected because it may be in the early stages of speciation or developing more complex population structure.

Given this evidence and the critical importance of a stock determination for PCFG gray whales in light of the Makah Tribe's proposed hunt, NMFS has to make this determination before continuing with the current decision-making process.

4. <u>The use of .50 or larger caliber rifles to kill gray whales does not comply with the MMPA's humane take standards:</u>

Even if a waiver is granted to the Makah Tribe, this only exempts the tribe from the prohibition against taking marine mammals under the MMPA. Other provisions of the MMPA, including the requirement to issue regulations and permits to govern the taking of gray whales, would be applicable. Any regulations proscribed must set forth the manner of take that will be allowed, while the requisite permits must specify the location and manner in which marine mammals may be taken. In addition, the Secretary must determine that the manner of take is humane. The MMPA defines the term "humane," in the context of taking a marine mammal, to mean the "method of taking which involves the least possible degree of pain and suffering practicable to the mammal involved." 16 U.S.C. § 1362(4).

Additional information about this standard is included in the Act's legislative history which provides that:

> 'Humane' in the context of taking marine mammals means the method of taking which involves the least possible amount of pain and suffering which can be inflicted upon the animals involved. It is not a simple concept and involves factors such as minimizing trauma to groups of highly intelligent, social animals such as whales and porpoises where the taking of any member may be distressing to the group. In many cases, where an animal may not be taken humanely the bill will prevent that animal from being taken at all.

H.R. REP. NO. 92-707 (1971), *reprinted in* U.S.C.C.A.N. 4144, 4154.

NMFS references the MMPA's "humane" mandate throughout the DEIS. This is particularly relevant in regard to the Makah's proposal to kill gray whales considering the increasing public concern for the suffering of animals, including those who are hunted, the ongoing consideration of cetacean welfare within the IWC, and since the gray whale illegally harpooned (four times) and shot (16 times) by rogue Makah whalers in 2007 took at least 11 hours to die.

In its waiver application, the Makah have proposed to use a .50 caliber rifle as the primary killing weapon after a gray whale is struck and penetrated by a steel toggle-point harpoon. The Makah used a .577 caliber rifle in the 1999 hunt and a same rifle along with smaller caliber weapons during the 2007 illegal hunt. Both weapons have been deemed to be adequate to kill gray whales, DEIS at 2-30, 3-169, 3-364 citing (Ingling 1999, Beattie 2001, and Graves et al. 2004). In their analyses of these two weapons, however these experts only compared the two larger caliber rifles against each other and against smaller caliber weapons; they did not test them against explosive grenades containing black powder or penthrite. One of the experts (Dr. Ingling) cited by NMFS in the DEIS suggested the .577 rifle may be preferable because it is lighter, has a 3-shot magazine, and it is quieter. NMFS, however, notes that gun manufacturers have improved the .50 caliber rifle to meet or exceed the alleged benefits of the .577 rifle. NMFS, therefore, concluded, “we consider the Tribe’s proposed .50 caliber rifle, with its readily available supply of ammunition, the weapon that Makah hunters would most likely use.” DEIS at 3-170.

As reported in the DEIS, the whale harpooned and shot in 1999 took a total of eight minutes to die from the initial harpoon strike to no evidence of life. DEIS at 1-38, 4-76. Both NMFS and the Makah seem to suggest that this is sufficiently “humane” and opine that, with experience, the time to death will decline if the Makah are allowed to kill gray whales. However, whether a kill with a high caliber rifle takes five or eight minutes or longer, that death is not instantaneous or near instantaneous and does not meet the “least possible degree of pain and suffering” standard under the MMPA particularly when less cruel killing methods are available. Furthermore, to use a single event (or a sample size of one) to determine if high caliber rifles are “humane” killing weapons or that the time to death will decrease with more experience is entirely inappropriate since, if the Makah had killed more whales in 1999 or in 2007, the time to death for those whales could have been longer.

Although NMFS appears to be prematurely satisfied that the .50 caliber rifle can “humanely” kill a gray whale, it did expand the analysis in the DEIS to consider the potential use of black powder and penthrite explosive grenades. Such grenades could either be delivered using a darting gun or a shoulder gun. A darting gun consists of a barrel to hold the explosive projectile which is attached to the wooden shaft equipped with a toggle point harpoon. DEIS at 2-13. A shoulder gun is like a rifle but designed to fire explosive grenades. For the Makah, just as they propose to use a rifle as the primary killing weapon after a harpoon has penetrated a whale, explosive grenades would be used in the same manner. A primary killing method is required in any gray whale hunt since a steel toggle-point harpoon, even if it is delivered in a perfect strike to the most sensitive part of the whale’s body, will not kill the animal. DEIS at 3-167.

The evidence contained in the DEIS, taken from a number of studies or reports from whaling activities in Alaska, Russia, Greenland, and Norway, provide compelling data demonstrating that explosive grenades containing penthrite are the least cruel existing method for killing such large whales and should be the only method NMFS permits the Makah Tribe to use if it, wrongly, grants the waiver application and prevails in any subsequent judicial proceedings.

The Alaskan Eskimos utilize explosive grenades as both their primary and secondary killing weapons. DEIS at 3-164. These grenades are delivered using hand thrown darting guns or a shoulder gun. The grenades either contain black powder or penthrite, although penthrite is preferred because black powder can taint the taste of whale meat. *Id.* After the grenade penetrates the whale’s body, it detonates and kills via shock waves and tearing of tissues, hemorrhage, and/or damage to internal organs caused by shrapnel. DEIS at 3-167. According to NMFS, a whale can respond to being struck with a grenade by death, insensibility, and stunning as well as diving, thrashing, and ramming boats. *Id.* (citing Knudsen and Øen 2003, Øen 1995, and Bockstoce 1986).

Such actions, however, are generally short in duration since penthrite results in the rapid death of a whale in most instances. Evidence of this is contained in the DEIS and includes:

- Øen (2006) noted that the instantaneous death rate in Norwegian minke whale hunts in which penthrite grenades were employed had increased from 17 percent from 1981 to 1983 to 80 percent in 2000 to 2002 due primarily to improved grenades and training. Overall, 95.5 percent of whales are killed with the first strike by a penthrite grenade. DEIS at 3-171.
- In a study of the killing efficiency of black powder and penthrite grenades used in the Alaskan bowhead hunt, Øen (1995) reported that seven of the eight whales struck with penthrite grenade(s) died from the first grenade thrown while the eighth whale required three grenades before he/she died. In addition, the results demonstrated a reduced time to death for whales struck with penthrite versus black powder grenades. In 1988, seven of the eight bowhead whales struck with penthrite grenades were landed (one died but was lost) and five of the whales (63 percent) died instantaneously or in less than 5 minutes, DEIS at 3-172, 3-176.
- In 2010, eight bowhead whales struck with penthrite grenades and five were landed after instantaneous or near instantaneous kills. DEIS at 3-174 (citing IWC 2011d). Of the remaining whales, one was lost under the ice, one sank after being killed, and in one whale the grenade did not explode and the whale was lost. *Id*.
- In the 2011 bowhead whale hunt, of the 38 whales landed, 26 whales were reported as instantaneous or near instantaneous kills including all but three of those taken using penthrite grenades. *Id*.
- In 2011, the then Chairperson of the AEWC reported that penthrite grenades "can reduce the time to death for a bowhead whale to four seconds," this being the length of time on the grenade's fuse." DEIS at 3-173, 3-177.
- Øen (2015; Attachment 4) reported the time to death data collected during the Icelandic fin whale hunt in 2014 revealed that "84% of the whales had died instantly." In that hunt, "the whales were killed with 90 mm Kongsberg harpoon canons and Whale Grenade-99 modified with 100 g of pressed penthrite as explosive. Grenade detonation in the thorax (chest), in or at the thoracic spine, neck or brain resulted in 100% instant death."

Notably, bowhead whales are larger than gray whales and, consequently, it is expected that, if a hunt were permitted, penthrite grenades would more rapidly kill gray whales. Nevertheless, despite this and other evidence contained in the DEIS demonstrating that penthrite grenades are a less cruel killing method compared to rifles, NMFS still claims that it is "uncertain what the average time to death would be for gray whales killed in a Makah gray whale hunt using explosive projectiles as the striking and killing weapons" although it then concedes that "it is possible that average time to death would be lower than with the alternate method (toggle-point harpoon and rifle) because the striking weapon has the potential to quickly kill the whale or render it insensible." DEIS at 4-77.

The DEIS also notes that, at an IWC workshop on Whale Killing Methods held in 2003, the United Kingdom presented a paper indicating that whales could experience stress as a result of being pursued which, in turn, can result in stress-related symptoms such as impaired immune defense, reduced fecundity, a failure to grow, and potentially succumb to "exertional myopathy." DEIS at 3-166. NMFS, in response, reported that exertional myopathy has not been reported in gray whales and that "there are no data at present to evaluate what level of activity would be required to induce this in gray whales." *Id.* What NMFS fails to disclose is what efforts have been made by its own scientists or others to examine whether pursuit results in stress related complications, including exertional myopathy. Just because exertional myopathy has not been reported in gray whales, doesn't mean that the risk is not real.

Finally, while the method of killing whales is directly relevant to "humane" concerns associated with the hunt, the efficiency of the hunt is also a critical consideration. Since struck and lost whales could be whales that are injured and suffering, a less efficient hunt will result in greater cruelty than a highly efficient hunt. The hunting proposal submitted by the Makah Tribe (Alternative 2) is the least efficient of all the action alternatives at 57 percent. DEIS at 4-78. The other action alternatives, according to NMFS, have predicted hunt efficiencies of 67 percent (Alternative 3), 100 percent (Alternative 4), 80 percent (Alternative 5), and 100 percent (Alternative 6). DEIS at 4-78/4-79.

Given the foregoing evidence and recognizing that the MMPA requires NMFS to mandate the most "humane" method for taking marine mammals, if NMFS wrongly elects to grant the Tribe's waiver application, it must require the use of explosive grenades containing penthrite as the primary as well as secondary killing method for gray whales. The fact that such grenades and the darting or shoulder guns used to fire the grenades into a whale are expensive is immaterial in this case. The MMPA does not allow cost to be considered in determining the most "humane" method available to kill a marine mammal. Conversely, allowing the Makah to kill gray whales with either the .50 caliber or .577 caliber rifles would violate the "humane" requirement contained in the Act. Furthermore, although significant concerns about public safety in regard to the use of these powerful rifles are addressed elsewhere in this comment letter, requiring the use of penthrite grenades would substantially reduce risks to public safety, as the grenades, due to their weight, have a significantly smaller range than a bullet (i.e., a grenade certainly could not travel as far as 5 miles like a bullet fired from a .50 caliber rifle).

Endangered Species Act

The Endangered Species Act is the nation's preeminent law protecting federally listed threatened and endangered species and their habitats. Its purpose is "to provide a means whereby the ecosystems upon which endangered species and threatened species depend may be conserved, to provide a program for the conservation of such endangered species and threatened species, and to take such steps as may be appropriate to achieve the purposes of the treaties and conventions" identified in the ESA. ESA Section 2(b). Furthermore, Congressionally-designated policy requires that "all Federal departments and agencies shall seek to conserve endangered species and threatened species and shall utilize their authorities in furtherance of the purposes of this Act." *Id.* at Section 2(c).

Section 7 of the Act mandates that "each federal agency … in consultation with and with the assistance of the Secretary, insure that any action authorized, funded, or carried out by such agency is not likely to jeopardize the continued existence of any endangered species or threatened species or result in the destruction or adverse modification of habitat of such species." ESA Section 7(a)(2). To facilitate compliance with the consultation process, "each Federal agency shall … request of the Secretary information whether any species which is listed or proposed to be listed may be present in the area of such proposed action." *Id.* at Section 7(c)(1). If the "Secretary advises, based on the best scientific and commercial data available, that such species may be present, such agency shall conduct a biological assessment for the purpose of identifying any endangered species or threatened species which is likely to be affected by such action" *Id.*

As indicated in the DEIS, there are 14 federally listed endangered (nine species) or threatened (five species) in or near the Project Area. NMFS does not identify any species proposed to be listed under the ESA that may exist in or near the Project Area, although it does identify the sea otter (Washington stock) as a species considered to be endangered by the State of Washington. DEIS at 3-206. Based on a review of information about state and federally protected species maintained by the Washington Department of Fish and Wildlife (accessible at http://wdfw.wa.gov/conservation/endangered/All/), it appears that there may be other federally protected species, particularly fish, including a number of stocks of salmon, that may live in or near the Project Area that were not identified in the DEIS. NMFS also fails to indicate if critical habitat has been designated for any federally protected species other than the Southern Resident killer whales in the Project Area. NMFS must disclose all federally listed threatened and endangered species in the Project Area and provide analysis of how the proposed hunt may affect those species and their habitat, particularly any critical habitat designated for the species. As NMFS has apparently failed to disclose all relevant information about ESA-protected species in the DEIS, this constitutes a violation of NEPA.

Furthermore, NMFS provides no discussion of the ESA consultation requirements and its efforts to satisfy that mandate. There is no reference to any discussion with its own protected species division or with the USFWS regarding federally protected species in the Project Area. Nor does NMFS report whether it is preparing a biological assessment, if said assessment is completed, and/or if it has initiated or concluded its own internal consultation process or the consultation requirement with the USFWS for protected species under its jurisdiction. NMFS must provide assurance that it has complied or is complying with the ESA. Ideally, NMFS should provide the public with an opportunity to participate in the consultation process but, at a minimum it must disclose that it has or is engaged in consultation and, if completed, share the results.

National Environmental Policy Act

NEPA is the basic national charter for protection of the environment. 42 U.S.C. § 4321 et seq. It requires that "environmental information is available to public officials and citizens before decisions are made and before actions are taken." 40 CFR § 1500.1(b). Said information "must be of high quality" and subject to "accurate scientific analysis." *Id.* Ultimately, a NEPA analysis and decision-making process is "intended to help public officials make decisions that are based on understanding of environmental consequences, and take actions that protect, restore, and enhance the environment." *Id.* at § 1500.1(c).

An Environmental Impact Statement (EIS) as required under NEPA "shall provide full and fair discussion of significant environmental impact and shall inform decisionmakers and the public of the reasonable alternative which would avoid or minimize adverse impacts or enhance the quality of the human environment." *Id*. at § 1502.1.

Impacts, in the context of NEPA, are synonymous with "effects." NEPA requires agencies to evaluate the direct, indirect, and cumulative impacts or effects of the proposal or any alternatives. Any alternatives included in a NEPA document must be reasonable, include reasonable alternatives not within the jurisdiction of the lead agencies, must include a no-action alternative, *id.* at § 1502.14(a)(c) and (d), and can also include alternatives that may require legislation to implement. DEIS at 2-2 citing 46 Federal Register 18027(2b). Qualitatively, reasonable alternatives include those alternatives that are practicable or feasible from a technical and economic standpoint and that use common sense, rather than being simply desirable from the standpoint of the applicant. DEIS at 2-2. The agency is required to "rigorously explore and objectively evaluate all reasonable alternatives" *Id.* at § 1502.14(a) and, for those alternatives considered but eliminated from detailed study, must discuss the reasons for eliminating alternatives from substantive analysis. *Id.*

Council on Environmental Quality (CEQ) regulations implementing NEPA – with which all agencies must comply – do not define "reasonable alternative" but explains that "reasonable alternatives to proposed actions will avoid or minimize adverse effects of these actions upon the quality of the human environment." 40 CFR § 1500.2(e). However, the National Oceanic and Atmospheric Administration's NEPA Handbook states "reasonable alternatives are those that may be feasibly carried out based on technical, economic, environmental and other factors, and meet the purpose and need for the proposed action (citing 40 CFR § 1502.14)." See NOAA NEPA Handbook at 5.4.4.1. This latter requirement – that a reasonable alternative meets the purpose and need for the proposed action – is not reflected in the NEPA statutory language or in the CEQ's NEPA regulations, including at § 1502.14, and consequently, may not be lawful. Indeed, as explained in more detail below, if a federal agency on its own behalf or when acting on behalf of a third party can dictate a particular outcome of a NEPA process by crafting its purpose and need to achieve that outcome – which is precisely what has been done here – it makes a mockery of the entire NEPA process.

In most cases, the agency should identify the "agency's preferred alternative or alternatives" unless another law prohibits the identification of a preferred alternative. 40 CFR § 1502.14(e). As explained in the NOAA NEPA Handbook, a "proposed action" and a "preferred alternative" are sometimes synonymous, while in other cases, a "proposed action" reflects a more general objective while the preferred alternative describes how the objective will be achieved. NOAA NEPA Handbook at 5.4.4. For NMFS, as stated in NAO 216-6: Environmental Review Procedures for Implementing the National Environmental Policy Act, if it does not have a preferred alternative, it "must provide a range of alternatives or other indication of the alternatives most likely to be selected, thus informing the public of the likely final action and its environmental consequences" so that "the public is … able to more effectively focus its comments." NAO 216-6 at 5.04(a)3. NMFS has not provided such an explanation in the DEIS.

The identification of alternatives (including any proposed action), description of the affected environment, and the analysis of environmental consequences are considered the "heart of the environmental impact statement." 40 CFR § 1502.14. An agency is required to "present the environmental impacts of the proposal and the alternatives in comparative form, thus sharply defining the issues and provide a clear basis for choice among options by the decisionmaker and the public." *Id.*

In addition, an EIS must include a discussion of "any adverse environmental effects which cannot be avoided should the proposal be implemented, the relationship between short-term uses of man's environment and the maintenance and enhancement of long-term productivity, and any irreversible or irretrievable commitments of resources which would be involved in the proposal should it be implemented." *Id*. at § 1502.16. The DEIS does not include a discussion of any of these required elements.

1. <u>NMFS has failed to provide a reasonable range of alternatives in the DEIS:</u>

The DEIS evaluates the environmental impact of six alternatives. Unfortunately, these alternatives do not comply with NEPA requirements to consider all reasonable and feasible alternatives. Additional alternatives, as described below, should have been evaluated in the DEIS. Two of these alternatives, both of which the Coalition would fully support, were not evaluated at all in the DEIS or were considered and rejected.

The first is a non-lethal use alternative whereby NMFS, other federal agencies, and even non-governmental organizations would collaborate with the Makah Tribe to establish marine animal (including whales) watching operations in Neah Bay. Such operations could incorporate the use of the traditional canoes for coastal animal watching excursions or employ motorized vessels to permit coastal and offshore excursions. Properly trained Makah tribal members could act as vessel captains, operators, paddlers, and naturalists on such vessels while the actual operation would be fully owned and operated by members of the Makah Tribe.

Considering, as described in the DEIS, the significant marine diversity and aesthetic beauty found in Northwest Washington, including in the Makah U&A, and the current lack of any marine wildlife viewing operations in the Neah Bay area, such an alternative would provide a unique opportunity for visitors to Neah Bay. In addition to creating paid employment on the Makah reservation, if properly marketed, such operations would increase visitation to Neah Bay, which would likely translate into increased revenue for the tribe and individual business owners for accommodations, food, services, and miscellaneous purchases. Unlike existing whale and other marine wildlife viewing operations in Washington or the Vancouver area, the Makah Tribe could use its programs to introduce visitors to its history, culture, and traditions (including its traditions related to whaling), which would then be reinforced if visitors also toured the Makah Cultural and Research Center (Museum).

If this alternative were evaluated and ultimately selected, the Makah Tribe would not give up its treaty right to whale but, rather, would agree to suspend its pursuit of an MMPA waiver and its resumption of whaling. While this alternative would not permit the Makah Tribe to kill whales, the Tribe could still use products from any drift/stranded or entangled whales that died and practice all of its traditions related to whaling. It could also, consistent with NMFS whale-watching regulations, interact with gray and other whale species in a non-lethal manner that would create jobs, increase visitation to the refuge, increase revenues, and provide an educational value for tourists.

A second reasonable alternative involves providing compensation to the Makah Tribe in exchange for its agreement to suspend its pursuit of an MMPA waiver and cease its efforts to resume whaling. A version of this alternative was considered in the DEIS but rejected (DEIS at 2-30/2-31). This alternative would not involve only financial compensation to the Tribe but, could also include the transfer of land, provision of equipment/supplies needed by the Tribe, federal grants to address known needs of the Tribe and/or individual tribal members, and/or increase the allocation of fishing quotas consistent with conservation needs, along with a federal funding package the Makah could use to address the many needs in Neah Bay. Some of those needs are referenced in the DEIS and include the development of the Makah Tribe's marine program and its harbor at Neah Bay, an upgraded marine fuel float, creating a deep harbor entry area, and a cruise ship facility. DEIS at 3-22.

Other potential uses of such federal assistance or funds, which would provide even greater benefits for more reservation residents and are also identified in the DEIS, are: expanding the reservation's forested land base, studying the feasibility of a marine fish hatchery; diversifying the Makah Tribe's fishing industry (particularly the whiting fishery); constructing a visitor center along with an associated ocean front cabin resort and motel, a boardwalk, a wellness/medical center, senior citizens apartments, housing for medical clinic workers, baseball fields, trails for tsunami escape corridors, walking paths, and a new Makah tribal council office; conducting road improvements; developing a new clean water source for the reservation, revitalizing the downtown area, expanding the Shi-Shi Trail, and upgrading the tribal communications network; developing wind energy generation units on the reservation; and facilitating improvements in the tribe's value-added seafood processing capacity. DEIS at 3-23.

If this alternative were selected, the Makah Tribe would retain its treaty right to whale but would agree to suspend pursuit of whaling for a set period of time (e.g., 25 years). This alternative is similar to the agreement reached by the Nuu-chah-nulth, a First Nations group that resides on Vancouver Island, with the Canadian government (see DEIS at 1-28). The benefits of such an alternative would be recognized by every tribal member who resides in Neah Bay and could be used to improve the quality of life on the reservation by improving urgent care capabilities, expanding existing medical facilities, enhancing the care of tribal elders, expanding and strengthening tribal substance abuse programs, improving housing standards, and meeting other urgent and critical needs in Neah Bay.

NMFS rejected this compensation alternative because it claimed that any of the activities under this alternative would be speculative and would involve uncertain negotiations between the Makah Tribe and other government and non-governmental entities. DEIS at 2-30. This is simply not accurate since, if such an alternative were selected, then once the negotiations on a compensation package began, specific components of such a package would be identified and articulated.

NMFS will also likely claim, as it already has for the second suggested alternative, that these alternatives cannot be selected as they do not satisfy the purpose and need for either the Makah Tribe or NMFS. As explained above, however, this claim is not consistent with NEPA. Even if it were, as also noted above, NMFS must restate its purpose and need (and delete the Makah Tribe's purpose and need) to ensure the NEPA decision-making process is legitimate (i.e., by ensuring the No Action Alternative is a viable alternative that can be selected at the conclusion of the NEPA decision-making process).

Another alternative that should have been evaluated would combine many of the most conservative elements of the existing action alternatives. In this case, such an alternative would permit whaling during a split season (i.e., three weeks in December and May), all whaling would be required to occur at least five miles offshore, maximum annual take would be limited to one whale (and no more than 6 over six years), a limit of a single struck and lost whale (with any lost whale counted as a PCFG whales), a limit on the take of PCFG whales to be 10 percent of the OR-SVI PBR (.23),[18] with no carryover of any unused limit, and expiration of the MMPA waiver and any associated regulations and permits after ten, three, and three years, respectively. In addition, the Makah Tribe would be required to use penthrite grenades as its primary killing weapon. Such an alternative would allow the Makah to take a limited number of whales during time periods when the risk to WNP gray whales would be reduced. It would also provide increased protection to PCFG whales that occur within the OR-SVI area (the area that the Makah Tribe identified as the recommended region for analysis) by imposing a restrictive take limit which, if a PCFG whale were killed, would require a hiatus in the hunt for as many as four years. In addition, because the hunt would take place well offshore and would require the use of penthrite grenades, it would result in more rapid death to struck whales and would reduce threats to public safety. The expiration of the permits, regulations, and waiver would ensure that NMFS revisits its decision with some frequency in order to make any adjustments as dictated by scientific evidence and social concerns (i.e., adaptive management).

While the Coalition would not support this alternative, it should have been evaluated since it combines many of the most conservative collections of elements from the other action alternatives, which would permit the Makah Tribe to engage in ASW but would limit the impact of any hunt to ENP, PCFG, and WNP gray whales and be more humane.

2. NMFS has failed to disclose all relevant information and to provide a clear and accurate analysis of the environmental consequences of the no action and action alternatives:

[18] Section 118 of the MMPA sets a goal of reducing incidental mortality of marine mammals in commercial fisheries to "insignificant levels approaching a zero mortality and serious injury rate." 16 U.S.C. § 1387, DEIS at 2-21. NMFS considers this goal as being met when commercial fisheries result in a mortality rate of marine mammals that is 10 percent or less of PBR. *Id*.

The affected environment and environmental consequences sections of the DEIS provide the heart of the analysis. The former is intended to fully document the characteristics of the affected environment, while the latter considers the impacts on that environment of the alternatives evaluated in the DEIS. Because of the linkages between these sections of the DEIS, they will be considered together here. Analysis is not provided of each of the environmental variables (e.g., water quality, public services) contained in the DEIS. This is not to suggest these variables are not important but only that the Coalition does not have substantive concerns with the relevant analyses contained in the DEIS, unlike the variables discussed below.

Prior to discussing the categories of environmental consequences where the Coalition has substantive concerns, there are broader issues relevant to the content of the affected environment and environmental consequences sections of the DEIS.

NEPA requires federal agencies to disclose all relevant information in an EIS. Here, the DEIS does not satisfy this important standard, as critical information has not been disclosed. Where NMFS has failed to fully disclose all relevant information in any of the categories of environmental consequences evaluated in the DEIS, a discussion of the missing information and its relevance to analysis of environmental impacts is included below. In some cases, NMFS has claimed relevant information is not available. While the Coalition questions the legitimacy of many of these claims, that analysis is also incorporated below.

The CEQ NEPA implementing regulations explicitly address how federal agencies are to deal with incomplete or unavailable information. For incomplete information that is "essential to a reasoned choice among alternatives and the overall costs of obtaining it are not exorbitant, the agency shall include the information in the environmental impact statement." 40 CFR § 1502.22(a). For information that cannot be obtained "because the overall costs of obtaining it are exorbitant or the means to obtain it are not known," the agency must provide, in the DEIS: "1) a statement that such information is incomplete or unavailable; 2) a statement of the relevance of the incomplete or unavailable information to evaluating reasonably foreseeable significant adverse impacts on the human environment; 3) a summary of existing credible scientific evidence which is relevant to evaluating the reasonably foreseeable significant adverse impact on the human environment, and 4) the agency's evaluation of such impact based upon theoretical approaches or research methods generally accepted in the scientific community." *Id.* at § 1502.22(b)(1-4). NMFS has failed to provide the required statement for information that it deems to be unavailable for analysis in the DEIS.

3. <u>NMFS has failed to define the impact levels used in the DEIS:</u>

The DEIS is also missing critical information relevant to the impact levels relied on in the analysis of environmental consequences. Impact thresholds for the purpose of this discussion are the terms used to identify the physical or temporal severity and/or the geographic scope of the environmental impacts caused by action alternatives. Throughout the DEIS, NMFS uses terms such as "negligible," "minor," "small," "temporary," "short-term," "no appreciable effect," "improbable," "localized," and other terms to describe its assessment of such impacts. NMFS "interprets" "negligible" in the DEIS to mean "an impact resulting from the specified activity that cannot be reasonably expected to, and is not reasonably likely to, adversely affect the species or stock through effects on annual rates of recruitment or survival (50 CFR § 216.103)," DEIS at 2-21, but it fails to provide a definition for any of the other impact level terms used in in the document.

The definition of "negligible" cited above is relevant to NMFS's analysis of incidental take of marine mammals by United States citizens engaged in specific activities (other than commercial fishing) within a specified geographic range. *Id.* It is not clear if NMFS is applying this same definition in the context of its analysis of the environmental impacts of the Makah Tribe's proposed whale hunt in the DEIS. If not, then NMFS has not provided a definition of "negligible" in the DEIS. If so, its use of this definition raises additional questions since, as NMFS notes in the DEIS, "in practice, we consider an incidental take that does not exceed 10 percent of PBR to have a negligible impact" DEIS at 2-21 (citing 64 Fed. Reg. 28,800, May 27, 1999).

Since, in the present context, the take of gray whales may be intentional and, at least for PCFG gray whales under several alternatives, the level of take will be at or in excess of PBR, it would not appear that the use of this term is appropriate. Furthermore, some claims of a "negligible" impact in the DEIS have nothing to do with impacts to a species or population stock, further suggesting that the definition of "negligible" in the DEIS is not relevant to the use of "negligible" in evaluating the environmental consequences of the proposed Makah hunt.

Moreover, with the exception of a few instances where it includes text in parentheticals to ostensibly explain the meaning of the term being used, NMFS has failed to include any definition of any of the other impact thresholds in the DEIS.

NMFS is well aware of the fundamental need to define such impact thresholds. For example, its Final Environmental Impact Statement for Issuing Annual Quotas to the Alaska Eskimo Whaling Commission for a Subsistence Hunt on Bowhead Whales for the Years 2013 through 2018 (Bowhead EIS),[19] published in January 2013, includes a section (see pages 74-76 in Bowhead EIS) explaining the "Steps for Determining Level of Impact." In that section, NMFS explains the legal basis for having to define impact levels:

> The CEQ regulations implementing NEPA state that an EIS should discuss the significance, or level of impact, of the direct, indirect, and cumulative effects of

[19] Available at: https://alaskafisheries.noaa.gov/protectedresources/whales/bowhead/eis0113/final.pdf

> the proposed alternatives (40 CFR § 1502.16), and that significance is determined by considering both the context in which the action will occur and the intensity of the action (40 CFR § 1508.27). Context and intensity are often further broken down into components for impact evaluation. The context is composed of the extent of the effect (geographic extent or extent within a species, ecosystem, or region) and any special conditions, such as endangered species status or other legal status. The intensity of an impact is the result of its magnitude and duration. Actions may have both adverse and beneficial effects on a particular resource. A component of both the context and the intensity of an effect is the likelihood of its occurrence.
>
> The combination of context and intensity is used to determine the level of impact on each type of resource. The first step is to examine the mechanisms by which the proposed action could affect the particular resource. For each type of effect, the analysts develop a set of criteria to distinguish between major, moderate, minor, or negligible impacts. The analysts then use these impact criteria to rank the expected magnitude, extent, duration, and likelihood of each type of effect under each alternative.

NMFS then goes on to include a number of definitions of different impact levels. For example, as to the impact of the proposed action and any alternatives on bowhead whales, NMFS defines "negligible," "minor," "moderate," and "major" based on the relevant "Q" values from the 2006 stock assessment report for this stock of bowhead whales. For other variables evaluated, NMFS provides definitions of terms such as "temporary," "long-term," "moderate," "frequent," "infrequent," and "likely."

In its Supplemental Draft Environmental Impact Statement on the Effects of Oil and Gas Activities in the Arctic Ocean (March 2013), it provides a more comprehensive (and useful) suite of definitions of impact levels used in its analysis. In that document, NMFS defines: "low," "medium," and "high" in regard to the intensity (magnitude) of the impacts; "temporary" and "long-term" in the temporal context of the duration of the impact; "local," "regional," and "state-wide" in regard to the extent of the impact; and "common," "important," and "unique" in terms of the value of the resources that may be impacted. It then, for its "qualitative thresholds," provides a definition of "negligible," "minor," "moderate," and "major." In that NEPA document, "negligible" is defined as "impacts (that) are generally extremely low in intensity (often they cannot be measured or observed), are temporary, localized, and do not affect unique resources." This definition is different from the definition of "negligible" in the context of incidental take analyses.

In the context of the DEIS, not only has NMFS failed to define the impact levels that it has used in its analysis, but it has even failed to provide a full complement of impact levels as reflected in the other NEPA documents identified above.

Importantly, it is not just a matter of defining impact levels, but the impact levels used also must be developed so they are distinguishable, such that the public and decisionmakers are able to easily understand the difference between the various levels used (e.g., how a "negligible" impact is distinguished from a "minor" impact).

As noted previously, the alternatives, affected environment, and environmental consequences sections of any EIS is considered the "heart" of the analysis and an agency "should present the environmental impacts of the proposal and the alternatives in comparative form, thus sharply defining the issues and providing a clear basis for choice among options by the decisionmaker and the public." 40 CFR § 1502.14. In order to sharply define the issues and to ensure, post-decision, that the agency's analysis of impact levels was accurate, it follows that the impact levels used must be meaningful, distinguishable, quantifiable, and/or measureable. If not, then the impact levels effectively become irrelevant since there would be no mechanism to differentiate between the reported impacts. In other words, the agency's analysis would be based largely on speculation as to severity of any impacts.

In *Bluewater v. Salazar* (721 F.Supp.2d 7 D.D.C. (2010)), the National Park Service was criticized for its failure to use meaningful, distinguishable, quantifiable, and measureable impact thresholds in its impairment analysis of allowing jet skis use in the Gulf Islands National Seashore. The court went into great detail to explain why impact levels (or thresholds) in the context of the NPS impairment standard must be distinguishable from each other. While the NPS impairment standard is not a component of NEPA, the impact level concept is exactly the same, suggesting that impact levels contained in NEPA documents must, at a minimum, meet the standards imposed in *Bluewater*.

Given the critical importance of the impact analysis in any EIS, the failure by NMFS to define the impact levels used in the DEIS, to provide a full complement of impact levels (i.e., to address the intensity, temporal context, extent, resource value, and physical impact of an action and its alternatives), and to differentiate between impact levels, is not an error that can be corrected in a Final EIS. Rather, at a minimum, NMFS needs to suspend the current NEPA process while it prepares a Supplemental EIS to address this (and other deficiencies) in the DEIS.

Other Federal Agencies and Additional Legal Concerns

1. NMFS has failed to adequately evaluate how the proposed whale hunt would impact other federal agencies with jurisdiction within the Project Area or to clearly explain management authorities of those agencies:

The Obama Administration has led a push towards the use of ecosystem-based management of our marine resources. In its 2011 EBM Strategic Action Plan Outline, the National Ocean Council (NOC) defined EBM as:

> an integrated approach to resource management that considers the entire ecosystem, including humans, and the elements that are integral to ecosystem functions. EBM is informed by science to conserve and protect our cultural and natural heritage by sustaining diverse, productive, resilient ecosystems and the services they provide, thereby promoting the long-term health, security, and well-being of our Nation.

In a 2013 report to the NOC, the Ocean Research Advisory Panel (ORAP) stated:

> EBM is an integrated approach to management that drives decisions at the ecosystem level to protect the resilience and ensure the health of the ocean, our coasts and the Great Lakes. EBM is informed by science and draws heavily on natural and social science to conserve and protect our cultural and natural heritage, sustaining diverse, productive, resilient ecosystems and the services they provide, thereby promoting the long-term health, security, and well-being of our Nation.

As described in the DEIS, the project area encompasses several federally designated and managed areas, including the Olympic Coast National Marine Sanctuary (OCNMS), the Washington Islands National Wildlife Refuges, Olympic National Park, and internationally designated areas, including a United Nations World Heritage Site and the Olympic Biosphere Reserve, as well as the Makah and Ozette Reservations. To be consistent with EBM, NMFS must take into consideration the environmental impacts of a proposed hunt on this larger geographic region, which it has not done in this DEIS, as explained below.

There are a number of federal agencies that manage lands or waters within the Project Area. These agencies include NOAA, the National Park Service, and the United States Fish and Wildlife Service. For each of the areas managed by these agencies, there are separate statutes and regulations that dictate wildlife management requirements.

Olympic Coast National Marine Sanctuary (OCNMS):

The OCNMS is managed by NOAA's Office of National Marine Sanctuaries. As noted in the OCNMS Final Management Plan and Environmental Assessment, the OCNMS encompasses 2,500 square nautical miles of marine waters off of Washington's Olympic Peninsula coast. See Figure 1. Its location enhances protections to the region's natural integrity provided by both Olympic National Park and the Washington Maritime National Wildlife Refuge Complex. The area's nutrient-rich waters contribute to the high primary productivity within the OCNMS, which attracts twenty-nine species of marine mammals, some of the largest seabird colonies in the continental United States, and a variety of commercially important fish species. It also supports the critical habitats of a number of unique communities of organisms, including deep sea coral and one of the world's most diverse seaweed communities.

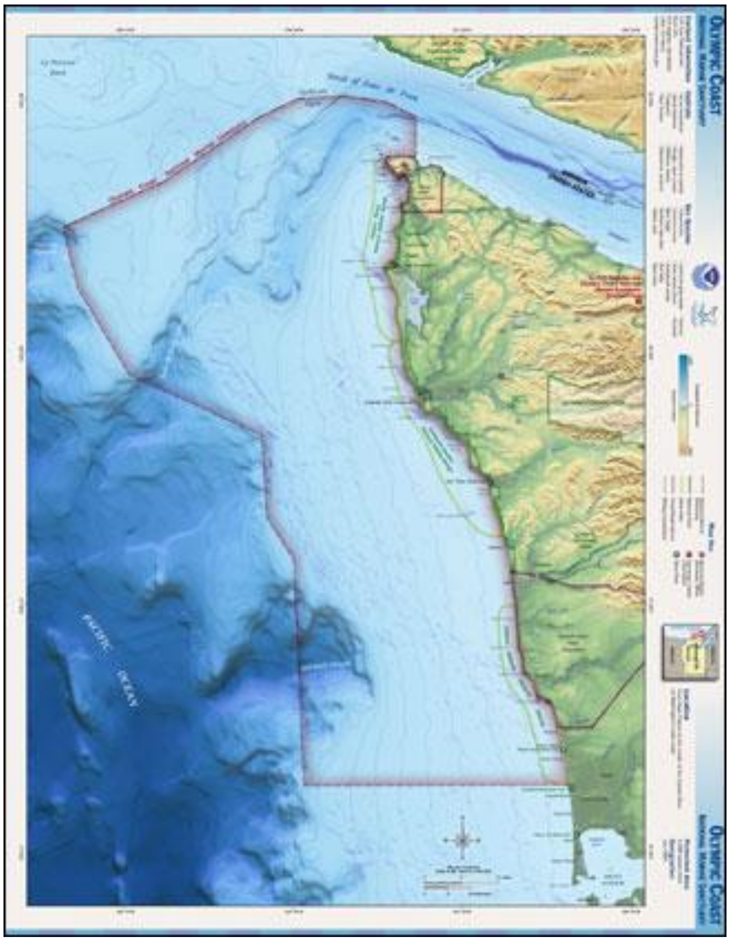

Figure 1: Map of OCNMS (available at http://sanctuaries.noaa.gov/pgallery/atlasmaps/oc.html)

The OCNMS is managed pursuant to the National Marine Sanctuaries Act (NMSA). The NMSA, enacted in 1972, authorizes the Secretary of Commerce to designate and protect areas of the marine environment with special national significance due to their conservation, recreational, ecological, historical, scientific, cultural, archeological, educational, or esthetic qualities as national marine sanctuaries. The primary objective of the NMSA is to protect marine resources, such as coral reefs, sunken historical vessels or unique habitats. Section 304(d) of the NMSA requires federal agencies whose actions are "likely to destroy, cause the loss of, or injure a sanctuary resource," to consult with the program before taking the action. The program is, in these cases, required to recommend reasonable and prudent alternatives to protect sanctuary resources. 16 U.S.C. § 1434(d).

The boundaries of the Makah U&A appear to overlap with the boundaries of the northern portion of the OCNMS. Regulations relevant to the OCNMS generally prohibit the taking of marine mammals and other species in or above the sanctuary, except if such taking is authorized by several laws or treaties. Specifically, the regulations prohibit:

> Taking any marine mammal, sea turtle or seabird in or above the Sanctuary, except as authorized by the Marine Mammal Protection Act, as amended, (MMPA), 16 U.S.C. 1361 *et seq.,* the Endangered Species Act, as amended, (ESA), 16 U.S.C. 1531 *et seq.,* and the Migratory Bird Treaty Act, as amended, (MBTA), 16 U.S.C. 703 *et seq.,* or pursuant to any Indian treaty with an Indian tribe to which the United States is a party, provided that the Indian treaty right is exercised in accordance with the MMPA, ESA, and MBTA, to the extent that they apply.

15 CFR § 922.152(a)(6)

While the whaling provisions in the Treaty of Neah Bay would appear to secure the Makah Tribe's ability to hunt whales within the OCNMS, information in the OCNMS Final Management Plan and EA suggests that a management plan is required to facilitate this exemption to the general prohibition against taking marine mammals in the OCNMS. As explained in the Final Management Plan and EA:

> NOAA's implementation of the NMSA and its duty to implement the federal trust responsibility toward American Indian tribes complement and support one another. The purposes and policies of the NMSA include the following, *"to maintain the natural biological communities in national marine sanctuaries, and to protect, and where appropriate restore and enhance natural habitats, populations, and ecological processes."* This statutory mission supports NOAA's implementation of its trust responsibility for the protection of treaty trust resources, tribal access to treaty resources and the sustainable development of treaty rights. One of the purposes and policies of the NMSA is *"to develop and implement coordinated plans for the protections and management of [sanctuaries] with …Native American Tribes and organizations…and other public and private interests concerned with the continuing health and resilience of these marine areas."* This policy statement in the NMSA supports OCNMS's efforts to defer to tribal management plans that achieve the statutory mission and obligations of OCNMS.

> Finally, the NMSA's objective *"to facilitate to the extent compatible with the primary objective of resource protection, all public and private uses of the resources of"* national marine sanctuaries supports implementation of NOAA's trust responsibility to protect the exercise of treaty rights, now and in perpetuity. The NMSA and the federal trust responsibility provide one basis, among many, for the determination OCNMS regulations do not restrict the ability of Coastal Treaty Tribes to exercise their treaty protected rights (15 CFR 122.152(f)). The Coastal Treaty Tribes and NOAA strive to develop joint activities and projects, and to engage in the collaborative development and implementation of coordinated plans for the management and protection of treaty resources, to ensure resilience of those resources, and to promote the continuing health of the OCNMS ecosystem.

(Final Management Plan and EA at 10; emphasis added).

This language indicates that OCNMS and the Makah Tribe either must develop a coordinated plan for the protection and management of treaty resources or the OCNMS can defer to a management plan promulgated by the Makah Tribe. Any such plan, however, must provide for the protection of treaty resources, ensure the resilience of those resources, and promote the continuing health of the OCNMS ecosystem. NMFS does not provide any information in the DEIS to suggest that such a management plan for gray whales or for all sanctuary resources that may be exploited by the Makah Tribe has been developed. If such a plan exists, it should be disclosed as part of the NEPA process. If no plan is available, the Makah must not be allowed to engage in whaling within the OCNMS until it, ideally in collaboration with OCNMS representatives, promulgates a plan. Such a plan should be subject to public notice and comment before it is finalized.

Washington Islands National Wildlife Refuges:

The Washington Islands National Wildlife Refuges include the Flattery Rocks, Quillayute Needles, and Copalis National Wildlife Refuges. See Figure 2. The refuge complex is under the jurisdiction of the US Fish and Wildlife Service (USFWS). For management purposes these refuges are managed as part of a complex. Flattery Rocks National Wildlife Refuge (NWR) is the furthest north of all three refuges and is the refuge most likely to be affected by the proposed Makah hunt. See Figure 3.

In 1907, President Theodore Roosevelt signed Executive Order 703, establishing the Flattery Rocks Reservation. That EO specified that:

> It is hereby ordered that all small, unsurveyed and unreserved islands lying off the coast of the State of Washington in the Pacific Ocean, between latitudes 48° 02' North and 48° 23' North, among which are those named and commonly known as Spike Rock, Father and Son, Bodiel-teh Islets, Flattery Rocks, Ozette Island and White Rock, as the same are shown upon coast survey chart No. 6400, or upon the General Land Office map of the State of Washington, dated 1887, and located within the area segregated by a broken line and shown upon the diagram hereto attached and made a part of this order, are hereby reserved end set aside for the use of the Department of Agriculture, as a preserve and breeding ground for native birds and animals. This reservation to be known as Flattery Rocks Reservation.

In 1940, by proclamation, Flattery Rocks, Quillayute, and Copalis reservations were redesignated as national wildlife refuges. In 1970, all three refuges were designated as wilderness areas.

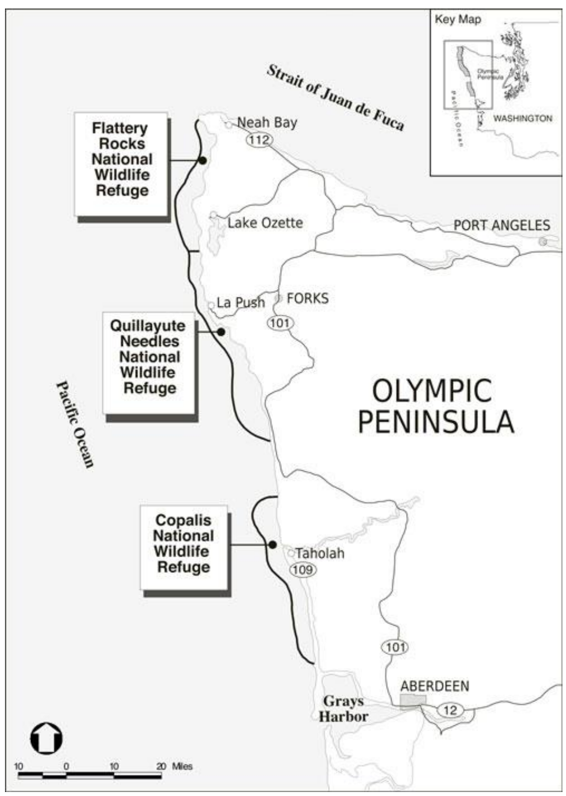

Figure 2: Map of the Washington Islands National Wildlife Refuges (available at http://www.thearm chairexplorer.com/washington/w-images/nwr-photos/Washington_Maritime_NWRC_Ma.jpg)

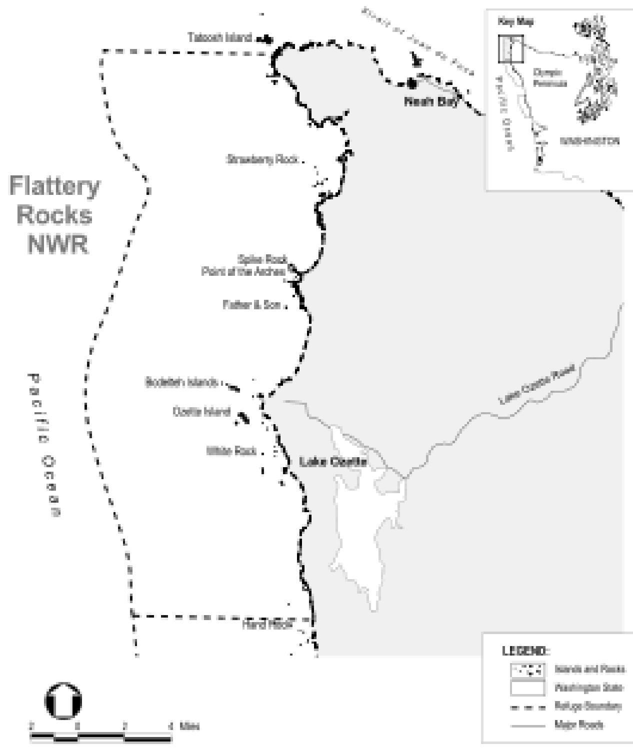

Figure 3: Map of Flattery Rocks National Wildlife Refuge (available at https://upload.wikimedia.org.wikipedia/commons/thumb/7/70/Flattery_Rocks_NWR_Map.svg/283px-Flattery_Rocks_NWR_Map.svg.png

Management of Flattery Rocks NWR is complicated given the multiple agencies, state and federal, and tribal that have separate or overlapping jurisdiction for the management of natural resources in the area. As explained in the Washington Islands National Wildlife Refuges Comprehensive Conservation Plan and Environmental Assessment (CCP/EA):

> The Service (USFWS) is responsible for most of the islands, rocks, and seastacks above the mean high water line. As with other national wildlife refuges, the Service is responsible for any wildlife, fish, and plants that occupy the Washington Islands NWRs whether they are seasonal or permanent residents. This includes seabirds, shorebirds, and marine mammals that use the Refuges' islands and shoreline. Although Service responsibilities cover terrestrial environments, the Refuges are vitally linked with the surrounding marine environment and its resources.

The waters surrounding the Flattery Rocks NWR are largely managed by the OCNMS although, given the purpose of the refuge to protect birds and animals and the legally designated refuge boundary that includes a large amount of ocean habitat, the USFWS must have some role in the management of this wildlife, including ocean species.

Management of Flattery Rocks NWR is governed by the National Wildlife System Administration Act, as amended by the National Wildlife Refuge System Improvement Act (16 U.S.C. § 668dd et seq.). While hunting can be permitted on national wildlife refuges, the USFWS must engage in an independent planning process to open a refuge to hunting or to amend or modify hunting practices once a refuge has been opened to hunting. In addition, refuge-specific hunting regulations must be promulgated. The Flattery Rocks NWR is not open to hunting or fishing, as there are no refuge-specific hunting or fishing regulations published in the Code of Federal Regulations (see 50 CFR 32.67).

Since the waters surrounding Flattery Rocks NWR appear to be managed by ONNMCS up to the "higher high water mark on Refuge islands," it would appear any hunting of whales by the Makah Tribe within the boundaries of the Flattery Rocks NWR does not require refuge-specific hunting regulations. However, if such hunting resulted in adverse impacts to the birds and mammals that utilize the islands, beaches, and rocky outcrops within the Flattery Rocks NWR, or if the Makah were to land a struck whale on lands under the jurisdiction of the USFWS, then the USFWS would have the authority to act to protect such species and their habitat despite NMFS's jurisdiction over whales under the MMPA and ESA. More than likely, given USFWS NWR regulations and policies, the Makah would not be authorized to land a whale onto any of the islands within the Washington Islands National Wildlife Refuges complex absent prior authorization to do so. As explained in the CCP/EA, the USFWS can enter into Memoranda of Understanding with tribal governments to permit their use of refuge lands and resources but, in this case, there is no evidence such an MOU has been negotiated between the Makah Tribe and the USFWS.

Given the confusing mixture of management jurisdictions among federal, state, and tribal agencies in this region, NMFS must include a more detailed analysis of the various agencies and their management responsibilities in a revised EIS. In particular, it must identify the legal standards, including those relevant to the USFWS, that govern management of terrestrial and aquatic species in the area and under what circumstances the agencies have a role in the wildlife management decision-making process. Furthermore, NMFS must clarify if the Makah can land a dead whale on USFWS refuge lands, what permits would be required to do so, and evaluate how that could impact refuge wildlife, including refuge birds, and wildlife habitat. While the DEIS does provide some broad analysis of the impacts of a hunt on birds, other marine mammals, and intertidal habitat, it fails to provide the level of detail that is required by NEPA in an EIS.

Olympic National Park:

Olympic National Park (ONP) is administered by the National Park Service (NPS). ONP protects 922,651 acres of three distinct ecosystem types: glaciers, coastline, and old growth and temperate forests. As described in ONP's Final General Management Plan and Environmental Impact Statement (ONP GMP EIS), the park provides habitat for 70 unique stocks of Pacific salmon and steelhead, 29 species of native freshwater fish, 1,100 species of native plants, 300 species of birds, including the federally protected marbled murrelet, and 70 species of mammals. ONP GMP EIS at 3. The 70-mile long, 43,000 acre Pacific coastal strip and off-shore islands of ONP provides protection to beached, intertidal areas, and rocky tidal pools as the park's boundary extends seaward to the "lowest low tideline." *Id.* See Figure 4. In addition, 95 percent of the park, including its coastal strip, is Congressionally designated wilderness managed pursuant to statutes governing national parks and the Wilderness Act (16 U.S.C. § 1131, et seq.).

Figure 4: Map of Olympic National Park (available at http://media.away.com/gifs/states/wa/m_olymov.gif)

ONP is managed pursuant to the NPS Organic Act (16 U.S.C. § 1, et seq.). The fundamental purpose of the NPS is to "promote and regulate the use of the Federal areas known as national parks, monuments, and reservations … as provided by law, by such means and measures as conform to the fundamental purpose of the said parks, monuments, and reservations, which purpose is to conserve the scenery and the natural and historic objects and the wild life therein and to provide for the enjoyment of the same in such manner and by such means as will leave them unimpaired for the enjoyment of future generations." 16 U.S.C § 1. Furthermore, the "authorization of activities (in national parks) shall be construed and the protection, management, and administration of these areas shall be conducted in light of the high public value and integrity of the National Park System and shall not be exercised in derogation of the values and purposes for which these various areas have been established, except as may have been or shall be directly and specifically provided by Congress. 16 U.S.C § 1a-1.

Regulations specific to ONP indicate that "all hunting or the killing, wounding, or capturing at any time of any wild bird or animal, except dangerous animals when it is necessary to prevent them from destroying human lives or inflicting personal injury, is prohibited within the limits of the park…" The Secretary of the Interior is also required to promulgate "regulations as he may deem necessary and proper for the management and care of the park and for the protection of the property therein, especially for the preservation from injury or spoliation of all timber, mineral deposits, natural curiosities, or wonderful objects within the park, and for the protection of the animals and birds in the park from capture or destruction, and to prevent their being frightened or driven from the park…" As dictated by statute, "possession within the park of the dead bodies or any part thereof of any wild bird or animal shall be prima facie evidence that the person or persons having the same are guilty of violating this Act." 16 U.S.C. § 256b.

While the majority of ONP is inland and, therefore, not likely to be directly impacted by the proposed hunt, the coastal portion of ONP could be affected. Such impacts could include park visitors observing a hunt, a dead whale being towed back to the Makah reservation, a whale injured by a hunt that strands on ONP lands, or a whale struck and lost by the Makah if it were to wash up on to ONP lands. In addition, albeit unlikely, Makah whalers under certain circumstances, including inclement weather or equipment failure, may elect to land a whale on ONP lands even though this would be illegal under existing ONP regulations.

With the exception of conceding that visitors to ONP may be able to see or hear a whale hunt, NMFS failed to consider other potential adverse impacts to ONP visitors like those summarized above. In addition, it did not provide any discussion in the DEIS about the laws relevant to the protection of ONP, what the Makah would be authorized to do (or not to do) on lands and waters under jurisdiction of ONP, nor did it adequately consider the requirements of the Wilderness Act in the context of Makah whaling.

<u>The Wilderness Act</u>

The Wilderness Act permits the designation of wilderness areas in order to protect these areas from increasing human population, expanding settlements, and growing mechanization. 16 U.S.C. § 1362.2(a).

A wilderness is defined as "an area where the earth and its community of life are untrammeled by man, where man himself is a visitor who does not remain," that retains "its primeval character and influence," where "natural conditions" are preserved, where there is no "natural improvements or human habituation," and that "generally appears to have been affected primarily by the forces of nature, with the imprint of man's work substantially unnoticeable." *Id.* at § 1362.2(c). Such areas are to be "administered for the use and enjoyment of the American people in such manner as will leave them unimpaired for future use as wilderness, and so as to provide for the protection of these areas, (and) the preservation of their wilderness character…"*Id.* at § 1362.2(a). Within wilderness areas, "there shall be no temporary road, no use of motor vehicles, motorized equipment or motorboats, no landing of aircraft, no other form of mechanical transport, and no structure or installation within any such area." *Id.* at § 1364.4(c).

NMFS has failed to evaluate the environmental impacts of the proposed whale hunt in the context of the Wilderness Act and its stringent standards for the protection of wilderness areas.

NMFS has failed to disclose all relevant information and to provide a clear and accurate analysis of the environmental consequences of the No Action and action alternatives:

The affected environment and environmental consequences sections of the DEIS provide the heart of the analysis. The former is intended to fully document the characteristics of the affected environment, while the latter considers the impacts on that environment of the alternatives evaluated in the DEIS. Because of the linkages between these sections of the DEIS, they will be considered together here. Analysis is not provided of each of the environmental variables (e.g., water quality, public services) contained in the DEIS. This is not to suggest that these variables are not important but only that the coalition does not have substantive concerns with the relevant analyses contained in the DEIS, unlike the variables discussed below.

<u>NMFS has failed to properly evaluate the impact of a proposed whale hunt on ENP, PCFG and WNP gray whales:</u>

This section provides an overview of each of the alternatives in the context of the potential timing of the hunt, number of hunting (and scouting) days, number and type of vessels involved in hunt related activities, number of ENP and PCFG whales killed, likelihood of striking a WNP, likely number of whales killed, number of unsuccessful harpoon attempts, number of approaches to whales, the number of shots fired, and the number of grenade explosions.

As indicated below, there are a number of questions, concerns, and errors in the analysis of the environmental impact of the proposed whale hunt on ENP, PCFG, and WNP gray whales. Most of these issues are raised in the analysis of specific alternatives. Some of the issues raised under one alternative may be also applicable to another alternative. In those instances, such relationships are noted in the text. Before engaging in an alternative-specific analysis, there are broader issues and concerns that warrant discussion and review.

Scope and focus of DEIS analysis:

In regard to the scope or focus of the analysis, as explained in the *Anderson* opinion and as quoted in the DEIS:

> Even if the eastern Pacific gray whales overall or the smaller PCFG group of whales are not significantly impacted by the Makah Tribes' whaling, the summer whale population in the local Washington area may be significantly affected. Such local effects are a basis for a finding that there will be a significant impact from the Tribe's hunts. Thus, if there are substantial questions about the impact on the number of whales who frequent the Strait of Juan de Fuca and the Northwest Washington coast, an EIS must be prepared.

DEIS at 3-122.

In the DEIS, NMFS attempts to evaluate the environmental impacts of the hunt on PCFG whales and those PCFG whales in the OR-SVI and Makah U&A regions. The Makah U&A region, as evaluated in the DEIS, does not include any portion of the Strait of Juan de Fuca as the Makah Tribe's proposal explicitly excluded whaling in the Strait. Consequently, if approved, a hunt would only be permitted in the Northern Washington PCFG region. In the waiver application, the Makah Tribe requests that the analysis of the impacts to PCFG whales be focused on those whales within the OR-SVI region. That region encompasses the Makah U&A and, based on PCFG observation records, there is considerable exchange or mixing of PCFG whales within the OR-SVI and Makah U&A regions. As explained below, the analysis provided by NMFS does not consistently focus or apply the correct statistics to the OR-SVI or Makah U&A regions, as requested by the Makah Tribe or directed by the court.

Pacific Coast Feeding Group:

The DEIS contains a large amount of information about PCFG whales. This information includes data (numbers and percentages) on gray whales in the PCFG observed over time, seen more than once, seen by PCFG region, and newly seen by year. The assortment of numbers and percentages used throughout the DEIS can be confusing and difficult to follow. For the purpose of this analysis, the key PCFG information contained in the DEIS is:

- Since 1977, approximately 650 gray whales have been seen at least once in the PCFG range from June 1 to November 30 and about half of these whales have been seen two or more times over the years. The whales seen more than once meet the definition of PCFG relied on in Alternatives 3-6 of the DEIS. DEIS at 3-144.
- Of the 603 whales observed in the PCFG range after June 1 from 1996 through 2011, 309 (51 percent) have never been resighted in the PCFG region, while 44 of the 603 (7.3 percent) have been resighted every summer and 265 (44 percent) have been seen more than once but not in every year. DEIS at 3-137 (citing Calambokidis et al. 2014).[20]
- 35.5 to 58.8 percent of whales seen in at least one year in the PCFG region from Northern California to Northern British Columbia were seen at some point within the Makah U&A, while 41.4 to 78.9 percent of whales seen within the PCFG region over at least two years were seen at some point within the Makah U&A. DEIS at 3-139 (citing Calambokidis et al. 2014).
- Based on PCFG observation records collected from 1996 through 2012, of the 181 whales sighted in the Northern Washington PCFG region (which corresponds to the proposed hunt area) prior to June 1, 73 (40.33 percent) were seen in the PCFG range after June 1, 67 (37.02 percent) were seen in the OR-SVI area after June 1 and 60 (33.15 percent) were seen in the Northern Washington-Strait of Juan de Fuca (i.e., the Makah U&A) area after June 1. DEIS at 3-140 (citing Calambokidis et al. 2014).
- The annual average of newly seen whales in the PCFG range, based on data from 1996-2012, was 35.4, 23.8, and 12.1 for PCFG, OR-SVI, and Makah U&A regions, respectively. DEIS at 3-147. The annual average of newly seen whales that were recruited into the PCFG population was 14.3, 11.8, and 6.1 for the PCFG, OR-SVI, and Makah U&A areas, respectively. DEIS at 3-148.
- The number of PCFG whales increased from 38 in 1996 to over 219 in 2005. The population has been relatively stable since 2002. The most recent (2012) population estimate was 209 animals. DEIS at 3-146. Within this region, the number of whales identified in the June through November period has averaged 146 whales from 1996 through 2012. DEIS at 3-148. Of these 146 whales, on average 35 are newly seen whales each year and 14 of these are recruited into the PCFG population (i.e., seen again in a subsequent year). *Id*. For calculating the PBR level, the Nmin for the PCFG whales is 173. DEIS at 3-145 (citing Carretta et al. 2014).

[20] It is not known why the numbers cited in the DEIS and repeated in this summary do not add up to 603 whales. NMFS may want to confirm that these numbers are accurate.

- For OR-SVI whales, the number of animals increased from 25 in 1996 to 181 in 2008, with the most recent population estimate (2012) being lower but stable at approximately 155 animals. DEIS at 3-154. Within this region, the number of whales identified in the June through November period has averaged 95 whales from 1996 through 2012, ranging from 30 in 2002 to 128 in 2001, with 127 in 2012. *Id*. Of these 95 whales, on average 24 are newly seen whales (ranging from 8 to 56 with 28 in 2012) and 12 of these (ranging from 3 to 37 with 3 seen in 2012) are recruited into the PCFG population (i.e., seen again in a subsequent year). DEIS at 4-86.[21] For calculating the PBR level, the Nmin for OR-SVI PCFG whales is 152. DEIS at 3-154 (citing Calambokidis et al. 2014).
- For Makah U&A whales, the number of animals increased from 18 in 1996 to 82 in 2008, with the most recent population estimate (2012) being somewhat lower but stable at approximately 77 whales. DEIS at 3-155. Within this region, the number of whales identified in the June through November period has averaged 33 whales from 1996 through 2012, ranging from 8 in 2002 to 75 in 2008. *Id*. Of the 33 whales, on average 12 are newly seen whales (ranging from 1 to 29 with 22 seen in 2012) and 6.1 of these (ranging from 2 to 17 with 4 seen in 2012) are recruited into the PCFG population (i.e., seen again in a subsequent year). DEIS at 4-86.[22] For calculating the PBR level, the Nmin of the Makah U&A whales is 73. DEIS at 3-155 (citing Calambokidis et al. 2014).
- Although the IWC has not formally identified the PCFG as a stock, its Scientific Committee noted that its Implementation Review of ENP gray whales (with an emphasis on the PCFG) was "based on treating the PCFG as a separate management stock (which may not be equivalent to a stock as defined under the MMPA)." DEIS at 3-156, footnote 53 (citing IWC 2012). The IWC has also determined that it is plausible the PCFG may be a "demographically distinct feeding group," DEIS at 3-123, while NMFS concludes that PCFG whales "appear to be a distinct feeding aggregation and may warrant consideration as a distinct stock [under the MMPA] in the future." *Id*. at 3-68, 3-123/3-124, 4-62, 4-65.

It is important to note that PCFG surveys cannot locate and identify every potential PCFG whale. Due to the size of the PCFG range, it is simply impossible to comprehensively survey the

[21] NMFS should reexamine these numbers, particularly the number of newly seen whales, given contradictions in the DEIS 3-154 and 4-86. This discrepancy may be due to how the data are presented in Calambokidis et al. (2014). They are presented as the average number of whales identified per year (95) (page 9) and as the average number of unique whales seen in Table 2 (page 32).

[22] NMFS should reexamine these numbers, particularly the number of newly seen whales, given contradictions in the DEIS at 3-155 and 4-86. This discrepancy may be due to how the data are presented in Calambokidis et al. (2014). They are presented as the average number of whales identified per year (33) (see page 9) versus as the average number of unique whales seen in Table 2 (page 32).

entire area each year. In addition, a lack of personnel, equipment, time, and funds do not allow for the survey metrics to be consistent each year. Consequently, the number of PCFG whales seen each year represents only a rough approximation of the whales actually observed each year. There are two reasons for this: there are likely more whales present each year than are photographed and identified, and it is likely that some whales were present in a previous year but were not photographed and identified. DEIS at 4-66. For example, from 1999 to 2011 there were 14.3 new recruits on average annually in the PCFG, of which 12.5 were not identified as calves, while 1.8 were. The calf estimate could possibly be higher because some of the new whales may have entered the PCFG earlier as calves and were not seen. *Id*.

Interestingly, when the PCFG, OR-SVI, and Makah U&A PBRs are compared to the PBR for the California/Oregon/Washington stock of sperm whales or the ENP stock of blue whales, those populations are much larger than any of the groups of PCFG gray whales, but their PBR is either half (for the sperm whale) or just slightly higher (for the blue whale) compared to the PBR for PCFG whales.

For example, for the CA/OR/WA stock of sperm whales, the estimated population size is 971 animals (Carretta et al. 2013), Nmin is 751, and the recovery factor is 0.1 (because the species is designated as endangered), resulting in a PBR of 1.5 animals. DEIS at 3-211. Using the estimate of 197 PCFG gray whales,[23] there are nearly 5 times as many sperm whales as PCFG whales yet, because the sperm whale is designated as endangered, its PBR is nearly half that of PCFG whales. Similarly, the ENP blue whale has an estimated abundance of 2,497 (Carretta et al. 2013). Despite there being 12.6 times more blue whales than PCFG whales, the recovery factor used for the blue whale is 0.3 (used for endangered species with a minimum abundance estimate of more than 1,500 and a CV Nmin of <0.5), resulting in a PBR (3.1) only 0.4 more than the PCFG PBR (2.7).

While PCFG whales are not presently designated as endangered or depleted, given their low population numbers, the potential for them to be designated as a stock in the future, and remembering the precautionary principle, the PCFG PBR should be calculated using a 0.1 recovery factor. If this were done, the PCFG PBR would be 0.54, while the corresponding PBRs for OR-SVI and Makah U&A PCFG whales would be 0.47 and 0.23, respectively.[24] Alternatively, if the 0.3 recovery factor was used (even though the number of PCFG gray whales is nowhere near a minimum population of greater than 1,500 animals), the PCFG, OR-SVI, and Makah U&A PBR levels would be 1.6, 1.4, and 0.7, respectively.

[23] 197 is the abundance estimate for PCFG whales used in the DEIS even though it is not the most recent abundance estimate, which is 209 whales. Calambokidis et al (2014).

[24] For these calculations, the Nmins for PCFG, OR-SVI, and Makah U&A that are included in the DEIS were used, along with the larger .062 Rmax (instead of the default value of .04).

The potential impact of each action alternative on PCFG whales, including those that utilize the OR-SVI and Makah U&A, along with WNP gray whales if the maximum permitted number of strikes is used, is summarized in Table 1.

Table 1. Estimated number of strikes on PCFG, OR-SVI, Makah U&A, ENP, and WNP whales per year in each PCFG region analyzed in the DEIS under each alternative based on maximum permitted strikes. (Data from Tables in DEIS on pages 4-16, 4-25, 4-29, 4-36, and 4-40/41).

	Percent of PCFG Whales (March-May)	Alt. 2	Alt. 3	Alt. 4	Alt. 5	Alt. 6
Maximum Number of Strikes (ENP)		7	6	1	5	3.5 (7 over 2 yrs)
PCFG	40.33	2.8	2.4	1	0.20	1.4
OR-SVI	37.02	2.6	2.2	1	0.18	1.2
Makah U&A	33.15	2.3	2.0	1	0.16	1.3
WNP		0.012	0.010	0	0.009	0.006

In regard to the potential impact of any of the action alternatives on PCFG whales, including whales in the OR-SVI and Makah U&A, NMFS largely dismisses any meaningful effects.

In evaluating the environmental impacts of the proposed hunt to PCFG whales, for Alternatives 3-6, NMFS concludes that "gray whales would continue using these survey areas during summer months" because: 1) the PCFG mortality limit is more restrictive than the bycatch formula used in Alternative 2; 2) struck and lost whales will count as PCFG whales; 3) other human-caused mortality will be subtracted from the calculated PBR (for Alternatives 4 and 6 only); 4) the IWC analysis demonstrates that PCFG whales would remain viable with a Makah hunt; 5) PCFG whales are dense and abundant in the OR-SVI area; 6) PCFG whales are highly mobile within the PCFG range; 7) many new and returning whales are available to replace killed whales; and 8) gray whales continue to return in large numbers to feeding areas (Chukotka) where scores are actively hunted and killed. DEIS at 4-89, 4-96, 4-103, 4-111, 4-118.

This suggestion that a hunt will not have any adverse impact on PCFG whales flat out contradicts other statements in the DEIS. For example, NMFS concedes in the DEIS that if external recruits don't replace killed PCFG whales, then under each of the action alternatives, it is "likely that the number of whales would decrease."[25] DEIS at 4-89, 4-96, 4-103, 4-111, 4-118. Considering that scientists continue to obtain data to better understand PCFG recruitment mechanisms, this possibility should not simply be dismissed to satisfy the Makah. This possibility is consistent with another statement in the DEIS that "killing even a few animals per year (especially over an extended period of time) from the relatively small PCFG stock could have long-lasting impacts for a group of whales whose population dynamics are not well understood." DEIS at 5-3. Indeed, considering the level of site fidelity seen in some PCFG whales, it is possible that removals of whales from the Makah U&A could result in a localized depletion that would require an extended time period to recover. Unlike calves of PCFG females who are known to be recruited into the feeding aggregation, it may take a unique ENP whale to not just use PCFG range but to use it annually (i.e., to become a PCFG recruit). If that unique whale is not common, then perturbations to PCFG whales may not be reversed for some time.

In regard to the specific conclusions noted above, the Coalition questions whether PCFG whales are "dense and abundant in the OR-SVI area," whether there are "many new and returning whales available to replace killed whales," and whether whales will continue to return to the OR-SVI area if subjected to hunting. As indicated above, from 1996 to 2012 the average number of whales seen in the OR-SVI area was 155. Considering the size of the area, this number hardly suggests a "dense and abundant" distribution. Furthermore, on average, only 12 whales per year are recruited into the OR-SVI region, which does not qualify as "many new and returning whales" available to fill the gaps left by any whales the Makah might kill or whales that may leave the hunt areas due to impacts of the hunt. These conclusions should be revisited.

Finally, assuming new whales will readily fill gaps left by dead whales based on the Chukotkan gray whale hunt may not be accurate, particularly considering that the Makah U&A is within the OR-SVI region. The mere fact that Chukotkan natives have killed an average of 116 gray whales over the past ten years (2004-2013)[26] is not sufficient information to determine if the characteristics of the whales' distribution have changed over time as a result of hunting pressure. To make that determination, additional information is necessary regarding catch-per-unit effort, the spatial and temporal distribution of the whales within their Russian feeding areas, how actual kill locations have changed over time (if at all), and if whales on the Russian feeding areas demonstrate different behaviors (i.e., alertness, flight response) to the approach by or presence of a vessel, including a whaling vessel. Even if maternal site fidelity to the feeding areas draws whales back to such areas year after year, it is still possible that their

[25] This finding is included in the analysis of Alternative 4. However, NMFS also notes in the DEIS that "Alternative 4 is less likely to affect PCFG viability compared to Alternatives 2 and 3 because the hunt would target males and would not affect matrilineal recruitment." DEIS at 4-101.
[26] Data obtained from https://iwc.int/table_aboriginal

distribution (within their feeding areas) or behaviors have been changed as a consequence of the hunt.

Similarly, for PCFG whales, unless maternal fidelity is specific to the Makah U&A region, PCFG whales have alternative feeding areas from North California to Southeast Alaska. That is, the Makah U&A, although it may be a desirable location for PCFG whales based on prey abundance, may be abandoned for alternative feeding areas – literally only miles away – if hunting is allowed. This means PCFG whales would no longer be "functioning elements of [the Makah U&A] ecosystem."

In addition, considering that gray whales have been largely protected along the entire west coast of North America for decades (with the exception of the gray whales killed in 1999 and 2007), gray whales are not accustomed to being hunted in this region (unlike Chukotkan gray whales who are subjected to hunts every year). Consequently, the behavioral impact of a hunt on an OR-SVI PCFG whale could be vastly different from how gray whales in Russia respond to a hunt; "naïve" OR-SVI whales may be more likely to abandon the area because of the novel, negative stimulus posed by a hunt. NMFS must reevaluate this analysis, recognizing that comparing the reactions of PCFG whales with those of Chukotkan whales may not be valid. It should seek out information, perhaps from new stocks of whales that suddenly became subject to a novel threat, to determine if those reactions could provide any guidance to how PCFG gray whales may react to a hunt.

NMFS must also reconsider its use of the Chukotkan whale hunt as a proxy for how a Makah hunt could physically and behaviorally impact PCFG whales. This analysis must consider the impacts within the PCFG and OR-SVI regions. It also should more comprehensively evaluate the impact of a hunt on PCFG whales in the Makah U&A region given the direction from the *Anderson* opinion to consider the impacts of a hunt on whales in the specific project location (i.e., the Makah U&A).

NMFS also claims the "loss of a feeding aggregation such as the PCFG may not affect the viability of the overall ENP stock" because "sighting data and diet studies indicate that ENP gray whales, including PCFG whales, have the ability to switch feeding areas over time." DEIS at 4-64. This statement ignores NMFS's determination that PCFG whales "may provide important flexibility to the species as a whole given potential challenges in a changing sub-arctic ecosystem," DEIS at 3-129, and also ignores the fact that the loss of this feeding aggregation would remove it as a functioning element of this ecosystem. In addition, in its analysis of Alternative 2, NMFS concedes "If PCFG whales are uniquely adapted to exploit feeding areas in the southern portion of the ENP summer range, and that adaptation were lost if the PCFG were compromised, Alternative 2 has the potential to affect the long-term viability of the ENP stock as a whole." DEIS at 4-82. Such conflicting statements and conclusions must be clarified and, in this particular case, NMFS must remove from its analysis any assertion that PCFG whales can be sacrificed without potentially significant adverse impacts to ENP gray whales and, in fact, to the entire population if the ongoing changes in the Arctic begin to adversely affect ENP gray whales.

Western North Pacific gray whales:

For WNP gray whales, NMFS relies entirely on the analysis by Moore and Weller (2013) to assess the potential of a Makah whale hunt to impact this endangered population of whales. Their analysis included consideration of the action alternatives evaluated in the DEIS. Their findings are presented in Table 2.[27]

Table 2: Percent Chance of Approaching, Attempting to Strike, or Striking One WNP Gray Whale Over Six Years

	Alt. 2	Alt. 3	Alt. 4	Alt. 5	Alt. 6
Approaching	97	97	≈0	72	97
Attempting to strike	35	31	≈0	27	20
Striking	7	6	≈0	5	4

While their modelling results provide probabilities for a WNP gray whale to be approached/pursued, subject to an unsuccessful harpoon attempt, or struck is low, it is not zero (except under Alternative 4, where the risk is likely near zero). Notably, any of these outcomes reflects a "take" under the MMPA and, if not authorized by permit or included in the waiver application,[28] could lead to prosecution of a Makah whaler and his crew for violating the MMPA and ESA. Furthermore, whether these probabilities accurately reflect the real risk is uncertain.

In the analysis by Moore and Weller, the percent chance over six years of actually striking at least one WNP "was relatively low but non-trivial," of attempting to strike at least one WNP gray whale was "fairly high," and of approaching at least one WNP whale was "high." DEIS at 3-93. Overall, Moore and Weller conclude the tribe "might strike a whale (WNP) approximately

[27] These findings, as indicated in the DEIS, are also based on a separate communications between NMFS and J. Moore.

[28] WNP gray whales are not included in the Makah Tribe's waiver application. In addition, the Makah could not qualify for any type of harassment authorization if it is allowed to hunt and any take of a WNP gray whale is considered intentional.

once every 100 years." *Id*. Even if this is accurate, NMFS determined "the loss of a single whale, particularly if it were a reproductive female, would be a conservation concern for this small stock," DEIS at 3-93/3-94, 4-82, 4-92, while the IUCN has "emphasized the urgent need for a comprehensive international strategy to eliminate or mitigate anthropogenic threats facing WNP gray whales throughout their range." DEIS at 3-94.

Furthermore, the analysis by Moore and Weller examined only the numerical probability of being affected by the hunt based on the total number of WNP gray whales and the proportion of the population known to have emigrated to the ENP gray whale range. They didn't consider any variable linked to time spent in the ENP range or, more specifically, in the Makah U&A. This is not a trivial concern since the more time a WNP gray whale spends in the hunting area, particularly during the time when a hunt is permitted, the greater the probability of an approach, pursuit, strike attempt, or strike.

Even NMFS notes that "Sakhalin whales were seen in an area of the ENP (i.e., Vancouver Island) where some whales tend to linger and feed during the northbound migration," and that "the long distance and potential open water crossing required for transit from the ENP to the WNP may make it more advantageous for whales to spend time feeding in the Pacific Northwest prior to undertaking a westerly passage to Sakhalin." DEIS at 3-89 (citing Darling et al. 1998 and Weller et al. 2012).

Another concern independent of any statistical probability of WNP whales being struck, killed, or even approached during a hunt is the fact that none of the action alternatives require the comparison of any photographs taken of killed and landed whales with the WNP gray whale photo-id catalog maintained by Alexander M. Burdin of the Vyatka State Agricultural Academy, Kirov, RUSSIA. Considering the critically endangered status of WNP gray whales and the fact that each whale is critical to the short and long-term conservation and recovery of the population, any hunt must include a photo-id requirement for WNP gray whales. While NMFS suggests in the analysis of each action alternative that, if a gray whale is taken and landed, it will be possible to determine if it is a WNP whale based on comparing photographs to the WNP photo-id catalog, DEIS at 4-82, 4-92, this is not reflected in the description of any of the alternatives. At present, all the action alternatives require photographs of gray whales killed by the Makah to be compared only with the PCFG photo-id catalog maintained by the Cascadia Research Collective. If NMFS grants the Makah request for a waiver and permits the Tribe to whale, it must include a requirement in the waiver, regulations, or permit language that all landed whales must be photographed and the images compared to both the PCFG and WNP photo-id catalogs. In addition, tissue samples from any dead whale must be taken for DNA analysis to obtain a greater understanding of gray whale genetics and population/feeding aggregation relationships.

NMFS also asserts that it might be possible to determine if a struck gray whale, even if it were lost, is a WNP whale. DEIS at 4-92, 4-99, 4-114. Unless the Makah or NMFS intend to take photographs of any targeted whale before he/she is struck with a harpoon or shot with a bullet or grenade or unless a WNP whale is otherwise marked or tagged, it is unclear how this could be accomplished. NMFS must clarify the methodology that would be employed to determine if a struck and lost whale is a WNP whale.

Alternative 1:

This is the No Action Alternative. If selected it would deny issuance of the requested MMPA waiver to the Makah Tribe. However, this alternative does not prevent the Makah Tribe from revitalizing its whaling traditions and/or continuing to engage in any rituals, songs, dances, ceremonies, or story telling that has reportedly been ongoing since the tribe ceased whaling in the 1920s. It also, as indicated in the DEIS, does not prevent Makah whalers from constructing whaling canoes, from engaging in physical training as practiced in the past, or in using the canoes in the Makah U&A as long as no protected marine mammal species is taken in violation of the MMPA.

In the DEIS, NMFS repeatedly claims that Alternative 1, if it were selected, would not reduce the number of gray whales killed since the United States would likely transfer its allocation of gray whales back to the Russian Federation for its native hunters consistent with a bilateral agreement between Russia and the United States. DEIS at 4-8. While the return of any unused quota to the Russian Federation may occur, that does not necessarily mean the same number of whales (i.e., 140 per year as currently permitted by the IWC) would be killed each year. The Chukotkan natives do not currently take the full quota allocation, averaging 126 whales annually from 2009 through 2013.[29]

At present,[30] if the no action alternative were selected, it would not necessarily correlate to an increase in Russian ASW kills. Conversely, if one of the action alternatives were selected, this would result in an increase in the number of whales killed because any gray whales killed by the Makah would be added to those killed by the Russian native whalers. Historically, the only other group that killed gray whales was Alaska Natives, who killed a total of seven from 1985 through 1995 but, at present, do not have an IWC-approved quota for gray whales.

Moreover, even if the United States transfers its gray whale quota to the Russian Federation, the additional whales that could be killed by the Chukotkan natives would likely not be the same animals that could have been killed by the Makah. In particular, transferring the quota

[29] Data obtained from https://iwc.int/table_aboriginal
[30] Based on discussions at recent IWC meetings, the Russian Federation may attempt to increase the ASW quota for gray whales in the future to compensate for “stinky” whales that are reportedly inedible.

would indisputably prevent the killing of PCFG and WNP gray whales, since neither group of whales are subject to hunting by Chukotkan natives. For the WNP and PCFG gray whales, this would be significant given their low population numbers and the many threats they face.

Benefits could also accrue to those who regularly observe PCFG whales and who may have named or otherwise developed a particular connection with select, distinguishable whales (this is further discussed below). Other benefits of selecting Alternative 1, whether the quota is transferred to the Russian Federation or not, would include preventing gray whales from being intentionally killed in United States waters by an aboriginal group that does not qualify for an IWC-approved ASW quota. This could be of great importance to the majority of Americans who oppose whaling.

As previously noted, the Coalition supports this alternative and believes it is the only alternative that is consistent with federal law.

Alternative 2:

This is the Makah Tribe's proposed alternative. It is the most liberal of the alternatives, allowing the most strikes per year, the most hunting days (along with Alternatives 3 and 6), the largest number of whales that could be killed per year (six) with a limit of 24 whales over six years, as well as the largest number of PCFG whales likely to be killed each year (2.8). The allowable bycatch limit (ABL) for PCFG whales calculated for this hunt is three,[31] which is in excess of the current calculated PBR for PCFG whales (2.7). It would limit strikes to seven per year or 42 over six years, allow for three stuck and lost whales per year or 18 over six years, and would not permit any carry-over of any unused annual limits. All landed whales would be photographed in order to compare them to the photo-identification catalogs of PCFG gray whales (this would be an element common to all of the action alternatives) maintained by the Cascadia Research Collective. Whaling under this alternative would not occur in the Strait of Juan de Fuca, nor could it occur within 200 yards of Tatoosh Island or White Rock.

Under this alternative, edible products from the hunt could not be sold, but could be consumed locally or shared with relatives on or off the reservation and with non-relatives on or off the reservation with whom the Makah whalers have familial, economic, social, or cultural ties. Non-

---

[31] As defined in the Makah Tribe's waiver application, the allowable bycatch level (ABL) is the "number of whales from the Pacific Coast Feeding Group that may be taken incidental to a hunt directed at the migratory portion of the Eastern North Pacific stock of gray whales. The ABL is calculated using the Marine Mammal Protection Act's potential biological removal approach but the minimum population estimate is based on the number of previously seen whales in the Oregon-Southern Vancouver Island survey area." DEIS at iv-v. Since the Makah Tribe uses the maximum recovery factor in calculating the ABL, the resulting number is larger than the PBR for the entire group of PCFG gray whales. This is problematic as it provides no buffer for other forms of anthropogenic mortality if the full ABL is taken.

edible products from any killed whale could be used to manufacture authentic native handicrafts that could be sold anywhere in the United States. [32]

Notably, the PBR calculation used in this Alternative is based on the abundance estimate for PCFG gray whales in the OR-SVI region. This is consistent with the Makah Tribe's waiver application, which recommended the analysis area be the OR-SVI region in order to limit the potential impact of a hunt on PCFG whales. This is also consistent with the recommendation of Calambokidis et al. (2004), who identified the OR-SVI region as the most appropriate for the hunt analysis given the significant mixing of whales between the Makah U&A and OR-SVI PCFG regions.

NMFS does not sufficiently highlight this caveat in its analysis of Alternative 2, nor does it employ the same limitation when evaluating the other action alternatives. It is precautionary to use the OR-SVI region instead of the entire PCFG region for the analysis. While consistent with the *Anderson* opinion's emphasis on evaluating the local impacts to gray whales, extending the analysis to Makah U&A whales would also be appropriate. It is therefore astonishing NMFS continues to evaluate impacts to PCFG whales at the largest possible scale. NMFS should prepare a revised analysis that utilizes the OR-SVI region as the primary analysis area for direct hunt effects or, ideally, that focuses the analysis on the OR-SVI and Makah U&A areas for all action alternatives.

If this alternative is selected and the Makah are allowed to kill up to 3 PCFG whales per year, this take would not only be in excess of the current PBR but it would not provide a buffer to compensate for any other anthropogenic mortality of PCFG whales, which could adversely affect the PCFG. Indeed, as noted in the DEIS, "as long as the total number of animals removed from the population as a result of human sources is no more than the calculated PBR of an affected stock of marine mammals, then the removals will not prevent the stock from recovering to, or being maintained within its OSP." DEIS at 3-55. Given this, even NMFS admits that the "Tribe does not propose to account for other sources of mortality when setting ABL for PCFG whales." DEIS at 2-10.

According to the Makah Tribe's 2005 waiver application, the ABL was to be calculated from a "conservative abundance estimate based on the number of gray whales that are seen in more than one year in the OR-SVI survey area between June 1 and November 30." Makah Waiver Application at ii. The abundance estimate used in the calculation is 165, which is the number of PCFG whales observed in the OR-SVI area in 2012. DEIS at 3-146 (citing Calambokidis et al. 2014). Based on that number, the Nmin is 152 which, when combined with an Rmax of 0.04

---

[32] As noted previously, the Coalition asserts that permitting the sharing of edible whale products throughout the United States would not be consistent with the IWC Schedule language for ENP gray whales.

(which is the Rmax used only for the analysis of Alternative 2), and a recovery factor of 1,[33] the PBR or ABL is three whales.

The Tribe proposes to stop hunting when the ABL is reached. The ABL will be dynamic and will be calculated annually based on PCFG observation data for the June through November period before any Makah hunt were to occur. To determine when this ABL is reached, all cataloged whales seen between June 1 and November 30, even if seen only once, would be used to define a PCFG whale. A second definition, whales seen at least twice over two or more years in the PCFG range from June 1 through November 30, is used in the analysis of the other action alternatives. The Makah's definition would mean that any landed whale could be categorized as a PCFG whale based on a single observation in the PCFG range in past seasons, even though it may not actually be a PCFG whale. However, the Makah's proposal does not count whales struck and lost against the ABL for PCFG whales.

The Makah Tribe's proposal does require photographs to be taken of any landed whales for comparison to the catalog of PCFG gray whales maintained by the Cascadia Research Collective. As indicated above, this must be amended to also require the comparison of photos of landed whales with the WNP photo-id catalog and the collection of tissue samples for DNA analysis.

This photo-identification requirement was recommended by the IWC Scientific Committee, which analyzed two possible hunt variants. Although both variants were deemed acceptable, neither corresponded exactly to the hunt proposal submitted by the Makah Tribe to the IWC; therefore, the Scientific Committee expressed concern that the actual conservation outcome of the proposed hunt was not tested. DEIS at 3-160. More specifically, the "aspect of the proposed hunt that had not been evaluated was the interaction between the actual number of strikes per month during the hunting season (December through May) and the assumption of whether a struck and lost whale belongs to the PCFG." *Id*. Despite this concern, the Scientific Committee indicated if hunt variant 1 (the variant that did not count struck and lost whales against ABL) was used, then it should be accompanied by a photo-id program to "monitor the relative probability of harvesting PCFG whales in the Makah U&A" with the results presented to the Scientific Committee each year. DEIS at 3-159.

Another potential flaw in the Scientific Committee's evaluation is that it assumed "a consistent level of non-hunting human-caused mortality." DEIS at 4-66. Considering the myriad threats facing gray whales throughout their migratory range and since those threats (i.e., oil spills, ship strikes, climate change impacts, ocean acidification) are increasing, not decreasing in severity,

---

[33] This recovery factor is used based on the Tribe's claim that the ENP stock of gray whales is not listed under the ESA and has been undergoing a steady or declining level of removals by aboriginal hunters. Makah Needs Statement at 30.

this assumption is almost certainly going to be violated, making all the impact predictions underestimations.

Alternative 3:

This alternative would not allow the Makah to strike a whale unless it was five or more miles offshore. It would also count struck and lost whales as PCFG whales, would establish a PCFG PBR of 2.7 whales (with a sub-quota of 1.6 females), and set the struck and lost limit at 2 whales. DEIS at 2-18. In addition, this alternative limits the number of whales killed annually to a maximum of five (24 over six years), allow only six strikes (36 over six years), restrict the number of struck and lost whales to two per year (12 over six years), and would limit the landing of PCFG whales to 2.7 with a subquota limit of 1.6 female PCFG whales. Under this alternative, any struck and lost whale would be considered a PCFG whale and would count toward the quota. All other elements of this alternative are identical to Alternative 2.

For struck and lost whales, they would be counted against the PCFG mortality limit in proportion to the availability of PCFG whales in the coastal portion of the Makah U&A from March through May. DEIS at 4-20. Calambokidis et al. (2014) determined that, of 181 whales observed in the Northern Washington PCFG Region (which is included as part of the Makah U&A) from March to May from 1996 to 2012, 40.33 percent were observed in the PCFG range after June 1, 37.02 percent were seen in the OR-SVI range after June 1, and 33.15 percent was seen in the Makah U&A after June 1. DEIS at 3-140. In determining the proportion of stuck and lost whales that would be counted as PCFG whales, NMFS uses the 40.33 percent applicable to the entire PCFG range.

The NMFS definition of a PCFG whale is a whale seen more than once over two or more years. Percentages used in this (and other action alternatives) presumably should reflect that definition. However, according to Calambokidis et al. (2014), the 40.33 percent figure refers to whales seen only once, while 36.46 percent would be the corresponding figure for whales that meet the PCFG definition used by NMFS. This may mean the 37.02 and 33.15 percentages do not reflect the NMFS definition of PCFG whales either. NMFS should revisit these figures to ensure they are consistently reflective of the agency's definition of PCFG whales.

The proportion of struck and lost whales that would be considered PCFG whales will change over time based on new data from PCFG surveys. As with Alternative 2, however, the schedule for this adjustment is unclear. Presumably data collected in the summer immediately prior to any hunting season would be used. However, that raises concerns as to whether the proportion of PCFG whales observed in different PCFG regions from June through November would correspond to proportions seen during a hunt that could occur from March to May of the following year. Alternatively, data to identify proportional presence could be collected contemporaneously with a hunt. NMFS fails to adequately explain how it will determine the percentages to use in this alternative (as well as Alternatives 4, 5, and 6). For example, while this will require the continuation of the PCFG monitoring program (which the Coalition assumes will be coordinate d by the Cascadia Research Collective), NMFS does not explicitly disclose who would perform this work. Further NMFS doesn't address how any changes to the PCFG mortality limit would be communicated to the Makah, law enforcement authorities, and the public.

This Alternative also establishes a sub-quota for females which is based on both the percent of PCFG whales present during the hunting period and the proportion of females within the entire PCFG population (which is currently 59 percent). Consequently, if using the 40.33 percent figure, a struck and lost whale would count as 0.24 PCFG female (0.4033 x 0.59). The use of the 0.59 figure is inconsistent with the findings of Ramarkrishan et al. (2001) and Steeves et al. (2001), who reported a significant male bias in the PCFG of 1.8 to 1 (N=45) and 1.7 to 1 (N=16), respectively. Makah Waiver Application at 27. NMFS must revisit this analysis to determine which correction factor is accurate.

Alternatively, because there is a struck and lost limit of 2, it is unnecessary to use these calculations at all. It would be simpler and far more precautionary to consider any whale struck and lost as a PCFG whale and, in order to maximize protection for PCFG females, to assume that each lost whale is female. Alternative 3 must be adjusted accordingly to be more precautionary.

As for the risk to WNP gray whales, while the offshore hunt location could reduce the potential risk to WNP gray whales, NMFS concedes there are "insufficient data to discern whether hunters would be more or less likely to encounter WNP whales if hunting is restricted to offshore area at least 5 miles from the coast, but tracking data for two whales indicate that they could be encountered in such areas." DEIS at 4-92.

In calculating PBR under this alternative (and for Alternatives 5 and 6), NMFS relies on data contained in Carretta et al. 2014. The gray whale population estimate in Carretta et al. (2014) is from 2006-2007, making it 8-9 years old. As indicated in NMFS (2005), "the minimum population estimate of the stock should be considered unknown if 8 years have transpired since the last abundance survey of a stock." Consequently, as long as NMFS continues to rely on the gray whale population estimate from Carretta et al. (2014) it cannot calculate a PBR for the ENP or PCFG whales. Even if NMFS claims the 2006-2007 estimate is only 8 years old and therefore still appropriate to use to calculate PBR, by the time NMFS completes this decision-making process the estimate will be significantly more than 8 years old.

An updated gray whale population estimate from 2010-2011 was published in new draft Stock Assessment Reports (SARs) for marine mammals in the Pacific Ocean (Carretta et al. 2015), but those SARs have not been finalized. This is presumably why NMFS was unable to include the updated estimate in the DEIS. However, given the restrictions associated with using a population estimate that is 8 or more years old to calculate PBR, NMFS must use the updated estimate in its decision-making process. While the public comment period on Carretta et al. (2015) has closed, given the importance of the gray whale population estimate to this issue and the DEIS analysis, the Coalition recommends that NMFS republish just the ENP and WNP draft SARs for public review and suspend the current decision-making process until any comments are evaluated and those SARs are finalized.

Regardless of which gray whale population estimate is used, the PBR calculation should be based on the OR-SVI Nmin rather than the Nmin for the entire PCFG range. This would be consistent with both the Makah's request (as reflected in Alternative 2), which was intended to limit the potential impact of a hunt on PCFG whales, and the direction provided by the *Anderson* opinion, which was particularly concerned with the potential for a hunt to impact the local gray whale population (i.e., the population in the Makah U&A).

Alternative 4:

This alternative, if selected, would allow whaling from June 1 through November 30 each year and would retain the prohibition on hunting in the Strait of Juan de Fuca and within 200 yards of Tatoosh Island or White Rock. Under Alternative 4, the hunt would be limited to seven days, the Makah could only strike male ENP whales, struck and lost whales would count as PCFG whales, and the PBR for PCFG whales would be a single whale. This alternative would permit up to five whales to be killed and seven struck per year with a struck and lost limit of a single whale and no carry-over of any unused annual limits. Due to the timing of this hunt, there would be close to no risk of hunters approaching, attempting to strike, or striking a WNP gray whale but PCFG whales would be killed. In addition, under this alternative "any whale landed would be presumed to be a PCFG whale even if it did not match a known PCFG whale." DEIS at 2-20.

In calculating PBR for PCFG gray whales under this alternative, NMFS utilized a conservative recovery factor of 0.35, while also subtracting estimated mortalities from other human causes (0.45) as reported in the ENP gray whale SAR (Carretta et al. 2014). DEIS at 2-19. According to Wade (1998), this restrictive recovery factor would allow the PCFG whales to equilibrate at 80 percent of carrying capacity over a 200 year period. *Id*. This results in a PBR of 1.43, which NMFS rounds down to 1 for use in this alternative. Since this alternative will necessarily target PCFG whales given the hunting period, a restrictive limit on PCFG gray whale mortality is appropriate. Notably, if the analysis under this alternative used the OR-SVI or Makah U&A regions, the corresponding PBR levels would be 1.19 and 0.34, respectively.

While this alternative is unique in that it explicitly targets ENP male whales, NMFS doesn't explain how Makah whalers, if permitted to whale, will be able to limit their pursuit and killing of whales to only males. This must be clarified. In addition, the deficiencies identified in the other alternatives are relevant here as well (i.e., use of an 8-year-old population estimate and lack of clarification on how, when, and by whom PCFG data will be collected in order to update the PBR calculations).

Alternative 5:

This alternative would permit whaling during a split season (December 1-21 and May 10-31), but it sets the PBR level for PCFG whales at 0.27 (10 percent of the current PBR for PCFG gray whales as reflected in Carretta et al. (2014)) and requires that stuck and lost whales (with a limit of a single whale) be counted toward PBR in proportion to their presence in the Project Area. Notably, if the PBR level in this alternative was calculated using the Nmins for the OR-SVI and Makah U&A regions, they would be 0.23 and 0.11, respectively.

This alternative is intended to reduce the potential for take of WNP gray whales based on limited data suggesting that WNP gray whales have not been observed in the Makah U&A during the split season dates. It is possible that, as scientists continue to monitor WNP gray whales, they will be found in the ENP regions during the split season dates.

The total days available for hunting under this alternative would be 14.7 to 22.[34] Under this alternative, as many as five non-PCFG whales could be killed each year, but NMFS anticipates an average of no more than four ENP whales to be killed annually. Even this would be unlikely, according to NMFS, given the PCFG struck-and-lost limit. In fact, NMFS anticipates that only one whale will be killed every five years under this alternative. If so, this alternative could substantially reduce the number of ENP gray whales killed by the Makah should a hunt be approved, which in turn would reduce risk to PCFG and WNP gray whales.

Although more conservative and Alternative 2, 3, and 6, this alternative suffers from the same deficiencies as in the other action alternatives (i.e., use of an 8-year-old population estimate and lack of clarification of how, when, and by whom PCFG data will be collected in order to update the PBR calculations).

Alternative 6:

Alternative 6 shares many of the same characteristics as Alternatives 2 and 3 in regard to the number of days available to hunt and the timing of the hunt. However, under this alternative

---

[34] The DEIS contains two different estimates for the number of hunting days under this alternative. Compare DEIS at 4-34 ("22 days of hunting in May") to DEIS at 4-35 ("14.7 hunting days per year").

the Makah could kill a maximum of four whales in any single year and could not kill more than 7 whales over two years. The maximum number of PCFG whales that could be killed under this alternative would be 3.5 per year, but 1.4 would be more likely, according to NMFS, due to struck and lost whales being limited to 3 and a PBR level set at 2 per year. Struck and lost whales would be counted as PCFG whales in proportion to their presence in the Project Area and there would be no carry-over of unused whales. This alternative would also impose a 10-year limit on the duration of any MMPA waiver and any regulations issued pursuant to the waiver would expire after three years. The limitations on the duration of the waiver and regulations are appropriate, as this will provide an opportunity to adjust the terms of the hunt, or cancel it altogether, depending on a review of the relevant data. Under the other alternatives the waiver would be valid indefinitely.

This alternative also suffers from the same deficiencies as identified in the other action alternatives (i.e., use of an 8-year-old population estimate lack of clarification of how, when, and by whom PCFG data will be collected in order to update the PBR calculations).

Given the deficiencies noted above with respect to alternatives 2-6, the Coalition presents a seventh alternative at page 38 of this letter. This alternative combines some of the more conservative elements from alternatives 2-6. While the Coalition would not support this seventh alternative, it is included to highlight NMFS' deficiency in presenting a comprehensive analysis of alternatives.

NMFS has failed to disclose all relevant information regarding marine species, including marine plants and invertebrates, and has downplayed the potential impact of a whale hunt on these species and the local ecosystem:

NMFS fails to disclose all relevant information about marine species in the DEIS. It includes information about ocean current patterns, the influence of upwellings on marine productivity, and the impact of large scale environmental perturbations (e.g., Pacific Decadal Oscillation, El Nino, La Nina) on the marine ecosystem. DEIS at 3-98. It also provides general information about phytoplankton, zooplankton, and other marine species, including marine plants, marine mammals, and marine birds.

What is lacking, however, is information relevant to evaluating the environmental impact of the hunt on many of these species. In particular, despite asserting that any impacts of a gray whale hunt on benthic marine plant, macroalgal species, shellfish, and kelp raft communities would be "negligible" due to high levels of background disturbance and a strong capacity of these species for growth and recolonization (DEIS at 4-56, 4-58, 4-59, 4-60), there are no data in the DEIS upon which to make that determination. Specifically, NMFS did not disclose any information about the composition, abundance, diversity, or productivity of marine plants, macroalgal species, and/or shellfish in the Project Area. This assertion may be true and may simply be common knowledge among NMFS and local biologists in the area but, for the purpose of a NEPA analysis, the evidence supporting a conclusion must be disclosed instead of asking the public to trust that an otherwise unsubstantiated finding is correct.

The potential environmental impacts of the proposed hunt on other wildlife species are largely dismissed by NMFS for all species either because the impacts will be "temporary (lasting a few minutes to a few hours)" and "localized (occurring near the hunt)." DEIS at 4-123, 4-126, 4-137, 4-143, 4-144. It also claims that the "number of marine mammals that would potentially occur close enough to hunting activities to be affected by the associated noise would probably be low." DEIS at 4-123. Only Alternative 4 is identified as having greater potential impacts on other wildlife since the hunt would occur during the summer when it is more likely to disrupt key activities such as breeding and nesting (although the limited number of hunting days under Alternative 4 could mitigate such impacts). DEIS at 4-142, 4-143.

The alleged lack of impacts of the hunt may be more wishful thinking than substantive finding, since a hunt is not merely a carved wooden canoe with a crew of Makah whalers pursuing a gray whale. Rather, given the significant controversy inherent to a Makah whale hunt, the atmosphere surrounding a hunt (if the 1999 hunt is any guide) is akin to an aquatic three-ring circus, with whalers, support personnel, media representatives (on land and sea and in air), law enforcement personnel, federal and state wildlife officials, and protesters (on land and sea) all seeking to achieve a certain objective. Such activities will contribute to the harassment of wildlife in the Project Area above and beyond the baseline disturbance from recreational boaters/anglers, commercial shipping, and private and commercial air traffic.

Instead of seriously considering this threat, NMFS compares it to a normal level of recreational angler trips, to suggest that the impacts would be similar. This is nonsense. While most humans using the Project Area may have no intention of disrupting or harassing other wildlife, including protected species, such impacts are inevitable. For seals that are hauled out on a beach, for nesting birds, or for other species engaged in daily behaviors (e.g., feeding, breeding, resting), the impacts of a hunt could be deadly, sub-lethal or, at a minimum, disruptive.

The scientific literature is replete with studies on the adverse impact of stress on birds, terrestrial and aquatic mammals, fish, and reptiles (e.g., Kuczaj 2007; Attachment 5). The potential for sub-lethal stress to adversely impact a host of species in or near the Project Area has not been even remotely evaluated by NMFS. Its attempt to evaluate the potential effects of stress on gray whales was similarly deficient as it largely disregarded such an impact claiming that stress-related symptoms triggered by pursuit have not been documented in gray whales. DEIS at 3-166. More than likely, such symptoms have not been documented because no one has specifically studied stress in gray whales.

Even if an animal does not flee from a threat, this does not mean it is not undergoing significant stress. In terrestrial mammals, for example, even if animals become habituated to particular perturbations in their environment, they may still experience elevated chronic stress levels, which can translate into reduced survival, a decline in productivity, or increased susceptibility to disease (Martin et al. 2011) NMFS must reconsider its analysis of such impacts to other marine species (i.e., mammals, fish, reptiles, and birds) and, in particular, focus on the potential impacts and implications of the hunt causing acute stress or contributing to chronic stress in these species.

As previously explained, NMFS has failed to explain the ESA consultation requirements or to provide any information about that process for federally listed threatened and endangered species in the Project Area. The DEIS does not describe whether NMFS has engaged or is engaging in the required internal and external reviews. While WNP gray whales are likely the most critically endangered species within the Project Area that could be impacted by a proposed hunt, there are several other endangered or threatened marine mammals, sea turtles, birds, and fish that may be affected by the proposed hunt and related activities. NMFS completely failed to even disclose that there are a number of federally protected fish, including salmon, in the Project Area that could be indirectly impacted by a hunt.

In general, for imperiled species within the Project Area, NMFS discounts potential impacts due largely to the rarity of the species. That is, it assumes that if a species is rare in the region the impacts of the proposed hunt will be limited. However, it is this rarity that should be of considerable concern and must merit additional analysis since, if there were an impact, its consequences would be more significant from a conservation standpoint on a rare species than on a species that is common. Recently, in *Conservation Council for Hawaii v. NMFS* (2015 WL 1499589 at *50 (D. Hawaii Mar. 31, 2015)(Attachment 6), the court criticized NMFS for dismissing potential adverse impact caused by training and testing activities of the US Navy conducted in its Hawaii-Southern California Training and Testing Study areas on imperiled species. Specifically, in regard to WNP gray whales, the court wrote:

> For Western North Pacific gray whales, NMFS says it does “not expect any western North Pacific gray whales to be involved in a ship strike event” because of “the low number of western North Pacific gray whales in the HSTT Study Area.” ECF No. 67-19, PageID # 12641. But if Western North Pacific gray whales are so scarce in the area, why does NMFS proceed to authorize mortalities for that species and on what basis does NMFS conclude that those mortalities in an area where the species is low in number “would not appreciably reduce the Western North Pacific gray whales’ likelihood of surviving and recovering in the wild”?

This same concept is applicable here in that the rarity of a species should not be used to disregard the potential adverse implications of an impact and, indeed, if anything, such impacts should be subject to more careful review when they could affect imperiled species.

For ESA-listed bird species (i.e., the short-tailed albatross and marbled murrelet), as well as the bald eagle (which is protected under the Migratory Bird Treaty Act and Bald and Golden Eagle Protection Act), NMFS again discounts the potential impact of a hunt (claiming that the risk of potential disturbance to albatross and murrelet is "extremely low" to "low," respectively, while indicating that it is unlikely that any whale hunt activities would occur close to bald eagle nests). DEIS at 4-127, 4-128. NMFS, however, failed to disclose sufficient information about these species to permit any assessment of these claims. For example, for the albatross it failed to disclose information about estimated population numbers, trends, likelihood of the species' presence in the project area, distribution and movement data, nor did it discuss the threats to the species. For the murrelet, the analysis was somewhat more robust, but much of the same information was lacking for that species. Failing to disclose such information violates NEPA.

NMFS concedes that the ESA-listed species that have the highest likelihood to encounter hunt-related activities include killer whales and humpback whales. Southern Resident killer whales (J, K, and L pods) are listed as endangered under the ESA. NMFS reports that, when this stock of killer whales was listed, the listing factors included noise and disturbance of vessel traffic. DEIS at 4-124. It also concedes that "disturbance from vessels, aircraft, and weapons associated with whale hunting also has the potential to disrupt the ability of killer whales to communicate or find prey." DEIS at 4-124/4-125. With only 80 Southern Resident killer whales remaining, NMFS is rather cavalier in its dismissal of the potential impacts of a whale hunt on this stock or its critical habitat (i.e., "none of the proposed alternatives would appreciably affect these elements[35] of critical habitat for this species" DEIS at 4-125). A far more detailed analysis of the impacts of any potential hunt on this population must be conducted in the context of NEPA and pursuant to the consultation requirements of the ESA.

For non-listed marine birds, NMFS makes conclusions for which there is no supporting evidence, does not provide a conclusion as to the potential impact of the hunt, dismisses potential impacts as "temporary and localized," DEIS at 4-130, or indicates that long-term effects on local populations "cannot be determined with certainty." DEIS at 4-144. For marine birds inhabiting beaches, bays, and estuaries, NMFS concedes that gunfire and helicopter noise "is particularly likely to flush birds off nests if it occurs close to shore where these birds are

[35] As stated in the DEIS, the elements referred to here are the primary constituent elements for the Southern Resident killer whale critical habitat. They include 1) water quality to support growth and development; 2) prey species of sufficient quantity, quality, and availability to support individual growth, reproduction, and development as well as overall population growth; and 3) passage conditions to allow for migration, resting, and foraging XXXX or critical habitat for this species. DEIS at 4-125

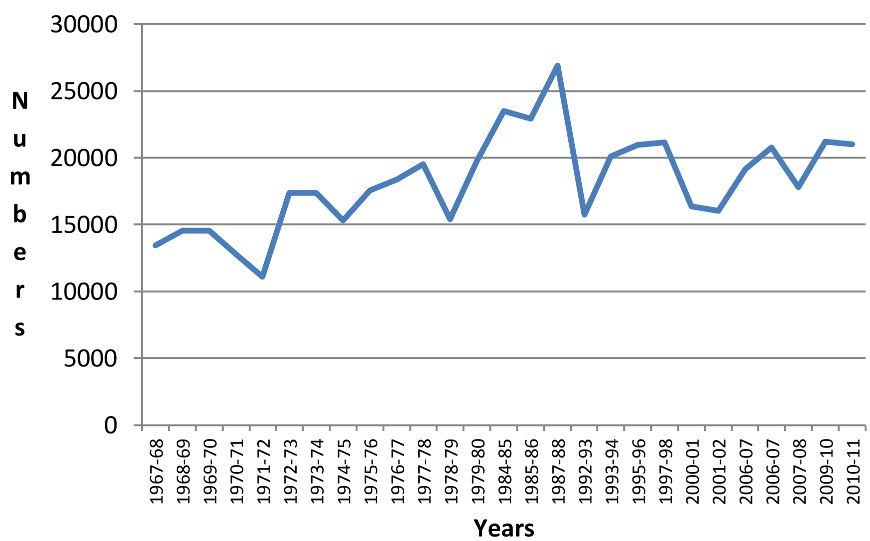
nesting or if they are foraging just off shore" but then concludes that it is "difficult to determine what impact this type of direct short-term effect would have on the long-term productivity of populations as a whole, although it might be a negligible loss." DEIS at 4-130. Or it claims such long-term effects "cannot be determined with certainty." DEIS at 4-139. Assuming that an impact "might be negligible" without providing evidence to support such a finding is reckless and may reflect an effort to discount some impacts of the proposed hunt. Similarly, for birds inhabiting coastal headlands and islands, despite concluding that "ledge nesting birds in the project area may be easily flushed off nest sites, leading to abandonment, predation on eggs or chicks, and subsequent nest failure," NMFS fails to make a determination as to the impact of the hunt on this assemblage of birds. *Id*.

NMFS has failed to fully disclose all relevant information about gray whales and has downplayed potential adverse impacts on the species posed by a Makah hunt:

Gray whale population trends and carrying capacity

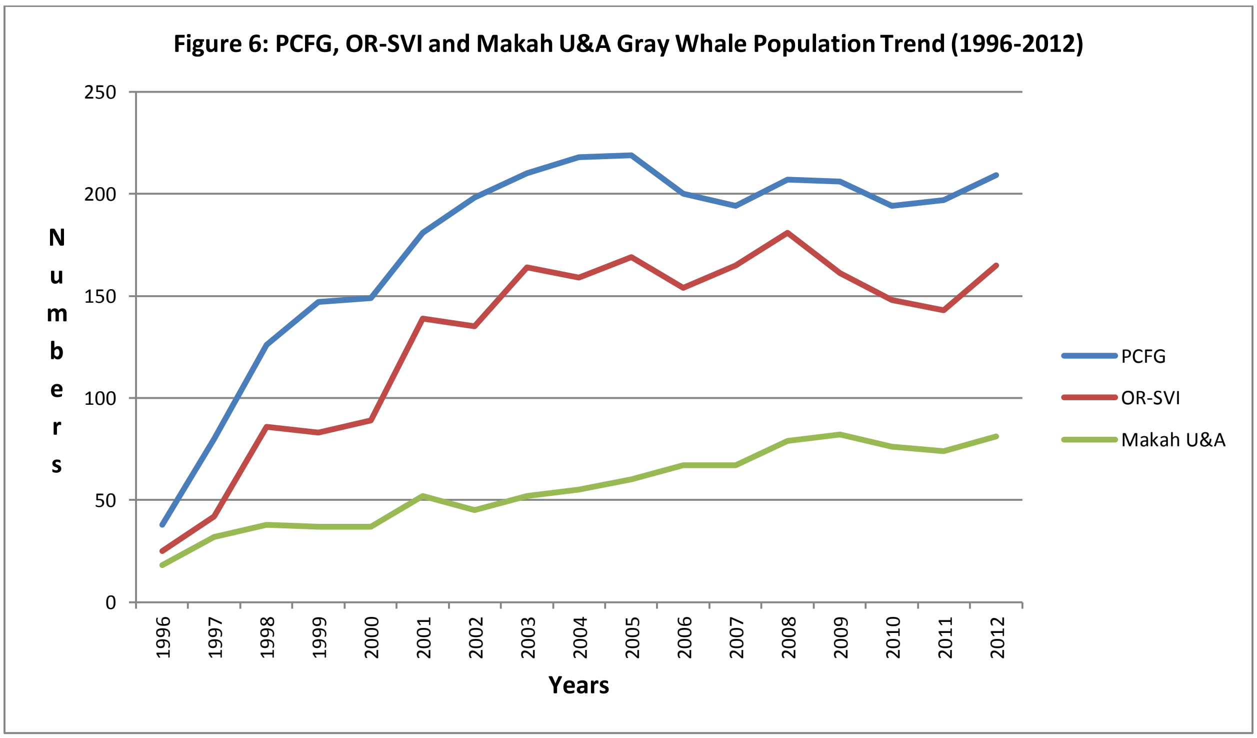
As reported in the DEIS, the estimated average annual rate of population increase for WNP gray whales is 3.3 percent per annum. DEIS at 3-67 (citing Cooke et al. 2013). The ENP gray whale population trajectory has remained relatively flat since 1980. DEIS at 3-110 (See Figure 5[36]). This suggests that the ENP gray whale population is at carrying capacity (or K), that births largely equal deaths, or there are other factors, natural or anthropogenic, that are preventing the ENP gray whale population from increasing its numbers.

Figure 5: ENP Gray Whale Population Trend (1967-2011)



[36] Data obtained from DEIS at 3-111.

Similarly, NMFS reports that the PCFG abundance trend appears to be flat at the current rate of recruitment. DEIS at 4-84, 4-100 (See Figure 6[37]). Noting that Punt (2015) found that PCFG whales are at 50 percent of K, the long-term stability of this population should be cause for concern, since the population should be increasing in size toward the region's carrying capacity. It is not entirely clear why the PCFG population's numbers have stabilized but, since they are only at 50 percent of K, permitting their lethal take by authorizing a Makah whale hunt is not appropriate. If Punt's estimate of K for the PCFG is correct, then it would qualify for a depleted designation if it were designated as a stock, which would prohibit NMFS from authorizing lethal take through a Makah whale hunt.



In regard to carrying capacity, NMFS reports that it interprets K as the "current" capacity versus the habitat's historic capacity. DEIS at 3-52. To substantiate that claim, NMFS cites from Gerodette and DeMaster (1990) who, in contrast to the NMFS claim, report that:

> in the context of OSP determination and as used in this paper, carrying capacity refers to an equilibrium population level before impact by man, either direct (through harvest or

[37] Data obtained from DEIS at 3-145/3-146.

> incidental killing) or indirect (through habitat degradation or harvest of predator, prey, or competitor species).

Id.

This quoted text contradicts the NMFS claim above. NMFS must clarify this issue and provide additional analysis of its recent practice in the use of current or historical K when, for example, making depleted designations for species or stocks.

Lack of disclosure of critical information and deficient analysis of impacts

The Project Area is confined primarily to the marine waters, islands, and land area near the Makah Tribe's U&A in the Pacific Ocean and Strait of Juan de Fuca that may be directly or indirectly affected by one or more of the project alternatives. DEIS at 1-3. In terms of any direct impacts of the hunt, this Project Area may be sufficient. However, as to indirect effects, the scope of the DEIS should have been extended to the entire range of ENP gray whales, as was done for the cumulative impacts analysis. In particular, with respect to the disclosure of information relevant to the analysis, NMFS should have provided more information about gray whales and their habitat throughout this larger area.

NMFS has disclosed some information about gray whales and their habitat in Alaska and elsewhere along the migratory corridor. The DEIS includes information about killer whale predation on gray whales, amphipod availability on gray whale feeding grounds in the Arctic, and briefly references the ecological regime shift that is ongoing in the Bering Sea. While some of this information is relevant to the cumulative impacts analysis, ENP gray whales would be killed in the proposed hunt. Therefore, given changing habitat conditions (particularly in the Arctic), there is a compelling need to disclose additional information about the ecology, prey species, distribution, movements, and habitat use patterns for gray whales in the Arctic.

Ocean warming caused by climate change is altering gray whale distribution, causing them to expand their summer range in order to find new feeding areas. DEIS at 3-196. This is due to changes in prey abundance, composition, productivity, and distribution. Indeed, the Arctic is experiencing a regime shift whereby a benthic ecosystem is transitioning into a pelagic ecosystem, as Arctic waters warm due to climate change (Grebmeier et al. 2006). In the past, a large proportion of the zooplankton and phytoplankton, including under ice algae, would die and settle to the ocean floor where it would sustain an enormous benthic community, including energy-rich amphipods. As the oceans have warmed, the zooplankton and phytoplankton blooms are occurring earlier and much of their production is being consumed by pelagic fish that have immigrated into the area. Without as much primary production settling to the ocean bottom, the abundance, density, and composition of the benthic invertebrate community has declined. DEIS at 3-99, 3-197.

This is consistent with findings by Highsmith and Coyle (1992), Grebmeier et al. (2006), and others who have studied the implications of this regime shift. In the Chirikov Basin, amphipod populations declined 30 percent between 1986 and 1988, DEIS at 3-99 (citing Highsmith and Coyle 1992, Sirenko and Koltun 1992), which, over time, forced gray whales to find alternative feeding areas. DEIS at 3-99. As a result, gray whale numbers in the Chirikov Basin were 3 to 17 times lower in 2002 compared to numbers observed in the 1980s. *Id*. (citing Moore et al. 2003, Grebmeier et al. 2006). Gray whales are now observed in areas that were historically devoid of the species or where the species was rare, including in the south-central Chukchi Sea, just north of St. Lawrence Island in the Bering Sea, and in the Beaufort Sea. *Id*. This, along with the reduction in sea ice, has contributed to a one-week delay in the timing of the southbound migration, DEIS at 3-100, resulting in a larger proportion of gray whales giving birth along the migratory route outside of the protective confines of the Mexican lagoons. This, in turn, has increased the risks to newborn gray whale calves as a consequence of predation, increased energy use for thermoregulation, and other threats (e.g., ship strikes, exposure to pollution, oil spills and seepage) that are more prominent along the west coast of the United States compared to those faced in or near the Mexican lagoons.

While some have suggested that gray whales, as generalist feeders, may adapt well to climate change impacts to their Arctic feeding areas, this may not be true. At present it is, at best, difficult to accurately predict what impact the changing Arctic will have on gray whales. Some of the information that would be needed – which is the evidence that should have been disclosed in the DEIS – includes data on the:

1) abundance, composition, diversity, and productivity of amphipods throughout the Arctic including in the Chukchi and Beaufort Seas;

2) the availability of pelagic prey for gray whales both in currently occupied Arctic feeding areas but also throughout Arctic waters given their expanding range;

3) the caloric content and energy value of potential gray whale prey in the Arctic;

4) ocean substrate survey data to determine potential future feeding areas for the species (particularly in regard to amphipod availability, given their preference for particular substrate types);

5) species-specific data on fish that are increasing in density in Arctic waters, including their preferred prey, to assess if gray whales will be competing with such fish for pelagic prey; and,

6) an assessment of any new potential health threats to gray whale in the form of exotic or invasive species, including viruses, bacteria, parasites, and natural toxins (e.g., saritoxin, domoic acid) that may be more prevalent or have greater pathogenicity as Arctic waters warm.

In addition, NMFS must disclose if there is any evidence of radionuclide contamination in Arctic waters linked to the Fukushima nuclear reactor meltdown in Japan in 2011. Only with such information can there be any meaningful analysis of the long-term survival potential of ENP gray whales.

Whether such evidence applies primarily to the analysis of indirect or cumulative impacts (which is addressed below), it should have been disclosed in the affected environment section of the DEIS so that interested stakeholders could consider and evaluate it in light of the full suite of potential impacts of the hunt.

NMFS also addresses the impact of PCFG whales within the ecosystems they occupy. This is a critically important issue, as it is directly relevant to the MMPA requirement to ensure that marine mammals remain a significant functioning element in the ecosystem. While ENP gray whales may transit the Project Area relatively quickly during their south or northbound migrations, there is also evidence that some ENP gray whales may linger within the range of the PCFG, including in the OR-SVI and Makah U&A, primarily to feed. While these whales will have an effect on the ecosystem while present in the area, PCFG whales have a far greater impact given their presence throughout the spring, summer, and fall. While present, PCFG whales can have substantial impact on the pelagic and benthic environments, which, in turn, can benefit other species.

Instead of acknowledging such potential effects, NMFS reports that "none of the action alternatives has the potential to appreciably affect the physical features and dynamic processes of the pelagic or benthic environments." DEIS at 4-51, 4-54. NMFS claims that these environments are subject to far greater impacts from larger scale oceanographic processes. The Coalition does not dispute that there are larger scale processes, including ocean currents, upwelling, oscillation events, and other factors that influence the pelagic and benthic ecology of the project area, but NMFS is evaluating the impacts at too large a scale and in doing so has wrongly dismissed the potential impact of a hunt on the role of gray whales in influencing pelagic and benthic ecology in the Project Area.

Gray whales are important to the ecological structure of the Bering Sea. Though they can consume pelagic prey, as primarily bottom feeders they suck up mouthfuls of sediment, which is then resuspended in the water column (Grebmeier and Harrison 1992, Oliver and Stattery 1985). In the early 1980s when the gray whale population contained approximately 16,000 individuals, it was estimated that they resuspended approximately 1.2 x 10^8 m^3 of sediment during a summer feeding season (Johnson and Nelson 1984, Nerini 1984). Resuspended sediments include various nutrients, microorganisms, invertebrate species that provide benefits to ocean ecology, as well as food to other species, including seabirds (Obst and Hunt 1990). PCFG whales provide the same ecosystem service in their range and, thereby, provide important benefits to the structure and function of the ecosystem, as well as to other species in the area. Dismissing such impacts, as NMFS has done in the DEIS, is wrong.

Indeed, if the hunt results in a reduction in gray whales in the Project Area, given the influence of gray whales on benthic ecology, this loss could at least result in an appreciable effect on ecology of the Makah U&A and OR-SVI. In addition, since gray whales, as generalist feeders, also consume pelagic prey, their impact on the structure and function of the pelagic ecosystem could also be higher than considered by NMFS. Quantifying this impact, however, is not possible given the lack of any specific data on benthic and pelagic species, their abundance, composition, productivity, and distribution within the project area. NMFS needs to disclose such information in the DEIS.

<u>NMFS has failed to adequately evaluate the economic impacts of the proposed whale hunt:</u>

As an initial matter, the description of the economic environment in the affected environment section of the DEIS is confusing. The variable use of numbers in some cases and percentages in others creates a data set that is difficult to interpret. NMFS should, at a minimum, review this section with the intent to clarify the statistics by, for example, consistently using numerical followed by percentage values in parentheses. For example, where the DEIS reports that "the per capita income of Makah Reservation tribal members is lower than per capita income countywide, registering 54 percent of the countywide level in 2010," DEIS at 3-281, it should insert a numerical value before the "54 percent" reference. By doing so, NMFS could then confirm that all of the data contained in any of the economic tables contained in the DEIS are accurate.

In addition, NMFS should compare the economic values contained in the DEIS on pages 3-246 to 3-269 with the data contained in the environmental justice section of the DEIS on pages 3-270 to 3-281 to ensure that they are consistent. Such a comparison would be unnecessary if NMFS removes the Environmental Justice text from the DEIS as recommended below.

The Coalition has no reason to question the accuracy of the economic data presented in the DEIS, although it is concerned that, as presented, the data used may not be consistent throughout the document. We note, however, that the overall economic impact analysis is incomplete.

NMFS's evaluation of the impacts to economics is based on the following economic variables: potential change in revenue, employment and/or economic value associated with tourist-related business activity; change in household consumption of whale products and manufacture and sale of traditional handicrafts; and economic impacts to the whale-watching industry, commercial shipping, and sport and commercial fishing, and hunt-related management and law enforcement. DEIS at 4-148. Based on an analysis of the information contained in the DEIS, there are a number of questions and concerns that NMFS must address.

Prior to articulating those concerns, there are several key statements or conclusions in the DEIS that are relevant to the analysis and must be noted and discussed. These include:

- The Makah Tribal Council financially supported the whaling crews in 1999 and 2000, but in 2002 the Council decided to end financial support for whale hunts, leaving it up to the whaling families to financially support any hunts consistent with tribal traditions. DEIS at 3-283, 4-147. Because of this, the economic impact analysis in the DEIS does not include an assessment of the economic burden on Makah tribal members or households that may choose to engage in whaling. The Coalition supports this decision and notes that, should the Makah Tribal Council elect to financially support tribal whalers in the future, NMFS must reevaluate the economic impacts of the hunt, since funds expended on whaling could not be spent on meeting other needs of the Makah people on the reservation. Moreover, if the Makah Tribe seeks federal funds (i.e., taxpayer money) for the purpose of subsidizing whaling from NMFS or any other agency, this too should trigger at least a supplemental Environmental Assessment under NEPA.
- The potential for any changes on the reservation under any of the alternatives to have a noticeable effect on economic conditions in Clallam County is negligible, because economic contributions by the Makah reservation to the countywide economy are so small. DEIS at 4-147. Given this conclusion it also would hold that the economic impacts of the No Action Alternative would also be negligible in the context of the economic conditions in Clallam County.
- There are no economic data demonstrating any positive economic impact from the influx of visitors during previous hunt-related events as a result of an increase in the number of rooms rented or in other economic activities in the region. DEIS at 4-149. This is notable since, as indicated below, NMFS ignores this point when evaluating the alternative-specific economic impacts. Nor has NMFS disclosed any economic data to suggest that there was any positive economic impact for Clallam County or the Makah reservation subsequent to the hunt because of the media attention focused on the Makah Tribe.
- Figures are not available for the amount of revenue generated by reservation tourism and recreation or the number of jobs and amount of personal income that depend on

visitor spending. DEIS at 4-148. This statement is at least partially false, given that the DEIS did include statistics in regard to the number of persons purchasing permits to recreate on the reservation, including to use the Cape Flattery trail, and the number of non-tribal members visiting the Makah Cultural and Research Center. It is also inconceivable that additional tourism data are not available. Surely the Makah or NMFS (or its environmental consulting firm Parametrix) could have surveyed any inns, hotels, motels, lodges, tourist cabin owners, or other tourism-linked companies on the reservation to obtain data on the nightly room rentals and/or other tourist expenditures. Similarly, considering that the Makah have attempted to improve the marketing of Neah Bay as a tourist destination through Washington State and through the Affiliated Tribes of Northwest Indians, DEIS at 4-419, the Makah Tribal government must have data that documents what impact, if any, such marketing efforts have had on tourist visits to the reservation. Since NMFS has not satisfied the requirements of NEPA in regard to incomplete or unavailable information in this case, it must secure this information and use it in a revised analysis.

- There is no evidence that calls for boycotts of Olympic Peninsula tourism as a result of the 1999 hunt had any negative economic impact on tourist businesses in the area. DEIS at 4-150. While this may be true, using this to predict the future is naïve. During the 1999 and 2000 hunts, it was known that litigation was being pursued that could stop the hunt. Consequently, although some advocated a tourism boycott of the Olympic Peninsula, others elected to determine the outcome of the judicial process instead of immediately supporting a boycott. If, as a result of this decision-making process, an MMPA waiver is granted and legal efforts to stop the hunt are not successful, there may be a renewed and more vigorous effort to promote a tourism boycott that could have adverse economic impacts on the Makah reservation and other businesses on the Olympic Peninsula.
- No revenue would be made from the sale of whale meat but such products would meet the nutritional needs of Makah families. DEIS at 4-150. NMFS also claims that "attaching a dollar value to food products from harvested whales is difficult," *id*., but that whale products could "potentially replace foods that families would otherwise have to purchase." *Id*. This statement is not entirely accurate since, as explained below, an estimate can be obtained as to the value of the reported 8-20 pounds of whale meat per capita and 16 to 20 pounds of oil or blubber per capita based on similar, currently available food products. With that estimate, the alleged economic benefit to Makah families if the whale hunt were to be allowed can be quantified.
- The Makah Tribe has a long tradition of manufacturing carvings, baskets, and other items for sale to collectors and tourists. Tribal artisans also produce carvings, jewelry, and silk screen designs for sale in local shops and regional galleries. DEIS at 4-151. Despite this claim, NMFS provides no data in the DEIS on the annual revenue generated

by the sale of these products. As explained below, this is relevant to the environmental impact analysis when NMFS asserts that whaling will increase revenue for tribal artisans because it will allow them to manufacture and sell native handicrafts from whale bone, baleen, and other non-edible parts of the whale. In addition, NMFS needs to provide some data on the value of native authentic handicrafts manufactured from whale products. Such data may be available from Native Alaskan artists who utilize non-edible products from the bowhead whale hunt to manufacture authentic handicrafts. Quantifying this potential effect requires understanding the current value of Makah authentic native art/handicraft sales and of the potential revenue that could be gained by selling native handicrafts manufactured from whale products.

- Information on the current number of whale-watching expenditures, passengers, revenues, and employment numbers in the Washington/British Columbia areas is "not available." DEIS at 4-152. In addition, NMFS claims that "current revenues of whale-watching operations are unknown, and there is no information available or that could reasonably be obtained that would allow an estimation of how much whale watching revenues might decrease if gray whale behavior or numbers were altered by a Makah hunt." DEIS at 4-154. Despite admitting to not having such data, NMFS reports that it is "unlikely that whale hunting under any of the action alternatives would have more than a negligible effect on whale-watching revenues or employment within or outside the Project Area." DEIS at 4-152. It is inconceivable that the whale-watching data reported above were not reasonably attainable. It could be that neither NMFS nor Parametrix (the consulting firm paid by NMFS to prepare the DEIS) endeavored to obtain the data but, surely, had NMFS contacted whale watching companies, they likely could have provided requested revenue, expenditure, passenger, and employment numbers. NMFS has not complied with the NEPA requirements in regard to incomplete or unavailable information, so since this information is reasonably available, NMFS must obtain it and use it in a revised analysis. It is also reasonable to conclude that tourists may not wish to watch whales they believe might be killed in a Makah hunt, which would result in a decrease in whale-watching bookings in the region and indeed throughout the North American Pacific coast. Claiming this likelihood is negligible because the Chukotkan hunt does not have a similar effect is disingenuous, given the attention the Makah hunt has received in the past by US media, compared to the relative lack of attention US media pay the Chukotkan hunt. Further, the remoteness of the Chukotkan hunts makes whale watching there currently almost impossible and therefore not a good comparison. Therefore, the conclusion in the DEIS that a hunt would have a negligible impact on whale-watching revenues is not necessarily true.
- Costs associated with any proposed hunt would include approximately $75,000 per year to continue a photo-identification study of PCFG gray whales, $263 per day to cover the costs of NMFS observers, and $91,670 per day for law enforcement costs, with the bulk

of the costs borne by the United States Coast Guard to cover the costs of its aircraft and vessels. DEIS at 4-155/4-156.

In evaluating the impacts of each action alternative, NMFS dismisses any potential impact on whale-watching operations as a result of a change in behavior of gray whales in response to vessels. This is based on the Chukotkan gray whale hunt in Russia, which has been ongoing, largely without any stoppage, for centuries. NMFS claims that the hunt "has not translated into a general avoidance of boats by gray whales." DEIS at 4-153. This is a rather simplistic analysis of the potential impact of a hunt in the Washington region on gray whale behavior. First, NMFS has not disclosed sufficient information in the DEIS to permit a credible assessment of the impact of a Chukotkan hunt on gray whales. While the Russians continue to kill approximately 123 gray whales per year, DEIS at 3-162, NMFS has not provided any information about catch-per-unit-effort, any change in gray whale distribution within their Russian feeding grounds, any change in the temporal use of near shore habitats, or any change in their behavior on those feeding grounds in response to vessels (i.e., are they more alert or more likely to flee compared to gray whales using feeding grounds within the Arctic waters of the United States where they are protected).

Although matrilineal site fidelity may be the dominant factor drawing gray whales into Russian feeding grounds where they are subject to hunting, it would not be surprising if there have been some changes, even if only subtle, in gray whale behavior within the Russian feeding grounds. For example, it is well known that white-tailed deer can learn where and when they are safe from hunters and where and when they are not. This allows deer to utilize forage resources by night in areas open to hunting during the day, only to return to more protected areas during the day. If white-tailed deer have this capacity, it is likely gray whales do as well. In other words, gray whales may recognize, after decades of near complete protection in Mexico, along the west coast of the US and Canada, and in US Arctic waters that they are safe from hunting, while those who occupy Russian waters may demonstrate different behaviors intended to minimize their risk of lethal take while in that area. NMFS must explore this issue in more detail before making such overreaching comments about the potential impact, or lack thereof, of any hunt on gray whale behavior.

NMFS also must consider how a hunt by the Makah Tribe, which would include harassment of gray whales through pursuit, unsuccessful harpoon attempts, and potential injury to gray whales due to non-lethal strikes of a harpoon or bullet, might impact the behavior of gray whales in the larger eastern Pacific region. The impact of the proposed hunt on gray whale behavior is not addressed in the DEIS. Similarly, NMFS entirely ignores the possibility that a Makah hunt could influence the popularity of gray whale watching along the entire Pacific coast of North America, including the unique experience of interacting with gray whales and their calves in the lagoons in Mexico.. It is possible that people interested in undertaking a gray whale watching excursion may choose to skip such a trip if they are aware that the whales they would observe could be killed in a hunt in US waters. At a minimum, the enjoyment of watching gray whales would likely be diminished if tourists were aware of the potential danger posed by Makah whalers.

In evaluating each action alternative, NMFS suggests each is likely to increase tourism to the Makah reservation. DEIS at 4-158, 4-162, 4-164, 4-168. This assumes that non-tribal members have an interest in watching the killing or butchering of a whale or that media attention to the hunt will increase tourism to the reservation. This claim completely ignores evidence from the 1999 hunt, as contained in the DEIS, that the Seattle Times reported that of the 400 calls it received after the 1999 hunt ran 10 to 1 against the hunt (DEIS at 3-286) and that more residents of Clallam County expressed disapproval of the hunt than expressed support. *Id*. at 3-288. If anything, given that most US citizens are opposed to whaling, including aboriginal whaling when the tribe does not have a legitimate need for whales, it is more likely the action alternatives will result in a reduction in tourism to the Makah reservation.

Similarly, for each action alternative, NMFS claims there will be a negligible change in whale-watching revenue. DEIS at 4-159, 4-162, 4-167, 4-168. This conclusion is curious considering NMFS claims data on whale-watching operation revenues was not reasonably available.

NMFS also claims, for each of the action alternatives, that the increase in the availability of whale meat/blubber/oil for consumption and non-edible whale products for use by artisans will provide an economic value for members of the Makah Tribe. DEIS at 4-160, 4-163, 4-166, 4-168. For the non-edible products, without data on current sales of Makah artisan products and some assessment of the value of products manufactured from whale baleen or bone, the alleged impact of a whale hunt on artisan revenues cannot be quantified.

For edible products, NMFS should have provided an estimate of the value of such products so as to quantify the potential savings to Makah tribal households. For example, the June 2015 price for uncooked beef steak in the western US is $7.67 per pound,[38] while olive oil (which, for this analysis is being used to represent whale blubber/oil; olive oil is often used to flavor foods as the Makah traditionally used whale oil) costs approximately $5.46 for 25.5 ounces[39] or $27.40 per gallon (which corresponds to $3.28 per pound). Using these figures, the estimated 8 to 20 pounds of whale meat would correspond to a value of $61.36 to $153.40, while the 16 to 20 pounds of blubber/oil would correspond to a value of $52.48 to $68.52. Combined, the value of the meat and blubber/oil would be $113.84 to $221.92. Depending on the household or family income of the Makah families that choose to consume whale products, the savings accrued by consuming these products may or may not be significant to a family/household

[38] See http://www.economagic.com/em-cgi/data.exe/blsap/APU0400FC3101
[39] http://www.walmart.com/ip/Great-Value-100-Extra-Virgin-Olive-Oil-25.5-oz/10316039

annual budget. This assumes any savings accrued from the consumption of whale products will not be spent on other food items.

In regard to the potential impacts of a hunt on law enforcement/management costs, Table 4-14 in the DEIS provides a summary of the estimated enforcement-related costs (including the costs for NMFS observers) of each alternative. These costs would range from a maximum of $5.6million per year under Alternatives 2, 3, and 6 to a minimum of approximately $717,000 per year under Alternative 4. As indicated previously, the majority of these costs will be borne by the United States Coast Guard, yet NMFS provides no discussion of whether the Coast Guard has the funds to cover this cost, if Congress would allocate funds for the Coast Guard to cover such costs, or how Coast Guard funding for these costs could impact other Coast Guard operations in the Washington area, including search and rescue, homeland security patrols, and any drug interdiction efforts. While admittedly the Makah hunt, if allowed, will not occur in the immediate future, given federal budgetary realities there must be some discussion of whether the funds needed to pay for a hunt are or would be available and if they would impact other Coast Guard operational programs. Similarly, since funds allocated by the Coast Guard and NMFS to a potential hunt are collected from taxpayers, if a waiver is granted then NMFS is effectively subsidizing with taxpayer dollars a hunt the public may strongly oppose. This impact to the taxpayer was not evaluated in the DEIS.

There are other gaps in the economic impact analysis that must be addressed. First, NMFS has not disclosed any information about the total amount of federal funds expended since the mid-1990s in an effort to facilitate the Makah's resumption of whaling. This would include, but not be limited to, costs for NEPA compliance, consultations with the Makah and other agencies, fees paid to consultants, legal costs, costs associated with scientific research relevant to the proposed hunt, and costs incurred in obtaining past ASW gray whales quotas from the IWC. This is directly relevant to any analysis of economic impacts of a Makah hunt, as it would provide interested stakeholders with additional information about the true costs of the Makah's whale hunting proposal.

Finally, NMFS completely fails to include any information about the economic value of gray whales. This is not uncommon, as most agencies, when evaluating the environmental impacts of an action that will affect a species, fail to recognize that the species has worth beyond its value, economic or otherwise, to humans (i.e., for hunting, fishing, or wildlife watching/tourism). This value extends well beyond the value to a whale watching company, to include the ecological value of gray whales (i.e., the value gray whales provide as part of an ecosystem, including as prey, predator, and how their behaviors may affect other marine species and the marine environment) and their intrinsic or existence values.

Calculating such intrinsic values can be done using an economic tool known as contingent valuation (CV). CV has historically been used by the Department of the Interior and the Department of Commerce, including NMFS, to assess the intrinsic value of natural resources lost as a result of an oil spill. Indeed, federal law requires that such intrinsic values be assessed in order to calculate the amount of damage caused to the environment. This damage calculation is used to assess penalties against those responsible for the damage. The CV concept, however, is equally applicable in this context and could – and should – be used to assess the intrinsic or existence value of a gray whale, in order for the cost of losing a whale due to a Makah hunt to be considered in the economic analysis. The CV process utilizes surveys to determine, in this case, the value local residents, regional residents, and citizens nationally apply to gray whales. The purpose of the analysis is to collect value data both from those who may observe gray whales in the wild and from those who have never seen, and may never see, a gray whale in the wild.

The Department of Commerce is well aware of CV as its National Oceanic and Atmospheric Administration empaneled a number of distinguished social scientists in the early 1990s to determine if CV "is capable of providing reliable information about lost existence or other passive-use values."[40] The report provided support for the use of CV to calculate such existence or passive-use values and included a series of recommendations to direct such assessments. NMFS must engage in this type of analysis using the CV methodology (or something similar), so that it can obtain data on the intrinsic value of gray whales to include in a revised analysis.

NMFS has improperly applied the environmental justice concept to the proposed Makah whale hunt:

NMFS has grossly misapplied the environmental justice requirements contained in Executive Order (EO) 12898 in the DEIS (59 Federal Register 7629, February 16, 1994). This EO mandates that "… each Federal agency shall make achieving environmental justice part of its mission by identifying and addressing, as appropriate, disproportionately high and adverse human health or environmental effects of its programs, policies, and activities on minority populations and low-income populations in the United States …" DEIS at 4-173, EO 12898 at 1-101.

Traditionally, this concept has been applied to, for example, the impact of constructing a road, refinery, waste storage facility, or feedlot in areas where the majority of the population is minority or low income. The idea is to ensure such populations are not disproportionately

[40] See Arrow, K., R. Solow, P.R. Portney, E.E. Leamer, R. Radner, and H. Schuman. Report of the NOAA Panel on Contingent Valuation. January 11, 1993 (available at http://www.economia.unimib.it/DATA/moduli/7_6067/materiale/noaa%20report.pdf).

impacted or unduly burdened by such a project compared to other human populations (i.e., non-minority and middle/upper income).

Here, however, NMFS is attempting to evaluate the environmental justice implications of allowing or not allowing a minority group, the Makah Tribe, to engage in whaling; an activity that the Makah have not pursued, save for once, for nearly 90 years. If the Makah Tribe was currently whaling and the government was considering prohibiting the hunt, the environmental justice implications of such an action would be relevant. Or, if the government was considering the construction of a road, military base, mine, port, or missile silo on or near the Makah reservation, environmental justice concerns would be applicable.

Attempting to apply such an analysis to an activity for which there has been such an extended period of inaction, however, is entirely inconsistent with the intent of the Executive Order. Indeed, the Coalition challenges NMFS to identify any other instance where it or any federal agency has applied the environmental justice analysis in the same manner as it has here.

An examination of EO 12898 reveals other elements that further demonstrate the inapplicability of its use in the present situation. For example, Section 2-2 states that:

> "Each Federal agency shall conduct its programs, policies, and activities that <u>substantially affect human health or the environment</u> in a manner that ensures that such programs, policies, and activities do not have the effect of excluding persons (including populations) from participation in, denying persons (including populations) the benefits of, or subjecting persons (including populations) to discrimination under, such programs, policies, and activities, because of their race, color, or national origin" (emphasis added).

Although unstated in the analysis in the DEIS, NMFS may be engaging in this analysis based on claims that depriving Makah access to whale meat, blubber, and oil is substantially affecting the health of the Tribe. As previously explained, however, this is not supported by the evidence.

Section 4-4 of the EO is specifically focused on subsistence consumption of fish and wildlife. This section mandates that federal agencies do the following:

> 4-401. Consumption patterns. In order to assist in identifying the need for ensuring protection of populations with differential patterns of subsistence consumption of fish and wildlife, Federal agencies, whenever practicable and appropriate, shall collect, maintain, and analyze information on the consumption patterns of populations who principally rely on fish and/or wildlife for subsistence. Federal agencies shall communicate to the public the risks of those consumption patterns.

> "4–402. Guidance. Federal agencies, whenever practicable and appropriate, shall work in a coordinated manner to publish guidance reflecting the latest scientific information available concerning methods for evaluating the human health risks associated with the consumption of pollutant-bearing fish or wildlife. Agencies shall consider such guidance in developing their policies and rules."

NMFS may believe these mandates permit the application of environmental justice in the case of the Makah whale hunt. If anything, based on the lack of any credible data or analysis in the DEIS on the fish and wildlife consumption patterns of Makah tribal members (i.e., what wildlife species are consumed, the quantity consumed, the contaminant profile of each consumed species), NMFS has clearly failed to comply with this section of EO 12898. Indeed, the only information contained in the DEIS regarding Makah consumption patterns of fish and wildlife includes statements about how frequently Makah families consume traditional foods, how many times per week they eat fish, how many pounds of fish they eat each year, and that they also engage in subsistence hunting of terrestrial wildlife.

NMFS also provides no information in the DEIS to suggest it has worked collaboratively with other agencies to publish guidance on methods used to evaluate the human health risks associated with the consumption of pollutant-bearing fish or wildlife or that it relied on such guidance in evaluating the environmental impacts of consuming gray whale products by the Makah. NMFS does provide data on contaminant loads in some species of fish and wildlife in the DEIS. It also refers to Washington State standards for what amount of whale blubber may be safe to consume (see DEIS at 3-373: "(e.g., an 8-ox [227 gram] meal size) yields a calculated 'allowable consumption rate' of 0.43 meals of blubber per month." It does not, however, identify any federal standards or guidelines for what is considered an acceptable or safe level of contaminants in fish and wildlife species used for subsistence purposes. Nor does it suggest that it has provided – or will provide – any guidance to the Makah in regard to its consumption of gray whale food products.

While the EO provides broad standards for all federal agencies to meet, it does not establish agency or department-specific standards for environmental justice review. Rather, Section 1-103 mandates that:

> "… each Federal agency shall develop an agency-wide environmental justice strategy, as set forth in subsections (b)–(e) of this section that identifies and addresses disproportionately high and adverse human health or environmental effects of its programs, policies, and activities on minority populations and low-income populations. The environmental justice strategy shall list programs, policies, planning and public participation processes, enforcement, and/or rulemakings related to human health or the environment that should be revised to, at a minimum: (1) promote enforcement of

> all health and environmental statutes in areas with minority populations and low-income populations; (2) ensure greater public participation; (3) improve research and data collection relating to the health of and environment of minority populations and low-income populations; and (4) identify differential patterns of consumption of natural resources among minority populations and low-income populations. In addition, the environmental justice strategy shall include, where appropriate, a timetable."

What NMFS fails to disclose in the DEIS is that the Department of Commerce (DOC) has adopted an Environmental Justice Strategy (DOC Strategy).[41] In this strategy, the DOC does specify that:

> "During National Environmental Policy Act reviews of major agency actions, <u>any potential disproportionate and adverse environmental or health effects</u> on low-income or minority populations are considered." (emphasis added) DOC Strategy at II.B.1.

Notably, this DOC language is not consistent with the EO language, which refers to a "substantial" effect on human health or the environment. Nevertheless, even without reference to a substantial effect, the impacts of the proposed whale hunt (or lack thereof) on the environment and health of the Makah people do not meet this standard and, therefore, the environmental justice analysis in the DEIS is improper. First, there would be no adverse environmental impacts if NMFS rejects the Makah Tribe's request for a waiver. Indeed, as documented in the DEIS, all of the adverse environmental impacts (differentiating environmental from cultural, social, and subsistence use impacts) would occur if NMFS allows the Makah to whale.

Moreover, as previously stated, NMFS concedes that "there is insufficient information to conclude that the lack of fresh whale products under the No-action Alternative would be expected to negatively alter current dietary conditions for any tribal member," DEIS at 4-259, so denying the waiver would have no known health effects on the Makah. If anything, as also conceded by NMFS, whale products, particularly blubber, "would likely contain higher levels of certain contaminants (e.g., PCBs) than other foods consumed by the Makah," DEIS at 4-257, suggesting that allowing a whale hunt could be adverse, not beneficial, to the health of the Makah people. The environmental justice analysis in the DEIS, however, fails to consider how allowing a whale hunt could adversely impact the health of the Makah Tribe.

In the DOC Strategy, NOAA is identified as an operating unit of the DOC that is in a position to advance environmental justice for affected populations. DOC Strategy at II.B.2.i. This is done through five overarching NOAA programs or activities; recovery of protected species, sustaining

[41] The Department of Commerce Environmental Justice Strategy is available at:
http://open.commerce.gov/sites/default/files/DOC_Environmental_Justice_Strategy.pdf

healthy coastal ecosystems, habitat protection, climate change and weather. While all of these programs or activities may be broadly relevant to the Makah (and indeed directly relevant to the conservation status of gray whales), only the recovery of protected species—gray whales—is directly relevant here. For the recovery of protected resources, the Strategy contains the following mandates:

> • NOAA will continue its current research and management activities to determine the impact of subsistence harvest on protected resources, and the impacts of other factors (e.g., commercial fishing, habitat loss, renewable energy development, oil and gas production, and pollution) on subsistence activities.
>
> • NOAA will continue to conduct research to determine the status of North Pacific marine mammals used by indigenous peoples. In addition, NOAA will continue to support the Eskimos' full participation in the International Whaling Commission and provide information in support of sustaining the bowhead whale quota allocated to subsistence use.
>
> • NOAA will also ensure that the activities it authorizes are conducted in a manner that ensures no unmitigatable adverse impacts on subsistence use of marine mammals. DOC Strategy at II.B.2.i.a.

None of these mandates specifically mention the Makah, as they do Alaska Natives. None are directly relevant to any decision by NMFS regarding the Makah Tribe's MMPA waiver application. Indeed, notably, there is no language in the DOC Strategy suggesting that NOAA will support the Makah Tribe's full participation in IWC meetings or that it will provide information to support or sustain the ASW quota for gray whales for the Makah.

Based on the foregoing evidence, NMFS has improperly included an analysis of environmental justice effects in the DEIS and it must be removed from future documents.

Regarding the analysis itself, it is, predictably, entirely one-sided. The criteria used to evaluate the environmental justice impacts were economics, ceremonial and subsistence resources, and the social environment. DEIS at 4-174. In regard to the latter criterion, NMFS concluded that "it is not possible to determine if the action alternatives would result in disproportionately high and adverse social effects on the Makah Tribe." DEIS at 4-176.

As for economic impacts, this analysis was linked to the potential effects of each alternative on tourism, with NMFS asserting, albeit inaccurately and without any supporting data, that a hunt would increase tourism to the Makah reservation. This ignores the widespread opposition to the Makah whale hunt in Clallam County and the broader region based on public outrage expressed in association with the 1999 hunt (see DEIS at 3-286, 3-288). It also ignores NMFS' own determination that there are no economic data demonstrating any positive economic impact from the previous hunt related events, DEIS at 1-149, nor has NMFS provided any evidence that there was an positive economic impact post-hunt as a result of media coverage of the event. Nevertheless, based on the NMFS claim that a hunt will increase tourism to the reservation, it concluded that the action alternatives would not have a disproportionately adverse impact on the Makah Tribe compared to the No Action Alternative.

Predictably, the NMFS analysis of the impacts of the proposed hunt on the ceremonial and subsistence criteria concludes that action alternatives would "have positive ceremonial and subsistence effects associated with a resumption of a Makah whale hunt." DEIS at 4-176. Conversely, it claims that the No Action Alternative - by preventing the preparation, hunting, butchering, sharing, consuming, dancing, singing and rituals associated with whale hunting - would result in a "disproportionate share of the adverse effects on subsistence uses, traditional knowledge and activities, spiritual connection to whale hunting, and cultural identity … upon the Makah Tribe." *Id*.

This analysis entirely ignores any consideration of the health effects of a whale hunt in the context of a review of environmental justice, although it is highlighted in EO 12898 and in the DOC Strategy. This is not to suggest that NMFS should merely add such information to the environmental justice text in any revision to the DEIS since, as recommended above, the entire section should be struck from the analysis due to non-relevance. Rather, this is noted to demonstrate that, as presented, the analysis does not even include a key element that is a focus of the EO.

<u>The DEIS contains substantial evidence to suggest the Makah Tribe does not have a subsistence or cultural need to whale or for whale products:</u>

The discussion of subsistence use in the DEIS largely focuses on the Makah Tribe's historic whaling practices and its traditional use of whale and whale products for ceremonial purposes and how these activities, if reinstated, may affect the social environment on the reservation. In other words, the analysis of the impacts of a whale hunt on subsistence use overlaps with the Tribe's desire for whaling and whale products for its traditional ceremonies, rituals, and other cultural practices. This section does not address any nutritional need for whale products, as this was evaluated separately in the DEIS. In addition, since this section of the DEIS shares a number of similarities with the analysis of environmental impacts of the proposed hunt on the social environment, these sections are analyzed together. The latter section evaluates the impact of a whale hunt on the social relationships among supporters and opponents of the proposed Makah hunt.

One critical element in evaluating subsistence and cultural need in this context is whether, in fact, the Makah Tribe has a legitimate subsistence/cultural need for whaling and whale products. Nevertheless, setting aside for the moment any discussion of whether the Makah Tribe has continued to practice its traditions associated with whaling (e.g., ceremonies, rituals, dances, songs, stories), the role of tradition in any potential future whale hunt must be addressed.

The DEIS and its appendices are replete with information about historical traditions associated with the Makah whale hunt. What is not clear is whether the Makah Tribe, if granted the authority to kill whales, will continue to practice such traditions. Considering the apparent importance of the Tribe's cultural and spiritual connection to whales, it would be expected that such traditional rituals, including frequent bathing, rubbing the body with nettles, and sexual abstinence would be continued. However, in the DEIS, the only statement regarding such practices being followed if the Makah Tribe resumes whaling is that "whaling team members may also partake in spiritual preparations." DEIS at 2-16 (emphasis added).

The Coalition is not advocating that the Makah Tribe must follow all of the past traditions. For example, in regard to the methods used to kill the whales, if whaling is allowed, the method used must, by law, cause the least suffering and cruelty (i.e., must be the most humane). The traditional methods of killing a whale with cold harpoons and floats, where the whale would sometimes linger for days before dying, are clearly no longer acceptable. To that end, if the Makah Tribe and NMFS elected to only utilize motorized vessels in order to reduce the amount of harassment inherent to a hunt and to more effectively and efficiently kill the whale (ideally utilizing an explosive grenade as the primary killing weapon), the Coalition, based on humane concerns alone, would not object. However, notwithstanding the killing methods, considering that the Makah Tribe's hunt, if allowed, represents a form of cultural ASW (since the evidence of subsistence or nutritional need is lacking), it is expected that all *cultural* traditions will be followed. Many of those traditions are described below.

While the Coalition reemphasizes its recognition of the Makah Tribe's history of whaling, the DEIS and its appendices contain considerable information suggesting the traditions the Tribe has claimed have continued during its nearly 90-year hiatus in whaling may not have been consistently practiced over the years. In this regard, the Makah Tribe has a dilemma. If it can prove, as it claims, that it has continued to engage in traditional whaling practices for the past nine decades, then this raises the question of why it needs to kill any whales to satisfy a cultural need. Alternatively, if it cannot prove that it has continually practiced such traditions, then the claims that it and the United States government have used to suggest that the Tribe can meet the "continuing traditional dependence on whaling"[42] language in the IWC's definition of ASW would simply not be true.

Admittedly, because Makah whaling has historically only been conducted by a limited number of powerful and influential families, some families may have retained and shared their whaling traditions more consistently than other families. Nevertheless, given that only a limited number of families had the qualifications, skill, and rank to engage in whaling, it is unclear if that social hierarchy will limit the number of families that can participate in any future whaling (if permitted) and whose members could serve as whaling captains. If only select families among the Makah Tribe qualify, through their ancestry, to engage in whaling, then NMFS should identify which families would have the authority to whale. This would allow the agency to gather more information from those families about their financial resources (i.e., can they afford to conduct whaling if it were allowed) and their history of sharing, both within their family and with other tribal members, of their family-specific whaling traditions (at least those traditions that are not secret). Conversely, if any member of the Makah Tribe, if he/she has the equipment and funds and regardless of ancestral connections to whale, can engage in whaling, then this raises questions about the Tribe's alleged cultural connection to whaling.

Traditionally, a Makah whaling canoe was helmed by the whaler or headman and contained seven crew members. Whalers, who provided the equipment for whaling and owned important ceremonial privileges acquired through heredity, were ranked at the top of the Makah society social pyramid. The whaler was also believed to have the ability to "interact with the natural and the supernatural to assure a successful hunt." 2002 Needs Statement at 9/10. Furthermore, given the hierarchy in Makah society (i.e., nobles, commoners, and slaves), DEIS at 3-295, positions on whaling crews "were restricted to men who could withstand the rigors of intensive ritualized training, possessed the hereditary access to the position and its ritualized knowledge, or underwent a supernatural encounter which engendered the gift of whaling ability." Makah Waiver Application at 6. The safety and success of the hunt was not limited to the crews' training, strength, or stamina, as it depended on the observance of rituals by the whaler, his crew, and their families. *Id*.

Training included "ritual bathing, praying, rubbing the skin with boughs or nettles, and imitative performance." DEIS at 3-297. Many if not all such rituals were conducted at secret locations and varied for each whaling family. Such details like the "bather's costume, the prayers, and the type of branches the whaler used were private knowledge that was passed from one generation to the next according to the rules of inheritance." *Id.*

---

[42] The Coalition believes that any claim that the Makah Tribe has continually engaged in traditional practices related to whaling does not meeting the "continuing tradition dependence on whaling and use of whales" standard to obtain an ASW quota as explained previously in this comment letter.

For the whaler's wife, tradition held that her movement during a hunt would determine the behavior of the whale. DEIS at 3-297. If she moved too much, the whale being pursued by her husband would be "equally active and difficult to spear." *Id*. Conversely, if she lay quietly, "the whale would give itself to her husband." *Id*. Lack of attention to such traditions, which included other proscribed behaviors, "could result in the capture of a whale that was not fat or large enough, or cause the harpooned whale to run out to sea instead of in toward the shore." 2002 Needs Statement at 11. For the chief whaler and his wife, the traditions required even greater sacrifice as "the whaler and his wife observe a long and exacting course of purification, which includes sexual continence and morning and evening baths at frequent interval from October until the end of the whaling season … about the end of June." *Id*. If the Makah Tribe desires to hunt whales to honor tradition, it would follow that tribal members would willingly follow such traditional practices.

Evidence of potential disruptions to the alleged sharing of whaling traditions extends back to even before the Treaty of Neah Bay was signed. According to the Makah Tribe's 2002 needs statement, in 1853, the Makah Tribe was devastated by an epidemic of smallpox. This and other diseases reduced the Tribe's population by 75 percent by 1890, resulting in the loss of much family-owned information that was therefore never passed down to younger generations. 2002 Needs Statement at 21. While this was and is a tragic period in Makah history, it is simply a fact that it caused the abrupt loss of knowledge about critical components of rituals and ceremonies. *Id*.

Considering the loss of historic knowledge during long ago epidemics and, more recently, the lengthy hiatus in whaling during which many of those alive in the 1920s passed away, and the potential lapse in transmitting traditions within a family, it is unclear how many Makah whaling families can demonstrate an unbroken link to the past. In the various Makah Tribe's needs statements submitted to the IWC, such links are assured, but beyond the words on the page, no other proof has been offered to verify such claims.

Although it is commonly reported that the Makah ceased whaling in the late 1920s, the decline of whaling as a tribal tradition extends to the mid-1800s, even before commercial whalers decimated gray whale numbers. DEIS at 3-302. At that time, as a result of contact with non-Indian traders and explorers who had come to the Pacific Northwest, whale products, particularly oil, became more of a marketable good than a subsistence need. Although the Makah had already been engaged in the trading of whale products, the new visitors to Neah Bay provided a new market for whale oil. By the late 1840s and 1850s, as the market for whale oil and dogfish oil increased, the whale oil purchased from the Makah Tribe (and presumably other Native Americans) became a major export of the Hudson Bay Company. 2002 Needs Statement at 17. By 1852, the Makah "were trading or selling some 20,000 gallons of whale oil and fish oil each year, with this amount escalating to 30,000 gallons per annum over the next two decades." *Id*. at 18. Whales had apparently become a cash commodity for the Tribe.

As whale populations declined in the 1870s, whaling by the Makah diminished in frequency, reportedly because it became too cost prohibitive. Makah Waiver Application at 8. Profits from whale products also declined. 2002 Needs Statement at 21. At that time, the Makah Tribe "increased their seal hunting efforts to compensate for a less profitable whale hunt."2002 Needs Statement at 20. Given their sealing and navigational skills, Makah tribal members were hired to work on commercial sealing ships plying the waters of the Washington coast and Vancouver Island in search of fur seals; the European-American ship owners relied on the Makah Tribe's aboriginal wage-labor force to succeed at sealing. DEIS at 3-304. The profits accrued from the seal hunts permitted Makah tribal members to purchase and operate their own schooners and, in a role reversal, they began to hire non-tribal navigators. 2002 Needs Statement at 20. By 1891, "sealing became so lucrative for the Makah and west coast native hunters that their traditional whaling expeditions virtually ceased." *Id*.

In 1897, an international convention signed by the United States effectively banned pelagic seal hunting. At that time, given the diminished number of gray whales, the intensive investment in time and ritual preparation to hunt whales "was too difficult to justify." *Id*. at 23. Consequently, in 1905 there were only three recorded whale hunts undertaken by the Makah whalers (although the success of these hunts is not known). *Id.* at 23.

Without whaling or sealing, Makah men engaged in a new, more productive venture – ocean fishing – that would continue to make use of their exceptional navigational and seafaring skills. 2002 Needs Statement at 23. At that time (the early 1900s), fishing "had become a more effective venture than whaling prior to the turn of the last century." *Id*. As noted in the 1889 Annual Report to the Commissioner of Indian Affairs:

> "the Makahs catch a great many fish, which they ship three times a week to Seattle, where they have a good market for them. They have caught and shipped as high as 10,000 pounds of halibut in one day." 2002 Needs Statement at 23.

As both gray and humpback whale populations continued to decline and as more Makah men shifted toward "the very successful subsistence and commercial venture of ocean fishing," whale hunts became an even riskier investment. 2002 Needs Statement at 24.

Based on these historical accounts, while the Makah Tribe has a long history of whaling, its whaling practices transitioned from true subsistence to a profit-making operation by the mid-1800s. Once profits from the sale of whale oil declined, the Makah Tribe transitioned to sealing to continue to profit from Northwest Washington's bountiful wildlife. When that hunt was largely banned by an international convention, the Makah transitioned again to ocean fishing –

an activity that continues today and that, given the revenue produced, must provide some Makah with substantial income.[43] Cumulatively, this evidence raises additional questions about the claims that the Makah have continually practiced and passed down from generation to generation their traditions related to whaling, given that, for many ancestral whaling families, whaling has not been practiced for approximately 165 years.

Despite a 90-165 year hiatus in whaling, the DEIS indicates that recently the "Makah Tribe has attempted to revive its cultural traditions for the past three decades" in order to "combat social disruption resulting from the rapid changes of the last century and a half," causing high rates of teenage pregnancy, students dropping out of high school, substance abuse, and juvenile crime. DEIS at 3-282, Makah Waiver Application at 9. To reverse these trends, the Makah "have reinstated numerous song, dance, and artistic traditions." *Id*. The Coalition supports the revival of the cultural traditions but notes that "revival" clearly suggests that these traditions – particularly those tied to whaling – have *not* been continually practiced since the late 1920s when the Tribe gave up whaling.

Furthermore, recognizing that these revitalizations were undertaken to address certain social ills on the reservation, NMFS has not provided any data to demonstrate the impact of such cultural revival on the rate of, for example, teenage pregnancy, substance abuse, or juvenile crime on the Makah reservation. Nor has it cited to any other data – for example from other Native American tribes – to suggest that, in this modern era, reviving cultural traditions can influence the rate of such societal ills. For example, have efforts by the United States Fish and Wildlife Service to facilitate the acquisition of feathers from bald eagles and other raptors for Native American tribes to use in their cultural celebrations helped any of those tribes in reducing social ills on the relevant reservations? The Coalition is not suggesting that restoring cultural traditions cannot aid in addressing social ills on reservations, but such claims have to be proven with credible data versus mere opinion.

Surely, the Makah Tribe has monitored and measured the rates of these societal ills that are of concern on the reservation and can demonstrate a trend in those rates over the past three decades. If such data were available, a proper analysis would also require the consideration of other tools, methods, or strategies the Makah Tribe may have implemented over the past decades, so that the impact of cultural revival can be considered in the full context of other methodologies used to address these problems. According to tribal survey results, "an overwhelming majority (93.9 percent) of the village believes the resumption of the whale hunt has positively affected the Tribe and 51.6 percent specifically cited moral and social changes as

[43] According to data in the DEIS the salmon fishery out of Neah Bay generated annual revenue between $226,000 to 1.4 million between 2003 and 2011, DEIS at 3-260,while overall commercial fish landings to Neah Bay for 2007-2011 were valued at 5.9 to 9 million dollars each year.

the most important benefit," 2002 Needs Statement at 1, but no other metrics have been provided to quantify such positive change.

Other examples of statements that call into question whether the Makah have continued to practice whaling traditions are evident throughout the DEIS and its appendices. For example, NMFS notes that the Makah Tribe's "desire to reinvigorate the whaling tradition never dissipated," DEIS at 3-306, which suggests the traditions have not continued, at least not substantially, over time. Similarly, NMFS concedes that "many traditions related to whaling have waned, however, since the Makah Tribe's cessation of the hunt in the 1920s." DEIS at 3-309. The DEIS also notes that "tribal members reported that whaling songs and rituals also resumed following the 1999 hunt, with more people participating in family songs and sharing traditional knowledge," DEIS at 3-313 (citing Braund and Associates 2007), which is counter to the claim that such traditions were continuously practiced since the 1920s.

NMFS also concedes in the DEIS that while the continuous practice of a cultural activity makes it "more likely that knowledge of that activity will pass from generation to generation," should there be "a hiatus in practicing the activity, the knowledge may be lost." DEIS at 4-197. Such a loss could take time, but inevitably "knowledge of specific elements of the activity wanes as elders die." *Id*. If that is true, given the Makah Tribe's nearly 90-year hiatus in whaling (with the sole exception of a whale killed in 1999), it would follow that the cultural knowledge of whaling has, at least, diminished, if not been largely lost.

If traditions regarding whaling, including the transfer of recipes on how to prepare whale meat and blubber, had been passed down between family members, then those receiving whale products after the 1999 hunt would have been able to use those recipes to prepare the meat and blubber consistent with tradition. Yet, according to tribal survey results, the majority of respondents "reported a desire to learn more about preparing whale products and using whalebone." DEIS at 3-313. While some "households began to use recipes held in family confidence for decades," others experimented with "techniques used for other sea creatures like seals and fish," suggesting those who experimented didn't have traditional family recipes. Even Makah whalers, after the 1999 hunt, expressed an interest in learning more about the "ancient activity of whaling," again calling into question the transmission of whaling traditions among family members. *Id*. Similarly, the Makah Tribe reports that "community members are ready to rise to this challenge and re-learn the techniques necessary to make the food from the whale a part of Makah life again," 2002 Needs Statement at 38, providing further evidence that such techniques have not been passed down through the generations.

According to the data in the Makah Tribe's 2002 needs statement from the first tribal household survey, of the 61.3 percent of survey respondents who received whale meat after the 1999 hunt, 41.5 percent made jerky, 43.9 percent ate roasts, 41.5 percent cooked stew, 35.4 percent grilled steaks, and 34.1 percent smoked meat; what is not clear is whether any of this was done with the use of traditional recipes passed down through the generations. 2002 Needs Statement at 15. Another 19.5 percent of respondents utilized "innovative methods" for preparing whale meat, including stir frying, kippering, deep frying, barbecuing, and boiling," *id*. at 16; this would suggest that these tribal members did not rely on traditional recipes to prepare whale meat. Similarly, for the 75.4 percent of survey respondents receiving blubber, 22.4 percent smoked it, 37.9 percent rendered the blubber into oil, 6.9 percent pickled it, 48.3 percent boiled it, and 65.5 percent ate the blubber raw, *id*., although again it is not clear if they used traditional recipes to prepare the blubber.

While traditions and traditional techniques do change with time, this occurs when these traditions are in continuous use. When *reviving* traditions that have fallen out of use, simply substituting modern methods of food preparation and recipes arguably defeats the purpose.

Makah whalers participating in the 1999 hunt also had "to learn whaling techniques and traditions from knowledgeable Canadian elders." DEIS at 3-315. While it is understandable that no Makah whalers in 1999 would be skilled in the killing technique (as none had ever killed a whale) the fact that they had to learn whaling traditions from Canadian elders suggests whaling traditions had not been passed down through their own families. Also, considering the fact that many of the whaling traditions are apparently family-specific, they were likely taught traditional practices that were inconsistent with those followed by their ancestors.

Even the process of butchering the whale killed in 1999 created confusion, as the Makah whalers and other tribal members apparently didn't know how to butcher the whale or have the requisite tools to do so. DEIS at 3-381. According to Renker (2012):

> Butchering the gray whale proved a huge task for the Makah people. Lack of familiarity with gray whale anatomy, tools poorly adapted for gray whale meat and blubber, and logistical issues presented immediate obstacles for the butchering process which began on Front Beach. Some confusion also centered on whale parts other than meat and blubber. DEIS at 3-381

Indeed, some of the Makah tribal butchering crew included tribal members who had traveled to Alaska to learn the processing techniques. DEIS at 3-382. On the day of the kill, they also had assistance from an Alaska Native. *Id*. As recorded in video footage of the 1999 hunt, at the end of the day, even though the butchering process had not been completed, the Alaska Native, one or more NMFS officials, and a number of bystanders were left alone with the carcass to continue the flensing process.[44] According to Sepez (2001), the "1999 whale harvest yielded

[44] The videotape footage was obtained by Erin O'Connell on May 18, 1999. A DVD of the footage will be mailed to NMFS to be part of the administrate record for the DEIS. Since it is submitted as part of the record it will need to

approximately 2,000 to 3,000 pounds of meat and 4,000 to 5,000 pounds of blubber," DEIS at 4-196, although there's no information as to how much meat and blubber may have been lost due to the difficulties butchering the whale.

Furthermore, although not reported by NMFS, given the difficulty the Makah whalers faced during the butchering process, it is possible they failed to comply with traditions associated with whale flensing, which were dictated by strict protocols that identified "the sequence of the butchering, the portions of the whale reserved for ceremonial use, and the portions to be distributed to the crew and other village inhabitants." Makah Waiver Application at 6. Tradition associated with the flensing process was not limited to protocols on how to butcher and apportion the whale but included who would make the first cut into the whale and the "need to decorate the whale with eagle feathers and white down." DEIS at 3-299. The chief whaler was responsible for entertaining the villagers with his family's songs and imitations while adorned in ceremonial gear. He was given the dorsal section of the whale, the section richest in oil, for his family's use, although it was often sold. *Id*. Based on eyewitness accounts of the flensing process in 1999, none of these practices were followed.

Much of the data the Makah Tribe uses to try to justify the resumption of whaling comes from the various household surveys that have been conducted on the reservation (in 2001, 2006, and 2011). These surveys, which were essentially identical, were prepared and the results analyzed by Dr. Ann Renker. Dr. Renker, however, is hardly an objective or independent expert in regard to Makah whaling, given that she is a longtime resident of Neah Bay and is married to a Makah whaler who is a current member of the Makah Whaling Commission. Consequently, whether these surveys provide a legitimate picture of the Makah Tribe's interest in resuming whaling, its use of whale products, and the cultural value of whaling to the Tribe is open to debate. Furthermore, as is the case with any survey, the design or content of the survey can be created to achieve a particular outcome.

The administration of the first survey in 2001 raises additional questions about its legitimacy. In that year, of 217 Makah households reportedly randomly selected to participate in the survey, 159 agreed to participate. This means that 58 (27 percent) elected not to participate. The reasons why those families elected not to participate in the survey were not disclosed (if even known). Although the DEIS contains conflicting information on this point, at least four households that were selected to participate in the survey either declined to participate or were not allowed to participate due to their known opposition to Makah whaling (compare DEIS 3-310 to 2002 Needs Statement at 49). Those conducting the survey filled in the survey for

---

be reviewed, including by agency decision-makers, so that they are familiar with its content. The content includes video and sound of the Alaskan native asking where the Makah were and if anyone knew how to reach them and explaining that he was "really tired right now and there is no one helping us." A NMFS official is also seen and heard on the DVD complaining about the lack of Makah present to help clean the whale intestines.

those four families, marking a negative response for all questions regarding support of the hunt or use of whale products. DEIS at 3-310. Reportedly, this was done "to minimize external influences on the survey administration." 2002 Needs Statement at 49.

In regard to those survey results, based on the results of the 2001 survey, only 38 percent of surveyed households reported participation in post-hunt ceremonies in 1999, DEIS at 3-312, and only 30 percent reported they "cooked whale meat." Makah Waiver Application at 10. Such percentages seem to be inconsistent with the claims of the importance of whaling to tribal members and to revive tribal culture. The percentage of Makah Tribal members participating in ceremonies related to whaling increased to 42.2 percent based on the results of the 2006 Household Survey (Renker 2007) but that statistic was not reported in the results of the 2012 Household Survey (Renker 2013).

Collectively, this evidence raises serious concerns about whether the Makah Tribe can demonstrate either a cultural or subsistence need for whaling and whale products. While the Coalition concedes that the information summarized above is only a fraction of the relevant evidence presented in the DEIS, NMFS must reinvestigate the claims of cultural and subsistence need with the Makah to confirm or reject the Tribe's alleged needs.

Notwithstanding the foregoing evidence that questions whether the Makah Tribe has a credible cultural or subsistence need for whaling and whale products, NMFS concludes in the DEIS that the action alternatives will facilitate subsistence use of whale products on the reservation consistent with the tribe's cultural and ceremonial needs and that whaling will improve the social environment on the reservation. Conversely, the No Action Alternative in both cases would prevent the Makah Tribe from exercising a treaty right, would prevent them from accessing freshly killed whale products not only for nourishment but would also adversely impact their cultural identity, sense of self-sufficiency, the self-esteem of the tribe and its individual members, and their trust in the United States government. In particular, according to NMFS, the impact of the No Action Alternative on subsistence use would: erode tribal identity in the absence of opportunities to participate in an activity central to Makah cultural identity; provide the community little or no incentive to work cooperatively to prepare for the hunt, to harvest, butcher, share and eat whale or to participate in song and dance festivals to celebrate the harvest; adversely affect community and individual pride and self-esteem, particularly among Makah tribal members who support the hunt; reinforce that the Makah are not in control of their destiny and would undermine a sense of autonomy within the community; and reinforce the Makah's feeling of disillusionment with the federal government. DEIS at 4-201.

Considering that the Makah Tribe has not been able to regularly engage in whaling since at least the late 1920s (and likely since the mid-1850s), this description of the implications of the No Action Alternative seems disingenuous, as it suggests the Makah Tribe is currently whaling and the United States is considering ending the practice. The reality is that no evidence has been offered to confirm the Makah are suffering from such cultural ailments. Indeed, since the Makah have been living without whaling for nearly 90 years, the description of the No Action Alternative proffered by NMFS is a significant overstatement of present day reality. It should be amended to reflect the fact that the Tribe has adapted to life without whaling and, while some may desire to resume a hunt, not doing so will not cause the cultural, spiritual, or physical collapse of the Makah Tribe as suggested in the DEIS.

NMFS has failed to comprehensively evaluate the adverse impacts of the proposed hunt on aesthetics:

NMFS concedes that a hunt may have impacts on the aesthetics of people who live and recreate near or in Neah Bay. It notes that, if the hunt is conducted 1-2 miles from shore, then there are few vantage points on land. However, "activities closer to shore, (e.g., towing a dead whale and butchering it) would be more readily viewed." DEIS at 4-227. It then contradicts itself and reports that "under all action alternatives, interested observers could view a whale being hunted, towed to shore, or butchered from numerous points along the shoreline near Neah Bay and, to a lesser degree, the Pacific coast portion of the Makah U&A." DEIS at 4-228. It claims that such impacts could be positive for those who may have an interest in observing a hunt and the butchering of a whale or negative for those who have no interest in observing whaling or the flensing process. DEIS at 4-228.

This is a simplistic analysis that doesn't do justice to the potential adverse aesthetic impacts associated with a hunt. This is because NMFS has based its analysis largely on the potential for observing certain activities associated with a whale hunt versus considering how such observations may impact a person's experience on the Olympic Peninsula (i.e., how the actual experience contrasts with the expected experience of using public lands in or near the Project Area). Nor is the scope of its analysis sufficient to capture the full range of aesthetic impacts.

Many who visit the Olympic Peninsula do so to enjoy Olympic National Park (ONP) or to explore the rugged Washington coastline. ONP includes a 70-mile-long coastal strip that is designated wilderness. Those who visit wilderness areas often do so to enjoy a primitive and relatively pristine experience in an area where the human imprint is, by law, supposed to be minimal if not non-existent. The experience of solitude and serenity is often a key attribute of the desired experience when using wilderness and backcountry areas of national parks. For such a visit to be disrupted by images of a whale hunt, the associated chaos surrounding the hunt, weapon fire, and the possibility of seeing a dead or dying whale is not consistent with the wilderness experience. For those who recreate along the Washington coast, they do so to enjoy the scenic beauty, and marine wildlife; very few if any expect a trip to the coast to include scenes of a whale being pursued, harpooned, shot, and killed, or the frenzy of media, protestors and law enforcement that is likely to accompany a hunt. NMFS has failed to consider such impacts in the DEIS. The analysis that should be undertaken is not just about how many people may observe a whale hunt or from what vantage points but, rather, has to evaluate how such observation will affect the tourist's (or resident's) experience based on his or her purpose for recreating (or living) in the area.

Tourists, residents, anglers, commercial shippers, among others, also use the Pacific Ocean for recreation, sport, or work. While the Coast Guard's RNA and MEZ may alert boaters to a hunt, permitting (or requiring) them to leave the area, it doesn't mean that they could not be adversely impacted by the hunt (due to disruption of otherwise legal activities which could cause economic loss or disrupt recreational activities) or through the mere contemplation of a whale being killed whether they observe it or not. Indeed, this same impact could affect anyone nationally or internationally that opposes the hunt. In *Fund for Animals v. Ridenour*, Civ. No. 91-0726 (D.D.C. 1991), the court held that that merely contemplating the killing of a bison near Yellowstone National Park was sufficient harm to demonstrate legal standing. These impacts were not evaluated in the DEIS. Nor did NMFS consider the impact to a resident, tourist, or boater upon seeing a whale that is injured or dying as a consequence of a Makah hunt (i.e., a struck and lost whale) in the ocean or stranded. Each of the action alternatives set a limit on the number of struck and lost whales so the potential to observe an injured or dying whale is real.

Finally, NMFS only considers the impact of the hunt on the economics of whale-watching in the DEIS. Such impacts, however, extend well beyond economics to include adverse effects on the social environment and on the aesthetic experience of those who enjoy observing whales in their natural habitat. NMFS largely dismisses the potential of the hunt to impact whale-watching operations, claiming that there are no such operations in the immediate project area and that it had no information to suggest that the hunt would stop people from taking whale-watching trips nearby. DEIS at 4-152. It also asserts that Washington-based whale-watching companies will not expend the time or funds necessary to access whales in the Makah U&A and, therefore, won't be adversely impacted by the proposed hunt. *Id*. Finally, it claims that because gray whales are not typically targeted by most whale-watching operators in the region, a decrease in gray whale numbers would not appreciably impact the public's incentive to pursue whale watching in the PCFG range. DEIS at 4-153. These conclusions are either wrong or not supported with any credible evidence.

The issue is not only about watching a whale die but, again, it must extend to the knowledge of the hunt and the contemplation of a whale being killed. For those who enjoy observing gray whales throughout their migratory range, from the Mexican lagoons to Alaska, the knowledge that the whales that they observe and, in some cases know by name, could be killed in a Makah hunt could result in emotional harm or cause them to choose not to partake in future whale-watching trips or visit the region. Indeed, contrary to the claim by NMFS that gray whales are not targeted by most whale-watching operations, a few minutes of online research revealed three operations in Oregon (oregonwhales.com, The Whale's Tail Chartered Whale Watching, and Tradewinds Charters) that appear to focus on gray whales.

Notably, several whale-watching operations offer whale adoption programs for named PCFG whales. For example, oregonwhales.com Whale Research EcoExcursions currently has a number of PCFG whales up for adoption (e.g., Scarback, Rambolina, Zebra Stripe). In addition, the company blogs on the activities of whales that it observes. On July 27, 2015, the blog entry was:

> Whale sightings have been excellent as usual. Ginger, Ridgeback, and Pearl have been in the bay and very active. There were 4 whales at on (sic) time in and around our boats. I have identified and along with my team, suggested by a group on one of our trips named a new whale, "BANDIT". A beautiful female with a large band of white on her dorsal area. Also we saw a couple of Mola Mola (Ocean Sunfish), one of which was over 8ft in size and lazily swam right up to the boats. We have had a 100% sighting rate for many weeks now. Trips leave every day from 8am every 2 hours through 6 pm and sometimes sunset tours. We would love to teach you all about our whales and other wildlife. Also check out our Baja information. We are going to Baja in February to see and pet the friendly gray whales. This is the only place in the world where you can have this kind of interaction. It is awesome!!!"
>
> (see http://www.oregonwhales.com/daily.html).

Cascadia Research Collective also provides an opportunity for people to adopt PCFG whales (see http://www.cascadiaresearch.org/adopt.htm).

As these websites reveal, many PCFG whales have names, they are known, and there may be people who have bonded to these animals. During excursions run by oregonwhales.com, clients are introduced to individual PCFG whales and are provided information about each whale and his or her history. While it is not known how many whale-watching operations from Alaska to Mexico promote PCFG whales, for those who do they are creating a connection between their clients and individual whales. If their clients, or those who adopt a whale, were to learn that their whale was killed by the Makah Tribe, the emotional impact could be significant. Even NMFS concedes that "many people who watch whales in the project area on a regular basis attach existence values to individual PCFG whales that regularly visit the area." DEIS at 4-188.

The likelihood that the public, including those who participate in whale-watching, will oppose the Makah hunt is high. Evidence of this is included in the DEIS (see DEIS at 3-286 and 3-288). In addition, according to Hoyt and Hvenegaard (2002), 75 percent of whale watchers surveyed in California said it was "morally wrong" to kill whales, while whale watchers surveyed in Vancouver registered an average score of 4.47 (based on a survey scale of 1 to 5, with 5 being "strongly agree") to the statement "it is wrong to kill whales." Another survey of New England whale watchers found that 83 percent agreed it was "morally wrong" to kill whales, regardless of the reason.

One need only consider the ongoing international outrage surrounding the case of Cecil, the lion from Zimbabwe, to understand the potential for adverse social impacts associate with the killing of a single, named whale. In that case, an American trophy hunter was involved in a hunt that illegally lured Cecil out of a national park after which he shot and injured him with an arrow. The injured lion was then tracked and killed, skinned and beheaded after 40 hours of suffering.[45] The social media backlash has been massive and the trophy hunter has disappeared from public view. NMFS has not evaluated such impacts in the DEIS related to the killing of a gray whale. Nor has it considered how, if the Makah Tribe is allowed to whale indefinitely, the hunt could harm the reputation of the whale-watching industry in Washington, Canada and throughout the species' migratory range; people may choose to avoid whale-watching or visiting the coast because they do not want to view whales who could be killed by the Makah Tribe.

<u>NMFS has failed to adequately evaluate the risks to public safety inherent to the proposed gray whale hunt:</u>

The DEIS significantly underestimates the substantial risk to public safety inherent to any Makah whale hunt. Unlike the Alaskan, Russian, or Greenlandic ASW hunts that take place in extremely remote regions of the world, the Makah hunt, if permitted, would occur in a region that is much more populated, is a destination for millions of tourists annually, and where commercial and recreational shipping/vessel operations are common. As an example of the population differences, there are an estimated 3,439,809 people live in the Washington Metropolitan Area (which comprises the Seattle-Tacoma-Bellevue region of Washington)[46] and, based on the 2010 US population census results, 71,404 people lived in Clallam County, WA.[47] This compares to a total of 736,732 people in the entire state of Alaska in 2014,[48] including only 4,373 (as of 2013) in Barrow, AK[49] (one of 11 whaling villages).

According to tourism data contained in the DEIS, 3 million people visit the Northern Washington Coast every year to enjoy the beautiful scenery, pristine wilderness, and opportunities to view wildlife. DEIS at 3-331. More specifically, Olympic National Park attracted an average of 3.0 million visitors per year between 2006 and 2010, with more than half of those visits occurring during the months of July through September, with an additional 25 percent occurring during the months of March through June. *Id*. Within the Makah reservation, 16,000 people visited the Cape Flattery Trail each year from 2005 through 2011, with more than 80 percent of those visits occurring during the months of July, August, or September. *Id*. For those using the area for commercial and recreational boat trips, 80 percent of such trips occur from May through August, six percent from November to March, with another four, seven, and three percent in April, September, and October, respectively. DEIS at 3-341.

While the risks to public safety may be lower during a hunt conducted in the winter months or offshore, simply due to the lower number of persons in the vicinity, even those hunts could adversely affect persons occupying any hunt support vessels, media vessels, or vessels operated by protesters. This is due to the likelihood of more challenging sea conditions further from shore potentially resulting in an errant shot, DEIS at 4-246, or an increased risk of boating accidents where any needed medical assistance would not be readily available. Conversely, a hunt conducted during the spring months or over the summer (Alternative 4) would increase public safety risks, although, if conducted well offshore, the risks would be less than if conducted near shore.

The use of high-powered rifles poses a significant public safety concern. As indicated in the DEIS, a 750 grain bullet fired from a .50 caliber rifle can travel nearly 5 miles. DEIS at 3-169 (citing Graves et al. 2004). A bullet from a .577 rifle, because it has a lower ballistic coefficient and greater rate of drop, would be expected to result in a shorter range than a bullet fired by a .50 caliber rifle, *id*., but that range is not identified in the DEIS. Due to the distance that such bullets can travel, Kline (2001) stated that “no firing should be conducted within 6,670 yards from shore and advised that a ricochet could travel almost 1,860 yards off the line of fire.” DEIS at 3-363.The use of an explosive projectile would substantially reduce the public safety risks since such grenades, due to their weight and size, will have only a very limited range.

If there were no public safety risks associated with the hunt, there would have been no need for the Coast Guard to establish a Regulated Navigation Area (RNA). In finalizing its rule establishing the RNA after the 1999 hunt, the Coast Guard reported that “the uncertain reactions of a pursued or wounded whale and the inherent dangers in firing a hunting rifle from a pitching and rolling small boat are likely to be present in all future hunts, and present a significant danger to life and property if persons or vessels are not excluded from the immediate vicinity of the hunt.” DEIS at 3-10 citing 64 Federal Register 61212 (November 10, 1999), DEIS at 3-349. The Coast Guard also created a 500 yard Moving Exclusionary Zone (MEZ) around tribal hunting vessels in order to ostensibly "keep protesters, reporters, and spectators out of the area where life and property would face the greatest risk of endangerment from an injured or pursued whale or a round from a .50 caliber rifle." DEIS at 3-349. Consequently, even the Coast Guard's 500 yard RNA is likely not sufficient to eliminate the potential risks to other vessels, including protest vessels, in the vicinity of the hunt.

The Makah Tribe has established, in its 2013 Whaling Ordinance,[50] rules that are intended to address the risks of the whale hunt. These rules include drug and alcohol testing of the riflemen, training and certification programs, and requirements regarding when a shot can be fired. DEIS at 2-15.[51] More specifically, the Makah Tribe has developed the following safety standards for any hunt:

> The Makah safety officer has authority to determine whether visibility is less than 500 yards in any direction in which case the whaling captain suspends the hunt; safety officer would not authorize the rifleman to discharge the weapon unless the barrel of the rifle was above and within 30 feet or less from the target area of the whale; safety officer would not authorize the rifleman to discharge the weapon unless the field of view is clear of all persons, vessels, buildings, vehicles, highways, and other objects or structures that if hit by a rifle shot could cause injury to human life and property. DEIS at 3-351.

The risks to public safety inherent to any Makah whale hunt are not limited to the weapons used or vessel collisions, since a struck gray whale can also pose a significant threat to public safety by ramming nearby boats or swamping the Makah canoe. DEIS at 4-249. While those vessels, including any Makah canoes, closest to the injured whale would be most at risk, an injured and distressed gray whale could cover a fair distance in a short period of time. As explained in the DEIS, the Russian Federation reported that of the 129 gray whales killed in its 2007 hunt, 49 animals (or 39 percent) were highly aggressive and even attacked hunting boats. DEIS at 3-166. Such violent struggles by struck gray whales can, as reported in the DEIS, "result in vessels being capsized, persons on vessels being knocked in to the water, or individuals become entangled in the lines fastened to the whale." DEIS at 3-357.

[50] The mere existence of a 2013 Makah Whaling Ordinance is of concern to the Coalition since the current decision-making process will likely take years to complete. Consequently, it is unclear why the Makah would expend the time and resources to create and approve a whaling ordinance when they cannot currently whale and may not receive the requested MMPA waiver. Perhaps the Makah Tribe presumes that it will receive a waiver given its treaty right, or its adoption of a new whaling ordinance may suggest that the outcome of this NEPA/MMPA process has been predetermined, which is illegal. The Makah Whaling Ordinance is discussed in greater detail in a latter section of this comment letter.

[51] NMFS suggests that the alcohol testing requirement for Makah riflemen is contained in the 2013 Makah Whaling Ordinance but a review of that ordinance reveals no such requirement.

Given the sheer numbers of people who live and recreate in the vicinity of any potential Makah whale hunt, there is a significant public safety risk associated with the hunt. Conducting a hunt well offshore with a strongly enforced RNA, and using explosive grenades as the killing weapon, would reduce public safety risks compared to conducting a hunt near shore using high-powered rifles. Nevertheless, even with an offshore hunt, there would still be a risk to the whalers, their support personnel, the Coast Guard (and other enforcement agency personnel), the media, protesters, and innocent onlookers, not just from the use of rifles as the primary killing weapon but also from a wounded whale. Regardless of where the hunt occurs, if rifles are used, the likelihood of *every* shot being fired at a safe downward angle, given that the rifleman is aiming at a swimming whale from a moving boat on a rolling ocean, is low. Consequently, a misfired bullet could travel an extended distance, potentially hitting something or someone and causing damage, injury, or death. Even with an RNA, an MEZ, and Makah safety standards, the potential risk of the whale hunt to public safety in such a highly populated and trafficked area is simply too high to justify a hunt for a Tribe that does not need to hunt whales. NMFS must reevaluate its analysis of the public safety risks inherent to the whale hunt and provide a more detailed and comprehensive risk assessment.

<u>The DEIS fails to substantiate the need for whale meat or other products to benefit the health or nutrition of the Makah Tribe:</u>

The Makah Tribe has repeatedly claimed in need statements submitted to the IWC that marine foods, including marine mammal products, are of nutritional importance in the diet of tribal members. In making this claim, the Makah Tribe has described the alleged nutritional benefits of whale products and the notion that access to whale products would help alleviate poverty on the reservation by providing food that would be shared and free of charge, reducing costs of store-bought foods. DEIS at 1-31.

Prior to contact with Europeans, the Tribe was able to exploit land and sea animals, including elk, deer, bear, seal, and a diverse population of fish, shellfish, and other marine species. Whale meat and oil were among their principle foods. 2002 Needs Statement at 33.

Traditionally, the Makah Tribe consumed nearly every edible part of whales, including the meat, organs, and blubber. In addition, whale oil extracted directly from dead whales or rendered down from blubber was widely used. Considering that some of the traditional hunts could take days to complete,[52] the oil was often the most important product from the whale, as

[52] According to the Makah Tribe's 2005 waiver application, historically some hunts occurred 30 or more miles from shore, even though at that time the Makah were using the traditional hand-carved canoes. Makah Waiver

it did not spoil as quickly as the meat. DEIS at 3-367, DEIS at 3-300. Interestingly, due to the tendency of whale meat to spoil easily, particularly when the process of towing a dead whale back to land could take several days, whale meat was not as important in the pre-contact and historical diet of the Makah compared to whale oil. 2002 Needs Statement at 33. Indeed, as the Makah Tribe concedes, only "about ten percent of the food the Makah people derived from whales can be attributed to meat." *Id*. Whale oil, which was not subject to spoilage, could be stored and used indefinitely, assuming it was rendered properly. *Id*.

While the historical quantity of whale products consumed per capita was not reported in the DEIS, Sepez (2001) calculated that the whale killed in 1999 resulted in about 2.4 pounds of whale meat and product per capita on the reservation, with an additional amount consumed at the community potlatch. DEIS at 3-367. In the future, if the Makah are allowed to resume whaling, Renker (2012) determined that if an average of four whales were killed per year, the hunts would yield 8 to 20 pounds of whale meat and 16 to 20 pound of oil or blubber per Makah tribal member (with a smaller amount of oil due to the rendering process). *Id*. Based on the reported number of Makah tribal members (1,121) living on the reservation in 2010, DEIS at 4-196, this would equate to 8,968 to 22,420 pounds of meat and blubber and 17,936 to 22,420 pounds of oil/blubber.

Results of the survey of Makah tribal members conducted in 2001 revealed that "most reservation households now desire whale products to be a regular part of their diets" with 86.5, 72.4, and 55.8 percent of respondents desiring whale meat, whale oil, and blubber respectively.[53] Makah 2002 Needs Statement at 2. Desiring to have whale meat and oil, however, is not the same as needing these products to reverse any health concerns caused by decades without access to such products. The Makah Tribe claims in its needs statement that the "restored (whale) hunt provides modern Makah people with a rich source of traditional foods which are nutritionally superior to many non-indigenous provisions which are available in the community," *Id*. Yet, it provides no evidence to substantiate that claim nor does it concede, as is made clear in the DEIS, that the same alleged benefits from whale products can be obtained from other marine foods.

As to the alleged consequences of not having regular access to whale products in their diet, in the Makah Tribe's 2002 needs statement, the majority of the claims regarding the health consequences of not eating a traditional diet are based on health concerns for American Indians generally, instead of focusing on particular health/disease conditions experienced by

Application at 5. At that time, the process of killing a whale "could take up to three to four days" followed by up to two days to tow the whale back to shore. *Id*. at 6.

[53] The percentages declined in 2006. Survey results that year revealed that 71.7, 67.1, and 47.4 percent of survey respondents desired whale meat, oil, and blubber, respectively. DEIS at 4-203.

members of the Makah Tribe specifically. For example, the needs statement claims the following regarding the health of American Indians:

- American Indians are generally considered to be one of the unhealthiest populations living within the United States. This observation is especially true for natives living within the confines of a reservation. Infant mortality and life expectancy rates for reservation residents are the lowest of all American citizens. 2002 Needs Statement at 35.

- Diminished life expectancy on American Indian reservations is compounded by the fact that certain systemic illnesses linked to food and nutrition appear in a statistically higher percentage among these populations. Diabetes, for example, is 234% more prevalent among American Indians than in all other US races. *Id*.

The only specific information about health concerns contained in the needs statement relevant to the Makah Tribe is that they "did not utilize plant foods to a great degree" in their historical diet, and thus they "still experience many digestive problems with diets high in fiber and cruciferous vegetables," 2002 Needs Statement at 35. In addition, it is noted that some tribal members, particularly descendants of whaling families, are frequently affected by rheumatoid arthritis and diabetic neuropathy. Reportedly, digestive disorders seem to be an issue for members of other Native American tribes who live along the NW coast, as the Makah Tribe reports that it "have the highest rate of digestive illnesses of all American Indian people and are the leading cause of hospitalizations." 2002 Needs Statement at 37. Yet no evidence is provided that whale products, especially to the exclusion of other marine foods, will address these digestive disorders.

Notably, when discussing the value of essential fatty acids (EFAs) in their diet, the Makah Tribe refers not to cetacean or even gray whale EFAs but, rather, to marine EFAs. 2002 Needs Statement at 37. General marine EFAs have reportedly improved conditions such as rheumatoid arthritis and diabetic neuropathy. Since the benefits can be obtained from any marine EFA, however, this does not provide justification for killing gray whales.

Today, the Makah tribal members consume a large quantity of subsistence food. Reportedly, "a majority of Makah households use traditional Makah foods (i.e., fermented salmon eggs, smoked fish heads and backbones, halibut cheeks and gills, and dried fish) at least once a week." Makah Waiver Application at 9. The DEIS reports both terrestrial and marine species (primarily fish) are taken in subsistence hunts. It does not, however, disclose any information about the quantity of terrestrial wildlife killed, the amount of meat/fat/other edible products obtained from those animals, nor does it provide any information regarding contaminant profiles of such subsistence foods. For fish, it is estimated the Makah consume 126 pounds of fish per capita each year, which is eight times higher than the average American. DEIS at 3-367 citing Sepez (2001), Makah Waiver Application at 9. Yet, again NMFS does not provide any data as to the contaminant loads contained in fish products regularly consumed by the Makah. Western foods are also available on the reservation, although NMFS does not disclose the type of such foods or the quantities consumed.

In evaluating the human health impacts of a whale hunt, NMFS considered three issues: the potential nutritional benefits associated with consuming whale food products; the potential for exposure to contaminants in food items from the whale harvest; and the potential for exposure to food-borne pathogens in food items from the whale harvest. DEIS at 4-256. NMFS concedes, however, that due to uncertainties associated with this analysis, it is not possible to "predict whether any of the alternatives would result in a net positive or negative effect on human health." *Id*.

Indeed, the DEIS lacks data needed to even begin to evaluate the alleged nutritional benefits of whale products to the Makah Tribe. This includes: a baseline evaluation of the health status of Makah tribal member (or at least data on a representative sample of tribal members), a lack of species-specific (terrestrial and marine) data on Makah consumption of subsistence foods; the quantity of such foods consumed per capita per week, month, or year; the nutritional value of such products; the contaminant loads of such products; the amount and type of western foods consumed; current health conditions of Makah tribal members (i.e., prevalence of heart disease, diabetes, kidney disease, obesity, and other diet or lifestyle-related diseases), and evidence of lifestyle factors that may affect disease conditions (i.e., activity levels, smoking, drinking, illegal drug use).

NMFS recognizes this void, given its own disclosure of a litany of information that would be required to determine if consuming freshly killed gray whale products would improve nutrition among the Makah. Such deficiencies include the current types and level of nutrition present in Makah tribal members' existing diet; what parts of the whales and how much would be consumed; what currently consumed food items and associated nutritional levels would be replaced by whale products; and how such food items are collected, stored, and prepared for consumption. DEIS at 4-257. NMFS claims that "none of this information is currently available or could reasonably be obtained" but it failed to meet the required standards for incomplete or unavailable information under NEPA. If the Makah or NMFS want to ever meaningfully address the Makah's alleged need for whale products, they would have to, at a minimum, collect and analyze this type of information.

In the DEIS, NMFS asserts that "whale products have a similar nutritional profile as other finfish, shellfish, wild game and domestic meats," DEIS at 3-368, that whale oils and blubber provide a richer source of energy (calories) than other food types listed in Table 3-46, DEIS at 3-370, while whale meat has higher levels of iron.[54] *Id*. NMFS concedes, however, that gray whale meat, blubber, and oil are not necessary to obtain the alleged nutritional benefit claimed by the Makah, since many of the vitamins, essential elements, and both essential and beneficial polyunsaturated fatty acids found in whale products can be obtained from other marine mammal food products, DEIS at 4-256, as well as from fish oils, vegetable oils, soybeans, nuts, meat from terrestrial mammals, and vitamin and other nutritional supplements. DEIS at 3-268, 4-256. For example, essential fatty acids that have reportedly been found to be beneficial in controlling diabetes, kidney disease, heart disease, hypertension, and other similar health problems, are found in fish food products. *Id*.

Fundamentally, despite the Makah's claims to the contrary, NMFS concludes in the DEIS that "there are no data to suggest that current diets of individual Makah members sufficiently lack (the) nutritional benefits" ascribed to whale products. DEIS at 4-259. Furthermore, as admitted by NMFS, "there is insufficient information to conclude that the lack of fresh whale products under the No Action Alternative would be expected to negatively alter current dietary conditions for any tribal member." *Id*.

<u>NMFS has failed to adequately evaluate the potential impact of environmental contaminants from whale products on the health of Makah Tribal members:</u>

There are a number of chemical compounds in the environment, including in the marine environment, which can have direct lethal effects or insidious sub-lethal effects on individual animals. Sub-lethal effects include impaired reproductive, metabolic, and immune functions. DEIS at 3-178. Such chemicals include organochlorines (e.g., DDT, PCB, dioxins, furans), heavy metals (e.g., copper, mercury, lead), and newly emerging chemicals (e.g., flame retardants). *Id.* The three heavy metals of greatest concern to cetaceans are mercury, cadmium, and lead. DEIS at 3-179 (citing O'Shea 1999).

The health of a gray whale is not always indicative of its contaminant load. For example, as revealed in the DEIS, the mean concentrations of PCBs (1200 µg /mg) and DDTs (520 µg/mg) in the blubber of gray whales that stranded in 1999 were well below levels measured in gray whales harvested in Russian waters (PCBs 630 µg/mg and DDT 150 µg /mg). DEIS at 3-373. Furthermore, the concentrations of chlordanes, DDTs, dieldrin, hexachlorobenzene, mirex, and PCBS in gray whales collected during Russian hunts in the Bering Sea in 1994 were two to three times lower than those measured in stranded gray whales collected over the 1990s in Washington. *Id.*

Such contaminants also occur and are documented in the diets of native subsistence populations. DEIS at 3-372. In determining the potential risk for members of the Makah Tribe to

[54] Notably, Table 3-46 does not provide any data for gray whale meat, blubber, or oil.

be exposed to contaminants, their existing and ongoing exposure to such toxins must be considered. For the Makah, due to their high consumption of seafood products, including finfish and shellfish, it is likely that they are exposed to high levels of contaminants.

This risk is also linked to the level of contaminants in gray whales. While gray whales are generalist feeders, their reliance on bottom feeding to acquire energy-rich amphipods exposes them to various contaminants that may settle to the ocean floor. Their pelagic prey may also contain contaminants through bioaccumulation or as a consequence of the contaminant loads in the waters in Washington State. Indeed, as noted in the DEIS, a number of "researchers have documented concentrations of organic and inorganic contaminants in the tissue (blubber, muscle, organs, etc.) of the gray whales proposed for hunting by the Makah." DEIS at 3-378 (citing numerous studies).

Importantly, as noted in the DEIS:

> "...concentrations for some of these contaminants in whale blubber can be quite high, resulting in quite low 'allowable consumption rates.' For example, the unweighted average PCB concentration for the 11 gray whale blubber samples in Table 3-47 is 44 µg /kg. While the Washington State Department of Health has not developed screening levels for gray whale blubber, this value – combined with the estimated per capita blubber consumption rates in the Tribe's needs statement (approximately 20-25 grams/day…) and other values applied by the Washington Department of Health (e.g., an 8-oz [227-gram] meal size) – yields a calculated 'allowable consumption rate' of 0.43 meals of blubber per month." DEIS at 3-374.

Notably, as also explained in the DEIS, this example is based on non-cancer endpoints and if cancer endpoints were used, the allowable consumption rates would be lower. *Id*.

While the concentration of persistent organic pollutants in whale blubber is typically higher or comparable to those in other tissues, heavy metal concentrations are typically higher in muscle tissues compared to blubber. Mean metal concentrations (in µg/kg dry weight) found in gray whales, as reported in the DEIS, range from 0.4 to 0.86 cadmium, 3.1 to 4.1 copper, 305 to 1,009 iron, 0.6 to 1.11 lead, 0.33 to 0.8 manganese, 0.145 mercury, 1.39 nickel, and 120 to 279 zinc.

Considering that contaminants are already found in foods presently consumed by the Makah, including fish and shellfish, as well as store-bought food, whether adding whale products will have a positive or negative effect is unclear. Since, as NMFS admits, no database is available to "compare the amount of contaminants currently being consumed by the Makah Tribe with the amount of contaminants found in fresh whale products," it is "difficult to determine the net change in contaminants to which tribal members would be exposed." DEIS at 4-257.

Nevertheless, since whale products, particularly blubber, "would likely contain higher levels of certain contaminants (e.g., PCBs) than other foods consumed by the Makah," *id*., NMFS cautions that whale products may exceed levels that trigger human health concerns based on guidelines published by state and federal agencies. *Id.* Similarly, NMFS reports that "changes in the quantity of freshly harvested whale consumed would probably not appreciably change the potential for food-borne illness to occur in Makah tribal members." DEIS at 4-258.

There are several deficiencies in the analysis of the impact of environmental contaminants in the DEIS.

First, NMFS has failed to disclose sufficient data to evaluate the relevant impacts of such contaminants on the Makah if they are allowed to hunt whales. Not only are there apparently no data on the current contaminant loads in Makah tribal members from their high-fish diet, but NMFS provides no data on the contaminant profiles of the fish species and other food products typically consumed on the Makah reservation.

Second, although NMFS refers to state and federal food safety standards in the DEIS, it fails to identify those standards, fails to provide any reference to them so that interested stakeholders could examine them, and fails to compare those standards, with the sole exception of the PCB example provided above, to the concentration of contaminants documented in gray whales.

Third, many of the studies cited in Tables 3-47 and 3-48 are also rather dated, which calls into question the accuracy of the documented concentrations in terms of what may be found in gray whales today. Despite these deficiencies, to be precautionary, particularly with regard to the health of Makah tribal members and recognizing that NMFS concedes that consuming whale products may trigger health concerns; NMFS should deny the MMPA waiver application on health grounds alone. Surely NMFS does not want to authorize a gray whale hunt when there is a distinct possibility that consumption of products from the hunt could compromise human health.

<u>NMFS has failed to adequately evaluate the precedential impacts of the issuance of a waiver to the Makah Tribe:</u>

One of the key issues emphasized in the *Anderson* opinion was the potential for a Makah whale hunt to create the precedent for other whale hunts in the United States and around the world. In evaluating this potential impact, NMFS considers the potential change in the number of requests for MMPA waivers to permit the killing of marine mammals in US waters (other than whales) and for regulatory action to permit the killing of whales in US waters. DEIS at 4-260. The DEIS identifies a number of US tribes between the Aleutian Islands and California who hunted gray whales and/or used drift whales for subsistence as part of their cultural and religious traditions. These tribes include the Aleuts, Koniag, Chugash, Tiglit, Haida, Tsimshian, Nootka, Makah (including the Ozette), Quileute, Klallam, and Chomash. DEIS at 3-176. However, this list is incomplete, as it does not include any tribes that live on the east or Gulf coasts that may have historically hunted whales.

NMFS concedes the fact that Northwest Indian tribes have previously expressed an interest in killing marine mammals, that an authorization of a Makah gray whale hunt could revive the interest of the Makah or other tribes in hunting marine mammals, and that it could increase interest by non-Indians in sport or commercial hunting of marine mammals. DEIS at 4-261. Despite this concession, NMFS largely dismisses the potential for an increase in waiver requests if the Makah's MMPA waiver is granted, claiming, for example, that "history suggests that there is little interest by other native groups to seek authorization to harvest whales." *Id*.

This conclusion may be misplaced, however, since both the Makah and other US coastal tribes, including those on the east and Gulf coasts, may simply be waiting for the outcome of the Makah waiver application before proceeding with their own request for whales or other marine mammals. While there is no evidence yet that this will occur, tribes with an interest in obtaining a waiver would not help their own cause – or the cause of the Makah to obtain a waiver to kill gray whales – if they were to prematurely announce their intent before the current process ended. Such an announcement would support the argument that the Makah Tribe's waiver application has had a significant precedential impact, thereby supporting a denial of the waiver.

Many tribes, particularly in the Northwest, have expressed a desire to kill seals and sea lions, given the perceived conflict with fisheries, particularly salmon fisheries. The Northwest Indian Fisheries Commission recently opined that "harbor seal and sea lion populations must be brought back into balance with the reality of today's ecosystems, which cannot support their steadily increasing numbers."[55] It is myopic for NMFS to conclude that the outcome of the Makah Tribe's waiver application will have no influence on the likelihood of these tribes applying for their own waivers. Even the Makah Tribe may choose to pursue additional waivers if its whaling waiver is obtained, considering that it ceased authorizing tribal members to take any marine mammals in 2005 as a result of the *Anderson* opinion. DEIS at 3-215.

Furthermore, the recent decision in *United States v. Washington* opens the door to a significant increase in MMPA waiver requests. In that case, initiated by the Makah Tribe to determine the boundaries of the usual and accustomed fishing grounds of the Quileute and Quinault tribes, the court concluded that "'fish as used in the Treaty of Olympia encompasses sea mammals and that evidence of customary harvest of whales and seals at and before treaty time may be the basis for the determination of a tribe's U&A." *United States v. Washington*, No. C70-9213, slip

[55] See http://nwifc.org/2015/04/10158/

op. at 78 (W.D. Wa. July 9, 2015; Attachment 7).[56] This is now a legal precedent defining a treaty right to fish to encompass the hunting of marine mammals, including cetaceans. Therefore, the Coalition concludes that MMPA waiver applications are very likely to increase. Admittedly, the ruling in *United States v. Washington*, issued on July 9, 2015, was not available to NMFS when it prepared the DEIS, but it now represents new information that must be considered as NMFS continues with the NEPA and MMPA waiver processes.

NMFS concludes that "it is also unlikely that other countries could use authorization of a Makah whale hunt under Alternatives 2-6 as leverage for increasing commercial or scientific whaling." DEIS at 4-267. To support this conclusion, NMFS cites to the skirmish between Japan and the United States over the Alaskan bowhead whale quota in 2002. While it is true this situation did not result in a "fundamental change in the United States position" on commercial or scientific whaling, it did result in the United States voting in favor of Japan's small-type coastal whaling proposal at a special meeting of the IWC called to address, in particular, the bowhead quota. In that case, though the US vote for small-type coastal whaling did not practically benefit Japan (as there were sufficient no votes to block the proposal even with the United States voting in support), it was clearly a psychological victory for Japan given by the United States in order to secure the bowhead whale quota. To think that Japan would not attempt to block a US ASW quota in the future to compel a change, even temporary, in a US position at a future IWC meeting is naïve.

Admittedly, the Makah ASW request may not provide Japan with the same leverage over the United States as did the bowhead whale quota. This is because the Makah ASW quota is for a small number of whales and, if blocked, the repercussions are not as significant for the Makah as are the implications for Alaska Natives. The Makah, as Japan is well aware, have not regularly engaged in whaling for nearly 90 years (and potentially as long as 165 years) and have access to a variety of other foodstuffs. Conversely, the bowhead quota is for a larger number of whales for which the 11 Alaskan whaling villages have a genuine nutritional, subsistence, and cultural need.

Furthermore, the suggestion that ASW was not a consideration in the effort to construct an agreement leading up to the 2010 IWC meeting that, if approved, would have undermined the commercial whaling moratorium is also without merit. The principal reason the US ASW quotas were not challenged at the 2007 meeting, held in Anchorage, AK, is because the late Senator Ted Stevens negotiated an agreement, believed to be unwritten, with Japan. In its simplest terms, that agreement ensured that Japan did not object to the United States quota request, particularly its request for bowhead whales, at the Anchorage meeting in exchange for US

[56] In the opinion, the court provides significant details as to the history of whaling, sealing, and fishing by both the Quileute and Quinault tribes. It also identifies several other tribes that also had a tradition of whaling.

leadership in the process that led to the proposed “deal” to lift the commercial whaling moratorium, which was soundly rejected at the 2010 IWC meeting.

Finally, NMFS’ dismissal of the potential adverse precedent that Makah whaling could have on other IWC countries seeking whaling opportunities for their own people, including aboriginal people, is in error. Fundamentally, the mere fact that the United States was able to secure a quota for the Makah in 1997, given that the Tribe did not qualify (and still does not qualify) for an ASW quota, has already substantially weakened the ASW criteria within the IWC. NMFS even admits that the Makah whale hunt is different from other aboriginal subsistence hunts because of “the Tribe’s 70-80 year hiatus in whaling.” DEIS at 4-268. While approval of the Makah quota as recently as 2012 has not been explicitly used by any country to seek IWC approval to allow its own people to engage in whaling, this may occur in the future. Indeed, considering that the Makah hunt has been prevented from occurring as a result of legal action, if NMFS is able to ultimately permit the Makah to begin to actively use the IWC-approved quota, this could be the trigger that other countries are waiting for to exploit the 1997 decision.

This does not mean that the damage done by the United States to the ASW standards in 1997 cannot be reversed. This is possible, but only if the US denies the Makah Tribe’s MMPA waiver request and does not pursue another gray whale ASW quota for the Makah at any future IWC meetings. This would not erase the adverse precedent set in 1997, but it would return some integrity to the IWC’s ASW standards.

<u>NMFS has failed to fully disclose all relevant information regarding the cumulative impact of the proposed hunt and to adequately analyze such impacts:</u>

NEPA requires federal agencies to evaluate the cumulative impact of any proposed action or other alternatives on the environment. Under NEPA, a “cumulative impact” is defined as an “impact on the environment which results from the incremental impact of the action when added to the past, present, and reasonably foreseeable future actions, regardless of what agency (federal or non-federal) or person undertakes such other actions. DEIS at 5-1 and 40 CFR § 1508.7. Much of the information contained in the cumulative impact analysis (CIA) section of the DEIS overlaps with information regarding other threats to gray whales. Consequently, those issues are addressed together in this section of the comment letter.

The geographic and temporal scope of the CIA included the entire range of ENP gray whales over an indefinite time period. DEIS at 5-2/5-3. These provide an appropriate scope for the CIA although, considering that WNP gray whales are known to emigrate into the ENP region and that one or more could theoretically be killed as a result of the hunt, not including the WNP range in the CIA is in error. DEIS at 5-2. Surely, if a Makah hunt resulted in the death of a WNP gray whale then understanding the impact to a critically endangered population of gray whales given other existing and increasing threats would be relevant and should have been included in the CIA.

In its analysis of the CIA, NMFS ostensibly evaluated past, present, and reasonably foreseeable actions in the following categories: harvest of gray whales, shipping, military exercises, fisheries, tourism, marine energy and mining projects, scientific research, natural mortality, climate change and US government policy. DEIS at 5-4. The background portion of the analysis simply confirms that these activities will continue in the future and will impact gray whales to some degree. NMFS then attempts to evaluate the actual cumulative impacts of these different actions in the section 5.2 of the CIA but its analysis is woefully inadequate. Consequently, it is of no surprise that NMFS concludes that nearly all of the 15 environmental factors evaluated will not result in a significant cumulative impact. The only exceptions to this is for the environmental justice and ceremonial and subsistence resources factors where NMFS concluded that Makah Tribe would experience negative cumulative effects if Alternative 1 (the No Action Alternative) was chosen. DEIS at 5-43, 5.44.

For some actions analyzed, NMFS claims that information was not available (e.g., from the Canadian, Russian, or Mexican governments) to assess certain actions under the control of those countries that may impact gray whales or their habitat. NMFS provides no information about the effort made to obtain such information, causing the Coalition to question whether NMFS adequately attempted to secure such evidence by, for example, contacting the relevant government agencies. Nevertheless, NMFS has failed to comply with the NEPA requirements as to unavailable and incomplete information, which further undermines the sufficiency of its CIA. This error must be corrected in a revised analysis either by obtaining the missing information or providing the requisite evaluation of the relevance of the information to the environmental impacts of the proposed action as required by NEPA.

Similarly, the CIA provides no evidence that NMFS contacted relevant state or provincial agencies to obtain information about past, present, and reasonably foreseeable state-approved actions that may impact gray whales and their habitat. The definition of "cumulative impact" explicitly includes actions by non-federal agencies. Yet, NMFS has apparently limited its analysis to those actions authorized and/or undertaken by federal agencies.

In California, for example, the California Coastal Commission (CCC) is responsible for approving projects that may impact coastal resources, yet there is no indication that NMFS reached out to CCC for information relevant to the CIA. Washington and Oregon have agencies similar to the CCC that review and approve coastal projects. At a minimum, NMFS must contact all appropriate state agencies in Alaska, Washington, Oregon, and California to seek information about coastal projects authorized at the state level that may impact gray whales. It must also contact authorities in British Columbia, Canada and in the state of Baja California Norte and Baja California Sur to seek out information from them to include in the CIA. In addition, NMFS should compile a list of all of the relevant IHAs, LOAs, and other authorizations (as published in the Federal Register) that it has issued at least over the past five years in order to include that information in the CIA.

While many of the individual projects authorized by NMFS (or by other countries or agencies) may not, independently, pose any substantive threat to gray whales, when considered together - as is the entire purpose of the CIA - the impacts become significant. Merely asserting that certain actions will continue into the future and that they will or will not result in cumulative impacts - as NMFS has done in the DEIS – entirely ignores the purpose of a CIA.

That purpose is to combine all of the past, present, and reasonably foreseeable future action that may impact, in this case, gray whales and to subject them to a comprehensive and scientifically robust analysis to determine how, when combined, will impact gray whales today and into the future. Such an analysis cannot be based merely on speculation and opinion but rather, must be credible with predictions or projections about how present and future actions will effect gray whale populations and their habitat. Qualitative conclusions are not entirely sufficient in a legitimate CIA unless they are confirmed through a quantitative analysis.

While there is no required methodology for conducting a CIA, a method that would be advisable in this case would involve a modelling exercise to quantify the potential short and long-term cumulative impacts of the various impacts in order to predict potential outcomes under different scenarios.

NMFS has not engaged in such an analysis in the DEIS. Indeed, the foundation of its CIA is speculation and opinion without any substantive underlying analysis. In many cases, while NMFS acknowledges current and future impacts, it doesn't take the next step to assess the cumulative impact of such threats on gray whales and their habitat or, what analysis it provides is deficient. Until NMFS provide a legitimate CIA in a revised analysis it must not continue the current decision-making process.

For the remainder of this section, the Coalition provides a summary of some of the relevant present and future threats to gray whales. While NMFS has included many of these in the DEIS, in many cases the information is inadequate or incomplete. In other instances NMFS has ignored an existing or future threat that it should have considered.

Harvest of gray whales

As discussed in this comment letter, permitting a new intentional take of gray whales by granting the Makah Tribe's request for an MMPA waiver is biologically reckless. There are too many ongoing threats to the species throughout its range, including in the PCFG region, to purposefully allow additional take. For WNP and PCFG, such take is particularly alarming given their small population sizes. Indeed, even NMFS concedes that "killing even a few animals per year (especially over an extended period of time) from the relatively small PCFG could have long-lasting impacts for a group of whales whose population dynamics are not well understood." DEIS at 5-3. Furthermore, since so little is known about the long-term implications of Arctic ecosystem changes attributable to climate change, there is no guarantee that the ENP gray whale population is secure.

The CIA in the DEIS, had it been done objectively and through a quantitative assessment of the combined threats to gray whales and their habitat, would have concluded that the cumulative impacts are substantial. Conversely, based on its deficient analysis, NMFS found that when adding potential impacts of a gray whale hunt under Alternatives 2 through 6 to past, existing, and future levels of disturbance then "reasonably foreseeable future actions would not be expected to have cumulative effects on gray whales in the PCFG, local survey areas within the PCFG range, and individual gray whales. DEIS at 5-40. Of note, NMFS doesn't appear to make a CIA finding for ENP gray whales (nor for WNP gray whales which, in error, it neglected to consider in the CIA.

Shipping

The DEIS includes information about current shipping traffic and how it will increase throughout the range of the ENP gray whales in the future. DEIS at 5-8/5-9. It recognizes that this will increase risks to gray whales as a consequence of ship strikes, ocean noise, and potential fuel spills. Id. at 5-8. It finds that shipping is a reasonably foreseeable future action, but fails to engage in any legitimate quantitative analysis of the potential threats of shipping traffic to gray whales in relationship to the actions identified.

Military exercises

NMFS largely discounts the potential cumulative impacts of military exercises (in waters of the US, Russia and Mexico).

NMFS reports that it was unable to obtain any information about military activities conducted by Mexico and Russia within their respective Exclusive Economic Zones. For Canada, NMFS notes the role of Maritime Forces Pacific (MARPAC) in ensuring the training and operational readiness for the Royal Canadian Navy but claims that it could not find information detailing the types of training or testing that MARPAC conducts within the NMFS CIA analysis area. The failure of NMFS to obtain such information is an ideal example of a weakness in the CIA. It is improbable that if NMFS or the US State Department, on behalf of NMFS, sought the relevant information from Mexico, Canada, and Russia that those governments would not have responded at least to provide basic information about relevant military training activities in the analysis area. Without that information, the CIA is incomplete.

As for the analysis of the impacts of military activities in US waters, NMFS evaluates the impacts of activities conducted within the Southern California Range Complex (SCRC), Northwest Testing and Training Range (NWTTR), and the Gulf of Alaska Range Complex (GOA). The potential impacts from these testing and training exercise include noise (from ships, explosives, sonar), direct harm (from ship strikes, projectiles, underwater explosions, consumption of expended materials), and indirect harm (hearing impairment and loss, disrupting communications, noise masking, behavioral impacts, general harassment).

Instead of providing a credible analysis of these impacts, NMFS largely dismisses any significant threat to gray whales by citing to its relevant Biological Opinions for the different ranges and complexes. These Biological Opinion's generally conclude the overall impact from such exercises, which they concede will result in harassment (primarily Level B). Notably, for the SCRC, NMFS has authorized 15 Level A takes (through harassment) of ENP gray whales and, in addition, 15 whale injury, mortality, or serious injuries for 15 gray whales of which three, shockingly, can be WNP gray whales. Considering that this population of gray whale is critically endangered, that level of mortality or serious injury rate is excessive. Furthermore, relying on old Biological Opinions for this CIA is inappropriate. NMFS should have engaged in a new analysis of these impacts specific to gray whales and their habitat.

In general, for all gray whales subject to military testing and training activities, NMFS dismisses potential adverse impacts claiming that "any stress responses or disruptions of normal behavior patterns of gray whales would not continue long enough to have fitness consequences for individual animals because these whales are likely to have energy reserves sufficient to meet the demands of their normal behavioral patterns and the additional demands of any stress responses." DEIS at 5-15. Of course, NMFS provides no data to support its contention that gray whale exposure to such military training exercises will be only temporary nor has it disclosed evidence to substantiate the assertions that gray whales have sufficient energy reserves to both meet daily demands and to deal with acute or chronic stress impacts. NMFS must provide such data if it wants to ensure that its CIA is credible and legal.

While NMFS concedes that in past Biological Opinions, WNP gray whales were not considered, it is evaluating impacts to that population in pending decisions regarding continuation of military testing and training activities in the NWTTR and the GOA ranges. In regard to the SCRC, a court recently ruled in favor of plaintiffs challenging a Biological Opinion prepared by NMFS to evaluate the impacts of the military's training and testing in that region. *Conservation Council for Hawaii v. NMFS* (2015 WL 1499589 at *48-50 (D. Hawaii Mar. 31, 2015).

In particular, given the increasing body of scientific evidence documenting the adverse impact of ocean noise, including sonar and seismic testing, on marine mammals and other ocean species, this issue in particular warranted far greater analysis in the CIA. Indeed, surprisingly, while NMFS provides some information about ocean noise in the affected environment and environmental consequences sections of the DEIS, it virtually ignores the issue in its CIA. Not only can such anthropogenic noise directly harm whales through temporary or permanent hearing loss, but the behavioral implications of acute and chronic exposure to human-caused noise sources can cause behavioral changes that can have serious consequences to gray whales. This can include disrupting feeding and breeding activities, abandonment of preferred habitat, and avoidance reactions that may result in increased stress and have adverse bioenergetics consequences.

Considering the increase in anthropogenic noise in the Pacific Ocean, including noise associated with military operations, and recognizing that climate change will increase human activities in the Arctic which, in turn, will increase noise impacts, NMFS must provide a far more substantive and scientifically robust evaluation of noise impacts in a revised document.

Fisheries

NMFS acknowledges the adverse impacts of various fisheries on gray whales and concedes that reported fishery-related mortality is an underestimate of actual mortality. This is, in part, due to the lack of observer coverage in many of the west coast fisheries that are known to pose a risk to gray whales. For example, no observers are assigned to most of the Alaskan gillnet fisheries, including those in Bristol Bay known to interact with gray whales. DEIS at 41. Similarly, due to a lack of observer data for mortality in Canadian commercial fisheries, data is not available but NMFS estimates it to be approximately two whales per year. The DEIS contains no information about any commercial fishery-related mortality of gray whales in Mexico.

Overall, NMFS reports a known, but minimum, estimate of commercial fishery-related mortality was 12.25 ENP gray whales between 2007 and 2011 (Carretta et al. 2014), or an average of 2.45 gray whale per year. DEIS at 3-195. This is limited to reported mortalities in US waters only indicating that the actual number is larger if mortalities in Mexico and Russia were included.

NMFS provides some limited gray whale entanglement data for Mexico for 2013 where six gray whales were reported entangled in fishing gear . DEIS at 5-19. For Russia, NMFS reports that no data on gray whale entanglements were available, *id*., and apparently none could be obtained from Canada either. For PCFG gray whales, for the same period of time, the DEIS reports a mortality rate of one whale or 0.15 whales per year; figures that must be underestimates given the commercial fishing activity within the PCFG range. Punt and Moore (2013) estimate that reported strandings of gray whales represent only 3.9 to 13 percent of actual mortality. DEIS at 3-193. Consequently, average actual fishery-related gray whale mortalities in US waters may range from 18 to 62 animals annually.

When evaluating the cumulative impacts of this action in relationship to the hunt, NMFS should not use reported mortality rates as that will significantly underestimate actual mortality. Furthermore, while the reported mortality statistics above are for US fisheries, there is likely unreported mortality associated with other forms of mortality (i.e., ship strikes, sonar use, seismic testing). If the mortality rate from Punt and Moore is used to determine actual mortality for all types or reported mortality, the estimated number of whales lost due to human-caused mortality may be far higher than expected.

Since gray whales are known to sink when they die, NMFS needs to identify unreported mortality rates for these other forms or mortality so that it can conduct a credible quantitative CIA as well as to determine if human-caused mortality exceeds PBR. This is precisely the type of analysis that NMFS should undertake in a comprehensive CIA.

Tourism

NMFS notes that the number of people engaging in whale-watching in the ENP increased from 2.8 million in 1998 to over 3.3 million in 2008. DEIS at 5-20. Since 2008 the numbers have likely increased. NMFS also acknowledges that the activity of commercial whale-watching vessels and private recreational boats has increased concerns about potential effects on gray whales. DEIS at 5-22. The Coalition concurs with this assessment. While whale-watching provides a unique opportunity for millions of people annually to enjoy whales in their natural habitat, to learn about marine species and marine ecology, and that whale-watching generates billions in revenue worldwide, it is not with potential risk to marine wildlife. Improperly or non-regulated whale-watching operations or even an excessive number of operators in a concentrated area can have adverse impacts on marine mammals and other species.

This constitutes another threat to gray whales which has not been sufficiently studied to understand the full range of direct and indirect impacts to these animals. NMFS has also failed to quantify this effect in its CIA in order to better understand its impact in the context of other impacts on gray whales and their habitat. Instead of engaging in such an analysis, NMFS has concluded that whale-based tourism is a reasonably foreseeable future action that will continue to impact gray whales throughout their range in the ENP. DEIS at 5-22. It does not appear that the CIA provides a determination as to the cumulative impacts to gray whales as a result of tourism when considered alongside the proposed hunt.

Marine energy and mining projects

NMFS discloses information about active and proposed energy and mining projects within the range of the gray whale. For example, it notes the proposed construction of a number of Liquefied Natural Gas terminals (DEIS at 5-9) while also providing some data on oil spills particularly in Washington State waters. It provides a basic explanation of oil and gas development in the Arctic and both its role and the role of the Bureau of Ocean Energy Management in overseeing, authorizing, or permitting such projects.

What it fails to do, however, is to engage in a credible analysis of the direct and indirect impacts of these projects on gray whales and their habitats. There's no serious analysis of the impacts of oil/gas exploration or production activities on gray whales (i.e., seismic testing, drilling noise, ship traffic), no substantive discussion of the lethal and sub-lethal impacts of oil on gray whales, and no assessment of the potential for a significant oil spill within the range of the gray whale or how such a spill would impact gray whales and their habitat. In the Arctic, since summer is the only time when drilling can be commenced, a spill associated with production processes would occur when gray whales are in the region. Given the controversy surrounding President Obama's recent decision to allow Shell Oil to drill in the Arctic, this emphasizes the need for a more complete analysis. The notion that such spills are unrealistic or unlikely due to the efforts made by the oil and gas companies to prevent such accidents is not (and never has been) cause for complacency particularly as a result of the Deepwater Horizon spill in the Gulf of Mexico several years ago.

Notably, NMFS failed to even disclose a mining project in Mexico that may significantly impact gray whales. Although not yet approved, a large phosphorous mining operation has been proposed in the Gulf of Ulloa between Apreojos and Cabo San Lazaro, Mexico. A summary translation of the first few paragraphs of the Environmental Impact Statement[57] prepared on the proposed mine states that:

[57] The EIS can be accessed at: http://consultaspublicas.semarnat.gob.mx/data/expediente/bcs/estudios /2014/03BS2014M0007.pdf

- The project is to be located within the Mexican EEZ in the Gulf of Ulloa, on the west coast of Baja California Sur between Apreojos and Cabo San Lázaro, about 22 km off the coasts.
- It is projected that 7 million tons of phosphates will be extracted each year for a period of 50 years, equal to a rate of 19,178 tons a day; the digging will be done 24 hour per day, 7 days per week or each year.
- The EIS does not mention the total quantities of other materials that would also be removed and then returned to the ocean as waste. An analysis by Dr. Janette Murillo Jimenez, however, indicated that to produce the quantity of phosphate indicated 150,000 tons of sediment would need to be removed daily. "These quantities are so large that they would require more than one processing vessel, would generate a plume of sediment and waste, of which argillaceous particles would be left permanently in the water in the area due to the continual agitation."
- The company seeking the permit, Exploraciones Oceánicas, S. de R.L. de C.V. (a subsidiary of a US company Odyssey Marine Exploration Inc, Omex) is a vessel salvage company which has no experience in submarine dragging, and even less in mining phosphates. In other countries in which similar proposals have been presented they have not been approved, and Namibia has a moratorium on such activities. This is due to concerns about fisheries.

Furthermore, in a recent article published in Excelsior[58], a periodical in Mexico, Dr. Jorge Urban-Ramirez, head of the Marine Mammal Research Program from the Universidad Autónoma de Baja California Sur, noted that the project would impact the migratory route of gray whales which for millennia have traveled 10,000 kilometers from the Arctic Ocean, through the Bering and Chukchi Seas between Alaska and Siberia, to the Baja California, peninsula in order to rest and give birth.

Dr. Urban-Ramirez, who is respected gray whale biologist with 32 years invested into the study of the species, states that “the underwater noise from the mining activity would mask the acoustic communication that exists between the whales principally in the Laguna complex at Bahia Magdalena, the closest point to the Don Diego (name of mining project) project, where every year a large number of gray whale calves are born,” and that “the greatest potential damage is to the north where the mothers with calves will be precisely in the drag zone.”

While he reports that the noise generated by the mine, if it were allowed, would not kill gray whales, it would trigger a behavioral response that would cause them to divert from their

[58] See http://www.excelsior.com.mx/nacional/2015/01/18/1003281

normal migratory route which, in turn, would result in greater energy expenditures while also potentially adversely impacting the whale-watching tourism industry in the area.

Natural mortality

NMFS notes the potential impacts of killer whale predation on gray whales but largely ignores the role of sharks as natural predators of gray whales, particularly gray whale calves. In addition, it does not sufficiently consider the potential impact of predation on gray whales in the context of the other threats and stressors on the population. For example, the delay in the south of the southbound migration, which is linked to ocean warming in the Arctic and the expansion of the gray whales' range, has led to an increase in births outside of the Mexican lagoons. Some births are now occurring in coastal waters as far north as central California. Gray whale calves born in these areas are more susceptible to predation than those born in the lagoons. NMFS has not quantified such impacts for the purpose of its CIA. Nor has it considered predation severity throughout the migratory range. Unimak Pass, Alaska, is an area where gray whales may be most susceptible to predation by killer whales, who take advantage of this relatively narrow passage way to kill gray whales. NMFS must provide a far more substantive analysis of the impact of predation on gray whales as both a separate threat to the species as well as in the context of a credible CIA.

Climate change

As previously noted, ocean warming caused by climate change is significantly impacting the Arctic. A regime shift is ongoing whereby a benthic driven ecosystem is transitioning into a pelagic system. This has significant potential implications to gray whales and their prey, including amphipods. As the composition and density of fish stocks increase in Arctic waters, benthic productivity is declining, forcing gray whales to expand their range. The consequences of this shift are documented in the scientific literature but, more recently, evidence of this shift is available in the form of an agreement between the US, Russian Federation, Canada, Norway, and Denmark (representing Greenland) to prevent unregulated commercial fishing in the Arctic. This agreement, signed on July 16, 2015 is a product of the regime shift in the Arctic linked to climate change. According to a press release issued by the US State Department about the agreement:

> The declaration acknowledges that commercial fishing in this area of Arctic Ocean – which is larger than Alaska and Texas combined – is unlikely to occur in the near future. Nevertheless, the dramatic reduction of Arctic sea ice and other environmental changes in the Arctic, combined with the limited scientific knowledge about marine resources in

> this area, necessitate a precautionary approach to prevent unregulated fishing in the area.[59]

The countries have agreed to initiate research in the region to better understand changes occurring to the Arctic. It is precisely this type of precautionary approach that must be applied in the context of the Makah hunt. Given the need to better understand the changing Arctic environment and what it means to whales and other Arctic and sub-Arctic species, permitting direct lethal take of gray whales at this time is reckless.

Another threat to gray whales linked to climate change is ocean acidification. NMFS provides some information about this threat in the DEIS. It notes, for example, that ocean acidification can change the chemical composition of ocean water, which will decrease its ability to absorb sound, thereby making the oceans even noisier than they are at present. DEIS at 3-198. While this could cause both direct and indirect adverse impacts on gray whales, the fact that ocean acidification will reduce the abundance and types of shell forming organisms, “many of which are important in the gray whales diet,” DEIS at 3-197, is also a significant concern. While gray whales are expanding their range to find additional food sources, such an expansion will be irrelevant if potential prey species are eliminated or reduced as a consequence of climate change.

Climate change is also increasing human activities in the Arctic, including oil and gas exploration and development and shipping traffic . Both of these activities also can adversely impact gray whales directly and indirectly as well as by impacting their habitat.

NMFS provides some information about hypoxic zones in the DEIS but its analysis is deficient. While it notes that such zones are now increasingly linked to climate change (as well as associated with poor land management activities), it fails to disclose where such zones exist within the ENP gray whale range, if the zones are increasing in size, if they are more prominent in certain seasons, or what direct or indirect impacts they have on gray whales and gray whale prey. Nor has NMFS adequately consider these zones in the CIA.

What NMFS failed to address in its assessment of climate change in the CIA is the predicted “strong” El Nino event for the upcoming winter season.[60] Considering that this prediction was made by NOAA, it is troubling that it was not addressed in the CIA. During a previous “strong” El Nino in 1997-1998, the ENP gray whale population was significantly and adversely impacted as

---

[59] Available at http://www.state.gov/r/pa/prs/ps/2015/07/244969.htm
[60] See https://www.climate.gov/news-features/blogs/enso/june-el-ni%C3%B1o-update-damn-torpedoes-full-speed-ahead

a result of substantial mortality. During and after that event, ENP population estimates declined from over 20,000 whales in the late 1990s to approximately 16,000 in the early 2000s. While no one can predict if this predicted El Nino will have similar impacts, the precautionary principle mandates that this potential be considered in management decisions.

Finally, NMFS fails to discuss "the blob," a warm water anomaly in the Northeast Pacific that has led to significant ecological destruction. Bond et al. (2015)(Attachment 8).

US government policy

This issue was addressed previously in this comment letter. No further comments are necessary.

Additional Comments:

The environmental consulting firm used by NFMS to prepare the DEIS has an unacceptable conflict of interest:

NMFS hired Parametrix, a Washington state-based environmental consulting firm, to prepare the 2008 and 2015 DEIS documents. In 2008, AWI and other NGOs raised concerns that Parametrix had a conflict of interest, as it had done work for the Makah Tribe (e.g., on the Cape Flattery Scenic Byway Corridor Management Plan). In 2008, Parametrix had a contract with NMFS and the Makah Tribe simultaneously. Appendix C-22. NMFS dismissed these concerns, claiming that: 1) Parametrix and its subcontractors signed disclosure statements affirming "that there is no conflict of interest by being employed by both the Tribe and NMFS (*id*. at C-23); 2) due diligence reviews by NMFS of Parametrix's role as a contractor for the Tribe did not pose a potential for conflict (*id*.); and 3) "no biased information could be inserted into the DEIS under our sole supervision." *Id*. NMFS also noted that producing an EIS is the responsibility of the Federal action agency and that it did "not consider the relationship between Parametrix and the Tribe to have compromised the integrity of Parametrix's work product." *Id*.

These statements do not reassure the Coalition that Parametrix does not have a conflict of interest and that its role in preparing NEPA documentation for the Makah hunt did not compromise the objectivity and integrity of the 2008 and now the 2015 DEIS documents. In the list of preparers of the DEIS (DEIS at 8-1/8-2), NMFS fails to include the affiliations of all but two of the 27 people identified. One person whose affiliation was disclosed was the DEIS project manager for Parametrix and the other is a NMFS employee. Independent research conducted by the Coalition reveals that of the remaining 25 people identified, 12 are employed by NMFS, nine are (or were) employed by Parametrix, and four were employed elsewhere.

Beyond mere affiliation, however, an examination of the Parametrix website (http://www.parametrix.com/) reveals the following description of who the firm serves:

> Parametrix has served more than 50 tribes, pueblos, and rancherias. We support tribal governments' long-term visions, concern for future generations, and efforts to strengthen their sovereignty. Integrity and trust are the foundation of our efforts to serve tribes and provide the highest level of client service.
>
> We frequently assist tribal clients with infrastructure improvements, economic development, environmental planning and protection, and comprehensive land use planning—all critical to enhancing the quality of life in tribal communities and creating economic self-sufficiency for members and business. We often assist tribes in identifying and obtaining grant funding through our understanding of BIA processes, other governmental funding programs, and innovative partnerships.
>
> We are proud of the relationships we have built with our tribal clients and are committed to growing and nurturing these relationships in the future.

(accessed at http://www.parametrix.com/who-we-serve/tribes-pueblos-rancherias)

This webpage includes a picture of Parametrix employees and Makah Tribal officials. See Figure 7. It is not just a picture that causes concern, but Parametrix's support for "tribal governments' long-term visions" and "strengthen[ing] their sovereignty," which suggests an inherent bias in favor of the Tribe's interests. Such support is admirable, but not for a consulting firm supposedly providing an objective and scientifically sound work product evaluating the environmental impacts of Makah whaling.

Figure 7: Lower left image is of a Parametrix project on the Makah reservation. Available at http://www.parametrix.com/who-we-serve/tribes-pueblos-rancherias

Given the close past and present ties between Parametrix and the Makah Tribe, the use of Parametrix to prepare the DEIS was a poor choice and raises serious questions about the credibility of the content and impartiality of the analysis. While this error cannot be undone, NMFS must cease its relationship with Parametrix and either engage in an internal reevaluation of the content and analysis in the DEIS or hire a new environmental consulting firm with no ties to the Makah or other Native American tribes to perform such a reevaluation.

The Makah Tribe's promulgation of its 2013 Makah Whaling Ordinance raises concerns about the integrity of the DEIS process:

Included in the DEIS is a 2013 Makah Whaling Ordinance that was enacted by the Makah Tribe in August 2013. While the Makah Tribe can adopt any ordinances it deems appropriate, the adoption of a whaling ordinance in 2013 is odd. Considering that the present DEIS would not be published for another 20 months, that the NEPA and MMPA processes that must be completed to determine if the Makah Tribe will receive a waiver could take several years, and that, without the waiver, the Makah Tribe cannot whale, it seems unusual for the Tribe to expend the time, energy, and resources to develop and promulgate a whaling ordinance. While this may simply represent a choice made by the Makah Tribe, it could also reflect the Makah Tribe's understanding that it will receive a waiver and will be allowed to resume whale hunting. If NMFS has tacitly or expressly conveyed any guarantees to the Makah Tribe to cause them to develop such an understanding, it means the outcome of this planning process has been predetermined, in violation of NEPA.

As NMFS may recall, in *Metcalf v. Daley* (214 F.3d 1135 (9th Cir. 2000)), the appellate court found in favor of the plaintiffs because NMFS entered into a cooperative agreement with the Makah Tribe days before it published its Final EA and Finding of No Significant Impact. The court held this action predetermined the outcome of the NEPA process. The facts here are different, but the concern is the same. While it is unknown if NMFS suggested, recommended, or directed the Makah Tribe to adopt a whaling ordinance in 2013, this issue warrants some discussion and explanation by NMFS.

Conclusion:

Based on the foregoing evidence and analysis, NMFS must deny the Makah Tribe's request for an MMPA waiver application and terminate the NEPA process. There is no other legal option. It is time for this 20-year effort to end. The Makah Tribe does not qualify for an IWC-approved ASW quota and NMFS cannot issue an MMPA waiver to allow a Makah hunt without violating the law. Furthermore, as exhaustively demonstrated in this letter, the DEIS is woefully inadequate—failing to satisfy the requirements of NEPA. The purpose and need statements are invalid, NMFS has not considered a reasonable range of alternatives, it has failed to disclose all relevant information, and its analysis of the environmental consequences of the hunt is neither complete nor accurate.

If NMFS, despite the overwhelming evidence, makes a preliminary determination to issue the MMPA waiver, the Coalition will participate in the process in order to demonstrate conclusively that issuance of the waiver is illegal and that, therefore, the Makah's whale hunt cannot be allowed.

Thank you in advance for considering this information. Should you have any questions or require additional information, please contact me at dj@awionline.org or, by telephone, at (609) 601-2875.

Sincerely,

DJ Schubert

ABSTRACT

The North Pacific Gray whales (*Eschrichtius robustus*) are considered to consist of a large (19,000) eastern population and a small (ca. 155) western population. Genetic comparisons between eastern and western gray whales indicate that the populations are distinct. However in recent years, satellite tagging and photographic and genetic matches have provided evidence of overlap of the migration routes of the eastern and western populations and raise questions as to whether these whales are distinct populations. This paper reviews the issue of stock structure of North Pacific gray whales and the status of the western gray whale population. We present a range of plausible stock structure hypotheses and a discussion of genetic methods needed to test them.

Introduction.—The gray whale (*Eschrichtius robustus*) was once common in the North Pacific and North Atlantic Oceans but was extirpated from the Atlantic by the early 1700s. The extant North Pacific population is considered to be comprised of two populations or stocks. An eastern North Pacific population (eastern gray whales) winters in the subtropical waters of Baja, Mexico and migrates along the continental shelf of western North America primarily to summer feeding grounds in the Bering, Chukchi and Beaufort Seas. A western North Pacific population (western gray whales), the subject of this paper, inhabits summer feeding grounds in the Sea of Okhotsk, off the northeast coast of Sakhalin Island and the southeastern coast of the Kamchatka Peninsula. However, its migratory and wintering habits are not well known. Information collected since the 1930s show the western gray whale to migrate in coastal waters of Japan and South Korea to wintering habitat somewhere in the South China Sea (Weller and Brownell, 2012). Recent genetic studies suggest that eastern and western gray whales are discrete (Lang et al., 2011a).

Both the Atlantic and Pacific populations were hunted extensively and over-hunting likely contributed to the extinction of the Atlantic population (Mead and Mitchell, 1984; Weller and Brownell, 2012). The Pacific populations were reduced to very low numbers as well. With regard to the level of depletion of the Pacific population, Alter et al. (2012) estimate the number of mature females at the bottleneck to be approximately 1,300. This estimate is based on genetic diversity of the extant North Pacific gray whale population and thus includes both stocks in its calculations. Pre-commercial whaling population size of the eastern Pacific gray whale population was estimated to be 15,000 to 20,000 based on an examination of whaling records (Henderson, 1984). However, little is known of the historical population size of the western North Pacific population. Berzin and Vladimirov (1981) estimated that the western North Pacific population numbered 1,000 to 1,500 individuals prior to 1910, and this number has been generally accepted. However, Alter et al. (2007, 2012a) used genetic methods to estimate historical population sizes and concluded that the Pacific population, including both eastern and western stocks, likely numbered approximately 100,000 individuals prior to whaling. The relative sizes of the eastern and western populations were not estimated. Notwithstanding the uncertainty of the pre-exploitation size of the western North Pacific gray whale, it clearly had a much larger distribution than the population that now summers in the Sea of Okhotsk (Reeves et al., 2008) and it was reduced to a much smaller size than the eastern population.

Currently, the western population only numbers about 155 (IUCN 2012a) and is considered as critically endangered (IUCN, 2008). Only 32 reproductive females have been documented in this population (Burdin et al., 2011) and the loss of a single reproductive female annually could be sufficient to lead to the loss of the population (IWC, 2006, pp.10, 67). This contrasts markedly with the eastern population which was reduced to approximately 2,000 but has made a strong recovery and now numbers about 19,000 (Laake et al., 2009). Potential threats to the western population include accidental takes by fishermen (IWC 1994; Kato et al., 2006), poaching, ship strikes, pollution, and oil and gas development near their summer feeding sites.

The western North Pacific gray whale population is believed to have been comprised of two subpopulations; a small Japanese subpopulation that wintered in the straits between the islands of Honshu, Kyushu and Shikoku, and summered north of the island of Hokkaido (Andrews, 1914; Mizue, 1951) and the Okhotsk-Korean subpopulation that summered in the Sea of Okhotsk and wintered in Korea and China. Whales of the latter population were hunted near Sakhalin Island, the Kuril Islands, and Korea in the first half of the 20th Century (Brownell and Chun, 1977) but by 1966 the population was considered to be extinct (Bowen 1974; Weller et al., 2002; Cooke et al., 2008). However, in the late 1960s and the 1970s small numbers of whales in groups of one to three were sighted in the Sea of Okhotsk, South China Sea and the Sea of Japan (Ilyashenko, 2011). The population was estimated to be 100-200 individuals by Berzin and Yablokov (1978; cited in Ilyashenko, 2011). In the 1980s larger groups of whales began to be observed.

It is generally assumed that the small population of whales that summers off the northeastern coast of Sakhalin Island is the surviving remnant of the western North Pacific gray whale population (Weller et al., 1999, 2012). Occasional sightings or strandings of whales in Japan, Korea and China give credence to the belief that this population summered in the Sea of Okhotsk and migrated south to wintering sites in Asia which is thought to be the historical migration pattern of the western North Pacific gray whale. One ostensibly migrating whale killed in Japan was matched photographically to a whale photographed as a calf in the Sea of Okhotsk (Weller et al., 2008; Weller and Brownell, 2012) providing the first confirmation of this migratory corridor in recent times. Since 2002 photographic and biopsy data have been collected from the whales that summer in the Sea of Okhotsk on the northeastern coast of Sakhalin Island and southeast Kamchatka (Tyurneva et al., 2012). Genetic studies have compared these whales to various samples taken from the eastern North Pacific gray whale population using mitochondrial DNA (mtDNA) sequences which track maternal lineages, and a moderate number (8-13 depending on the study) of microsatellite loci which are biparentally inherited markers. Both the mtDNA and microsatellite loci show statistically significant differentiation of the eastern and western populations (Lang et al., 2010).

Taken together, the evidence appears to support the hypothesis that this small population is the remnant of the once presumed extinct western North Pacific gray whale population. However, in 2010 a satellite tag was placed on a 13-year old male western gray whale off the northeast coast of Sakhalin Island (Mate et al., 2011). The whale, known as “Flex” began his migratory journey on December 12, 2010 by travelling eastward to the west coast of the Kamchatka Peninsula. He swam around the southern tip of Kamchatka and proceeded north along the coast to Kamchatka Bay. By January 3, 2011 Flex began to swim east across the Bering Sea towards the North American continent. He crossed the Gulf of Alaska and arrived at the coast of Washington, USA by February 2, 2011. The transmitter failed three days later on February 5 near the Oregon coast with Flex apparently heading south along the North American coast.

Better data were obtained from a transmitter placed on a female western North Pacific gray whale at Sakhalin named “Varvara” in 2011. That transmitter lasted for more than a year and Varvara was tracked from Sakhalin to the eastern North Pacific gray whale wintering areas off western Baja, Mexico, and then back again to Sakhalin (IUCN 2012b).

Flex’ surprising journey prompted examination of other possible records to determine if the whales that summer in the Sea of Okhotsk might generally migrate to and from North America rather than, or in addition to wintering habitats in Asia. Matches of photographs of whales taken at Sakhalin were made with photographs of whales from British Columbia (n = 6, Weller et al., 2011) and Mexico (n = 13, Urban et al., 2012) and genetic matches (n = 2, Lang et al., 2011a) of whales biopsied at Sakhalin and Southern California have now been reported as well as the whales with satellite tags (unpublished). Thus, a total of 23 whales have been identified that have travelled between the Sakhalin Island summering localities and North America. This represents approximately 15% of the western North Pacific gray whale population.

Clearly questions remain about the population biology of the whales that summer in the Sea of Okhotsk. Central to this is the finding of significant mtDNA and nuclear gene differences between this population and the eastern gray whales in the face of what appears to be a high level of mixing. This paper seeks to clarify the potential stock structure scenarios that are consistent with the data on genetics, distribution and movements of these whales and makes recommendations regarding genetic methods to help resolve the issue.

Genetic differentiation of western and eastern North Pacific gray whales.—The genetics of the western North Pacific gray whale population has been studied and compared to the eastern gray whale population using mtDNA (LeDuc et al., 2002; Kanda et al., 2010; Meschersky et al., 2012), nuclear microsatellites (Lang, 2010; Lang et al., 2010b), and both (Lang et al., 2011a). These studies consistently show evidence of genetic divergence between the populations expressed as statistically significant differences in mtDNA haplotype frequencies (Fst) and microsatellite allele frequencies (Fst). The level of genetic diversity (e.g., heterozygosity) is similar for microsatellites as is nucleotide diversity of mtDNA, but mtDNA haplotype diversity is substantially greater for the eastern population than for the western population (Lang et al., 2011a). The findings that two of the estimates of genetic diversity are similar and the values for these estimates are fairly high indicate that a substantial amount of genetic variation exists within the small western population, despite the severe population reduction caused by hunting. However, the distributional pattern of haplotypes is distinct between the two populations with two haplotypes being of very high frequency in the western population (haplotype A, 0.51 and B, 0.44) whereas the most common haplotype in the eastern gray whale population was 0.15

(haplotype A). The genetic results are consistent with the two populations being distinct, and of drastically different sizes especially with respect to the number of breeding females.

The question of genetic distinctness between the two populations, however, seems to be inconsistent with the observation of a substantial (but as yet unknown) proportion of western gray whales migrating to North America rather than to wintering habitats in Asia. And it must also be recognized that an apparently high level of (primarily) male mediated gene flow has been documented by Lang et al. (2011a) who report a significant Fst for microsatellites for females, but not for males between the eastern and western populations. (When the sexes are combined the analysis shows a significant Fst, but when sexes are analyzed separately only the female comparison is significant. Of course, statistical power is inevitably lost when the sample sizes are reduced for separate analyses of the sexes.). The fact that both males and females in approximately equal numbers (but from an admittedly small sample size) of the western population are known to migrate to North America (Urban et al., 2012), further questions the population structure of gray whales in the Pacific basin.

Population structure hypotheses.—In light of the uncertainty of the nature and history of the western population it is useful to consider stock structure hypotheses that could be consistent with current information on genetics, movements, and distribution of the eastern and western North Pacific gray whale populations.

- Hypothesis 1: a single panmictic population (the eastern gray whales, the western population is extinct; no population structure within the eastern population).
- Hypothesis 2: a single metapopulation (the eastern gray whales includes a genetically distinct subpopulation that summers in the Sea of Okhotsk, genetic differentiation could be due to familial structure or founder effect, or driven entirely by matrilineal fidelity).
- Hypothesis 3: A large eastern population that co-inhabits with the surviving remnant of the western population on the summering range in the Sea of Okhotsk, but the two populations do not interbreed (eastern animals migrate to NA, western animals to Asia).
- Hypothesis 4: A large eastern population that interbreeds with the surviving remnant of the western population (eastern animals migrate to NA, western animals to Asia).
- Hypothesis 5: Two surviving populations, one very large eastern population and a small western population (ca. 155 animals). The Sea of Okhotsk population consists entirely of western gray whales which migrate to both NA and Asia.

These five hypotheses are not exhaustive of stock-structure possibilities but will serve to frame a discussion of what is needed from genetics to resolve the issue. To begin, it must be stated that the well entrenched hypothesis of two geographically isolated and genetically distinct pre-depletion North Pacific gray whale populations consisting of an eastern population that migrated along the North American coast and a western population that migrated along the Asian coast might not be correct. There is very good evidence of the two migratory corridors, but there is no data available regarding genetic differentiation of Asian and North American wintering populations. The best way, and perhaps the only way, of determining the genetic makeup of the pre-depletion western gray whale is by genetic analysis of historical samples as was previously suggested by Brownell et al. (2009). While tissue samples that predate the depletion are not available, bones, baleen or other sub-fossil materials, and even cultural artifacts from the period might be used. Such material has been successfully used to help reconstruct the population structure of bowhead whales (Alter et al., 2012b; Borge et al., 2007; Morin et al., 2012) and to investigate the impacts of whaling on eastern North Pacific gray whales (Alter et al., 2012a).

Hypothesis 1 considers a single panmictic population representing the extant eastern North Pacific gray whale population. The hypothesis implies both the absence of the (extinct) western gray whale, and a lack of substructure within the extant population. While the western gray whale might be extinct, clearly there is ample evidence of genetic differentiation of the Sea of Okhotsk population (Lang et al., 2011a) to reject the hypothesis of panmixia.

Hypothesis 2 considers the eastern population to be a metapopulation with subpopulations that can be somewhat genetically distinct but not necessarily completely isolated. There is already evidence that the eastern population is functioning as a metapopulation in that the Pacific Coast Feeding Group (PCFG) is genetically distinct in terms of mtDNA (Frasier et al., 2011) from the main population and the Sakhalin population might also be functioning as a "feeding group". Under this hypothesis the western population would not be a remnant of the pre-depletion western gray whale population, but instead a small population founded by a group of eastern emigrants that have diverged genetically due to a strong founder effect and genetic drift. This is consistent with the observations of no signature of a bottleneck and a non-significant Fst for males (Lang et al., 2011a). Thus the population that summers in the Sea of Okhotsk would represent an expanding population established by a small number of founders and whose genetic differentiation is driven by female fidelity to the summer feeding area. It is also consistent with the observed migration data wherein Sea of Okhotsk whales migrate to the NA wintering lagoons in Mexico. Whales that have migrated south along the Asian coast and to Japan are explained as wanderers from the eastern population as discussed in previous studies (Nishiwaki and Kasuya, 1970; Bowen, 1974; Ilyashenko, 2011).

Hypothesis 3 considers the whales summering in the Sea of Okhotsk to include animals of eastern descent along with the surviving remnants of the pre-depletion western North Pacific gray whale population. The two populations do not interbreed as mating takes place during migration toward the respective wintering areas. This is consistent with the genetics data, as well as the observations of movements between the Sea of Okhotsk and both NA and Asia. However, a Wahlund effect would be expected to cause diploid loci to be out of HW equilibrium and to be maintained across generations. A Wahlund effect is a reduction of observed heterozygosity in a sample caused by subpopulation structure. It stems from the fact that when samples from two populations with different allele frequencies are inadvertently mixed and analyzed as a single population, there appears to be a deficit of heterozygosity. This occurs even when both populations are in Hardy-Weinberg equilibrium. The severity of the Wahlund effect is determined by the degree of genetic differentiation of the two populations.

Hypothesis 4 also considers the whales that summer in the Sea of Okhotsk to include animals of eastern descent along with the surviving remnants of the pre-depletion western North Pacific gray whale population but in this scenario the two populations interbreed. This is consistent with the genetics data, as well as the observations of movements between the Sea of Okhotsk and both NA and Asia. The Wahlund effect would be reduced in each generation at a rate depending on the level of interbreeding.

Hypothesis 5 considers the Sea of Okhotsk whales all to be descendants of the pre-depletion western North Pacific gray whale population but the population includes animals that migrate to NA as well as animals that migrate to Asia. The Sea of Okhotsk whales that migrate to North America maintain a degree of reproductive isolation from eastern gray whales because of temporal differences in the timing of the migrations of the respective populations, during which time mating occurs. Under this scenario, one would expect to have observed significant bottleneck test results, but those tests are not very sensitive. This hypothesis is consistent with the data on gray whale movements, and the genetics data showing overall mtDNA and microsatellite differentiation of the eastern and western populations.

Of the five stock structure hypotheses given above the most unlikely is hypothesis 1 as there is ample evidence of genetic subdivision. Hypothesis 5 also seems unlikely as 1) the population does not show a significant signature of a bottleneck, 2) paternity analysis revealed a high percentage of "missing fathers" within this population (Lang et al., 2010a), these likely are part of the eastern gray whale population, and 3) the population possesses a number of nuclear microsatellite loci that are out of Hardy-Weinberg equilibrium which could be evidence of a Wahlund effect (mixing of populations).

So the most likely scenarios are hypotheses 2, 3 and 4 which differ in their assumption of whether the genetic signatures of population differentiation between the Sea of Okhotsk whales and the eastern gray whale population is due to founder effect resulting from a small number of eastern gray whales establishing the population (2) or the existence of surviving western gray whales (3 and 4), and if there are surviving western gray whales do they interbreed with eastern whales (3) or not (4). It is not possible to prove one way or the other which of these is correct with the current data so we will make recommendations as to the methods and sample design that could be followed to better understand the history and makeup of these populations.

Recommendations.—To establish the genetic makeup of the pre-depletion western North Pacific gray whale population we must obtain adequate samples of sub-fossil or cultural artifacts as explained above. This could be done by visiting appropriate museums that might have skeletal material, and possibly historical whaling sites in Japan, Russia and Korea. In addition, a much more extensive assessment of the genetics of the eastern population should be undertaken. This could include analysis of the samples already collected from the Mexican wintering lagoons, but also samples taken from summer feeding sites in the Bering and Beaufort Seas.

Clearly a weakness in the current data is the high proportion sampled of the small Sea of Okhotsk population versus the very low proportion sampled of the eastern North Pacific gray whale population. Based on current data one can conclude that the Sea of Okhotsk population differs significantly from the eastern gray whale samples that have been analyzed, but our confidence in saying they differ significantly from the eastern North Pacific gray whale population is dependent upon how representative are the current samples of the very large eastern population.

The most recent study (Aimee Lang, Pers. Comm.) to address the issue of genetic stock structure within the eastern Pacific gray whale included 177 individuals taken from the summer feeding grounds in the Pacific Northwest (northern California to British Columbia), Chukotka (Russia), and Barrow (Alaska). This latest study is an improvement over previous eastern gray whale genetic studies in that it included samples from animals from feeding sites, as opposed to only including samples from animals that stranded during migration. Nonetheless, the adequacy of sampling is still clearly not optimal as it fails to comprehensively cover the large summer range of the eastern gray whale and represents such a small fraction of the estimated 19,000 animals in the population.

The major point here is that our understanding of genetic diversity of the eastern North Pacific gray whale population is weak and will require analyses of large numbers of samples taken from feeding grounds and wintering grounds.

We must also improve upon the methods currently being used. The mtDNA control region is widely used in population and evolutionary studies of mammals including cetaceans. Nonetheless, it is known to have limitations especially due to homoplasy caused by recurrent mutations at hyper-variable sites (Phillips et al., 2009, 2012). To get around this problem, additional protein coding genes, which are more conservative and less subject to recurrent mutations, should be sequenced for all of the animals in the existing database as well as in the future. Minimally this should include two genes such as cytochrome b and ND2. This has already been done by Meschersky et al. (2012) and Alter et al. (2007) examined cytochrome b in eastern North Pacific gray whales. But if next generation sequencing is performed it could be possible to sequence the entire 16,000 bases of the mtDNA molecule.

We should also change the methods used to analyze nuclear DNA genetic markers. Microsatellite loci have an advantage over almost any other nuclear markers in typically possessing very high rates of mutation and hence high levels of variability. But the disadvantages of this method include 1) they are markers of identity by state rather than identity by descent, 2) they cannot be used effectively in analytical methods that are based on phylogenetic analyses, and 3) they are not easily reproduced from lab to lab. Whereas mtDNA studies use sequence analyses and build upon data produced in previous studies deposited in GenBank, microsatellite data must be generated anew for each study.

The current suite of microsatellite loci being used (Lang et al., 2011a) have the additional drawback that they have all been identified and developed from other species of whales. This has been shown to lead to problems with scoring due to potential inexact matches between the primer sequences of the source species compared to that of the species being studied. And, whereas there is no cause for questioning the veracity of the data produced in previous studies, it is simply not the best analytical method available today.

Single Nucleotide Polymorphisms (SNPs) have been shown to be more reliable in scoring, can be used in phylogenetic methods, are reproducible from lab to lab, and the sequences can be deposited in GenBank and thus built upon study by study as is presently done for mtDNA. Moreover, they can be used to analyze ancient or historical samples whereas microsatellites cannot (Morin et al., 2012). The only remaining advantage of microsatellites is that the larger number of alleles per locus provides greater analytical power than for SNPs. But even this can be compensated for by increasing the number of SNP loci. By using genomics methods, it is possible to identify and analyze thousands of SNP loci which provide the best possible resolution even in analyses requiring high analytical power such as kinship analyses.

With a large set of SNP loci available for analysis, studies can employ a wider variety of experimental designs depending upon the questions to be addressed. For example, markers can be selected for analysis from genes of the immune system, genes open to selection, neutral markers, DNA repair genes, etc. Since it is likely that in the future questions regarding gray whale genetics will expand beyond the current focus of gene diversity and population structure, a more robust tool kit for genetics is needed. Such studies might include examination of genes related to health (such as immune function), development, the sensory adaptations of gray whales (vision, hearing, and smell), longevity, detoxification systems, etc.

We propose that a gray whale genome program be initiated. Whereas the ultimate goal will be to sequence and annotate the genome of the species, the immediate goal of the program will be the development of a SNP panel for use in population genetics. Such a panel could be developed and the primers and methods published with data validation within two years. The methods of next-generation sequencing have advanced to the point where such a "reduced representation" genomic analysis can be done quickly and is less expensive than was possible just a few years ago.

Concluding remarks.—Because of the status of the western North Pacific gray whale as critically endangered according to the IUCN, the Scientific Committee of the International Whaling Commission has adopted a conservation plan and further recommended that a collaborative Pacific-wide study be developed under the auspices of the IWC (IWC 2011). The methods proposed in this paper, if developed and implemented, will provide data to better resolve issues, such as population structure and historical demography that are keys to the development of a sound conservation and monitoring program and will provide the opportunity for investigators to build upon databases developed in previous studies. Clarification of the demographic history of the extant North Pacific gray whale will also potentially impact the conservation status of the Sakhalin population. For example, if it is determined that this population is a subpopulation of the eastern gray whale (e.g., hypothesis 2) it might reduce the priority status of the population. However, if it is found that the Sakhalin population includes both eastern and western gray whales (hypotheses 3 and 4) the identification and protection of the small number of western gray whales would remain a high priority.

Acknowledgments.— We thank Jon Scordino for reviewing a draft of the manuscript and we thank Bruce Mate for helpful comments. This study was funded by Exxon Neftegas Ltd. and Sakhalin Energy Investment Company LTD.

Abstract

Quantifying Uncertainty and Incorporating Environmental Stochasticity in Stock Assessments of Marine Mammals

John Robert Brandon

Chair of the Supervisory Committee:
Professor André E. Punt
School of Aquatic and Fishery Sciences

Incorporating scientific uncertainty and accounting for potential effects of environmental variability in stock assessments are vital aspects of providing sound management advice. This dissertation focuses on these issues in the context of estimating sustainable quotas for aboriginal subsistence hunting of marine mammals.

Bayesian model averaging was used to take into account both parameter and model uncertainty in the assessment of the Bering-Chukchi-Beaufort Seas (BCB) stock of bowhead whales. The lower 5th percentile of the Bayesian model-averaged posterior for an aboriginal whaling catch quantity (Q_1^{1+}) was estimated to be 155 whales in 2002. This estimate provides confirmatory evidence that current catch quotas for this stock are sustainable.

In order to assess the robustness of Bayesian assessments to alternative methods for constructing a joint prior distribution which respects biological realism, sensitivity analyses were performed in the context of a risk assessment. The probability of meeting a management objective for aboriginal subsistence hunting was found to be robust for the data-rich BCB bowhead example. However, the data-poor East Greenland walrus example was shown to be sensitive to this issue.

A framework was developed and applied to the assessment of the eastern North Pacific stock of gray whales which incorporated environmental stochasticity by estimating the relationship between residuals in birth and survival rates to an environmental time series. The scenarios which accounted for the effect of the mortality event in 1999 and 2000 led to less optimistic estimates of population status during recent decades with concomitant recovery generally attributable to higher survival rates as opposed to higher birth rates. This framework was then used as an operating model conditioned on forecasts of sea-ice, which has been hypothesized to regulate recent calf production in the population. Future population trajectories were then used to test the performance of the current catch control rule for this stock. Performance was measured by the ability to satisfy different levels of future aboriginal subsistence need, and was shown to be satisfactory under the range of trials examined here.

The methods developed in this dissertation are generally applicable for providing management advice for exploited populations of marine mammals and other renewable natural resources.

ACKNOWLEDGEMENTS

I thank André Punt for being my advisor and major professor. Through this process I have come to trust him completely and am honored to have had the opportunity to be one of his students. His dedication and passion are unsurpassed. There may be other advisors which are as good, but I am certain there can be none better.

My committee members have provided outstanding feedback and a critical eye on my research. Paul Wade was the reason I came to Seattle, and he sat down with me during the first phase of this research and patiently helped me cut my teeth on some very challenging problems. Just as importantly however, he has opened many doors in my life outside of this research. Every time I have gone to Paul for advice, he has been there and I have walked away better for it. Judy Zeh possesses the rare combination of statistical expertise and pragmatism that make her the consummate problem solver. I have been fortunate to have seen her in action in the Scientific Committee of the IWC; when Judy speaks everyone listens because the solution to the problem is not far behind. Tim Essington has provided a valuable breadth of perspective to my committee. More than anyone, he has challenged me to see the big picture. This is something I hope to continue to struggle with (in a good way) for the rest of my career. Eliot Brenowitz served as my GSR and generously took time away from his own research to join us in meetings whenever the occasion arose.

The highlight of this research has been working with and learning alongside other graduate students, especially my lab-mates: Teresa A'mar, Jason Cope, Gavin Fay, Melissa Haltuch, Doug Kinzey, Tommy Garrison, Rod Towell, Chantel Wetzel and Motoki Wu.

Many people have provided reviews and ideas during this process. I would like to thank members of the Scientific Committee of the IWC for their feedback, especially: Jeff Breiwick, Robert Brownell Jr., Doug Butterworth, Justin Cooke, Geof Givens, Bill Koski, Sue Moore and Lars Witting. I would also like to thank Dave Rugh and several anonymous reviewers for their reviews on the published chapters. Likewise, this work would not be possible were it not for the many colleagues in the field who have collected and analyzed the data used in the analyses. I thank Muyin Wang for providing the global climate model forecasts of sea-ice. I would also like to extend my thanks to Wayne Perryman for his help with my research on ENP gray whales.

Financial support was provided by Washington Sea Grant, University of Washington, pursuant to the National Oceanic and Atmospheric Administration Graduate Fellowship Program in Population Dynamics and Marine Resource Economics, and also through the Minerals Management Service, the IWC and the School of Aquatic and Fishery Sciences.

Finally, I would like to thank Tim Gerrodette for getting my foot in the door and my wonderful girlfriend Janna Wemmer for her love and support along the way.

DEDICATION

To my father and mother, John and Dorothy Brandon.

Thank you.

INTRODUCTION

Incorporating scientific uncertainty and accounting for potential effects of environmental variability in stock assessments are vital aspects of providing sound management advice (Punt and Hilborn, 1997; Maunder and Watters, 2003). This dissertation focuses on these issues in the context of estimating sustainable catch quotas for aboriginal subsistence hunting of marine mammals. Case studies utilize data for three stocks subject to hunting: the Bering-Chukchi-Beaufort seas (BCB) stock of bowhead whales (*Balaena mysticetus*), walrus off East Greenland (EG) (*Odobenus rosmarus rosmarus*), and the eastern North Pacific (ENP) stock of gray whales (*Eschrichtius robustus*). Specifically, this work advances existing Bayesian stock assessment methods by examining and applying methods which: 1) account for model uncertainty through Bayesian model averaging; 2) evaluate the sensitivity of assessment results to alternative approaches for constructing coherent joint prior distributions which respect biological realism; 3) synthesize information relating environmental variables and population processes, and 4) use simulations to test the robustness of an existing management procedure given climate forecasts and plausible scenarios for how population dynamics might be affected by such. The overarching theme is incorporation of uncertainty at different levels (e.g. parameter, observation, process, and model uncertainty), to better represent and improve the current understanding of population dynamics and resulting estimates of sustainable catch quotas, hence providing the best available management advice.

A great deal of progress has been made during the last decade to better quantify and integrate various sources of uncertainty which are inherent in calculating sustainable catch quotas. The Scientific Committee of the International Whaling Commission (IWC) has played an instrumental role in the development of Bayesian stock assessment methods to meet this goal. The Bayesian methods that were pioneered by the IWC were initially in response to the challenge of providing management advice on catch quotas for the aboriginal hunt of BCB bowhead whales, given uncertainty surrounding biological parameters and stock abundance (Raftery *et al.*, 1995). Subsequent extensions of that approach have formed a widely accepted paradigm for integrating a variety of sources of information and concomitant uncertainty into fisheries stock assessments (Punt and Hilborn, 1997). However, one aspect of uncertainty that is still largely underestimated is model uncertainty (Clyde and George, 2004). While model selection has become an increasingly more popular tool (Burnham and Anderson, 2002), it is not always advisable to base inference on a single model or hypothesis. This is especially true when ambiguity exists with respect to which model best fits available observations. Indeed, this is exactly the case for the BCB bowheads; different population dynamics models are able to fit the data nearly equally well, yet the resulting estimates for quantities of management interest differ substantially among models. Model averaging provides an attractive technique for dealing with such a conundrum. Therefore, the first chapter of this dissertation expands upon earlier IWC assessments of the BCB stock of bowhead whales by explicitly accounting for this additional dimension of uncertainty, through Bayesian model averaging.

Bayesian analysis allow for various sources of prior knowledge (or ignorance), to be combined into a joint prior distribution, upon which inference may proceed for estimated parameters and derived quantities. However, some aspects of prior information may be inconsistent with each other. Such inconsistencies are likely to be more common for models that contain many estimated parameters that are functionally related. Bayesian stock assessments of marine mammals using deterministic age-structured population dynamics models are an illustrative example of this problem. In this context, life history parameters and the parameter for the population growth rate are functionally related, which raises two related issues: 1) placing explicit priors on each life history parameter as well as on the population growth rate parameter results in an incoherent joint prior distribution (i.e. two different priors on the estimated parameters), and; 2) certain combinations of values drawn from the priors may result in biologically implausible solutions for the remaining parameter (which can be solved for analytically, to form a coherent joint prior, given the functional relationship mentioned above). Different approaches have been applied in recent assessments of marine mammals to deal with this problem and the issue of how best to satisfy constraints on parameter values given the realm of biological plausibility. However, the sensitivity of assessment results to this issue has not been explored in any detail to date. Thus, the second chapter of this dissertation investigates the sensitivity of assessment and risk analysis results, using data-rich (BCB bowhead) and data-poor (EG walrus) case studies for comparison, to better understand the potential consequences of these alternative approaches on the estimates of sustainable catch quotas,.

It is becoming increasingly more certain that climate is changing at unprecedented rates (IPCC, 2007). Stock assessments of marine mammal populations conducted by the U.S. National Marine Fisheries Science Service (NMFS) and the IWC are generally based on age- and sex-structured population dynamics models, with density dependence acting on fecundity (Breiwick *et al.*, 1984; Punt, 1999a; Wade, 2002a). An underlying assumption of these models is that fecundity is related deterministically to the size of some component of the population, and is independent of changes in the physical environment. However, the number of studies providing evidence that environmental variability (e.g. timing and extent of sea-ice break-up) is correlated with female foraging and reproductive success are growing. Examples include: polar bears (e.g., Stirling *et al*. 1999), northern and Antarctic fur seals (Goebel, 2002; Forcada *et al.*, 2005), northeast Atlantic fin whales (Lockyer, 1986), north and south Atlantic right whales (Green *et al.*, 2003; Leaper *et al.*, 2006), sperm whales (Whitehead, 1997) and ENP gray whales (Perryman *et al*., 2002). Simmonds and Isaac (2007) review expected effects of climate change on a variety of marine mammal species, highlighting, "…the need to take projected impacts into account in future conservation and management plans, including species assessments."

Accordingly, management strategies should strive to be robust to a range of plausible consequences of climate change. This issue is of immediate importance to stocks of marine mammals in the arctic and sub-polar oceans, because it is in these areas of the world where the effects of climate change are likely to be most profound (ACIA, 2004). For example, climate forecasts predict a massive decrease in the extent of arctic sea ice (Overland and Wang, 2007). This change is expected to have major impacts on populations of marine mammals which live in or migrate to the arctic, many of which are also important to aboriginal subsistence and culture (Lowry, 2000). Consequently, understanding the biological influences of environmental variability, especially with regards to marine mammals in the arctic and sub-polar oceans, is an area of special concern to both conservation and management. Hence, the third chapter of this dissertation advances existing stock assessment methods for marine mammals by investigating a framework to synthesize information relating environmental variables and population processes. The goal of this work is to provide improved estimation and evaluation of management quantities and strategies given natural variability in ecosystem conditions, and forecasts of climate change. The ENP gray whale is used as a case study because this stock is currently the target of aboriginal subsistence hunting and there exists suitable data to complete the objectives of this research.

While stock assessments are an important aspect of monitoring recoveries and understanding population dynamics, management procedures are increasingly being adopted as a way for setting catch quotas to achieve sustainability and conservation goals (Butterworth, 2007; Punt and Donovan, 2007). A fundamental component of the selection of a management procedure is the use of computer simulations to examine the performance of a proposed catch control rule (for aboriginal subsistence whaling the IWC catch control rule is referred to as a Strike

Limit Algorithm, *SLA*, and determines the number of allowable "strikes" each year). Underlying the simulation testing structure is an operating model, which takes the major sources of identified uncertainty (e.g., population growth rate, stock structure, etc.) into account. The operating model corresponds to a hypothesized underlying 'true' state of nature and is used to generate the simulated data that is provided to the management procedure. Given this information, the strike (or catch) limit is computed by the management procedure and the resulting mortality subtracted from the population represented in the operating model. This feedback process is repeated as the underlying population is projected forward through time. At the end of the projection period, performance statistics are compiled based on management criteria. Often, multiple operating models are used during this process to investigate the performance of a proposed management procedure relative to alternative scenarios regarding the 'true' state and dynamics of nature. Recommend catch limits for ENP gray whales are based on the 'Gray Whale *SLA'*, which has undergone extensive simulation testing. However, it would be prudent to revisit the performance of these control rules given the availability of new and detailed forecasts for changes in sea ice, and evidence which suggests that variability in calf production for ENP gray whales may be related to variability in sea ice. Therefore, the fourth chapter of this dissertation involves the development of an operating model (based on the assessment in chapter 3) to evaluate the performance of the Gray Whale *SLA* and hence assess its robustness to environmental variation.

Objectives

The objectives of this dissertation are:

1. perform an assessment of the BCB stock of bowhead whales based on a variety of alternative population dynamics models, which represent competing hypotheses, and use Bayesian model averaging to incorporate model uncertainty in the resulting management advice;

2. perform and summarize the sensitivity of assessment and risk analysis results to alternative approaches for constructing a coherent joint prior while respecting biological realism. Compare the sensitivity of the results between data-rich (BCB bowhead) and data-poor (EG walrus) case studies;

3. develop methods for synthesizing environmental time series with existing stock assessment models for marine mammals, to capture alternative assumptions regarding biological processes (e.g. fecundity is not only related to population size, but also to some function of an environmental variable) and apply the framework to an assessment of the ENP gray whales; and,

4. use the framework developed in chapter 3 as an operating model within a simulation modeling approach, to evaluate the performance of the IWC Gray Whale *SLA* given hypotheses regarding the nature and extent of future environmental stochasticity and forecasts of a relevant climate index.

Chapter 1:

Assessment of the Bering-Chukchi-Beaufort Seas stock of bowhead whales using Bayesian model averaging[1]

ABSTRACT

Bayesian estimation methods are used to fit an age- and sex-structured population model to available data on abundance and stage-proportions (i.e., calves/mature animals in the population) for the Bering-Chukchi-Beaufort Seas stock of bowhead whales (*Balaena mysticetus*). The analyses consider three alternative population modeling approaches: 1) modeling the entire population trajectory from 1848**,** using the 'backwards' method where the trajectory is back-calculated based on assigning a prior distribution to recent abundance; 2) modeling only the recent population trajectory, using the 'forwards from recent abundance' method, where the population is projected forwards from a recent year and the abundance in that year is not assumed to be at carrying capacity; and 3) a version of 2) that ignores density-dependence. The 'backwards' method leads to more precise estimates of depletion level. In contrast, the 'forwards from recent abundance' method provides an alternative way of calculating catch-related quantities without having to assume that the catch record is known exactly from 1848 to the present, or having to assume that carrying capacity has not changed since 1848. Not only are all three models able to fit the abundance data well, but each is also able to remain consistent with available estimates of adult survival and age of sexual maturity. Sensitivity to the stage-proportion data and the prior distributions for the life history parameters indicates that use of the 1985 stage-proportion data has the greatest effect on the results, and that those data are less consistent with data on

---

[1] This chapter was published in The Journal of Cetacean and Research Management:

Brandon, J. and Wade, P.R. 2006. Assessment of the Bering-Chukchi-Beaufort Seas stock of bowhead whales using Bayesian model averaging. *J. Cetacean Res. Manage.* 8: 225-39.

trends in abundance and age of sexual maturity. The analyses indicate that the population has approximately doubled in size since 1978, and the 'backwards' analyses suggest that the population may be approaching carrying capacity, although there is no obvious sign in the data that the population growth rate has slowed. Bayes factors are calculated to compare model fits to the data. However, there is no evidence for selecting one model over another, and furthermore, the models considered in this study result in different posterior distributions for quantities of interest to management. Posterior model probabilities are therefore calculated and used as weights to construct Bayesian model-averaged posterior distributions for outputs shared among models to take this ambiguity into account. This study represents the first attempt to explicitly quantify model uncertainty when conducting a stock assessment of bowhead whales.

1.1 INTRODUCTION

Bowhead whales (*Balaena mysticetus*) have been caught by Alaskan Eskimos in an aboriginal fishery for at least hundreds of years; active whaling started along the arctic coast around 1800-1700 BP (Braham, 1989; Dinesman and Savinetsky, 2003). A commercial fishery began takes from the Bering-Chukchi-Beaufort Seas (B-C-B) stock of bowhead whales in 1848, and the population is thought to have been severely depleted by the substantial commercial catches that occurred during the 1800s (Bockstoce and Botkin, 1983; Breiwick and Braham, 1990; Breiwick *et al*., 1984). Although the commercial fishery almost completely collapsed early in the 1900's, aboriginal catches of B-C-B bowheads continue (*e.g.*, Braham, 1995; George *et al.*, 1988; Suydam and George 2004).

Most of the B-C-B bowhead stock migrates seasonally along the north slope of Alaska between wintering areas in the Bering Sea and summer feeding areas in the Beaufort Sea. Surveys have been conducted during the spring migration past Pt. Barrow in eleven years since 1978 to estimate the abundance and trends of this population (George *et al.,* 2004). The ice-based counts have resulted in abundance estimates substantiated by estimates using mark-recaptures of individually identifiable whales in aerial photographs (da Silva *et al.*, 2000). These abundance estimates have served as the primary basis for assessments of the status of and management advice for the B-C-B bowhead stock by the Scientific Committee of the International Whaling Commission (IWC).

Given a history of catches, it was possible to conduct an initial assessment of the status of the population once the first abundance estimate was made in 1978. This assessment suggested that the population had experienced some recovery since its depletion in the 1800s, but that it was still below carrying capacity (Breiwick *et al.*, 1984). Breiwick and Braham (1990) noted that estimates of carrying capacity and depletion level are sensitive to the current estimated population size. However, it is now possible to make more precise estimates of these quantities (conditioned on the accuracy of the catch data and population dynamics model) because the number and precision of the abundance estimates has increased substantially.

Givens *et al*. (1993) and Raftery *et al*. (1995) introduced Bayesian methods (*e.g.*, Press, 1989) to the assessment of bowhead whales. These methods can make use of multiple sources of data and fully characterise uncertainty. Bayesian assessments of the B-C-B bowhead stock (e.g. Givens *et al*., 1995) using the BALEEN II model (de la Mare, 1989) have consequently been used extensively by the Scientific Committee of the IWC (Punt, 1999a). Although there was general agreement that using multiple sources of data in assessments was desirable, considerable debate ensued in the Scientific Committee of the IWC regarding the details of the statistical methods to be used in bowhead assessments (*e.g.*, Butterworth and Punt, 1995; Punt and Butterworth, 1999, 2000; Poole *et al*., 1999; Poole and Givens, 2001; Schweder and Ianelli, 2000). One troublesome outcome of the results in the standard ‘forwards from K’ assessment (i.e. projecting the population dynamics model forwards from a prior distribution for the population size in 1848, which was assumed to be carrying capacity) was that the observed rate of increase of the population (ROI) differed substantially from the resulting posterior distribution for the ROI, even though the data on ROI were the main data source used in the analysis (*e.g.* Punt and Butterworth, 1999; Raftery and Poole, 1997). This and other related issues were determined to be due in part to a methodological issue associated with the forwards method and the specification of prior distributions. It was also determined that these issues could essentially be resolved by the use of the 'backwards' method, in which no prior is specified for the population size in 1848; instead, a prior distribution is specified for the abundance in a recent year, and the population level in 1848 (assumed to be carrying capacity) is then back-calculated from that recent abundance (Butterworth and Punt, 1995; Punt and Butterworth, 1999; Poole and Raftery, 1998).

An important assumption made in bowhead assessments is that the catch history is known without error. It has been found that the catch record going back to 1842 for eastern North Pacific stock of gray whales cannot be reconciled with the population's current dynamics (Punt and Butterworth, 2002), without assumptions that the catch record has been substantially under-estimated and/or that carrying capacity has changed since the mid 1800s. While it appears from past assessments that the bowhead catch record can be reconciled with the current dynamics, it is still appropriate to investigate an alternative assessment that does not make use of the historical catch record. This can be achieved using the method developed by Wade (2002a) for gray whales, where a model is projected forwards from the abundance in a recent year, with a separate prior distribution specified for carrying capacity. Such an assessment does not use the historic catch record prior to 1978, and does not need to assume that carrying capacity has remained constant since the mid 1800s. Therefore, such an assessment should be robust to problems with these assumptions.

The 1998 assessment of the B-C-B bowhead stock (IWC, 1999; Punt, 1999b) used 'backwards' Bayesian estimation based on the BALEEN II model, and the then-available abundance estimates and the data on the proportion of calves and mature animals in the population during 1985-94 (the 'stage-proportion' data). New information available for this stock since the 1998 assessment includes: 1) a mark-recapture estimate of adult survival from aerial photographs (Zeh *et al*., 2002); 2) an estimated age at sexual maturity and an estimate of maximum age (George *et al*., 1999); 3) a recalculation of the stage-proportion data (Koski *et al*., 2006); and 4) an estimate of abundance for 2001 (George *et al.*, 2004).

This chapter examines the sensitivity of the results of the B-C-B bowhead assessment to: 1) modeling the entire population trajectory from 1848 (using the 'backwards' method); and 2) modeling only the recent period (where the population is projected forwards from a recent year, and the abundance in that year is not assumed to be at carrying capacity). A third set of analyses is conducted using a Leslie matrix with no density-dependence. The population model used in this assessment is the density-dependent Leslie matrix model (Leslie, 1945, 1948) developed by Breiwick *et al*. (1984) except that reproduction and natural mortality are assumed to occur before removal by catches. When parameterized in equivalent ways, the results of the BALEEN II model and this Leslie matrix model have been found to be nearly identical (Wade, 2002a; Punt and Butterworth, 2002).

This chapter also examines the sensitivity of the model outputs to the sources of data included in the assessment and the specifications for the prior distributions. Scenarios are specified to investigate the sensitivity of the results to data-based informative vs. uniform (less informative) prior distributions, as well as to how the stage-proportion data are constructed. The stage-proportion data are excluded altogether in some analyses, and varied in others based on whether the aerial photographic survey data from 1985[2] are included in their calculation or not. Within a scenario, identical prior distributions are assumed for the life-history parameters and matching data-sets are used in the likelihood function for each of the three modeling approaches to enable comparisons to be made among them.

Model uncertainty is accounted for within a Bayesian framework, and Bayes factors (Kass and Raftery, 1995) are calculated to quantify the evidence provided by the data in favour of the different modeling approaches. For the 'reference scenarios,' there is no evidence for selecting one model over another, but there are important differences in the estimates of quantities that would be of interest to management. Therefore, we follow the philosophy outlined by a number of authors (e.g., Kass and Raftery, 1995; Buckland *et al.*, 1997; Hoeting *et al.*, 1999; Patterson, 1999; Durban *et al.*, 2005; Raftery *et al.*, 2005) and present quantities of interest as Bayesian model averages; weighting the output of contending models based upon their relative likelihoods, as opposed to selecting between them.

1.2 METHODS

Available data

The population dynamics models are fit to three sources of data: 1) abundance estimates from ice-based surveys at Pt. Barrow, Alaska between 1978 and 2001 (Table 1.1); 2) proportion calves/mature animals in the population from 1985 to 1994 (Table 1.2); and 3) annual catches in individuals from 1848 to 2002 (Table 1.3).

All of these sources of data were used in the 1998 assessment but have been updated since. The first ice-based survey since 1993 was conducted in 2001, and has provided an abundance estimate for that year of 10,545 with a coefficient of variation of 0.128 (updated from George *et al.*, 2004 by Zeh and Punt, 2005). The

[2] 1985 appears to have been an anomalously late migration year; the aerial survey in 1985 is believed to have ended too early to have sampled the tail-end of the migration, typically when most cow/calf pairs are in the study area (Koski *et al.*, 2006)

catch data have been updated with the post-1998 catches and revisions to the catches for 1994-96. Two additional years of aerial photographic data have been analyzed since the previous assessment, and the stage-proportion data have been recalculated (Angliss *et al*., 1995; Koski *et al*. 2006).

Additional information available for this stock since the 1998 assessment includes a mark-recapture estimate of survival (Zeh *et al*., 2002), and a recent estimate of age of sexual maturity and the maximum age (George *et al*., 1999). This information was included in the analyses of this chapter as data-based informative priors (see the section on model parameters and prior distributions).

Population dynamics model

The underlying population model is a simplified age- and sex- structured Leslie matrix (Leslie, 1945, 1948) projected as:

$$\underline{n}_{t+1} = (\mathbf{A_t}\,\underline{n}_t) - \underline{h}_t \tag{1.1}$$

where:

$\underline{n}_t$ is vector of population size in each age class at the start of year *t* (defined when calving and natural mortality occur);

$\mathbf{A_t}$ is the Leslie matrix for year *t*; and

$\underline{h}_t$ is the vector of age-specific catches during year *t*.

The catches and birth rates are assumed to be equal for both males and females (i.e. the vectors above are divided equally by sex). The parameters that define the entries of the Leslie matrix are: 1) S_{juv}, the survival rate of immature whales (assumed identical for calves and juveniles); 2) a_T, the last age with survival rate S_{juv}; 3) S_a, the survival rate of mature whales; 4) a_m, the age at sexual maturity (the last age class with zero fecundity); 5) $f_{\max}$, the maximum fecundity rate; and 6) $a_{\max}$, the maximum age, after which survival becomes zero. Fecundity is assumed identical for all mature animals, and is calculated as the number of female calves per mature female. Recruitment to the fishery is assumed to be knife-edged and to occur at age 1, and the catch is distributed uniformly over all recruited age-classes (i.e., uniform selectivity across recruited age-classes).

The projections are initialized from a stable age distribution for the population in the year prior to that with the first catch (e.g. 1977 or 1847) based on the values for the parameters sampled from the prior. This population vector is then projected one year forward without catch, and the population vector re-scaled so that the 1+ population size in the year with the first catch equals that generated from the prior for 1+ abundance for that year.

Density dependence is assumed to affect fecundity according to**:**

$$f_t = f_0 + (f_{\max} - f_0)\left[1 - \left(\frac{N_t^{1+}}{K^{1+}}\right)^z\right] \tag{1.2}$$

where:

f_t is the fecundity during year *t*;

$f_{\max}$ is the maximum fecundity (in the limit of zero population size);

N_t^{1+} is the (1+) population size at the start of year *t*;

K^{1+} is the pre-exploitation (1+) population size;

z is the shape parameter; and

f_0 is the fecundity at carrying capacity.

Given values for the life-history parameters in the model, the value for f_0 is determined from the characteristic equation of the Leslie matrix given equilibrium conditions:

$$f_0 = \frac{1 - S_a}{S_{juv}^{(a_T)}\, S_a^{(a_m - a_T)}\,[1 - S_a^{(a_{\max} - a_m - 1)}]} \tag{1.3}$$

Model parameters and prior distributions

Table 1.4 lists the parameters and their priors used in three 'reference' scenarios. The population trajectory is modeled in three ways: 1) a density-dependent model initialized in 1848 (abbreviated: '1848 DD'); 2) a density-dependent model initialized in 1978 ('1978 DD'); and 3) a density-independent model initialized in 1978 ('1978 NON DD'). The six life-history parameters of the Leslie model are included in each of three models, but the remaining parameters differ among models. The '1848 DD' model includes a parameter for the population size in 1993, N_{1993}^{1+}, and one for the maximum sustainable yield level, $MSYL^{1+}$. The '1978 DD' model also includes the parameter $MSYL^{1+}$ but instead of placing a prior on N_{1993}^{1+} places one on N_{1978}^{1+}. This model also includes an additional (explicit) prior on the carrying capacity, K^{1+}. The '1978 NON DD' model includes priors on N_{1978}^{1+} and the maximum population growth rate in the absence of density dependence, r. For this model, fecundity and population growth rates apply only to the specified period, and where the distinction is appropriate, they are referred to as f and r. However, when methods are consistent across models, these rates are referred to as $f_{\max}$ and $r_{\max}$ for the sake of simplicity.

'Data-based' prior distributions are assigned to adult survival rate and the age at sexual maturity, and the maximum age of the Leslie matrix is determined from the results of recent research on ageing. The informative prior for S_a (Table 1.4) approximates the Bayesian posterior calculated for this parameter based on a mark-recapture analysis of photoidentification data (Zeh *et al.* 2002). Information on age-at-maturity is taken from a study by George *et al*. (1999) that estimated ages of caught animals based on the chemistry of eye lenses. Those authors fit a growth curve to these ages from known lengths, and combine this relationship with previous data on length at sexual maturity to provide an estimate of the age-at-maturity. The aging results also estimated some animals were older than the previously accepted maximum age, and this result is supported by the recent recovery of traditional whaling tools in five whales (reported in the same study). The maximum age in the Leslie matrix is therefore set to 200 to reflect this information.

Punt and Butterworth (1999) note that placing a prior on S_{juv} would be an instance of Borel's Paradox (i.e. effectively placing two priors on the same parameter) due to the functional relationships among the life-history parameters in an age-structured population model; instead the value of S_{juv} is solved for analytically in this study by rearranging the characteristic equation of the Leslie matrix given the values for the remaining five parameters and λ, the dominant eigenvalue of the Leslie matrix (i.e. $r_{\max}+1$) (Breiwick *et al*., 1984):

$$S_{juv} = \left[\frac{\lambda^{(a_m+1)} - S_a \lambda^{(a_m)}}{S_a^{(a_m - a_T)} f_{\max} \{1-(S_a/\lambda)^{(a_{\max}-a_m-1)}\}} \right]^{\frac{1}{a_T}} \tag{1.4}$$

The value for S_{juv} is forced to be less than that of S_a. If necessary, values for $f_{\max}$ and S_a are re-sampled (see below), until this condition is met, or 1000 re-samples occur. If this maximum is reached, a new value for $r_{\max}$ is re-sampled, and the process repeated until an acceptable sample from the prior occurs.

The priors for the remaining life history parameters are also based on available information. The prior distribution for $f_{\max}$ is based on an assumed range of a 2.5- to 4-year calving interval for large baleen whales (IWC, 1998). Note that $f_{\max}$ is specified in the standard Leslie matrix formulation as female calves per female per year (i.e., a fecundity rate of *0.125* implies a female calving interval of 8 years, and therefore a total calving interval of 4 years, assuming an equal sex ratio of calves). The age of transition from immature to adult survival is assigned a discrete uniform prior over the interval 0 to 8 years.

Output quantities

Posterior distributions are calculated for several output quantities that are functions of the parameters in Table 1.4. The maximum sustainable yield rate ($MSYR^{1+}$) is calculated as $\lambda - 1$ based on the f_t value associated with $MSYL^{1+}$. Maximum sustainable yield (MSY^{1+}) is calculated as the product, $MSYR^{1+} MSYL^{1+} K^{1+}$. Current replacement yield (RY^{1+}) is calculated as the difference between the number of 1+ animals in 2002 (prior to the removal of catches in that year) and the number of such animals at the end of 2001. The quantity Q_1^{1+}, designed to meet the intent of aboriginal whaling management objectives (Wade and Givens 1997), is also calculated. This quantity has the property that the proportion of net production allocated to recovery increases at higher levels of stock depletion[3]. Specifically:

$$Q_1^{1+} = \min(MSYR^{1+} * N_{2002}^{1+}, 0.9MSY^{1+}) \quad (1.5)$$

The post-model-pre-data distribution is reported for the parameters. This distribution arises after conditioning the specified priors on the model (i.e. by eliminating combinations of parameters for which the juvenile survival rate implied by equation (1.4) exceeds the adult survival rate drawn from the joint prior distribution). Likewise, post-model-pre-data distributions for output quantities are calculated as the distributions for these quantities in the sampled joint prior space.

Parameter estimation

[3] This definition applies to a population above some minimum level, P_{min} (assumed here to be $0.1K^{1+}$), below which catches are set to zero.

The Sampling-Importance-Resample (SIR) algorithm (Rubin, 1988; Smith and Gelfand, 1992; Wade, 2002a) is used to generate samples of parameter vectors (and output quantities of interest) from the posterior distribution. This algorithm involves randomly sampling a large number of parameter vectors $\underline{\theta}_i$ (draws) from the prior distribution. A population trajectory is then calculated for each vector of parameter values, and this trajectory is used to determine the likelihood of the data for each random draw. 10,000 draws (which form the numerical representation of the posterior distribution) are then selected by sampling (with replacement) from the initial samples from the prior, with probability proportional to the likelihood. Following Punt and Butterworth (1999) and Raftery *et al*. (1995), the SIR algorithm is considered to have converged if the number of unique parameter vectors in the sample from the posterior is fairly high (>5,000) and if the most frequently re-sampled parameter vector did not occur in the posterior sample more than ten times.

The total negative log-likelihood of a model trajectory, given a vector of parameters and the data, consists of contributions from four data sources: 1) the estimate of abundance for 1993; 2) the estimates of abundance for the remaining years; 3) the proportion of calves in the population; and 4) the proportion of mature animals in the population. The abundance estimates are assumed to be indices of the 1+ component of the population. The scientific surveys at Pt. Barrow are assumed to have occurred after the aboriginal catch, and the likelihood function is calculated accordingly (i.e. catches are removed before calculating the likelihood of the data for a given year). Model-predicted proportions are calculated over the period 1985 to 1994, as the actual stage proportions are based on data for these years.

The estimate of abundance for 1993 is assumed to be independent of the remaining estimates (Punt and Butterworth, 1999), and to have normally as opposed to log-normally distributed sampling error. The contribution of the abundance estimates to the negative of the log-likelihood function is:

$$L_1 \propto 0.5 \frac{(\hat{N}_{1993} - 8293)^2}{626^2} \qquad L_2 \propto 0.5 \sum_{t_1} \sum_{t_2} (\ell n \hat{N}_{t_1} - \ell n N_{t_1}^{obs})^T \Sigma_{t_1,t_2}^{-1} (\ell n \hat{N}_{t_2} - \ell n N_{t_2}^{obs}) \quad (1.6)$$

where:

N_t^{obs} is the estimate of abundance for year *t*;

$\hat{N}_t$ is the model estimate of 1+ abundance for year *t*; and

Σ is the variance-covariance matrix for the logarithms of the estimates of abundance (excluding 1993).

The estimates of abundance (Table 1.1) are based on combining the data from visual counts at Point Barrow, Alaska, and estimates of the proportion of animals which passed within visual range based on acoustic data. Equation (1.6) accounts for the correlation among the non-1993 estimates of abundance that arises because the proportion within visual range is treated as a random effect when constructing the estimates of abundance (Zeh and Punt, 2005).

The contribution of the proportion data to the likelihood function follows Punt (2006), i.e. given the bootstrapping approach adopted to calculate the length-frequency distributions from which the proportion data were calculated (Koski *et al.*, 2006), it was reasonable to assume that the estimates are normally distributed:

$$L_3 \propto \frac{1}{2(\sigma_{p_c})^2}(p_c - p_c^{obs})^2 \qquad L_4 \propto \frac{1}{2(\sigma_{p_m})^2}(p_m - p_m^{obs})^2 \quad (1.7)$$

where:

p_c^{obs} is the observed fraction of the population that consisted of calves between 1985 and 1994;

σ_{p_c} is the standard deviation of p_c^{obs};

p_c is the model-estimate of the fraction of the population that consisted of calves between 1985 and 1994;

p_m^{obs} is the observed fraction of the population that consisted of mature animals between 1985 and 1994;

σ_{p_m} is the standard deviation of p_m^{obs}; and

p_m is the model-estimate of the fraction of the population that consisted of mature animals between 1985 and 1994.

Model comparison

The three models considered in this chapter are compared using Bayes factors (Kass and Raftery, 1995). The Bayes factor is calculated as the probability of observing the data given one hypothesis (model) divided by the probability of observing the same data given an alternative hypothesis, i.e.:

$$B_{12} = \frac{pr\left(D|H_1\right)}{pr\left(D|H_2\right)} \tag{1.8}$$

In the context of model comparison, the hypotheses represent competing models and the Bayes factor is used as the evidence provided by the data in favour of one model over another. Although equation (1.8) has the form of a likelihood ratio, if there are unknown parameters in either of the competing models, the probability densities must be found by integrating, as opposed to maximizing, over the parameter space. Therefore, for a given a model, the probability of the data is:

$$pr\left(D|H\right) = \int pr\left(D|H,\theta\right) pr\left(\theta|H\right) d\theta \tag{1.9}$$

This integration is based on the sample from the prior using the equation:

$$\hat{pr}(D|H) = \frac{1}{n_1} \sum_{i=1}^{n_1} pr(D|\underline{\theta}_i, H) \tag{1.10}$$

where $\underline{\theta}_i$ is the i[th] (of n_1) samples from the prior distribution.

Model averaging

Model uncertainty is accounted for by calculating the posterior probability of each model conditioned on the data and the priors, and then combining results across models as a weighted average of the posterior densities for a quantity of interest (Kass and Raftery, 1995). Hoeting *et al*. (1999) provide a convenient method of calculating the posterior probability of model H_k (where, *k*=1,2, …, *K* models are being considered) based on Bayes' theorem:

$$pr(H_k|D) = \frac{pr(D|H_k)\, pr(H_k)}{\sum_{i=1}^{K} pr(D|H_i) pr(H_i)} \tag{1.11}$$

where $pr(H_k)$ is the prior probability that H_k is the true model and $pr(D|H_k)$ is the estimate of the probability of the data (equation (1.10)). All of the probabilities are conditional on the set of models being considered (Hoeting *et al*., 1999). For $f_{\max}$, $r_{\max}$ and quantities related to carrying capacity, only the two models incorporating density dependence could be used to derive model averages. Under the set of models considered, these posterior model probabilities were used to determine model-averaged posterior probability distributions for the model outputs, θ:

$$pr(\theta|D) = \sum_{i=k}^{K} pr(\theta|H_k, D)\, pr(H_k|D) \tag{1.12}$$

In the context of the SIR algorithm used here, Bayesian model averaging was accomplished by selecting a number of random draws from the posterior for each model and combining them to form a model-averaged posterior. This number was determined by the posterior probability for each model. All models were considered equally probable *a priori* (i.e. objective ignorance regarding the true model), so the posterior probability of a given model was determined using the values from equation (1.10) normalized to sum to one over models.

1.3 RESULTS

Fits to the data

Fig. 1.1 shows the fits to the abundance estimates for three reference scenarios and the Bayesian model average. All three models provide a relatively good fit to these data, although the abundance estimate for 2001 falls well above the upper 90% credibility limit from the '1848 DD' model. This occurs because the median of the posterior distribution for 1+ population size in 2002 for this model (9,496) is smaller than the posterior medians for the other two models (Fig. 1.2, Table 1.5).

The abundance estimates indicate the population has been increasing steadily over 1978-2001, and the data on adult survival, age of sexual maturity, and the stage-proportion data (excluding 1985) are all relatively consistent with this increase (i.e., the inclusion of those data in the analysis does not lead to the model being unable to mimic the abundance data).

Backwards to 1848 (density dependent model): 1848 DD

The upper left panel of Fig. 1.1 shows the posterior median time-trajectory of 1+ population size along with its 90% credibility interval for the reference scenario. The population size is estimated to have declined dramatically during the 1800s, being reduced to approximately half of its pre-exploitation level within five years of the start of the commercial fishery, and 10% of this size by the early 1900s. However, the population recovered steadily thereafter. The 90% credibility interval for the post-model-pre-data distribution for K^{1+} is [8,000-30,000], with lower values favoured (Fig. 1.2). In contrast, the 90% credibility interval for the posterior distribution of K^{1+} is [9,000, 14,000] (Table 1.5) indicating that the data update the prior distribution substantially. The 2002 population size is estimated to be above 50% of K^{1+}, and there is a high probability of it being above $MSYL^{1+}$ (Fig. 1.3, Table 1.5). The posterior distribution for replacement yield in 2002 has a mode around 200, with a lower 5th percentile of 61 (Fig. 1.4, Table 1.5). In contrast, the lower 5th percentile for Q_1^{1+} is 99 (Fig. 1.4, Table 1.5). These two quantities differ because the current population size is estimated to be larger than $MSYL^{1+}$, and approaching K^{1+}. Therefore, density dependence has slowed population growth and RY^{1+} has decreased. This is the same situation which led to the use of Q_1^{1+} as a more appropriate measure of sustainable catch (to achieve IWC management goals) for the eastern North Pacific stock of gray whales (Wade, 2002a).

The constraints imposed by the relationships among the life-history parameters constrained $r_{\max}$ to be less than about 0.07 (Fig. 1.3), although they also reduced the (prior) probability of values of $r_{\max}$ larger than 0.06. The posterior for $r_{\max}$ assigns most support to values larger than 0.03 (posterior median 0.041, Table 1.6). The posterior distributions for adult and immature survival favour higher values than implied by the prior distributions for these parameters, and that for a_{m} values lower than implied by the prior distributions (Figs 1.5 and 1.6). The post-model-pre-data distribution for fecundity favours higher values (~0.20, Fig. 1.6), but the posterior median is 0.171, or a calving interval of approximately 3 years (Table 1.6). The results in Figs 1.3, 1.5 and 1.6 show that the data are clearly capable of updating the prior distributions for the life-history parameters.

The results for this model are not particularly sensitive to changing the prior distributions for S_a and a_{m} and to ignoring the proportion data (Table 1.5). The most noteworthy feature of these sensitivity tests are the changes to the catch-related outputs (RY^{1+}, Q_1^{1+} and MSY^{1+}). Results are not shown in Table 1.5 for the case in which the 1985 stage-proportion data are included in the analyses due to computational difficulties in achieving convergence. Preliminary analyses including these data indicated, however, that they are inconsistent with what is known about bowhead life history and the time series of abundance estimates. This inconsistency was the cause of the inability to achieve convergence.

Forwards from 1978 (density dependent model): 1978 DD

The posterior for K^{1+} from this analysis is much more uncertain than that from the '1848 DD' analysis (Fig. 1.2). This is because this analysis ignores the information contained in the 1848-1977 catch record, and because the abundance estimates show no evidence for a reduction in trend (which would be expected as the population approaches carrying capacity) and, unlike the '1848 DD' model, the '1978 DD' model does not make the assumption that the population size in 1848 was K^{1+}. Therefore, although this model confirms that the population is increasing (Fig. 1.1), it infers that the population is currently at a much lower fraction of its (current) carrying capacity than the '1848 DD' model (Fig. 1.3; Table 1.5). The posterior for N_{2002}^{1+}/K^{1+} is strongly influenced by the prior distribution assumed for K^{1+} given the inability of the data to place an upper bound on K^{1+}. This is clearly evident from the results of the sensitivity test in which the upper limit of the prior for K^{1+} is increased from 30,000 to 100,000. The results for this sensitivity test imply an increase to the median of the posterior for K^{1+} of 165% and a reduction to the posterior median for N_{2002}^{1+}/K^{1+} of 62% (Table 1.5) as the upper bound for K^{1+} is increased by 233%.

Given that there is little independent information on which to base a prior distribution for K^{1+}, the choice of the prior for K^{1+} is essentially arbitrary, and it should be recognized that this 'forwards' analysis consequently does not provide robust estimates of quantities related to K^{1+} (such as N^{1+}_{2002}/K^{1+}). However, Punt and Butterworth (1999) note that some key management-related quantities (e.g., RY^{1+} and Q^{1+}_{1}) are relatively insensitive to the prior assumed for K^{1+}, so this approach still has some value. The implicit (post-model-pre-data) distribution for RY^{1+} favours (is skewed towards) values less than 200 (Fig. 1.4). Despite this, the posterior median is 324, with a lower 5th percentile of 147 (Table 1.5). A similar result is evident for Q^{1+}_{1}, with low values favoured by the post-model-pre-data distribution, but higher values supported by the data (median 295, lower 5th percentile 160)(Fig. 1.4, Table 1.5). In essence, the joint prior distribution for the parameter values, conditioned on the population dynamics model, is not neutral (non-informative) with respect to these catch-related quantities, but the data are influential enough to move the posterior distribution away from the mode of the prior distribution.

The posterior distributions for $r_{\max}$, $MSYR^{1+}$ and the life history parameters for this model are generally similar to those for the '1848 DD' model. The most noteworthy difference between the posterior distributions for the '1978 DD' and '1848 DD' models in Table 1.6 relates to the posterior median for S_{juv} which is larger for the '1978 DD' model. As was the case for the '1848 DD' model, there is again little sensitivity to changing the priors for S_a and for a_m, and ignoring the stage-proportion data (Tables 1.5 and 1.6). In contrast, inclusion of the 1985 survey data when calculating the stage-proportion data has a large impact on the results. Specifically, K^{1+} and $MSYR^{1+}$ are estimated to be lower, and N^{1+}_{2002}/K^{1+} higher, with the population estimated to be above $MSYL^{1+}$ with almost 100% probability. $r_{\max}$ is estimated to be higher (as the population is estimated to be closer to K^{1+}

and therefore experiencing a growth rate much lower than $r_{\max}$). The estimates of the catch-related quantities are considerably lower for this scenario (e.g. the posterior median and the lower 5% percentile for RY^{1+} are 166 and 44 respectively).

Forwards from 1978 (density independent model): 1978 NON DD

The posterior median for RY^{1+} for this model ranges from 310 to 414 across the scenarios (166-217 for the lower 5$^{\text{th}}$ percentile for RY^{1+}). The posterior for r for the '1978 NON DD' model is centred on lower values than those for the other two models (Fig. 1.3). This is to be expected because the r for the '1978 NON DD' model' pertains to the current rate of increase rather than the increase rate in the limit of zero population size. The inclusion in the analyses of the 1985 stage-proportion data is again very influential. For example, the posterior distribution for fecundity for the 'include 1985 proportion data' sensitivity test does not overlap with that for the reference scenario.

Model comparison and Bayesian model averages

Bayes factors based on pair-wise comparisons of models range from 1.10 to 1.51, and indicate that there is no evidence for selecting one model over another (Table 1.7). Rather, these Bayes factors imply that the best approach to summarizing the state of the B-C-B bowhead stock is to consider all three models, e.g. through Bayesian model averaging. Average likelihoods of draws from the initial sample range from 0.522 ('1848 DD') to 0.789 ('1978 NON DD'). The two models that involve forward projection from recent abundance ('1978 DD' and '1978 NON DD') have slightly higher average likelihoods, and hence posterior model probabilities, than the model which started the population projection in 1848, although differences are not large (Table 1.8).

The time-trajectory of 1+ population size (medians and 90% credibility intervals) from the Bayesian model-averaged posterior provides, as expected, a good fit to the abundance estimates (Fig. 1.1, lower panel). The fit to the estimate of abundance for 2001 for the model-averaged posterior is not quite as good as for the '1978 DD' and '1978 NON DD' models because of the impact of including the '1848 DD' model in the average. The model-averaged posterior distribution for K^{1+} (Fig. 1.2) has a mode close to that of the posterior median for the '1848 DD' model, and a long tail caused by the uncertainty associated from the '1978 DD' model. The model-average posterior for N^{1+}_{2002}/K^{1+} (Fig. 1.3) is wide, but less so than that for the '1978 DD' model. The model-averaged posterior for RY^{1+} is slightly irregular because it consists of the combination of a bimodal posterior (for the '1848 DD' model) and a symmetric posterior (for the '1978 DD' model). In contrast to the model-average posterior for RY^{1+}, that for Q^{1+}_{1} is quite symmetric (Fig.1.4, Table 1.5).

The '1978 NON DD' model estimates only the recent fecundity and rate of increase for the population, whereas the two density-dependent models estimate the maximum fecundity and rate of increase. Therefore, the posterior for $f_{\max}$ and $r_{\max}$ is averaged across the two models with density dependence only. Maximum fecundity and population growth rate are relatively consistent across these two models and have a median of 0.171 and 4.3% respectively (Fig. 1.6 and Fig. 1.3, Table 1.6). Likewise, both adult and juvenile survival rates are consistent across models, with a median for adult survival of 0.990 and for juvenile survival of 0.932 (Fig. 1.5, Table 1.6).

It is straightforward to calculate model-averaged posterior probability distributions given different prior probability distributions for the models. For example, the models based on starting the projections in 1978 could be assigned probabilities of 0.25 and that which starts the population projections in 1848, a prior probability of 0.5 to indicate, for example, that the assumption that carrying capacity has not changed over the last 150 years is equally as likely as some shift in the equilibrium population size during this time. Alternatively, the models with density-dependence could be assigned prior probabilities of 0.25 each, and that which ignores density-dependence a prior probability of 0.5.

1.4 DISCUSSION

The three models have shown a good concurrenence. However, use of the historic catch record leads to lower estimates of RY^{1+} because the analysis estimates the population to be close to carrying capacity and so the growth rate is reduced compared to that at low population size. However, there is no (visual) evidence in the abundance estimates for a reduction in trend. It therefore appears that it is the combination of the magnitude of the historical catches and the values for the biological parameters that determines the estimate of the carrying capacity. One implication of starting the population projection in 1848 is that the model under-predicts the 2001 estimate of abundance (probably because if the population is approaching carrying capacity, a near-linear growth in population size could not still be occurring). The '1848 DD' model is assigned less weight than the '1978 DD' and '1989 NON DD' models using Bayes factor, but the discrepancy between the predictions of the '1848 DD' model and the data remains sufficiently small that the '1848 DD' model cannot be rejected.

RY^{1+} is the catch that will keep a population at its current size. This quantity is less useful as the basis for management advice for the B-C-B bowhead stock now that at least some of the analyses suggest the recruited population may be approaching K^{1+}. Obviously RY^{1+} will be zero if the population stops increasing because it reaches carrying capacity. Q_1^{1+} is therefore a more appropriate catch-related quantity to examine because it does not become zero at carrying capacity. Furthermore, this quantity represents a catch level that has been argued to meet the requirements of aboriginal subsistence management (Wade and Givens, 1997; Wade, 2002a). The fact that there is no evidence to select one model over the others, and not all models result in similar estimates of catch quantities is a reason why model uncertainty is important to include when conducting assessments of marine renewable resources. The lower 5th percentile of the Bayesian model-averaged posterior of Q_1^{1+} is 155 whales, and represents our best estimate of the catch level that would meet the intent of aboriginal whaling management objectives, taking into account both parameter, and model uncertainty (to the extent that model uncertainty can be captured by the three models considered in this study). It should be noted, in light of recent discussions regarding stock structure (IWC, 2005b), that the results presented here are based on the assumption that the B-C-B population of bowhead whales is composed of a single stock.

The actual aboriginal catch quotas are driven by need, and have averaged 36 whales per year from 1978-2002. There appears to be little effect on population size due to this catch level. In fact, during this timeframe the B-C-B stock of bowhead whales is estimated to have more than doubled. Another way of putting an average take of 36 whales per year into perspective is to examine the annual net production over the last 25 years. If it is assumed that the population was increasing at a constant 3.5% per year (the median rate estimated from the density independent Leslie matrix analysis), the population increased by about 175 whales per year in 1978 (population size ~5,000), about 260 whales per year in 1990 (population size ~ 7,500), and about 350 whales per year in 2002 (population size ~ 10,000). Given that the population has increased from about 5,000 whales to about 10,000 whales, in this timeframe an average kill of 36 whales per year represents an annual catch rate between 0.35-0.70% of the total population size.

What is known about B-C-B bowhead life-history vital rates (survival, fecundity, etc.) appears consistent with the available data on trends in abundance and the proportion of the population in three stages (calves, immature and mature). Overall, the results support a value of r_{max} of between 0.03-0.05, a range often assumed for cetaceans, particularly species with delayed sexual maturity and a longer than 2-year calving interval (Reilly and Barlow 1986, Wade 1998, Wade 2002b). In light of the reproductive life-history of this species, the results make clear that the observed population growth rates can only be supported by extremely high survival rates, as already suggested by the estimates of adult survival (0.990) in Zeh *et al*. (2002), and the observations of exceptionally old individuals (George *et al*., 1999).

The analyses of this chapter are based on the same types of data that were available for the 1998 assessment of this stock. Several other sources of data exist. For example, Schweder and Ianelli (2000) examine whether the data on the age-composition of the 1973-93. Catches are consistent with the abundance and proportion data. Punt (2006) shows that it is possible to reconcile the abundance, proportion, length-frequency and age-composition data within a Bayesian framework. It would be straightforward conceptually (but perhaps computationally challenging) to use the approach outlined in this chapter to compare models that utilize these additional data sources. Bringing in those additional data, as well as doing a full model comparison of a variety of models, was beyond the scope of this chapter, but we agree this would be important future work, particularly in light of the methods now developed in Punt (2006).

This study represents the first attempt to quantify model uncertainty when conducting assessments of the B-C-B bowhead stock. The analyses consider three alternative models and take model uncertainty into account by weighting alternative models based on their posterior model probabilities and by calculating a Bayesian model-averaged posterior. The only previous attempt to consider model uncertainty when conducting assessments of whale stocks was by Wade (2002a), who compared models for the Eastern North Pacific stock of gray whales with and without additional variance about the abundance estimates. In that case, one model received almost all the weight making model-averaging redundant. In contrast, in this study all three models were assigned non-negligible weight and led to different estimates of quantities of interest (e.g., carrying capacity and related measures). The Bayesian model-averaged posterior distribution clearly represents our best efforts to incorporate all levels of uncertainty in the estimates of these quantities.

Table 1.1

Estimates, CVs (actually the standard errors of the log abundance estimates, which are approximately equal) and the correlation matrix for the indices of abundance for the Bering-Chukchi-Beaufort Seas stock of bowhead whales. Source: Zeh and Punt (2005).

Table 1.4

Prior distributions used for the reference scenarios for each model type. Dashes (-) represent prior distributions that are equal to those from the model in the column to the left (e.g. the 1978 NON DD model had the same prior on the size of the 1+ population in 1978 as the 1978 DD model). 'N/A' represents a prior that was not applicable to a certain model or models. Fecundity is defined as female calves per mature female. For the 1978 NON DD model r_{max} and f_{max} are not maxima, but constant values. Results from the reference scenario were used in all figures and when performing the Bayesian model averaging. The reference scenarios are based on the stage-proportion data set that ignores the data for 1985.

Parameter		Model Type		
		1848 DD	1978 DD	1978 NON DD
S_a	adult survival	N(0.990, 0.02), truncated at 0.940 and 0.995[a]	-	-
f_{max}	maximum fecundity	U[0.125, 0.200][b]	-	-
a_T	age-at-transition to adult survival	U[0, 8][c]	-	-
a_m	age-at-sexual maturity	N(20.0, 3.0) truncated at 13.0 and 26.0[d]	-	-
$r_{max} = \lambda - 1$	intrinsic population growth rate	U[0.005, 0.075][e]	-	-
N_{1978}^{1+}	1+ population size in 1978	N/A	U[3000, 9000][f]	-
N_{1993}^{1+}	1+ population size in 1993	N(7800, 1200)[g]	N/A	N/A
K^{1+}	1+ carrying capacity	N/A	U[8000, 30000][h]	N/A
$MSYL^{1+}$	*MSYL* in terms of the 1+ component	U[0.40, 0.80] [i]	-	-

Table 1.4 continued

a – based on the posterior distribution for adult survival rate obtained by Zeh *et al*. (2002).

b – the prior for the maximum number of calves (of both sexes) per mature female selected by the Scientific Committee of the International Whaling Commission was U[0.25, 0.4] (IWC, 1995). This is the corresponding prior given fecundity has been defined here as female calves per mature female per year.

c – selected by the Scientific Committee of the International Whaling Commission (IWC, 1995) although there is little information on the value of this parameter (Givens *et al*., 1995).

d – based on a best estimate of 20 years and a lower confidence for the age-at-maturity of 14 years (IWC, 1995).

e – preliminary trials indicated there was no posterior probability outside this range, which was confirmed in the final analyses. This range was therefore selected to improve the efficiency of the numerical integration while not affecting the results.

f – selected to encompass a plausible range of values for 1+ population size in 1978.

g – selected by the Scientific Committee of the International Whaling Commission (IWC, 1995) based on the prior distribution assumed for the Bayes empirical Bayes estimate of abundance (Raftery and Zeh, 1991).

h – based on the range selected by the Scientific Committee of the International Whaling Commission (IWC, 1995).

i – selected to encompass the range of values commonly assumed when conducting assessments of cetacean populations.

Table 1.5

Posterior medians (5th , 95th percentiles) for eight management-related quantities. This table includes results for all models and scenarios, and Bayesian model-averaged results for the reference scenarios. Model averages for all quantities, except RY and N^{1+}_{2002} (i.e., the two quantities not dependent on *K*), could only be based on the 1848 and 1978 DD models. Where noted, additional scenarios are based on the reference scenarios in Table 1.4, but changed to examine the sensitivity of the results to different proportion data sets and less informative priors. The uniform prior for S_a is U[0.940, 0.995], and that for a_m is Discrete U[13, 26]. Unique draws and the maximum number of times an individual draw is included in the final SIR resample are listed in rightmost two columns.

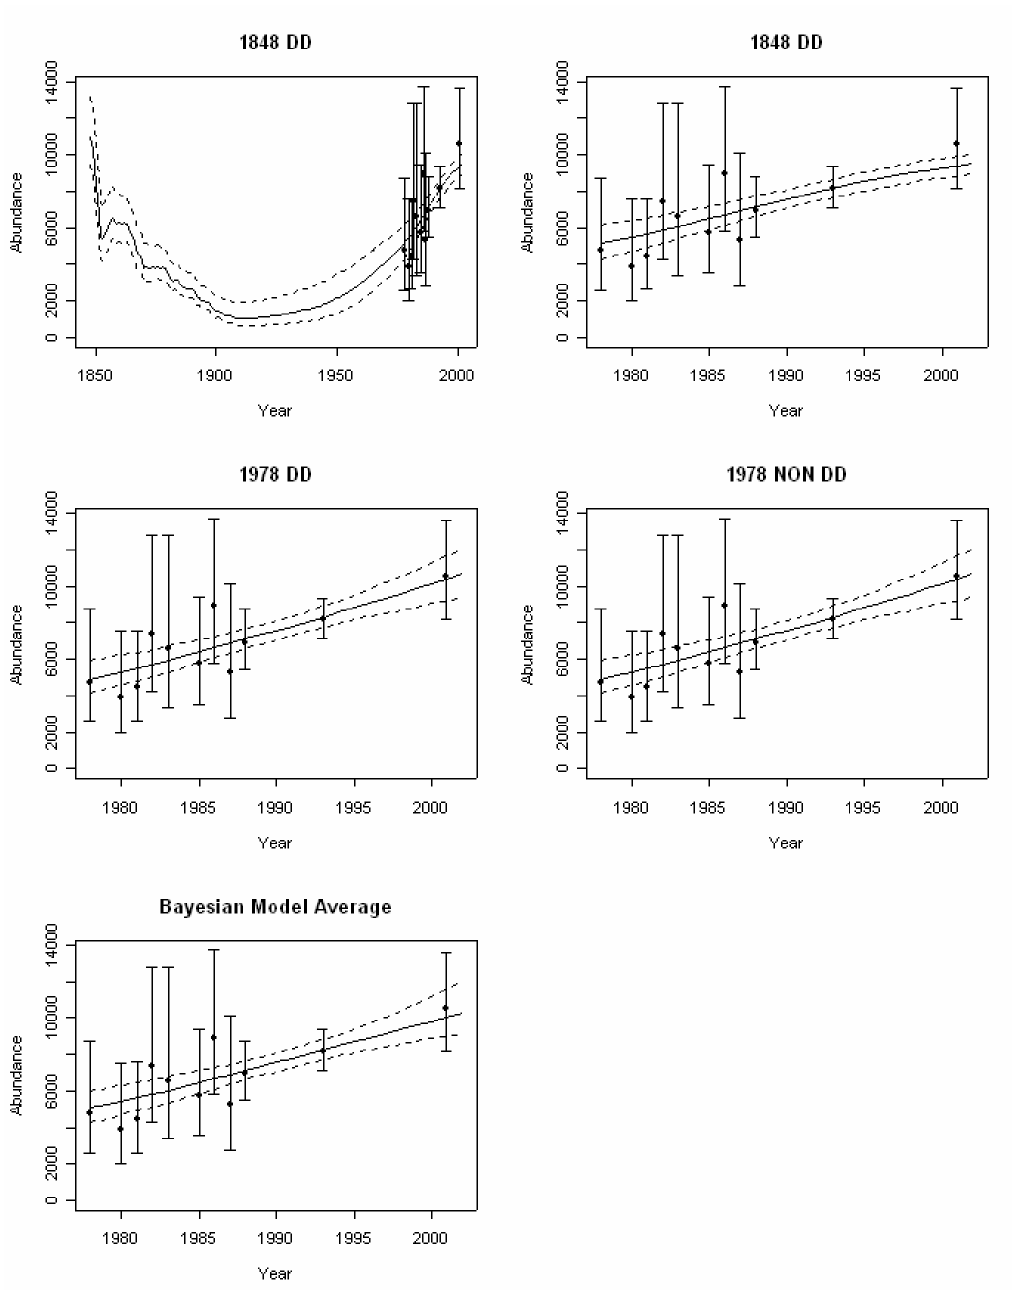

Figure 1.1: Time trajectories (medians and 90% credibility intervals) for 1+ population size for the three reference scenarios and the Bayesian model average. The two uppermost plots are for the 1848 DD model, showing the entire trajectory from 1848, and only the recent trajectory from 1978 for comparison. Error bars represent 95% CI's, and are assumed to be log-normally distributed for all abundance estimates except 1993 (second to last), which is assumed to be normally distributed.

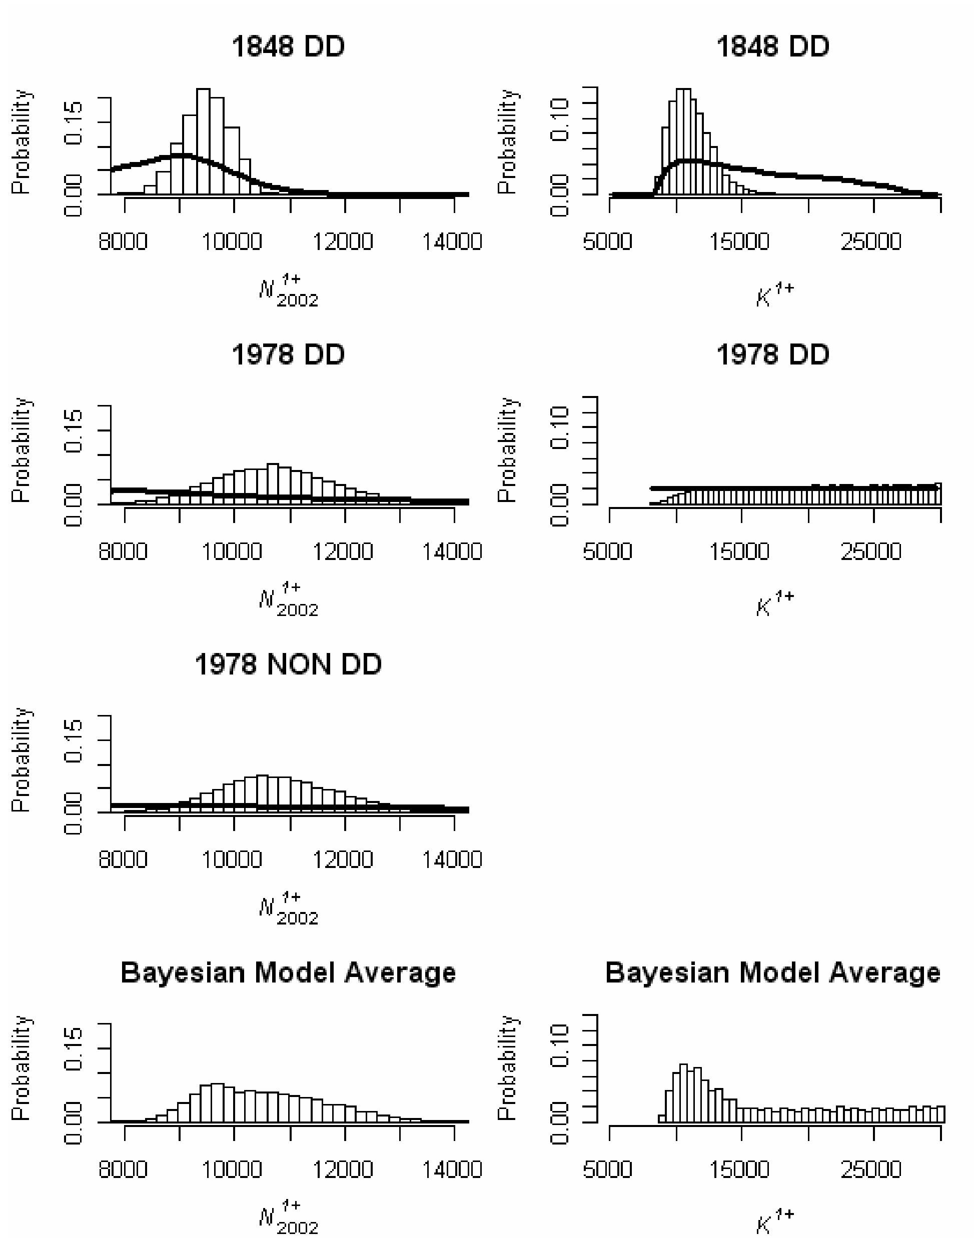

Figure 1.2: and Posterior (vertical bars) and post-model-pre-data (solid lines) distributions for 1+ population size in 2002, N^{1+}_{2002} (left panels) and 1+ carrying capacity, K^{1+} (right panels). Results are shown for only two of the three reference scenarios for K^{1+}, and the Bayesian model average for K^{1+} is based on the results of these two scenarios only.

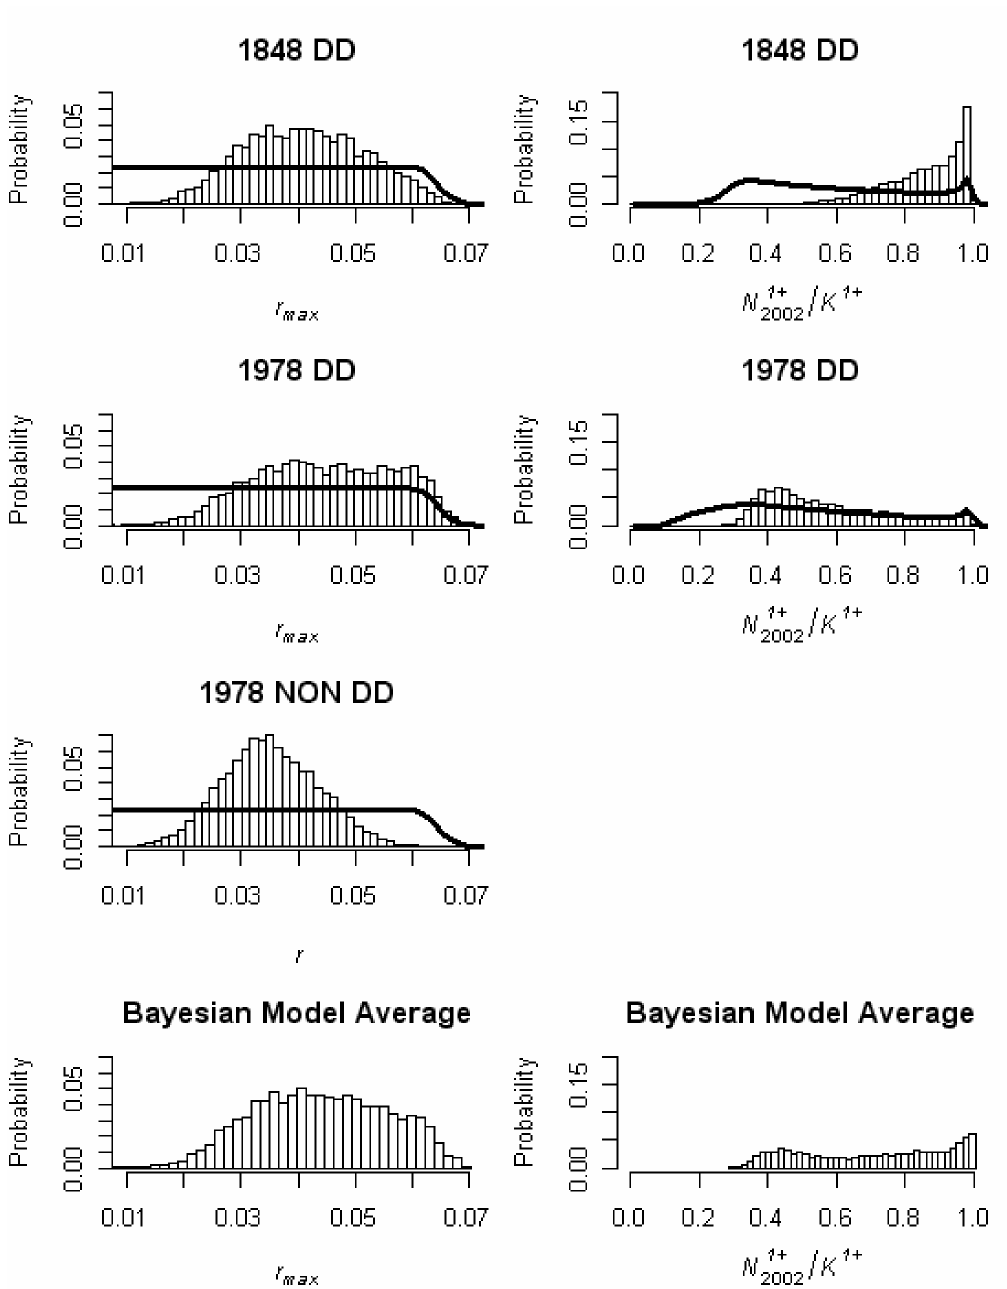

Figure 1.3: Posterior (vertical bars) and post-model-pre-data (solid lines) distributions for intrinsic population growth rate, $r_{\max}$ and r (left panels) and recent depletion in terms of the 1+ component, N^{1+}_{2002} / K^{1+} (right panels). The Bayesian model average is based only on the two models with density dependence.

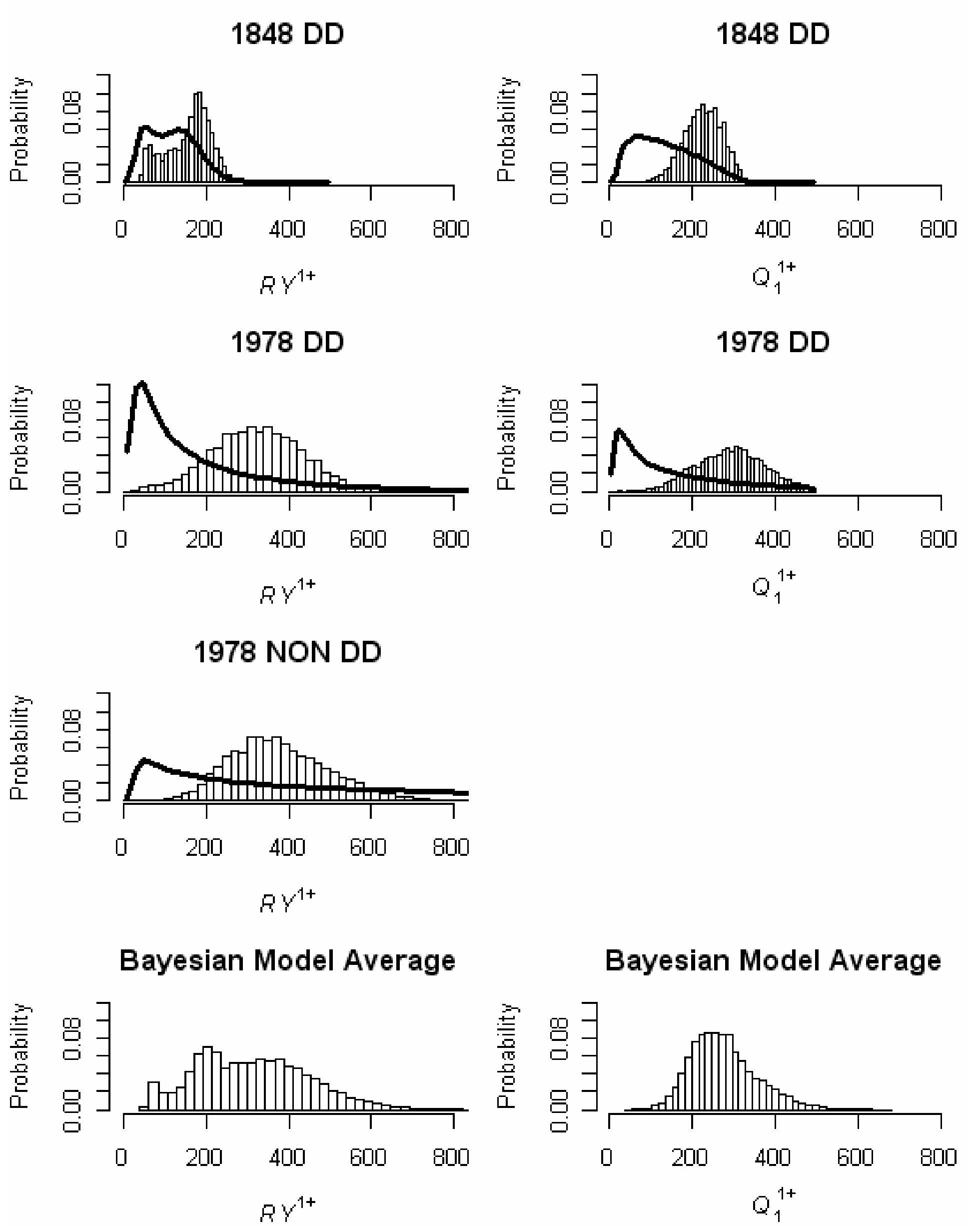

Figure 1.4: Posterior (vertical bars) and post-model-pre-data (solid lines) distributions for replacement yield, RY^{1+} (left panels) and Q_1^{1+} (right panels). Results are shown for only two of the three reference scenarios for Q_1^{1+}, and the Bayesian model average for Q_1^{1+} is based on the results of these two scenarios only.

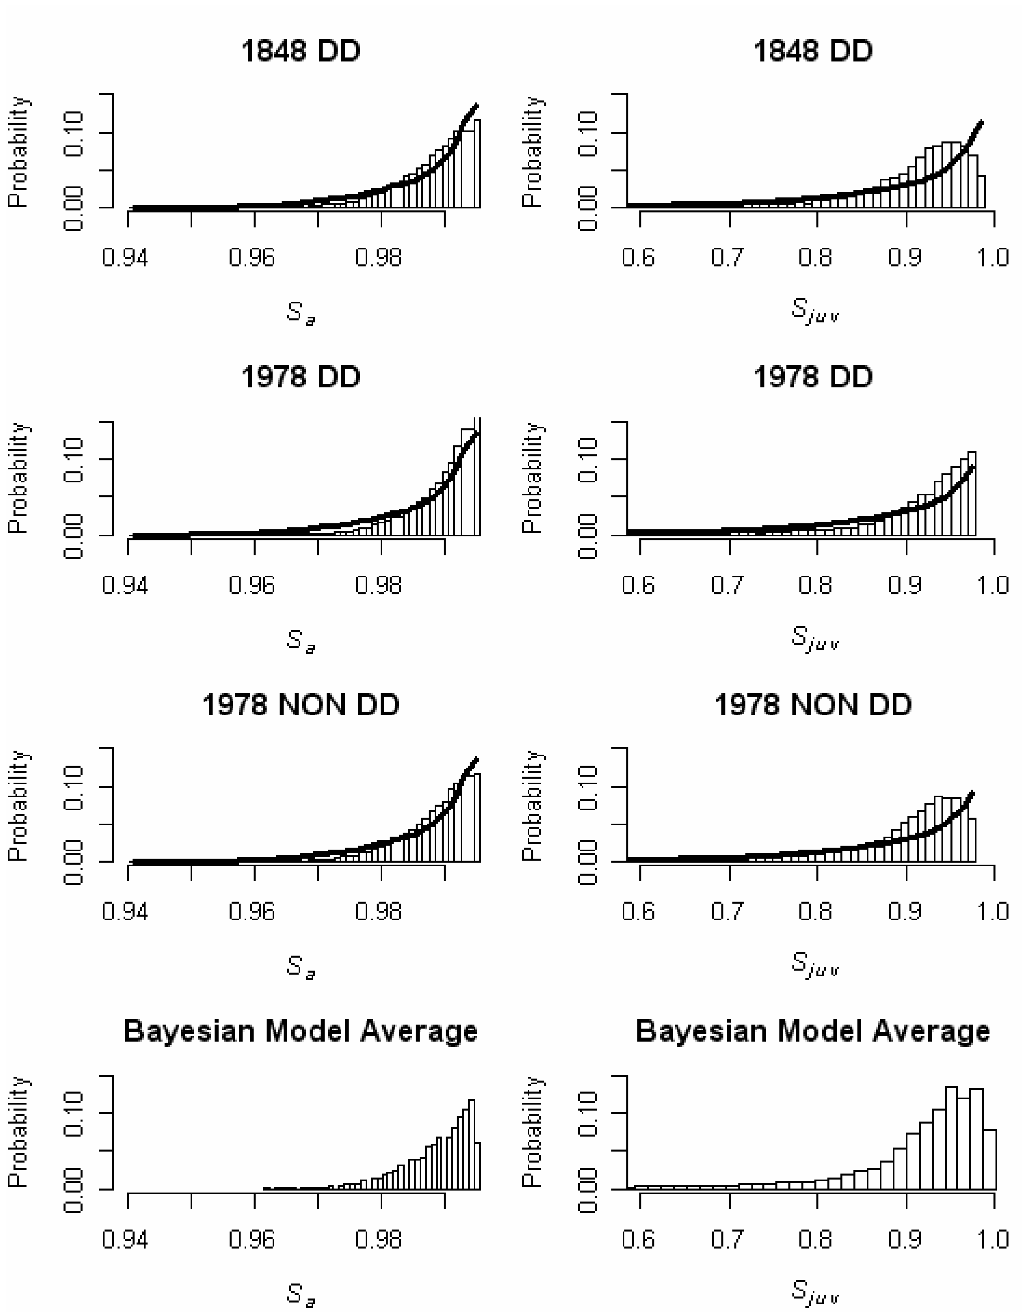

Figure 1.5: Posterior (vertical bars) and post-model-pre-data (solid lines) distributions for adult survival rate, S_a (left panels) and calf and juvenile survival rate, S_{juv} (right panels). Results are shown for the three reference scenarios and for the Bayesian model average.

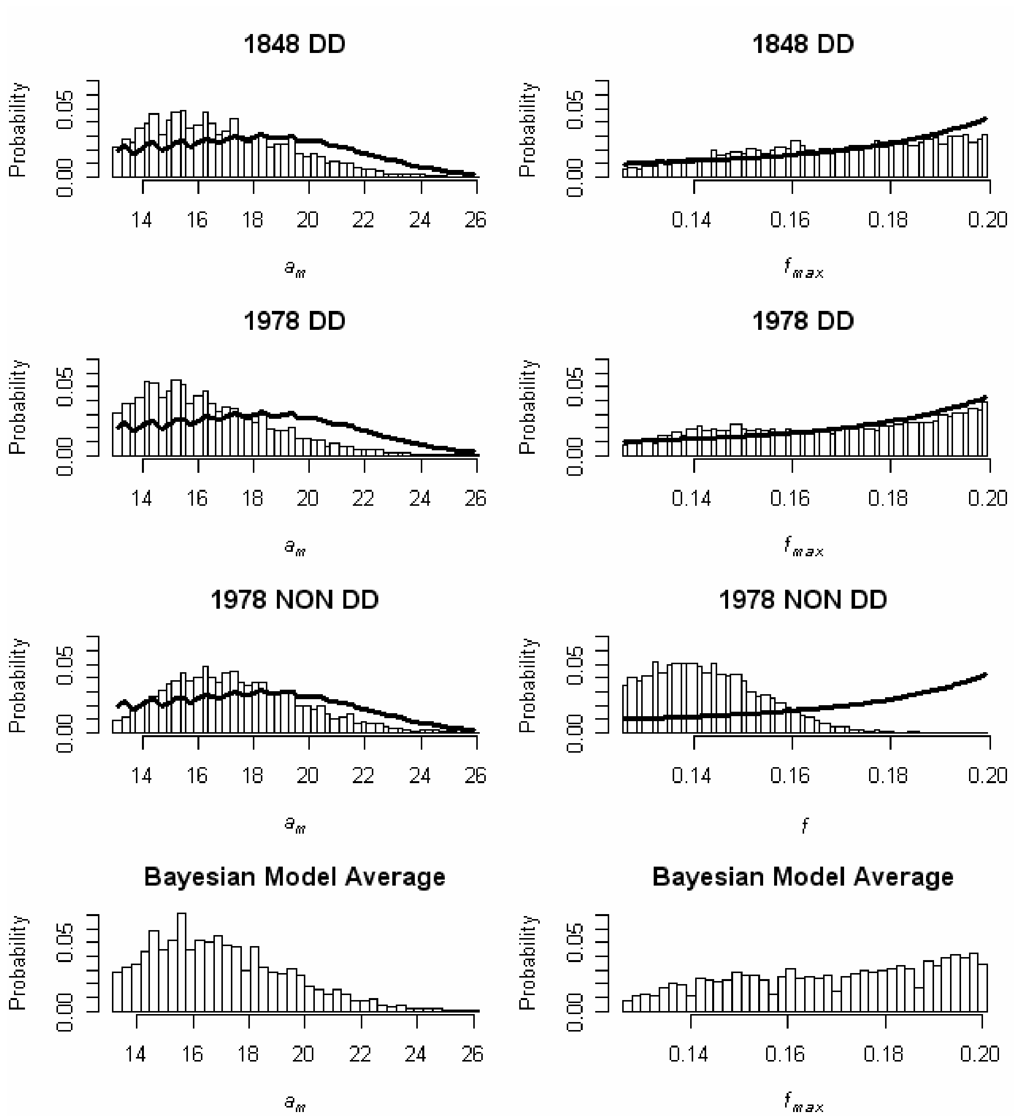

Figure 1.6: Posterior (vertical bars) and post-model-pre-data (solid lines) distributions for the age-at-maturity, a_m (left panels) and fecundity, f_{max} or f (right panels). Results are shown for the three reference scenarios and for the Bayesian model average, which is based only on the two models with density dependence for fecundity.

Chapter 2:

Constructing a coherent joint prior while respecting biological realism: sensitivity of marine mammal stock assessments to recent methods[4]

ABSTRACT

Bayesian estimation methods, employing the Sampling-Importance-Resampling algorithm, are currently used to perform stock assessments for several stocks of marine mammals, including the Bering-Chukchi-Beaufort Seas stock of bowhead whales (*Balaena mysticetus*) and walrus (*Odobenus rosmarus rosmarus*) off Greenland. However, due to the functional relationships among parameters in deterministic age-structured population dynamics models, placing explicit priors on each life-history parameter in addition to the population growth rate parameter results in an incoherent prior distribution (i.e., two different priors on the same parameter). One solution to constructing a coherent joint prior is to solve for juvenile survival analytically, given values generated from the prior distributions for the remaining parameters in the model (including population growth rate). However, certain combinations of parameter values result in solutions for juvenile survival that are larger than adult survival, which is biologically implausible. Therefore, in order to respect biological realism, parameter values must be rejected for some or all of the remaining parameters. This study investigates several alternative resampling schemes for obtaining feasible solutions for juvenile survival. The sensitivity of assessment results is investigated for data-rich (bowhead) and data-poor (walrus) scenarios. The results based on limited data are especially sensitive to the choice of alternative resampling scheme.

Brandon, J.R., Breiwick, J.M., Punt, A.E. and Wade, P.R. 2007. Constructing a coherent joint prior while respecting biological realism: application to marine mammal stock assessments. *ICES J. Mar. Sci.* 64: 1085-1100.

2.1 INTRODUCTION

Bayesian methods utilizing age-structured population dynamics models (PDMs) have formed the basis for recent stock assessments of several marine mammal populations, including those for Atlantic walrus, *Odobenus rosmarus rosmarus*, in Greenland (Witting and Born, 2005); the Bering-Chukchi-Beaufort Seas (B-C-B) stock of bowhead whales, *Balaena mysticetus* (Brandon and Wade, 2006; Punt, 2006); British grey seals, *Halichoerus grypus* (Buckland *et al.*, 2004; Thomas *et al.*, 2005); the Eastern North Pacific stock of gray whales, *Eschrichtius robustus* (Wade, 2002a; Witting, 2003; Punt *et al.*, 2004); New Zealand sea lions, *Phocarctos hookeri* (Breen et. al., 2003; Breen and Kim, 2006); Northeastern offshore spotted and Eastern spinner dolphins, *Stenella attenuata* and *Stenella longirostris orientalis* (Wade, 1994; Alvarez-Flores, 2002; Hoyle and Maunder, 2004); and Steller sea lions, *Eumetopias jubatus* (Fay, 2004; Fay and Punt, 2006; Winship and Trites, 2006). These assessments use Bayesian estimation methods to calculate posterior probability distributions for model parameters and management-related quantities, and to form the basis for risk analyses to evaluate the implications of potential management actions (Hilborn and Walters, 1992; Ellison, 1996). A brief review is provided below of the developments required for commonly used Bayesian methods when applied to age-structured PDMs for marine mammal stock assessments: the necessity of constructing a coherent joint prior distribution; one solution to this challenge that has been employed in several recent stock assessments; and, finally, the importance of investigating the sensitivity of those results to alternative schemes for constructing a coherent joint prior while respecting biological realism.

Adopting similar approaches to Butterworth *et al.* (1987) and Nakamura *et al.* (1989), Givens (1993), Raftery *et al.* (1995) and Givens *et al.* (1995) developed and influenced the application of Bayesian methods to age-structured PDMs for marine mammal stock assessment. The method developed, ‘Bayesian synthesis,’ was a departure from the ‘standard Bayesian’ approach in that it allowed explicit prior distributions on *both* model inputs *and* model outputs. During the development of these methods, it was shown that Bayesian synthesis (as originally proposed) is inappropriate on theoretical grounds (Wolpert, 1995; Schweder and Hjort, 1996). Givens and Raftery (1997) clarified the concerns by distinguishing two problems: 1) Borel’s paradox (i.e., conditioning on an ill-defined distribution, resulting in this case from explicit priors on both model input and outputs, and ultimately leading to posterior distributions that are not invariant to model parameterization); and, 2) prior incoherence (i.e., the partly implicit presence of two different prior distributions on the same parameter). Bravington (1996) provides illustrative examples of these issues using a simple model of exponential population growth. Borel’s paradox does not apply to a standard Bayesian analysis. However, the issue of prior incoherence is a potential concern for all Bayesian stock assessments. As Givens and Roback (1999) stress, simultaneous and competing prior distributions for the same parameters are common occurrences in Bayesian modeling.

A coherent joint prior must be constructed before inference may be drawn from Bayesian analyses. Punt and Hilborn (1997) advise that care needs to be taken in order to avoid *implicitly* specifying contradictory priors for the same parameter in Bayesian stock assessments. Those authors demonstrate how explicit prior distributions on both unexploited biomass and current depletion (the ratio of current biomass to unexploited biomass) lead to incoherent priors. Such subtleties become more insidious as PDMs (and the functional relationships among parameters therein) increase in complexity. Fortunately, several approaches have been developed to address this issue in the context of age-structured PDMs. However, we postpone consideration of alternative methods at this stage, and instead return to this during the concluding discussion. The sensitivity analyses presented here focus on only one approach for constructing a coherent joint prior while respecting biological realism: the most commonly employed during recent assessments of large whales as outlined below (e.g., Punt and Butterworth, 1999; 2002; Wade, 2002a; Punt *et al.* 2004; Punt, 2006; Brandon and Wade, 2006).

Due to the functional relationships among life-history parameters and the parameter related to population growth rate in a deterministic age-structured PDM (Lotka, 1907; Euler, 1970), placing priors on life history parameters in addition to a prior on the population growth rate would result in effectively placing two (most likely incoherent) priors on the same parameter. Therefore, one option for constructing a coherent joint prior is to place marginal priors on all but one of these parameters, and then solve for the value of the remaining parameter analytically. Given that many of the key model outputs (e.g. the current rate of increase) are almost directly proportional to the population growth rate, having an explicit prior on the latter parameter allows clear consideration of the impact of the priors on these model outputs. For example, placing a uniform prior on the population growth rate, to the extent that it is possible, essentially imposes a non-informative prior on some of the model outputs of interest to management.

There exists very little information on which to base a prior on juvenile survival S_{juv} for the majority of marine mammal populations. Therefore, it has been argued that placing an explicit prior on this life history parameter is unfounded for most species, and that a more appealing approach would be to simply impose some biological bounds instead of a full probability distribution (Butterworth, 1995). Additionally, a common assumption in age-structured PDMs for marine mammals, is that juvenile survival is less than adult survival S_a (e.g. IWC, 1995; Chivers, 1999; Witting and Born, 2005). This assumption is based on observed mammalian mortality patterns, which are typically U-shaped with age (Caughley, 1966; Barlow and Boveng, 1991). Thus, one solution to constructing a coherent joint prior is not to place an explicit prior on S_{juv} (Punt and Butterworth, 1996), but instead to solve for this parameter analytically given the values for the other life history parameters and the population growth rate (Breiwick *et al.*, 1984; Punt, 1999a). Furthermore, the solution for S_{juv} is subject to the constraint, $S_{juv} < S_a$. This approach is appealing because it is a relatively simple, minimizes the influence of priors for life history parameters on key model outputs of interest to management, and results in a coherent joint prior distribution that also respects biological realism.

Sensitivity tests to alternative prior specifications should be conducted during the assessment processes to ensure that inference is robust. Effectively, the constraint $S_{juv} < S_a$ is an element of the joint prior on the life history parameters. However, certain combinations of otherwise reasonable parameter values result in solutions for S_{juv} which seem biologically implausible - if not completely impossible. Specifically, solutions for S_{juv} may result that are larger than those for adult survival (including values larger than 1.0; Figure 2.1). In these cases, it is possible to construct a coherent joint prior in more than one way. For example, in addition to completely ignoring that parameter space which violates the constraint, one could also resample values for different subsets of the life history parameters (effectively re-weighting the marginals) until a feasible solution for S_{juv} is attained. Both of these approaches satisfy the constraint $S_{juv} < S_a$ and both have been applied in marine mammal stock assessments. However, the question of sensitivity to such alternative resampling schemes has not been explored in any detail to date.

The Sampling-Importance-Resampling[5] (SIR) algorithm for approximating Bayesian posterior distributions is employed in this chapter to generate realized prior distributions (also referred to as post-model-pre-data distributions). These distributions represent the actual (implicit) marginal prior distribution for each parameter after the explicit marginal prior distributions have been reconciled (via the model and resampling schemes) into a coherent joint probability distribution. It would be expected that the realized prior distribution will differ under alternative resampling schemes, but little is known about whether and how, if at all, the

[5] 'Resampling' parameters values to find a feasible solution for S_{juv} should not be confused with the 'resampling' step in the SIR algorithm.

posteriors for the quantities of management interest are affected. The results of these interactions are potentially relevant to the calculation of management-related quantities and hence to the provision of management advice.

This chapter therefore explores the sensitivity of Bayesian assessments for marine mammal populations to several alternative resampling schemes used to construct a coherent joint prior, while simultaneously respecting biological realism. Results are provided for two populations that differ in terms of the amount of available data to illustrate the consequences in terms of quantities of management interest. The B-C-B bowhead stock is data-rich in that considerable information is available on abundance and trends in abundance (e.g. Zeh and Punt, 2005); in contrast the walrus off East Greenland (E-G) are data-poor, with only one (fairly imprecise) estimate of abundance on which to base assessments, and hence management advice (Born *et al.*, 1997; Witting and Born, 2005).

2.2. METHODS

To ease subsequent comparison, similar methods are used for the analyses of both the bowhead and walrus data. Hence, unless noted otherwise, the methods described here apply to both populations. Similarly, all parameters related to abundance or catch statistics are reported in terms of the 1+ component of the population (all age groups except calves), except for the trajectories of walrus population size which are plotted on the same scale as the prior for recent abundance (total population size including calves).

Available data

B-C-B bowhead whales

The PDMs utilise three sources of data: 1) abundance estimates from ice-based surveys at Pt. Barrow, Alaska between 1978 and 2001 (Table 2.1); 2) proportion calves/mature animals in the population from 1985 to 1994 (Table 2.2); and 3) annual catches in individuals from 1848 to 2002 (see Punt, 2006 for this catch table).

E-G walrus

A single abundance estimate of 1000 exists for the E-G walrus population. This estimate is based on opportunistic and systematic observations (Born *et al.*, 1997; Witting and Born, 2005) and is assumed to relate to the total population (i.e., including young of the year). Following Witting and Born (2005), the coefficient of variation for this estimate is arbitrarily set to 0.35 to encompass the plausible range for abundance in 1995. This estimate forms the basis for the prior on abundance in 1995 (see below).

Born *et al.* (1997) report, or in some years estimate, catches of walrus off East Greenland during 1889-1999. These catches are treated as known (or estimated without error) in the model. No attempt has been made in this analysis to take into account the potential number of animals struck and lost, or the numbers landed and not reported in a given year (i.e., this corresponds to the "low" catch history analyzed by Witting and Born (2005)). The reader is referred to Born *et al.* (1997) and Witting and Born (2005) for the catch table and a detailed list of sources regarding these catches.

Prior to 1956, there is no information on the sex-ratio of the catch. In 1956, walrus off East Greenland were protected north of ca. 72°N, effectively ending the foreign fishery on this population. After 1956, the sex-ratio in the Greenlandic catch is highly skewed towards males (~90%; Born *et al.*, 1997). Therefore, we follow the methods of Witting and Born (2005), and assume an even sex ratio prior to 1956, and a 9:1 M:F sex-ratio thereafter.

Inflated catches

The implications of higher levels of catch on model outputs are examined by multiplying the catch history by five, for both B-C-B bowheads and E-G walrus.

Population dynamics model

The underlying PDM is an age- and sex- structured Leslie matrix (Leslie, 1945, 1948) projected as:

$$\mathbf{N_{t+1}} = (\mathbf{A_t N_t}) - \mathbf{C_t} \tag{2.1}$$

where:

$\mathbf{N_t}$ is the matrix of population size by sex and age class at the start of year *t* (defined when births and natural mortality occur);

$\mathbf{A_t}$ is the Leslie matrix for year *t*; and

$\mathbf{C_t}$ is the matrix of sex- and age-specific catches during year *t*.

The parameters that define the entries of the Leslie matrix are: 1) S_{juv}, the survival rate of immature animals (assumed identical for calves and juveniles); 2) a_T, the last age with survival rate S_{juv}; 3) S_a, the survival rate of mature animals; 4) a_m, the age at sexual maturity (the last age-class with zero fecundity, i.e., birth occurs at age a_m+1 years, the age at first parturition); 5) $f_{\max}$, the maximum fecundity rate; and 6) $a_{\max}$, the age after which survival becomes zero. Fecundity is assumed to be identical for all mature animals, and is calculated as the number of female calves per mature female. The sex ratio at birth is assumed to be 50:50 male:female. Recruitment to the fishery is assumed to be knife-edged and to occur at age 1, and the catch is hence distributed uniformly over all recruited age-classes.

Density dependence and initial conditions

Density dependence is assumed to affect fecundity according to a Pella-Tomlinson functional relationship based on the depletion of the 1+ component of the population (Pella and Tomlinson, 1969; Allen, 1976):

$$f_t = f_0 + (f_{\max} - f_0)\left[1 - \left(\frac{N_t^{1+}}{K^{1+}}\right)^z\right] \tag{2.2}$$

where:

f_t is the fecundity during year *t*;

N_t^{1+} is the (1+) population size at the start of year *t*;

K^{1+} is the pre-exploitation (1+) population size;

z is the Pella-Tomlinson shape parameter; and

f_0 is the fecundity at carrying capacity.

Given values of the life-history parameters, the value for f_0 is determined from the characteristic equation of the Leslie matrix given equilibrium conditions (Breiwick *et al.*, 1984; Punt, 1999a):

$$f_0 = \frac{1 - S_a}{S_{juv}^{(a_T)} S_a^{(a_m - a_T)} [1 - S_a^{(a_{\max} - a_m - 1)}]} \tag{2.3}$$

The population projections are initialized from a stable age distribution at the start of the year before the first catch is removed, given values for the parameters sampled from the joint prior distribution.

Modeling approaches

B-C-B bowhead whales

The population trajectory is modeled in two ways: 1) a density-dependent model initialized in 1848 (abbreviated: '1848 Bkwd'), and; 2) a density-dependent model initialized in 1978 ('1978 Fwd'). The six life-history parameters of the Leslie model are included in each model. However the approach used to estimate the equilibrium population size, or carrying capacity, *K*, differs between the two modelling approaches. The '1848 Bkwd' model includes a parameter with associated prior for the population size in 1993, N_{1993}, and the 'backwards' method

(Butterworth and Punt, 1995, 1999) is used to back-calculate to the population size in 1848 (assumed to be equal to *K*). Instead of placing a prior on N_{1993}, the '1978 Fwd' model involves placing a prior on the population size in 1978, N_{1978}, and projecting 'forwards' from that initial year (Wade, 2002a). This model includes an additional (explicit) prior on *K*. However, unlike the '1848 Bkwd' model, it does not make the assumption that the catch history is known without error or that *K* has remained unchanged over the last 150 years. Both models include a parameter for the depletion at which *MSY* is achieved (referred to as the 'maximum sustainable yield level' or *MSYL*), and one for the maximum population growth rate in the limit of no density dependence, λ_{max} (the dominant real eigenvalue of the Leslie matrix). These two modeling approaches have been used in recent assessments of the B-C-B bowhead whale (e.g., Brandon and Wade, 2006); it is therefore of interest to include them both in this analysis for the sake of comparison.

E-G walrus

The analyses for this population are based on a density-dependent model initialized in 1899 (corresponding to the model '1848 Bkwd' for B-C-B bowheads)., This model also includes a parameter for the population size in 1995, N_{1995} in addition to the six life-history parameters and *MSYL*. Note that the assumption that harvest selectivity is uniform above age 1 differs from the assumption that selectivity increases with age from age 0 to age 10 made by Witting and Born (2005). However, this difference is inconsequential for the analyses of this chapter.

Model parameters and prior distributions

Calves are defined as young of the year (i.e., age 0) and f_{max} is specified in the standard Leslie matrix formulation as female calves per female per year (e.g., a fecundity rate of *0.125* implies a female calving interval of 8 years, and therefore a total calving interval of 4 years, assuming an equal sex ratio of calves).

B-C-B bowhead whales

'Data-based' prior distributions are assigned to adult survival rate and the age-at-maturity (Table 2.3), and the maximum age in the Leslie matrix is set to 200 years following the results of recent research on ageing (George *et al*, 1999).

E-G walrus

The prior distributions for the life history parameters for walrus are based on various field and modeling studies (Table 2.4). The age at which survival changes from immature to adult is fixed, and set to age 3. The maximum age after which survival becomes zero is set to 60 years.

While we attempt to follow the methods of Witting and Born (2005) in most regards, this study treats juvenile survival rate differently. We choose to follow methods recently employed in stock assessments used by the IWC (e.g., Punt and Butterworth, 1999; Wade, 2002a), i.e. we place a uniform prior from 1.01 to 1.12 on λ_{max}, and do not place a prior on juvenile survival. The details of this treatment are given in the following section (and apply to the bowhead analyses as well).

Alternative resampling schemes

The assumption that juvenile survival must be less than adult survival is followed here. However, as Punt and Butterworth (1999) note, placing an explicit prior on S_{juv} (in addition to priors on the remaining life history parameters, and a prior on the population growth rate) would result in an incoherent prior due to the functional relationships among the life-history parameters. Instead, the value of S_{juv} is calculated analytically by rearranging the characteristic equation of the Leslie matrix given the values for the remaining five life history parameters and λ_{max} (Breiwick *et al.*, 1984):

$$S_{\text{juv}} = \left[\frac{\lambda_{\max}{}^{(a_{\text{m}}+1)} - S_{\text{a}} \lambda_{\max}{}^{(a_{\text{m}})}}{S_{\text{a}}^{(a_{\text{m}}-a_{\text{T}})} f_{\max} \left[1 - (S_{\text{a}} / \lambda_{\max})^{(a_{\max}-a_{\text{m}}-1)} \right]} \right]^{\frac{1}{a_{\text{T}}}} \tag{2.4}$$

The resulting value for S_{juv} is forced to be less than that of S_{a} through one of the alternative resampling schemes below. These schemes involve resampling the following parameters from their prior distributions if $S_{\text{juv}} > S_{\text{a}}$:

1) $f_{\max}$, S_{a} and a_{m};
2) $f_{\max}$ and S_{a}; and,
3) No parameters (abbreviation 'None'), meaning the current vector of life-history values is simply ignored and a completely new set of values is drawn from the marginals (see 'Parameter Estimation').

Values for the parameters are re-sampled until $S_{\text{juv}} < S_{\text{a}}$, or 1000 re-samples occur for resampling schemes 1) and 2). If this maximum is reached, a new value for $\lambda_{\max}$ is selected, and the process is repeated until an acceptable sample from the prior occurs.

Output quantities

Posterior distributions are calculated for several output quantities that are derived from the parameters in Tables 2.3 and 2.4. The maximum sustainable yield rate (*MSYR*) is calculated as (λ_{MSY} - 1) based on the fecundity value, f_{MSY}, associated with *MSYL*. The quantity Q_1, designed to meet the intent of IWC aboriginal whaling management objectives (Wade and Givens 1997), is also calculated. This quantity has the property that the proportion of net production allocated to recovery increases the more depleted a population is assessed to be[6]. Specifically:

$$Q_1 = \min(MSYR * N_t,\ 0.9MSY\ ) \tag{2.5}$$

[6] This definition applies to a population above some minimum level, $P_{\min}$, (assumed here to be $0.1K$), below which catches are set to zero.

where N_t is the population size in 2000 for walrus or 2002 for bowheads.

The realized prior is reported for the parameters. This distribution arises after conditioning the specified priors on the model and the resampling scheme by eliminating combinations of parameters for which: 1) the juvenile survival rate implied by Equation (2.4) exceeds the adult survival rate drawn from the joint prior distribution, and 2) population trajectories that go extinct. Likewise, post-model-pre-data distributions for output quantities are calculated as the distributions for these quantities in the sampled joint prior space.

Parameter estimation

The SIR algorithm (Rubin, 1988; Smith and Gelfand, 1992) is used to generate samples of parameter vectors (and output quantities of interest) from the posterior distribution. This algorithm involves randomly sampling a large number of parameter vectors from the prior distribution. A population trajectory is then calculated for each vector of parameter values, and this trajectory is used to determine the likelihood of the data for each random draw[7]. 10,000 draws (which form a numerical representation of the posterior distribution) are then selected by sampling (with replacement) from the initial samples from the prior, with probability proportional to the likelihood (i.e., the importance function is set equal to the joint prior, so the importance weight is the likelihood). Following Punt and Butterworth (1999) and Raftery *et al.* (1995), the SIR algorithm is considered to have converged if the number of unique parameter vectors in the sample from the posterior is fairly high (>5,000) and if the most frequently re-sampled parameter vector does not occur in the posterior sample more than ten times.

B-C-B bowhead whales

The total negative log-likelihood of a model trajectory, given a vector of parameters and the data, consists of contributions from four data sources: 1) the

[7] The likelihood is 1 for the walrus case because there are no abundance data for this population except for that on which the prior for the abundance in 1995 is based.

estimate of abundance for 1993; 2) the estimates of abundance for the remaining years; 3) the proportion of calves in the population; and 4) the proportion of mature animals in the population. The abundance estimates are assumed to be indices of the 1+ component of the population. The scientific surveys at Pt. Barrow are assumed to have occurred after the aboriginal catch[8], and the likelihood function is calculated accordingly (i.e. catches are removed before calculating the likelihood of the data for a given year). Model-predicted proportions are calculated over the period 1985 to 1994, as the actual stage proportions are based on data for these years.

The estimate of abundance for 1993 is assumed to be independent of the remaining estimates (Punt and Butterworth, 1999), and to have normally rather than log-normally distributed sampling error. The contribution of the abundance estimates to the negative of the log-likelihood function is (ignoring constants independent of model parameters):

$$L_1 = 0.5\frac{(\hat{N}_{1993} - 8293)^2}{626^2} \qquad L_2 = 0.5\sum_{t_1}\sum_{t_2}(\ell \text{n}\hat{N}_{t_1} - \ell \text{n}N_{t_1}^{obs})^{\mathbf{T}}\mathbf{V}_{t_1,t_2}^{-1}(\ell \text{n}\hat{N}_{t_2} - \ell \text{n}N_{t_2}^{obs}) \qquad (2.6)$$

where:

N_t^{obs} is the survey estimate of abundance for year t;

$\hat{N}_t$ is the model estimate of 1+ abundance for year t; and

V is the variance-covariance matrix for the logarithms of the estimates of abundance (excluding 1993).

The estimates of abundance (Table 2.1) are based on combining the data from visual counts at Pt. Barrow, Alaska, and estimates of the proportion of animals that passed within visual range based on acoustic data. Equation (2.6) accounts for the

8 In reality, there are two seasonal (spring and fall) hunts each year, with the survey immediately following the spring hunt. However, as catches are a relatively small proportion of the total population size, the simplification made will hardly affect the quantitative results.

correlation among the non-1993 estimates of abundance that arises because the proportion within visual range is treated as a random effect when constructing the estimates of abundance (Zeh and Punt, 2005).

The contribution of the proportion data to the likelihood function follows Punt (2006), i.e. given the bootstrapping approach adopted to calculate the length-frequency distributions from which the proportion data were calculated (Koski *et al.*, 2006), it is reasonable to assume that the estimates are normally distributed, i.e. ignoring constants independent of model parameters:

$$L_3 = 0.5\frac{(p_{\rm c} - p_{\rm c}^{\rm obs})^2}{(\sigma_{p_{\rm c}})^2} \qquad L_4 = 0.5\frac{(p_{\rm m} - p_{\rm m}^{\rm obs})^2}{(\sigma_{p_{\rm m}})^2} \tag{2.7}$$

where:

$p_{\rm c}^{\rm obs}$ is the observed average fraction of the population that consists of calves between 1985 and 1994;

$\sigma_{p_{\rm c}}$ is the standard deviation of $p_{\rm c}^{\rm obs}$;

$p_{\rm c}$ is the model-estimate of the average fraction of the population that consists of calves between 1985 and 1994;

$p_{\rm m}^{\rm obs}$ is the observed average fraction of the population that consists of mature animals between 1985 and 1994;

$\sigma_{p_{\rm m}}$ is the standard deviation of $p_{\rm m}^{\rm obs}$; and

$p_{\rm m}$ is the model-estimate of the average fraction of the population that consists of mature animals between 1985 and 1994.

Risk analysis

Forward projections are initialized from the posterior distribution corresponding to the status of the stock at the start of 2000 (walrus) or 2002 (bowheads). Following

Witting and Born (2005), the catch during the first five years of the projection period is set equal to that for during the last year of the assessment (e.g., 80 walrus, with a sex ratio 9:1 M:F), and the population is then projected forward under different levels of constant catch *C*, for another 5 years (applying the assumed sex-ratio and selectivity pattern of the current hunt). The management objective, *ob*, used to summarize the results of the decision analysis follows the aboriginal whaling guidelines of the IWC (2000), as interpreted by Witting and Born (2005):

$$ob = \begin{cases} N_{\mathrm{yr+5}} > N_{\mathrm{yr}} & \text{if } N_{\mathrm{yr}} < N_{MSYL} \\ C \leq 0.9MSY & \text{if } N_{\mathrm{yr}} \geq N_{MSYL} \end{cases} \qquad (2.8)$$

N_{yr} is the population size in 2005 for E-G walrus, and 2007 for B-C-B bowheads. The probability of meeting the objective, given a future catch level and one of the alternative re-sampling schemes, is calculated as the proportion of trajectories at the start of $N_{\mathrm{yr+5}}$ that meet the objective. These probabilities are conditioned on reported catch history.

2.3 RESULTS

B-C-B bowhead whales

In general, all three resampling schemes lead to reasonable fits to the data (see, for example, the results for the '1978 Fwd' model in Fig. 2.2). However, there are certain noteworthy differences in the outputs of the models among resampling schemes, especially those from the '1978 Fwd' model. Specifically, resampling f_{max}, S_{a}, and a_{m} consistently leads to higher values for stock productivity, as quantified by λ_{max}, and hence to better fits to the estimate of abundance for 2001. One consequence of this is that resampling f_{max}, S_{a} and a_{m} leads to the largest estimate of 2002 population size for the '1978 Fwd' model (Fig. 2.2; Table 2.5).

As expected from previous research (e.g. Punt and Butterworth, 1999), the '1848 Bkwd' model is relatively insensitive to modifications to the prior. This is likely the result of conditioning the model on the historical catch record from 1848, which is assumed known without error. There are basically no differences between median estimates of current population size among resampling schemes for this model (although the CV of current population size for the first resampling scheme is appreciably smaller). The posterior median for K is slightly lower when f_{max}, S_a and a_m are resampled, resulting in a higher probability that the stock is less depleted according to this resampling scheme (Table 2.5; Fig. 2.3).

It is useful to examine the original (explicit) priors, the realized priors and the posteriors for the model parameters to better understand the reasons for the differences among the three resampling schemes for some of the model outputs. Qualitatively, the results for the age-at-maturity are relatively insensitive to the resampling scheme (Fig. 2.4, left panels) with both the realized prior and posterior distributions being unimodal. Closer inspection of the results reveals, however, that resampling f_{max}, S_a and a_m leads to lower posterior medians than the other schemes. The situation for f_{max} is similar, with this scheme again leading to the most optimistic posterior (Fig. 2.4, right panels). Likewise, the realized priors and posterior distributions assign less probability to the highest values of adult and juvenile survival when none of the parameters are resampled (scheme 'None') (Fig. 2.5).

The realized prior for the maximum rate of increase differs substantially from the explicit prior when no parameters are resampled. Resampling 'None' assigns almost no realized prior probability to high ($\geq$ 1.05) values for λ_{max}, but this is not the case when f_{max} and S_a, and (particularly) when f_{max}, S_a and a_m are resampled (Fig. 2.6).

B-C-B bowheads: sensitivity analysis with inflated catches

Fig. 2.7 compares the posterior distributions for the time-trajectory of 1+ population size given the reported catch history (top panel) with that from the analyses in which the catch history is increased fivefold (bottom panel). The estimates of K are obviously very different between catch histories. However, these estimates are effectively insensitive to the choice of resampling scheme for each catch history (Table 2.5). The estimates of the catch quantity Q_1 are only moderately more sensitive to the choice of resampling scheme than those given the reported catch history (Table 2.5).

B-C-B bowheads: sensitivity of risk analysis

There is essentially no difference between resampling schemes in the probability of meeting the management objective (i.e., all predict ~100% success) for future catches as high as 100 whales (Fig. 2.8, left panel). Regardless of the resampling scheme, the resulting prediction is consistent across a wide range of plausible future catch levels. At higher catch levels, resampling 'None' leads to more conservative results (Fig. 2.8, left panel).

E-G walrus

The results for E-G walrus illustrate how alternative resampling schemes may potentially impact posterior distributions when the data set is uninformative (Table 2.6). Given the reported catches, the population trajectories for E-G walrus show little sensitivity to alternative resampling schemes (Fig. 2.9, top panel). The median and 90% credibility intervals for N_{2000} are nearly identical for all three schemes. This is perhaps not unexpected because the population is estimated to be at a large fraction of K (Table 2.6). As expected from the bowhead analyses, the results of resampling only a subset of the life history parameters are more similar, and differ from those for resampling 'None'. Resampling f_{max} and S_a, and (particularly) f_{max}, S_a and a_m is again more optimistic in terms of management-related quantities such as Q_1. However, unlike the case for the B-C-B bowheads, the impact of the choice of resampling scheme on the management-related quantities can be quite large (e.g. ~50% differences among schemes in the posterior median for Q_1; Table 2.6).

The posterior distributions for some of the management-related quantities are nearly identical among the three resampling schemes. For example, the posterior distribution for *K* is centred around 1000 (slightly higher for 'None') and skewed to the right, that for *MSYL* is very similar to its prior, and the posterior for the catch related quantity Q_1 is skewed to the right and its median differs among resampling schemes (Table 2.6). The sensitivity of the posterior distribution for λ_{max} to the choice of resampling scheme is consistent with that observed for the B-C-B bowheads, although the size of the effect is much larger for E-G walrus (Table 2.6).

E-G walrus: sensitivity analysis with inflated catches

Fig. 2.9 (bottom panel) shows the posterior distributions for the time-trajectory of 0+ population size from the analyses in which the historical catches are increased fivefold. In contrast to the situation for the 'low' catches on which Fig. 2.9 (top panel) was based, the estimates of historical population size are sensitive (i.e., greater than 20% difference in median terms) to the choice of resampling scheme. This sensitivity arises because the catches are now large enough to have reduced the population to well below its carrying capacity; in this situation the stock's current status does depend on how productive the resource is assessed to be which, in turn, depends on λ_{max}, and hence the choice of resampling scheme.

E-G walrus: sensitivity of risk analysis

The diverging population trajectories in recent years among resampling schemes for the analyses based on the higher catches (Fig. 2.9, bottom panel) are noteworthy. This pattern is much more pronounced than that for B-C-B bowheads (Fig. 2.7, bottom panel) and has implications for management advice. Therefore, it is not surprising that the results of the risk analysis (e.g., calculating the probability of achieving a management objective given different levels of catch) are also sensitive to the choice of resampling scheme, even when the analyses are based on the reported (rather than increased) catches. Again, resampling 'None' leads to more conservative results (Fig. 2.8, right panel).

2.4 DISCUSSION

These sensitivity analyses suggest that the choice of resampling scheme when implementing the constraint $S_{juv} < S_a$ can impact the results of stock assessments and hence the scientific management advice arising from such assessments. In particular, resampling f_{max}, S_a, and a_m to achieve a near uniform realized prior distribution for λ_{max} consistently leads to more optimistic results given the ranges of the prior distributions considered here (which are representative of many marine mammal populations). The effect can be marked in cases for which the data are uninformative. This is an example of a well known property of Bayesian analyses: when the information content in the likelihood is low, the prior will dominate the resulting posterior. Alternative resampling schemes correspond to different specifications for the realized joint prior, and therefore results of assessments based on limited data are especially sensitive to this issue.

It is noteworthy that the realized prior distribution for λ_{max} when resampling life history parameters assigns higher prior probability to large values for the intrinsic rate of growth. It is also well-known that there are fewer combinations of parameter values for which $S_{juv} < S_a$ when the intrinsic rate of growth is high (Fig. 2.1; Punt and Butterworth 2000). The scheme ('None') that does not retain the original value drawn from the prior for λ_{max} in order to find a feasible solution for S_{juv} is therefore assigning greater prior probability to low values for the intrinsic rate of growth. This is because the other two resampling schemes continue to resample the life history parameters when the intrinsic rate of growth is high - to sample that part of parameter space that satisfies the constraint on S_{juv} - but are not having to do this when the intrinsic rate of growth is low.

In essence, the resampling schemes are a way of re-weighting the marginal priors. The issue is whether one considers the fact that there is less feasible parameter space for larger values of λ_{max}, means that larger values are less likely. Resampling 'None' accepts with equal weight all points of parameter space which respect biological realism. The other extreme is to resample values for all of the life history parameters, which to the maximum extent possible, maintains the prior on λ_{max}. This approach basically ignores the drop in feasible parameter space for larger values of λ_{max}, and appears (for the cases investigated here) to provide the least conservative outcome.

These schemes (except resampling only f_{max} and S_a) have been employed at one time or another during recent assessments of marine mammals: Punt and Butterworth (1999) based their analyses on resampling 'None', and Wade (2002a) resampled f_{max}, S_a, and a_m. The choice among the resampling schemes depends on several factors. The realized prior distributions for the intrinsic rate of growth are nearly uniform when f_{max}, S_a, and a_m or, f_{max} and S_a are resampled (Fig. 2.6). Such distributions are therefore more consistent with the intended prior for λ_{max}. Choosing a resampling scheme that maintains a near uniform prior on λ_{max} is defensible if it is believed that the resampled life-history parameters are essentially nuisance parameters, recognizing that the status of a population depends critically on the value of the parameter that determines productivity, which is λ_{max} in these models. Such an alternative might be appealing, if, for example, there is limited prior information on life history parameters, and instead, there exist a precise series of abundance estimates over a relatively long time-period. In fact, this approach appears to provide a better fit to recent abundance estimates for the B-C-B bowhead stock (Fig. 2.2).

This study was originally motivated by a desire to ensure that, based on the results of recent stock assessments (e.g., Brandon and Wade, 2006) current aboriginal strike limits for the B-C-B bowhead whale are well-founded and sustainable. We emphasize here that this is certainly the case. However, the B-C-B bowhead whale is one of the most well studied populations of marine mammal in the world, and therefore its stock assessments are exceptionally data-rich. This situation is an exception, not a rule. As we have shown, there are other populations of marine mammals for which these issues are an important consideration.

It is not our intention that the results presented here for E-G walrus are directly comparable with those of Witting and Born (2005). The selectivity ogive assumed here for E-G walrus is probably oversimplified (certainly different), and likewise, we explore a catch series that is five times the reported (or estimated) values, purely to illustrate the potential sensitivity of these results. Although the increase in catches is obviously exaggerated, there is undoubtedly considerable uncertainty in this catch history (e.g., Witting and Born (2005) explore a struck and lost rate of up to 25%). It is noteworthy that the estimates of the quantity Q_1 for bowheads are only moderately sensitive to the inflated catch history (Table 2.5). This result is consistent with previous analyses which showed that, given uncertainty or bias in the historic catch record before 1915, the abundance estimates from survey data are the dominant influence on the posterior distributions for quantities related to management (Givens and Thompson, 1996; Givens, 2005).

We have attempted to consistently apply the methods explored here to both case studies. However, it is not practical to use the 'forwards from recent' modeling approach for E-G walrus. There is insufficient data from which to independently specify a prior on recent abundance for this stock and hence fit a population trajectory. If this technique had been used to estimate management quantities for E-G walrus, the results would have been even more sensitive to the specification of priors than was the case for the backwards method. Another difference between the case-studies is the prior chosen for λ_{max}. However, both are uniform with an upper bound that is chosen to coincide with the realized upper bound dictated by the constraint on S_{juv} (Fig. 2.1). Although different, the upper bounds do not constrain the results, but do make the numerical integration more efficient. The method investigated here is perhaps the most common approach to constructing a coherent prior for marine mammals in recent years, largely based on assessments performed for the IWC. The consistent methodology allows for comparison between a data-rich and data-poor scenario, highlighting the sensitivity of data-poor scenarios to an easily overlooked aspect of constructing a coherent joint prior while respecting biological realism.

The degree of sensitivity between data-rich and data-poor scenarios is well illustrated by the results of the risk analyses, which are based on the reported catch history. A future catch of 100 bowheads (a catch larger than the current catch) would lead one to predict a consistent ~100% chance of meeting the management objective, regardless of the resampling scheme used (Fig. 2.8, left panel). Whereas, there are large differences in the probability of meeting the management objective for E-G walrus, depending on which resampling scheme is used to construct a coherent joint prior while applying the constraint on juvenile survival (Fig. 2.8, right panel). For example, given an annual catch of 15 animals, resampling 'None' indicates that the management objective will be met with only a 60% probability, while resampling f_{max} and S_a (and a_m) would lead one to predict a greater than 90% probability. If the technique examined here - solving for a free parameter – is to be used to construct a coherent joint prior given a biological constraint, we recommend exploring different resampling schemes during the initial phase of the stock assessment to determine the sensitivity of the results to this choice. Given the results of these analyses, it seems that two coherent joint priors that respect biological realism could be constructed and the assessment run twice, resampling 'f_{max}, S_a and a_m' or 'None.' This amounts to a sensitivity analysis to alternative joint priors. These two schemes are likely to bracket intermediately conservative weightings of the marginals. If the results are not consistent between these two schemes, then some consideration should be given to the sensitivity of the assessment results to the priors. We emphasize this recommendation for data poor stock assessments.

Alternative approaches are available to construct a coherent joint prior distribution. For example, a variant of the technique explored here was used by Witting and Born (2005). They imposed a joint prior distribution on (S_{juv}, S_a), with S_{juv} conditional on S_a such that values of S_{juv} greater than S_a were set equal to S_a. Then, given values of the life history parameters from the prior, they solved for the productivity parameter *MSYR* (the population growth rate at *MSYL*). Such an approach (setting population growth rate as the free parameter) is appealing if there is good prior information on life history, but not population growth rate. Indeed, walrus populations are an example of this scenario: there exist reliable measurements of life history parameters (e.g. fecundity and age-at-sexual maturity), but accurate surveys of abundance have proven elusive. Solving for *MSYR* will more closely maintain the explicit priors on life history parameters, for which there is a greater degree of confidence.

Solving for the population growth rate analytically (instead of a life history parameter) does not circumvent biologically impossible solutions (e.g., $\lambda_{max} < 1.0$). Goodman (1984) clearly demonstrated this fact using Monte Carlo simulation with life history parameters for the spotted dolphin, *Stenella attenuata*. Witting and Born (2005) resampled 'None' of the parameters when they arrived at a solution for the maximum population growth rate that was negative. It is just as conceivable to resample only a subset of life history parameters until a feasible solution for population growth rate is obtained. This approach would result in certain realized priors on life history parameters being more consistent with their intended distributions. Choosing to analytically solve for the population growth rate in order to construct a coherent joint prior, instead of a solving for a life history parameter (e.g., S_{juv}), does not circumvent the need to resample (or ignore) values from the priors when parameter combinations result in solutions for population growth rate that violate biological realism.

Obviously, the population growth rate is an extremely influential parameter with regards to model outputs that are important to management. However, if this parameter is solved for analytically to construct a coherent joint prior, it should be recognized that the resulting implicit prior will be sensitive to the limits placed on the priors for the life history parameters. For instance, given uniform priors on all life history parameters, the resulting implicit prior distribution for population growth rate will be bell-shaped with a mean and variance that shifts according to the upper and lower limits of the uniform priors for life history parameters (c.f. Fig. 1 of Goodman, 1984). So, while very little is often known about certain life history parameters, the range for which this "ignorance" is bounded may be more informative than desired. For example, the resulting implicit prior distribution for the intrinsic population growth rate will differ substantially (all else being equal) between priors for S_{juv} ~U[0.70, 0.90] or ~U[0.10, 0.90]. This sensitivity is likely to be unsatisfactory.

If a life history parameter is solved for, then the prior distribution on population growth rate, or at least its upper bounds could be based on a meta-analysis for related species for which there exists trend data from populations recovering from depletion (e.g., Best, 1993). Unfortunately, reliable trend information does not exist for most walrus populations. However, it is worth noting that the constraint on juvenile survival rate, in concert with the ranges of the other life history parameters, is what effectively imposes the upper bound on the realized prior for λ_{max} (Fig. 2.1). Therefore, any uniform prior on λ_{max} will lead to the same results, as long as the upper bound on the explicit prior provides support up to those values for λ_{max} beyond which there is zero realized prior probability. Following the prior distributions for life history parameters used by Witting and Born (2005), we have chosen a suitable upper limit for E-G walrus $\lambda_{max} = 1.12$. It is clear from the values for the upper 95th percentiles of the posteriors for this parameter (Table 2.6), that the upper bound on this prior does not constrain the results for E-G walrus.

Setting one parameter to be calculated, given values from the priors of the remaining parameters potentially ignores information. In certain cases, this might be justifiable (e.g., given a lack of knowledge regarding juvenile survival). However, there are other methods for constructing a coherent joint prior while retaining explicit prior distributions on all inputs (and outputs). Poole and Raftery (2000) extend Bayesian synthesis to include logarithmic pooling of priors (French, 1985; Genest and Zidek, 1986). This technique, termed 'Bayesian melding', provides a coherent joint prior on model inputs and outputs and is not subject to Borel's paradox. To our knowledge, this method has only been applied to an age-aggregated surplus production model for the B-C-B stock of bowhead whale (Givens and Robuck, 1999; Poole and Raftery, 2000). It remains to be seen how a biological constraint like $S_{juv} < S_a$ could be implemented using Bayesian melding with an age-structured PDM. Moreover, it is not obvious how any approach can escape the necessity of resampling (or not) parameter values given that parts of the prior space violate biological realism.

Ideally, whatever method is used to construct a coherent joint prior, an explicit correlation structure between the parameters is involved, given observed and hypothesized relationships among the model parameters (e.g., between fecundity and adult survival). However, completely specifying a joint prior distribution with explicit correlations among the parameters is a complex endeavor for age-structured PDMs. It is interesting to note that implementing the constraint on juvenile survival imposes a correlation structure among the parameters (Fig. 2.10; Punt and Butterworth, 1999), and this is probably an improvement over a naive assumption of independence.

In addition to incorporating correlations among life history parameters, it is desirable that the method used to construct the prior, should change the explicit marginal priors as little as possible. However, it is apparent that resampling (or not) updates the explicit marginal priors, resulting in different realized marginal priors. Further, different resampling schemes change the marginals of the parameters differently. For example, compare the explicit and realized marginals for B-C-B bowhead S_a and λ_{max} (Fig. 2.5 and Fig. 2.6). Radke *et al*. (2002), in an example from another field of natural resource modeling, achieve a coherent joint prior distribution using Bayesian melding (via SIR), while explicitly incorporating rank correlations among input parameters (see Iman and Conover, 1982; Guan, 2000). The method is analogous to a 'normal copula' (e.g., Wang, 2004), which induces a target correlation structure among parameters while retaining the explicit marginal priors. We tested this approach, but it does not appear to be a valid substitution for the constraint on S_{juv} (at least for the cases investigated in these analyses).

It seems certain that the number of assessments using similar Bayesian methods will increase in the future. Our objective is not to advocate a single 'best' approach for constructing a coherent joint prior while respecting biological realism. However, as we have shown, Bayesian inference based on assessment scenarios for which data are limited are likely to be quite sensitive to the issues explored here. Likewise, these issues are also relevant to other long-lived marine taxa, for which similar biological assumptions, PDMs and assessment methodologies are appealing, but time-series of abundance and anthropogenic mortality are likely to be limited and imprecise (e.g., some sea-birds, sharks and sea-turtles).

Table 2.2

The average proportion of observed calves (p_c^{obs}) and mature (p_m^{obs}) animals, with associated standard errors, over the years 1985 to 1994. Proportions are given based on ignoring the potentially anomalous data set for 1985. Source: IWC (1999) and Koski *et al*. (2006).

p_c^{obs}	σ_{p_c}	p_m^{obs}	σ_{p_m}
0.0580	0.0062	0.4366	0.0106

Table 2.3

The prior distributions for the B-C-B bowhead whales. Dashes (-) represent prior distributions that are equal to those from the model in the column to the left. 'N/A' indicates a prior that is not required for the model concerned. Fecundity is defined as female calves per mature female. The abbreviations for these distributions are: U ~ Uniform, DU ~ Discrete uniform, and N ~ Normal. Sources are given below.

Parameter		Model Type	
		1848 Bkwd	1978 Fwd
S_a	adult survival	N(0.990, 0.02), truncated at 0.940 and 0.995[a]	-
f_{max}	maximum fecundity	U[0.125, 0.200][b]	-
a_T	age-at-transition to adult survival	DU[1, 9][c]	-
a_m	age-at-sexual maturity	N(20.0, 3.0) truncated at 13.0 and 26.0[d]	-
λ_{max}	intrinsic population growth rate	U[1.005, 1.075][e]	-
N_{1978}	population size in 1978	N/A	U[3000, 9000][f]
N_{1993}	population size in 1993	N(7800, 1200)[g]	N/A
K	carrying capacity	N/A	U[8000, 30000][h]
MSYL	*MSYL* in terms of the 1+ population component	U[0.40, 0.80] [h]	-

a – based on the posterior distribution for adult survival rate obtained by Zeh *et al*. (2002).

b – the prior for the maximum number of calves (of both sexes) per mature female selected by the Scientific Committee of the International Whaling Commission was U[0.25, 0.4] (IWC, 1995). This is the corresponding prior given fecundity has been defined here as female calves per mature female per year.

c – selected by the Scientific Committee of the International Whaling Commission (IWC, 1995) although there is little information on the value of this parameter (Givens *et al*., 1995).

d – based on a best estimate of 20 years and a lower confidence interval for the age at first parturition (age at sexual maturity + 1 year) of 14 years (IWC, 1995).

e – preliminary analyses indicated there was no posterior probability outside this range, which was confirmed in the final analyses. This range was therefore selected to improve the efficiency of the numerical integration while not affecting the results.

f – selected to encompass a plausible range of values for 1+ population size in 1978.

g – selected by the Scientific Committee of the International Whaling Commission (IWC, 1995) based on the prior distribution assumed for the Bayes empirical Bayes estimate of abundance (Raftery and Zeh, 1991).

h – based on the prior selected by the Scientific Committee of the International Whaling Commission (IWC, 1995).

Table 2.4

The prior distributions for E-G walrus. The abbreviations for these distributions are: U ~ Uniform, DU ~ Discrete uniform and LN ~ Log-normal. Sources are given below.

Parameter		Prior
S_a	adult survival	U[0.900, 0.980][a]
f_{max}	Maximum fecundity	U[0.167, 0.250][b]
a_m	age-at-sexual maturity	DU[5, 9][b]
λ_{max}	intrinsic population growth rate	U[1.01, 1.12][c]
N_{1995}	population size in 1995	LN[ln(1000), 0.35^2][d]
MSYL	*MSYL* in terms of the 1+ component	U[0.50, 0.80][e]

a – prior assumed by Witting and Born (2005), with ranges set wide enough to encompass plausible values as no direct evidence is available for this parameter.

b – Mansfield (1958), Fay (1982) and Born (2001). The range of fecundity values used by Witting and Born (2005) has been divided by two because these values are taken here to relate to the number of female calves per mature female per year.

c – preliminary analyses indicated there was no posterior probability outside this range, which was confirmed in the final analyses. This range was therefore selected to improve the efficiency of the numerical integration while not affecting the results.

d – Born *et al.* (1997). This is the abundance estimate used for 1995 by Witting and Born (2005), where the CV is taken to be approximately equal to the standard error of the logarithm.

e – prior assumed by Witting and Born (2005).

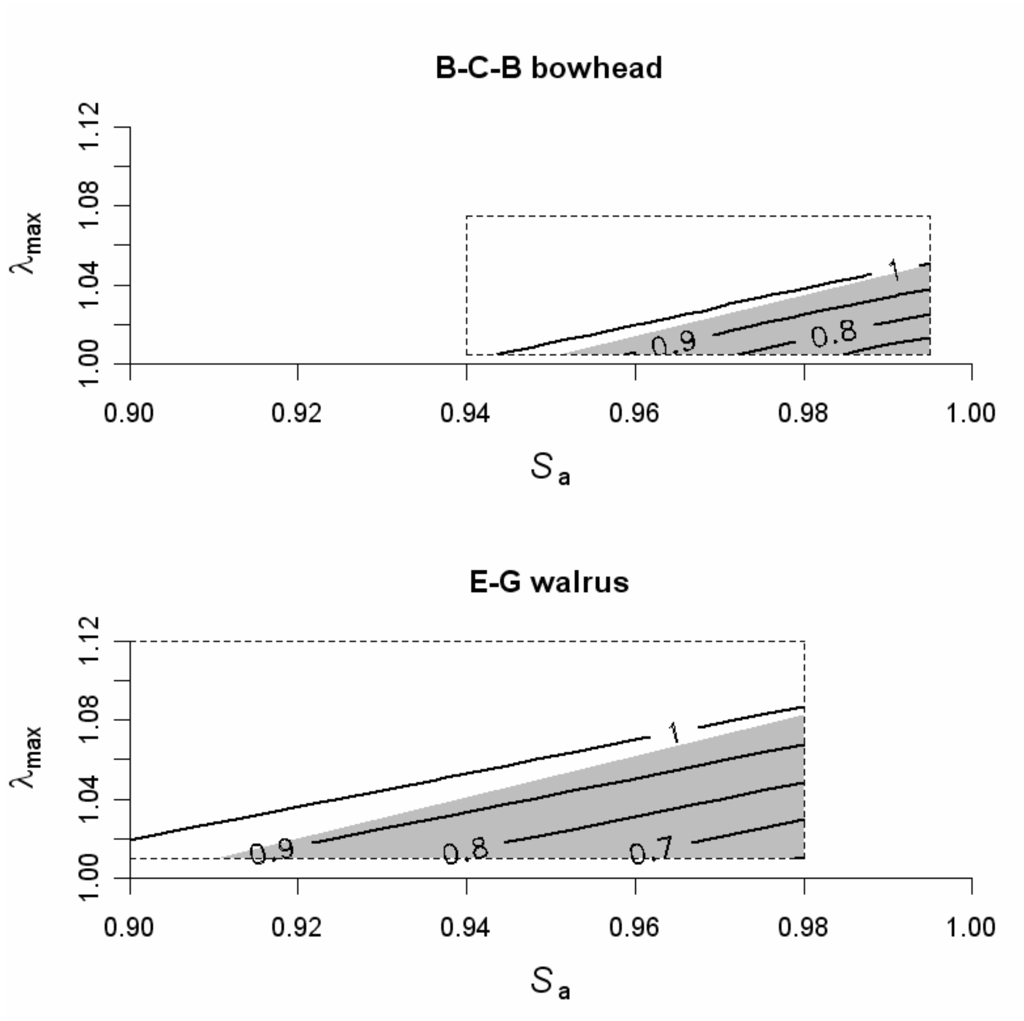

Figure 2.1: Contour plots showing solutions for S_{juv} (from Eqn. 2.4) given a range of values for S_a and λ_{max}. These diagrams are created by setting the remaining life history parameters constant, equal to the expectation of their explicit prior marginal distribution (e.g., a_m = 20 for B-C-B bowheads). The shaded triangular region in the lower right hand corner is the feasible parameter space, subject to the constraint on survival rates. The blank space in the upper left corner represents biologically impossible solutions for S_{juv} which are greater than 1.0. The area between the contour of 1.0 and the shaded region shows the biologically implausible region where $S_{juv} > S_a$. These plots illustrate the fact that there is more parameter space (given the constraint) consistent with smaller population growth rates.

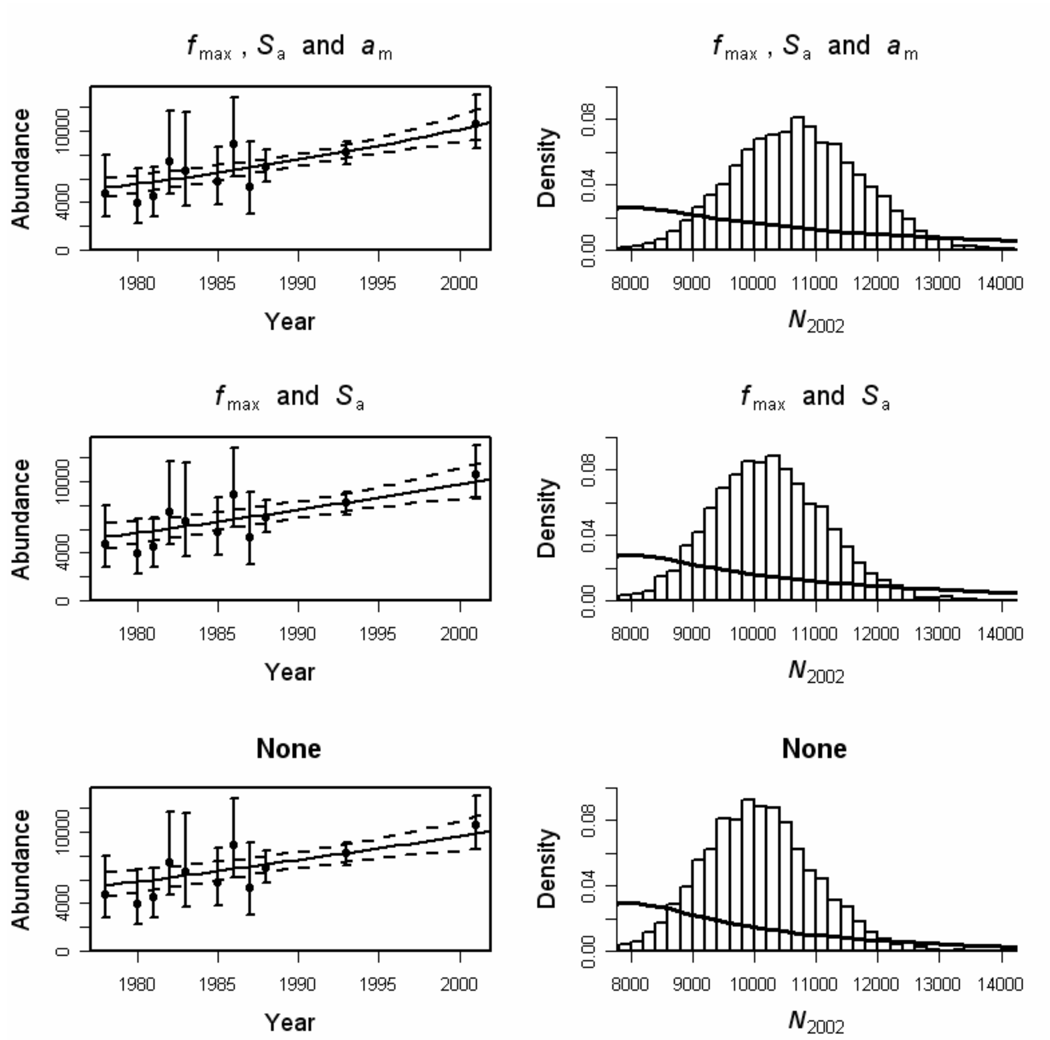

Figure 2.2: Model fits and estimates of recent abundance according to the '1978 Fwd' model for B-C-B bowheads. The left panels show the posterior distributions (medians and 90% credibility intervals) for the time-trajectory of population size. Error bars represent 90% CI's from survey estimates, and are assumed to be log-normally distributed for all abundance estimates except 1993 (second to last), which is assumed to be normally distributed. The commercial catch during the second half of the 19th century was much higher than the current level, which averages 36 whales during the time period shown. The right panels show the posterior distribution of population size in 2002. The solid lines in the right panels are the realized prior distributions and the bars are the posterior probabilities.

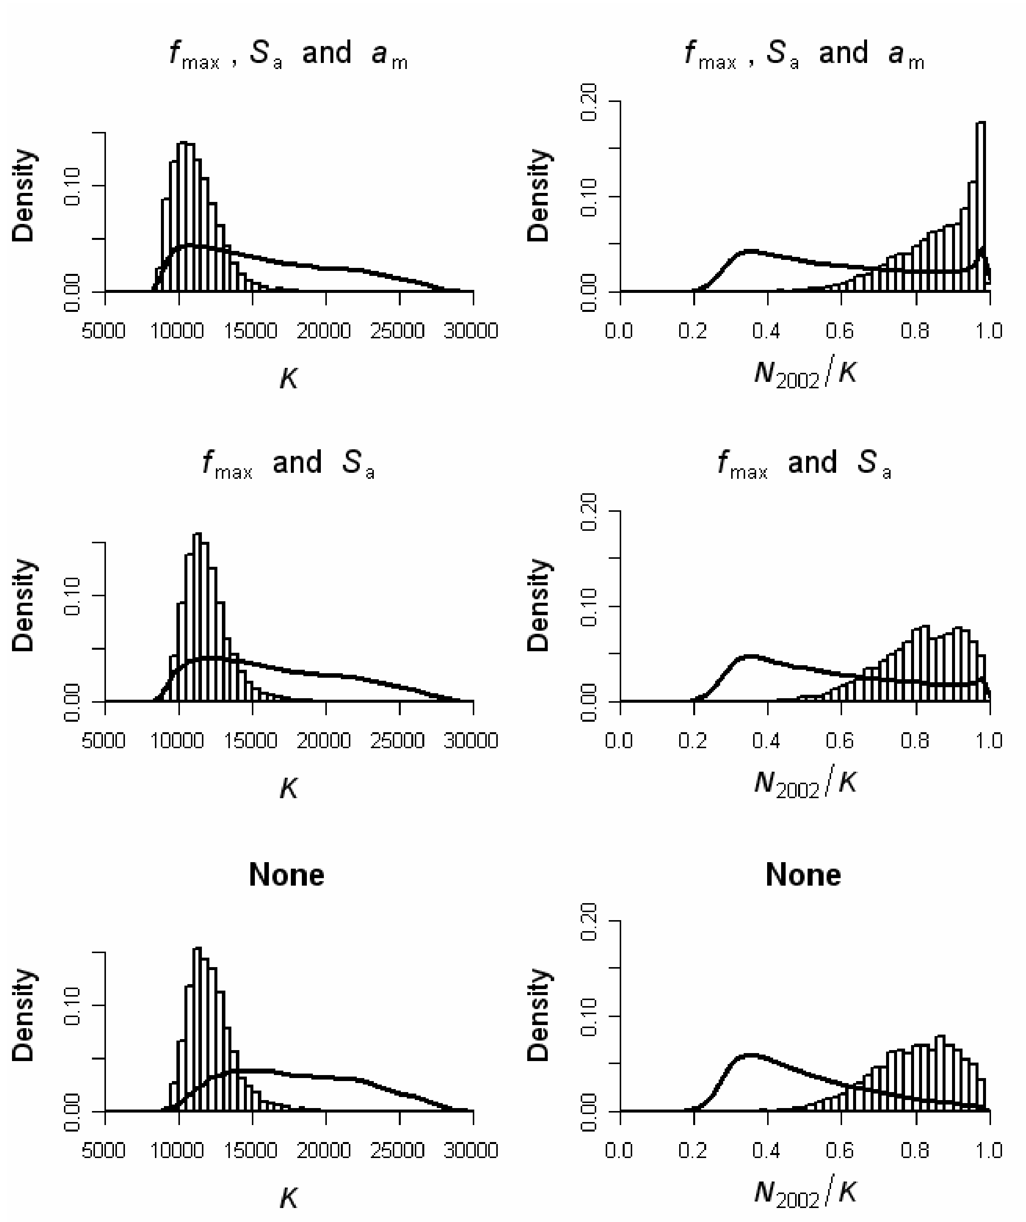

Figure 2.3: Realized prior distributions (solid lines) and posterior distributions (bars) for *K* and depletion in 2002, according to the '1848 Bkwd' model for the B-C-B bowhead population.

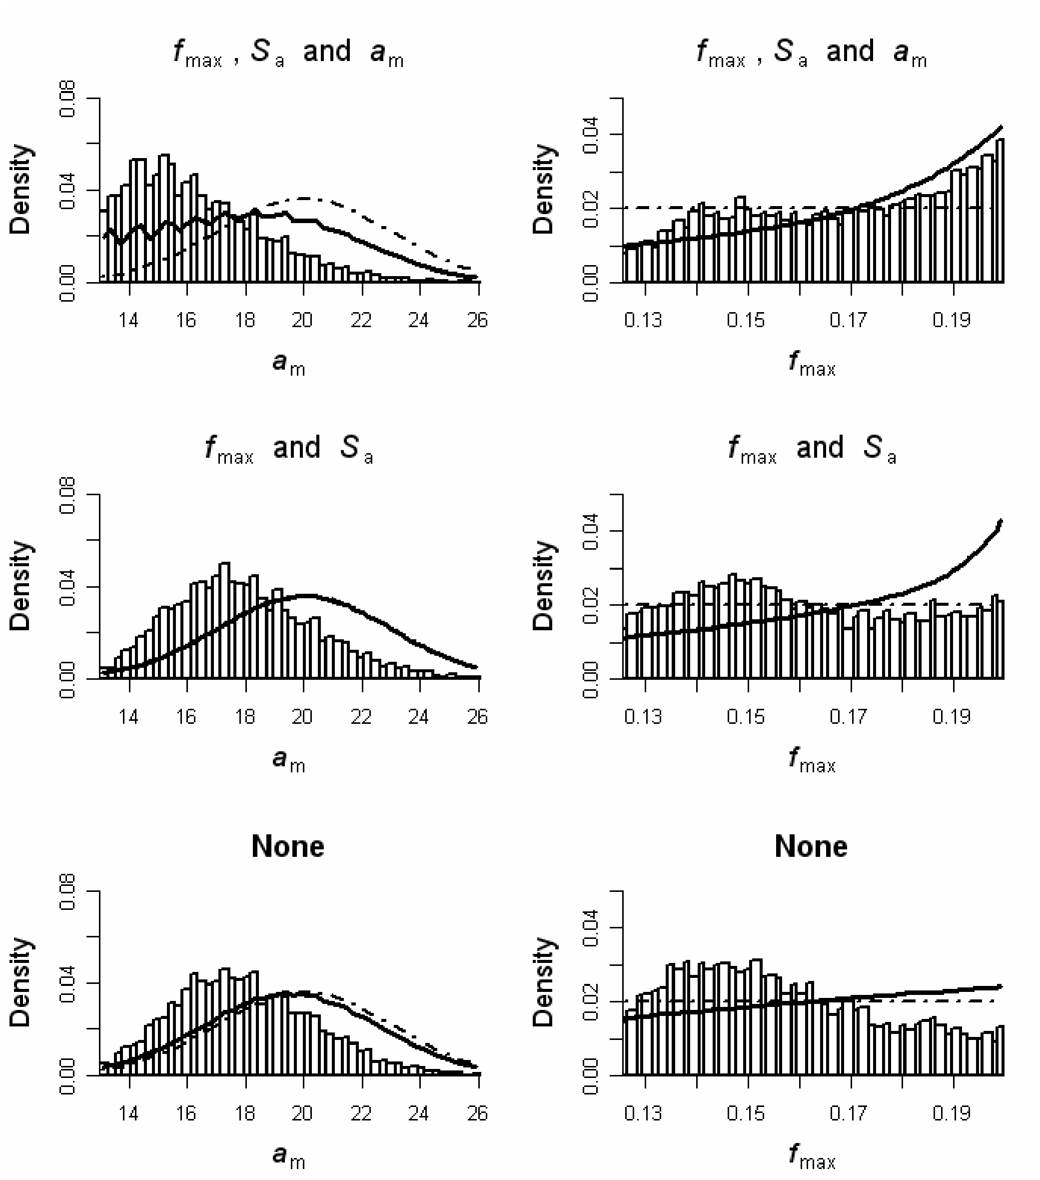

Figure 2.4: Explicit priors (dashed lines), realized priors (solid lines) and posterior distributions (bars) for a_m and f_{max}, according to the '1978 Fwd' model for the B-C-B bowhead population.

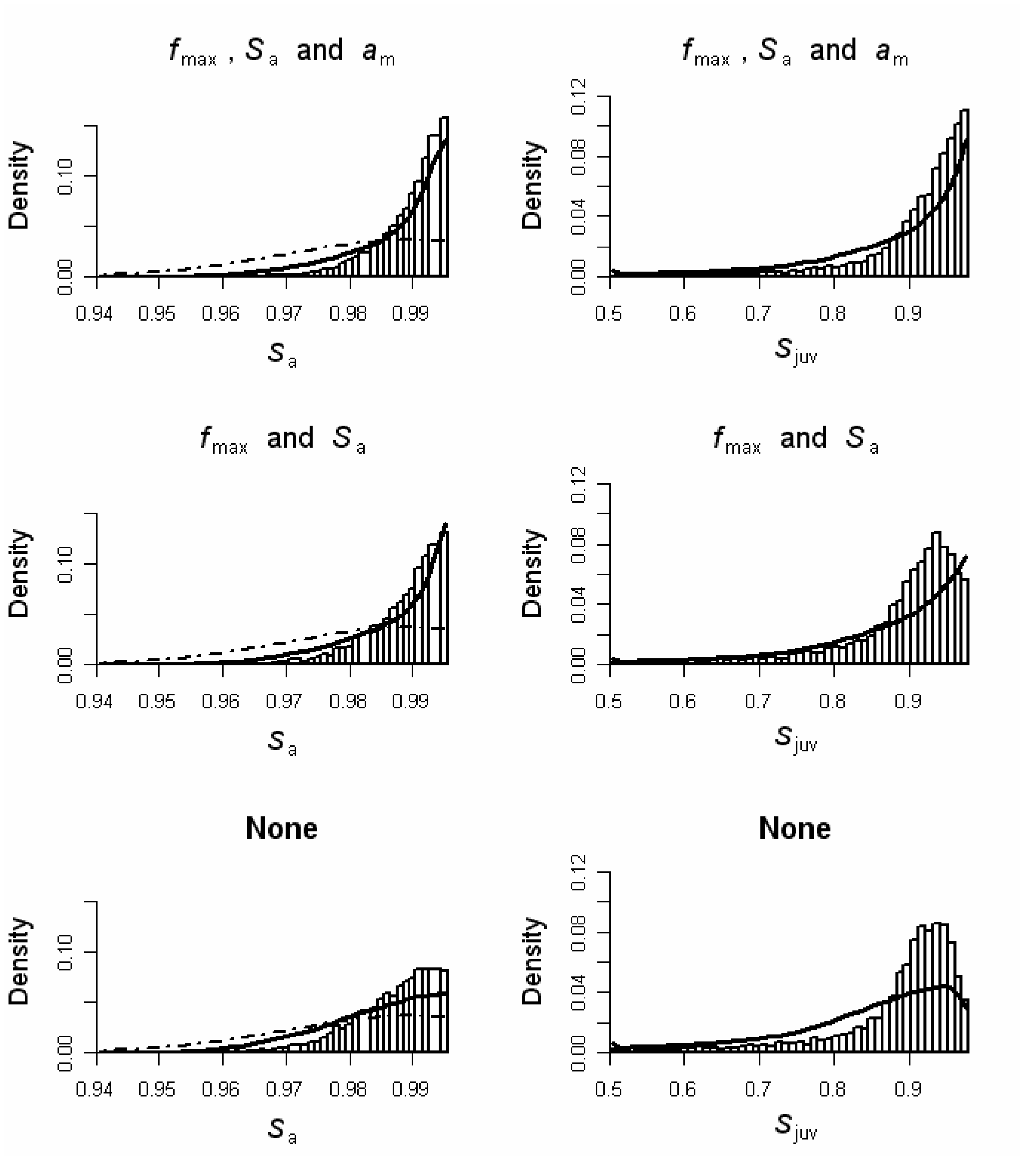

Figure 2.5: Explicit priors (dashed lines – left panels only), realized priors (solid lines) and posterior distributions (bars) for S_a and S_{juv}, according to the '1978 Fwd' model for the B-C-B bowhead population. Note the ranges of the x-axes differ between parameters.

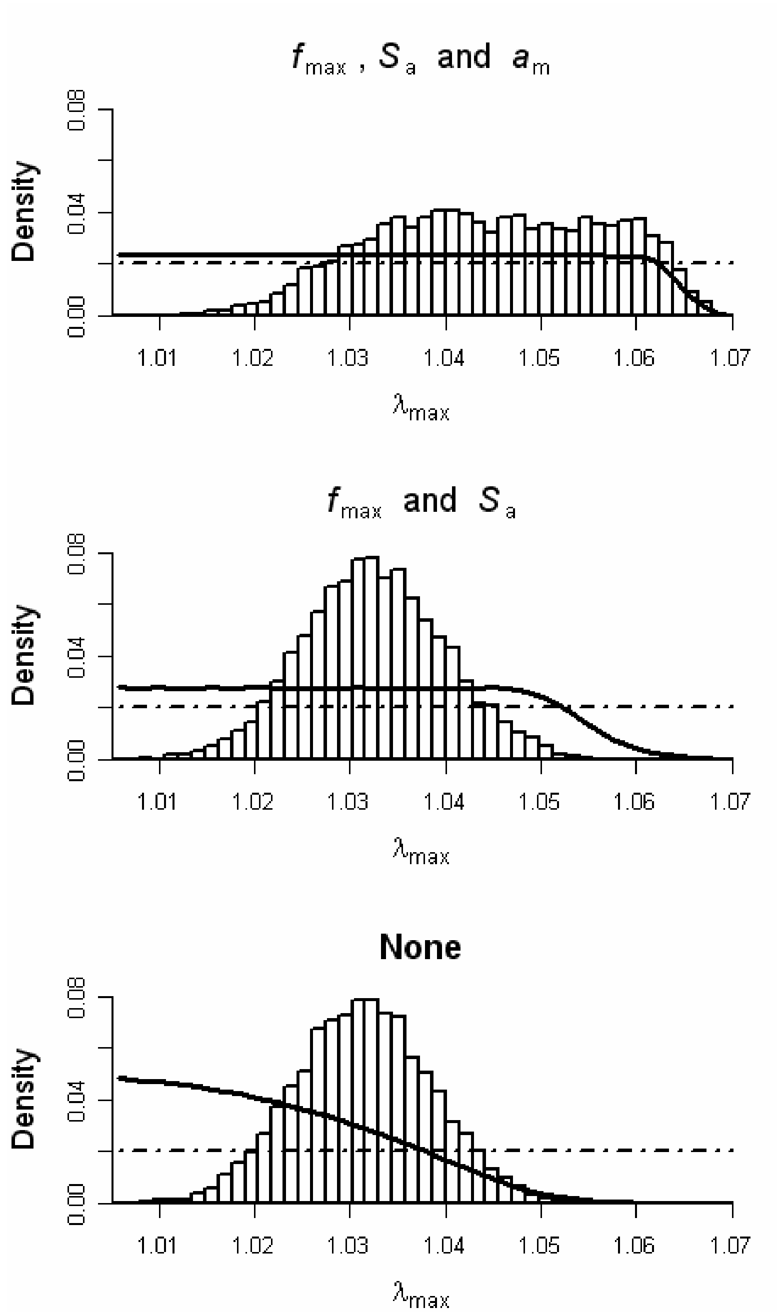

Figure 2.6: Explicit priors (dashed lines), realized priors (solid lines) and posterior distributions (bars) for the intrinsic rate of growth λ_{max}, according to the '1978 Fwd' model for the B-C-B bowhead population.

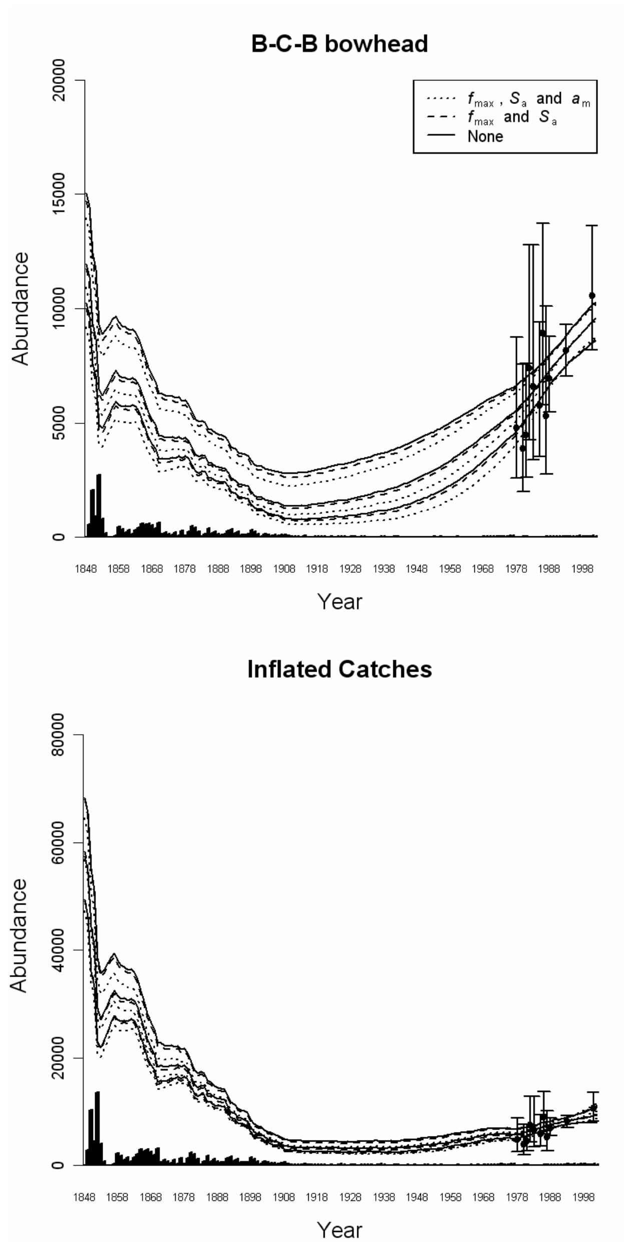

Figure 2.7: Time-trajectories of 1+ abundance (medians and 90% credibility intervals) for the B-C-B bowhead population when the reported catch history is used (top panel) and that when the inflated catch history is used (bottom panel). Note the ranges are different for each y- axis. Catches are plotted along the x-axes. Abundance estimates are shown with error bars representing 90% confidence intervals.

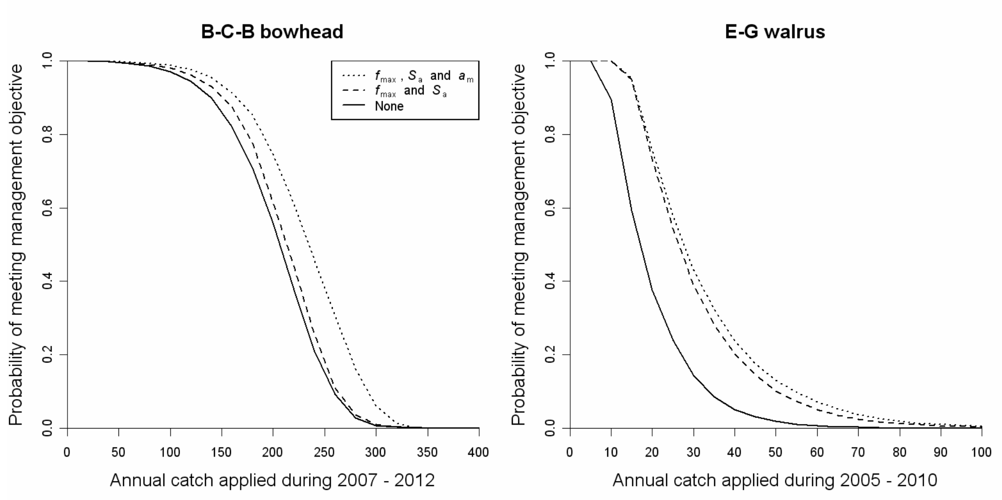

Figure 2.8: The probability of meeting the management objective selected by Witting and Born (2005), for each alternative resampling scheme, as a function of constant future catch for B-C-B bowhead (left panel) and E-G walrus (right panel). Probabilities are shown for each analyses using the reported catch history.

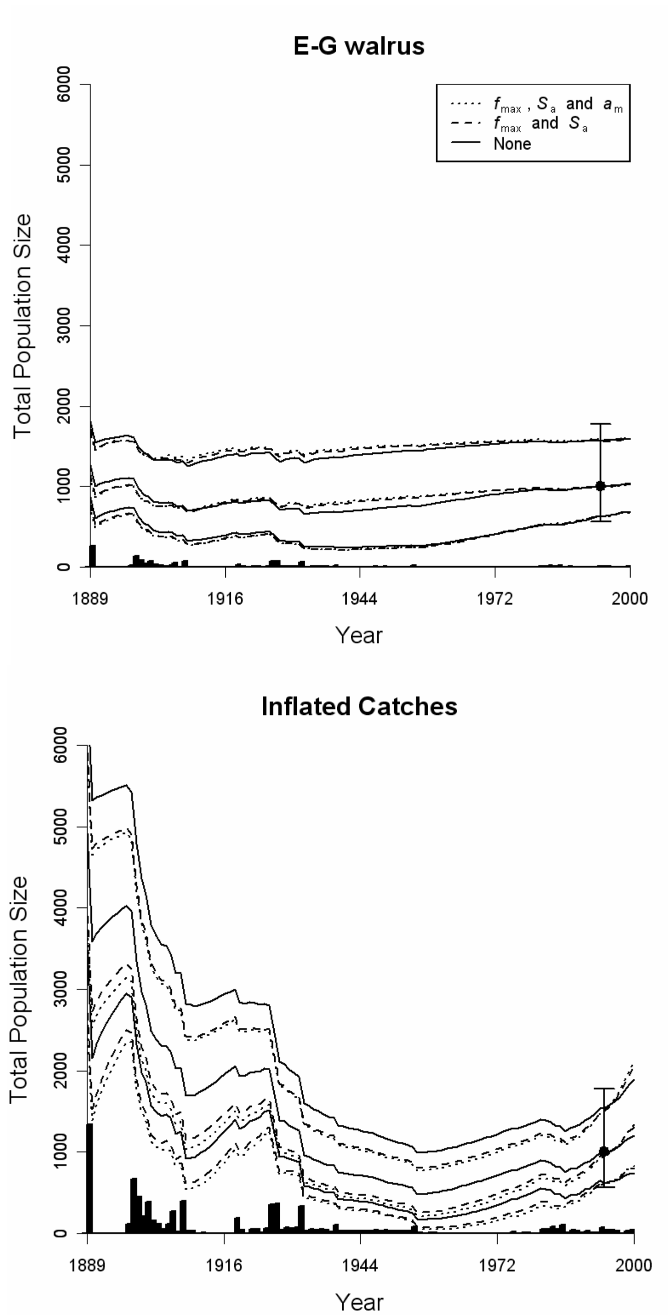

Figure 2.9: Time-trajectories of 0+ population size (medians and 90% credibility intervals) for the E-G walrus population when the reported catch history is used (top panel) and that when the inflated catch history is used (bottom panel). Catches are plotted along the x-axis. The mean of the prior for 1995 abundance (0+) is shown with error bars delimiting the 90th percentiles for the sampling distribution.

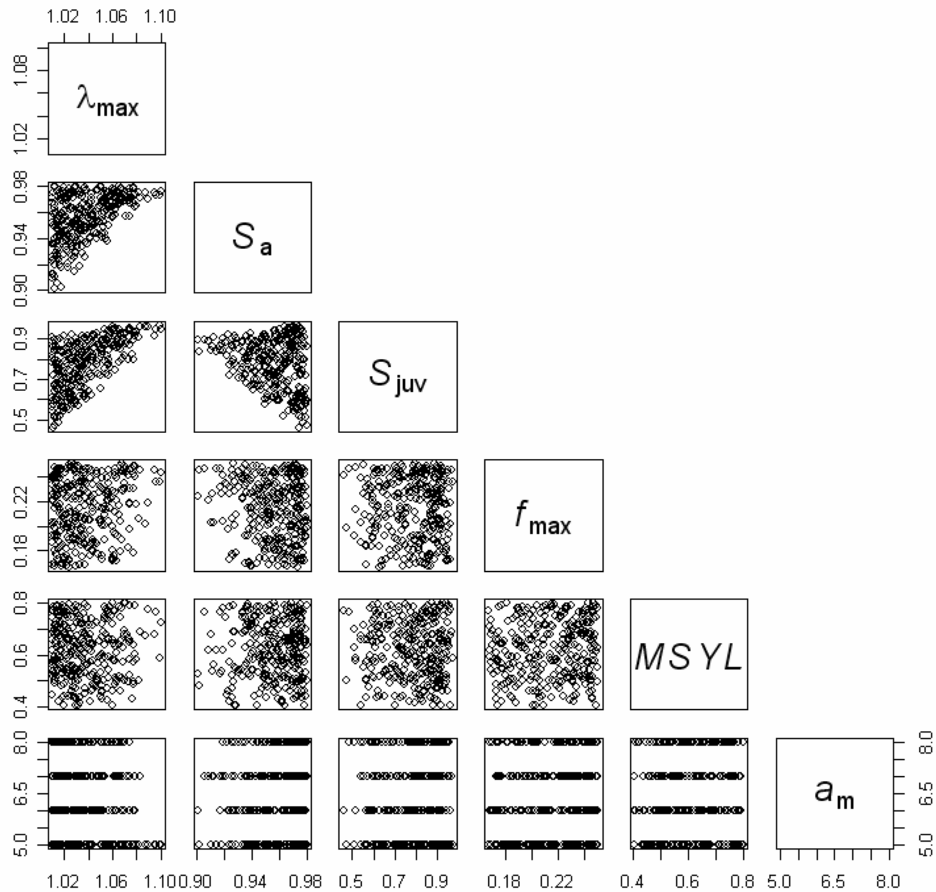

Figure 2.10: Bivariate scatterplots of parameter values from the coherent joint prior achieved by the resampling 'None' for E-G walrus.

Chapter 3:

Assessment of the eastern stock of North Pacific gray whales: incorporating calf production, sea-ice and strandings data

ABSTRACT

A stochastic population dynamics modeling framework that integrated a hypothesized relationship between an environmental variable and process error in life history parameters was developed for the eastern North Pacific stock of gray whales. The case study incorporated an index of sea-ice, which has been hypothesized to regulate calf production in this population. The framework also allowed for stochasticity in both birth and survival rates, and was fit to an index of strandings to capture the dynamics observed during the mortality event of 1999 and 2000. Sensitivity tests were preformed to evaluate the consequences of various assumptions with respect to the extent of stochasticity and data weightings, and the results of this framework were compared to those based on a deterministic model that was only fit to the abundance data. These alternatives were each able to fit the abundance data well and estimated that the population is very close to the carrying capacity of its environment at present. However, those scenarios which accounted for the effect of the mortality event in 1999 and 2000 led to less optimistic estimates of population status during recent decades with concomitant recovery generally attributable to higher survival rates as opposed to higher birth rates. This study represents the first time that the effects of environmental forcing and the mortality event of 1999 and 2000 have been taken into account during a stock assessment of this population. The framework developed here can be used as an operating model with which to test the Gray Whale *SLA*, given climate forecasts and hypotheses regarding environmental impacts on population dynamics.

3.1 INTRODUCTION

Management of cetacean populations involves determining risk-adverse management strategies that account for natural variability in the environment and impacts of climate change on ecosystems (IWC, 1994; Tynan and DeMaster, 1997). Stock assessment methods that incorporate relationships between environmental factors and population processes offer the potential to improve management in several ways: (1) to increase the precision of parameter estimates for population dynamics models and hence catch or by-catch related quotas (Maunder and Watters, 2003); (2) to provide a tool to evaluate the performance of existing and alternative management strategies given forecasts of future climate (e.g. A'mar *et al.*, 2009); (3) to increase the understanding of factors that might affect the recovery of depleted populations; and (4) to identify priorities for future research and management guidelines (IWC, 1997).

The eastern North Pacific (ENP) stock of gray whales is currently subject to aboriginal hunting, with strike limits based on the Gray Whale Strike Limit Algorithm (SLA) under the Aboriginal Whaling Management Procedure (AWMP) of the International Whaling Commission (IWC 2004, 2005a). The life history of this stock follows a typical baleen whale migration between low and high latitudes (Lockyer, 1984). In general, the majority of animals in the population probably derive most of their annual caloric intake from rich benthic prey communities of the northern Bering and southern Chukchi Seas during the summer feeding season. Measurements of weight and girth support the hypothesis that whales on the northbound leg of the migration have lower fat reserves than their counterparts on the southbound migration, due to reduced feeding during the winter migration (Rice and Wolman, 1971; Perryman and Lynn, 2002). Furthermore, observations from individuals killed off California during the 1960's suggest that pregnant females are the first to migrate northward to the feeding grounds after breeding (Rice and Wolman, 1971). Given these factors and the observed variability in calf counts during the northbound migration, it has been hypothesized that the extent of sea-ice covering feeding grounds during the early feeding season might act to dictate calf production by affecting feeding opportunities (Perryman *et al*., 2002).

This chapter provides the first attempt to integrate available estimates of abundance, calf production, strandings and an environmental index that is potentially related to calf production for ENP gray whales in a population dynamics modelling framework. This is one of the most well studied stocks of whales, and therefore provides an ideal candidate to illustrate the results of an assessment method for cetaceans which incorporates an environmental time series. The approach for integrating a relationship between the environmental data and stochastic population dynamics is similar in some respects to that of Maunder and Watters (2003), but differs in that the environmental observations are treated as data and included as a component of the likelihood function (Schirripa *et al*., 2009). This allows an environmental index with missing years to be incorporated in the analysis. The same approach has been used to assess bigeye tuna (*Thunnus obesus*) in the eastern Pacific (Harley and Maunder, 2004) and is currently being adopted for assessment of sablefish (*Anoplopoma fimbria*) off the US west coast (following, Schirripa and Colbert (2006)).

Unlike previous assessments of this stock, the population dynamics model allows for stochastic birth and survival rates and accounts for three female stages: immature, mature receptive (fertile), and mature with calf. Mature females alternate between calving and receptive stages, with the number of calving females in a given year determined by the stochastic birth rate and the number of receptive females that survived the previous year. This underlying population dynamics model is therefore similar to that of Cooke *et al*. (2007), except that it is age-structured rather than being individual-based. The population dynamics model also attempts to take into account the unusual mortality event that occurred during 1999 and 2000, when anomalously high numbers of individuals were reported dead along the west coast of North America (Gulland *et al.*, 2005).

Results from the application of this approach are compared with those from a deterministic version of the same model, which is not fit to calf production and strandings data, and does not take potential environmental forcing into account. The results of alternative scenarios are also presented for the stochastic model. These scenarios correspond to different assumptions regarding the weights assigned to different data sources or different levels of inherent demographic stochasticity, and allow an evaluation of the sensitivity of the results to key assumptions with respect to these concerns.

3.2 METHODS

Population dynamics model

The analyses were based on a sex- and age-based population dynamics model with an annual time-step. The model included stochastic birth and survival rates, and explicitly considered the transition between receptive and calving stages for mature females (Fig. 3.1). The total number of animals in the population was consequently divided into the number of males $N_{a,t}^{male}$ by age and year, the number of immature females by age and year $N_{a,t}^{i}$, the number of cows with calves by year $N_{x,t}^{c}$, and the number of receptive females by year $N_{x,t}^{r}$.

It was not necessary to explicitly track the age-structure of receptive and calving females because the values for their population dynamic parameters, including harvest rate, were the same for all mature ages. Hence, all females that reached the age-at-maturity were lumped into one of the two mature reproductive stages (denoted as age '*x*'). These mature stages are also referred to as the 'plus-groups' hereafter, because they included animals which had reached the age at first parturition, plus all animals older than that age. Mature females transitioned between receptive and calving stages as determined by annual birth rates, with the only exit from these stages through mortality (Fig. 3.1).

Density dependence

Density dependence was assumed to act through the birth rate[9] according to the Pella-Tomlinson model:

$$b_t = \max\left\{0,\ b_{\text{eq}} + (b_{\max} - b_{\text{eq}})\left[1 - \left(\frac{N_{1+,t}}{K_{1+}}\right)^z\right]\right\} \tag{3.1}$$

where:

$b_{\max}$ is the maximum birth rate (in the limit of zero population size);

K_{1+} is the carrying capacity of the 1+ component of the population (all animals aged 1 yr and older);

b_{eq} is the equilibrium birth rate at carrying capacity;

z is the degree of density-dependent compensation (assumed to equal 2.39, which implies maximum sustainable yield at a population density approximately 60% of K_{1+}), and;

$N_{1+,t}$ is the size of the 1+ component of the population (both sexes combined) in year *t*.

Stochastic birth and survival rates

Birth rates varied annually about the deterministic value given by Eqn. 3.1. Since this rate must lie between zero and one, its realization in any one year was calculated using a logistic transformation:

---

[9] This is really the rate at which receptive females successfully conceive and then survive with calf to make it past central California on the northbound migration. Therefore, this rate will be less than the true birth rate due to early calf mortality, and even more so less than pregnancy rates due to the combined effects of prenatal mortality. Also note that, a constant birth rate of 1.0 corresponds with roughly 50% of mature females having a calf in any given year, due the nature of the population dynamics model.

$$b_t^* = \left[1 + \exp(-(\Phi^{-1}\left(b_t\right)\sqrt{2.76 + \sigma_\varepsilon^2} + \varepsilon_t + \varepsilon_{\text{add-1},t}))\right]^{-1} \tag{3.2}$$

where:

b_t^* is the realized birth rate during year *t*;

Φ^{-1} is the inverse standard normal cumulative distribution function;

ε_t is the process error deviation during year *t*, such that $\varepsilon_t \sim N(0, \sigma_\varepsilon^2)$;

σ_ε is a measure of the extent of variability in the process error, and;

$\varepsilon_{add-1,t}$ allows for additional process error in the birth rate for 1999 and 2000 (in other years, this parameter was set equal to zero).

This formulation of stochastic birth rates ensured that the expected birth rate in a given year was equal to the deterministic value from Eqn. 3.1 (see Appendix A for the derivation, including an explanation of the number 2.76). This transformation leads to a realized standard deviation (taken across years) for the process error deviations that is less than σ_ε (Punt, 2009). Therefore, the realized standard deviation $`\sigma_\varepsilon$ was also calculated for comparison.

Natural (i.e. non-fishing) survival rates were also allowed to vary annually with the same process error residuals as birth rates (i.e. the deviations in birth and survival rates were assumed to be perfectly correlated). It was assumed that these rates were independent of sex and perfectly correlated among ages in a given year, such that:

$$S_{a,t}^* = \left[1 + \exp(-(\Phi^{-1}\left(S_a\right)\sqrt{2.76 + \sigma_\varepsilon^2} + \varepsilon_t + \varepsilon_{add-2,t}))\right]^{-1} \tag{3.3}$$

where:

$S_{a,t}^*$ is the realized age-specific survival rate during year *t*;

S_a is the deterministic survival rate from age a to a+1, and;

$\varepsilon_{add-2,t}$ is a parameter which allows for additional process error in survival rates in 1999 and 2000 (in other years, this parameter was set equal to zero).

Note, only two natural survival rates were modeled in these analyses: (i) calf survival (S_0) to age 1; and (ii) the survival rate of animals aged 1 year and older (S_{1+}). That is, survival rates were assumed equal for all animals aged 1 and older (i.e., $S_{a>0} = S_{1+}$). Additional details are provided below, under 'Parameterization and scenarios'.

Preliminary analyses indicated that the distributional assumption for the process error deviations did not allow the model to fit the relatively extreme observations of strandings during 1999 and 2000. Thus, ε_{add-1} and ε_{add-2} were introduced into Eqns. 3.2 and 3.3 for those years to try and capture the population dynamics during the mortality event of 1999 and 2000. Two sets of scenarios were run: 1) $\varepsilon_{add-1}=\varepsilon_{add-2}$ (the base-case), and; 2) ε_{add-1} and ε_{add-2} estimated individually (Table 3.1).

Female dynamics

The number of immature females by age depended on the number of births, an assumed 50:50 sex ratio at birth, maturation, and mortality from natural causes and hunting. Maturity was assumed to be knife-edged at age 6 (i.e. all females reached the age at first estrous at age 6). The gestation period was assumed to be one year, so the age at first possible parturition was 7 yr, which is equivalent to the median of the prior distribution for this life history parameter adopted in previous assessments of the ENP gray whales (IWC, 1993; Wade, 2002a). The plus-group age was set equal to the assumed age at first parturition (i.e., x=7 years or older, i.e., 7+), so there was no need to implement a plus-group for the immature stage:

$$N^i_{a,t+1} = \begin{cases} 0.5N^c_{t+1} & \text{if } a = 0 \\ N^i_{a-1,t}S^*_{a-1,t}\left(1 - E^{fem}_t V_{a-1}\right) & \text{if } 1 \le a \le 6 \end{cases} \tag{3.4}$$

where

E^{fem}_t is the exploitation rate during year t on females:

$$E^{fem}_t = C^{fem}_t / \left(N^r_{x,t} + N^c_{x,t} + \sum_a V_a N^i_{a,t} \right) \tag{3.5}$$

V_a is the selectivity on animals of age a, assumed to be constant with regard to sex and time, and uniform on ages 5+, following the approach of previous IWC assessments (IWC, 1993):

$$V_a = \begin{cases} 0 & \text{if } a < 5 \\ 1 & \text{if } a \ge 5 \end{cases} \tag{3.6}$$

C^{fem}_t is the total catch of females during year t.

This formulation assumed that selectivity was the same for all animals of a given age, and was independent of sex, time, and reproductive condition. Hence, the assumed selectivity pattern allowed for cows, but not calves to be killed in the hunt.

The number of receptive females and cows with calves was (given full selectivity on these plus-groups) is given by:

$$N^r_{x,t+1} = S^*_{1+,t}\left[\left(1 - b^*_t\right)\left(N^i_{6,t} + N^r_{x,t}\right) + N^c_{x,t}\right]\left(1 - E^{fem}_t\right) \tag{3.7}$$

$$N^{c}_{x,t+1} = S^{*}_{1+,t} b^{*}_{t} \left(N^{i}_{6,t} + N^{r}_{x,t} \right) \left(1 - E^{fem}_{t} \right) \tag{3.8}$$

Male dynamics

Males were modeled using an age-structured model that ignored maturity because the number of males was assumed not to be a limiting factor for female reproductive success. However, plus-group dynamics (x=7+) were modeled for males because this avoided the assumption that all animals died after a certain age (given full selectivity on the plus-group):

$$N^{male}_{a,t+1} = \begin{cases} 0.5 N^{c}_{t+1} & \text{if } a = 0 \\ N^{male}_{a-1,t} S^{*}_{a-1,t} \left(1 - E^{male}_{t} V_{a-1} \right) & \text{if } 1 \le a < x \\ S^{*}_{1+,t} \left(1 - E^{male}_{t} \right) \left(N^{male}_{6,t} + N^{male}_{x,t} \right) & \text{if } a = x \end{cases} \tag{3.9}$$

where:

E^{male}_{t} is the exploitation rate during year t on males:

$$E^{male}_{t} = C^{male}_{t} / \sum_{a} V_{a} N^{male}_{a,t} \tag{3.10}$$

C^{male}_{t} is the total catch of males during year t.

Initial conditions

Population trajectories were initiated in 1930, under the assumption of a stable-age-distribution given some level of hunting mortality in 1930. A numbers-per-female-calf approach was taken to solve for the numbers-at-age in 1930 given values for the life-history parameters of the model, the relative size of the 1+ component in 1930, and the hunting mortality rate in 1930, E_{init}.The number of females per calf is given by (given full selectivity on the plus-group):

$$NPR_a^{(E)} = \begin{cases} 0.50 & \text{if } a = 0 \\ NPR_{a-1}^{(E)} S_{a-1} \left(1 - E_{\text{init}} V_{a-1}\right) & \text{if } 1 \le a < x \\ NPR_{x-1}^{(E)} S_{1+} \left(1 - E_{\text{init}}\right) \Big/ \left(1 - S_{1+}\left(1 - E_{\text{init}}\right)\right) & \text{if } a = x \end{cases} \tag{3.11}$$

The birth rate at unexploited equilibrium b_{eq} is the inverse of the number of receptive females per-calf which can give birth. Since the maturity ogive was assumed to be knife-edged and the age at first parturition was assumed equal to the age at which individuals entered the plus group, the number of mature females-per-calf was $NPR_x^{(E=0)}$. Given this, b_{eq} is:

$$b_{eq} = \left(NPR_x^{(E=0)} - 1\right)^{-1} \tag{3.12}$$

The numbers-per-recruit approach of Punt (1999a) was modified to take account of hunting mortality in 1930. This involved calculating b_{1930} using Eqn. 3.1 given b_{eq}, $b_{\max}$ and the relative size of the 1+ component in 1930, and using Newton's method (Press *et al.*, 1992) to solve for the value of E_{init} such that:

$$1 = b_{1930}\left(NPR_x^{(E=E_{\text{init}})} - 1\right) \tag{3.13}$$

The age- and sex-structure at the start of the 1930 was then calculated by scaling the numbers-per-calf by the number of calves corresponding to K_{1+}. The numbers-at-age of each sex in 1930 was then the total numbers-at-age divided by two.

Data and likelihood function

Four sources of data were considered when fitting the full model: (1) estimates of population size during 1967-2006 (starting year of survey) from the southbound migration at Granite Canyon, California (Rugh *et al.*, 2005, 2008); (2) estimates of calf production during 1994-2008[10] from the northbound migration at Point Piedras Blancas, California (Perryman *et al.*, 2002; Perryman, *unpublished data*), (3) the number of stranded animals on the coasts of California, Oregon and Washington state, for which a combined annual count was available during 1975-2006 (Brownell Jr. *et al.*, 2007)[11], and; (4) estimated sea-ice area covering the Bering Sea, averaged over March and April during 1953-2006 as calculated by the Hadley Center for their sea-ice and sea surface temperature data set version 1 ('HadSST') (Fig. 3.2, left panel; Rayner *et al.*, 2003).

The HadSST ice index was used here because it represents a good compromise between a shorter high-resolution and a longer less-precise environmental index. It is a compilation of several sources of data including the 'Walsh' charts of sea-ice extent prior to 1978 (Walsh, 1978), and satellite observations for recent decades. Therefore, this index provides a relatively long time series, calibrated by recent satellite observations. It is also worth noting that one of the major goals of these analyses is to use those results to test the Gray Whale *SLA* given predictions of future sea-ice. Since the primary purpose of the HadSST index is to form the basis for forcing atmospheric circulation models during simulations of future climate, and because we plan on using the results from such simulations of future climate when testing the Gray Whale *SLA*, the HadSST is the sea-ice index most consistent with the objectives of this research.

Catches by sex are available from 1930-2006 (Fig. 3.2, right panel). Selectivity-at-age resulting in the observed catches was treated as known. Hence no attempt was made to fit the catch data. Instead, catches were simply subtracted from the population each year according to the assumed selectivity ogive. The catches during 2007 and 2008 were assumed equal to those in 2006.

[10] The two early estimates of calf production during 1980-1981 (Poole, 1984) were not used in these analyses, as they are not currently used when testing the Gray Whale *SLA*.

[11] Data on strandings are collected in other locations (e.g. Mexico and Alaska), but the stranding network effort in California, Oregon and Washington has been more consistent through the years

The total negative of the logarithm of the likelihood function is the sum of the contributions for each data source. In addition, penalties were added to the likelihood function to impose a normal prior with standard deviation σ_ε on the process error deviates and to ensure that trajectories resulting in extinction were assigned zero likelihood. Previous studies using similar, but not identical methods of including process error in the population dynamics have assigned values for σ_ε using an approach which relies on the convergence of the root-mean-squared-error between the logarithms of expected vs. observed recruitment (Methot, 2000). However, that approach is not suitable given the transformation applied here (Equations 3.2 and 3.3). Instead, a default value for σ_ε of 0.50 was used following preliminary analyses which suggested that this value was consistent with observed inter-annual variability in the data. Analyses were also conducted in which σ_ε = 0.30 and 0.70 to assess the sensitivity of the results to the value assumed for σ_ε.

Abundance estimates

The abundance estimates are based on survey seasons which span two calendar years. They are referred to here by the year during which the survey started (e.g., the 1967-68 abundance estimate is referred to as "1967"). In this way, the abundance of the population was considered to be surveyed after births and deaths in a given year. An additional variance term $CV_{\text{add-1}}$ was incorporated into the likelihood component for the abundance estimates following Wade (2002a) and Butterworth *et al*. (1993). The residuals of the fit to the abundance estimates were assumed to be independent between years and log-normally distributed. Moreover, it was assumed that the surveys provided estimates of the number of animals aged 1 and older. These assumptions led to the following component of the negative log-likelihood function[12]:

$$L_1 = \sum_t 0.5\left(\ln\left(\sigma_t^2 + CV_{\text{add-1}}^2\right) + \frac{1}{\sigma_t^2 + CV_{\text{add-1}}^2}\left(\ln N_{1+,t}^{\text{obs}} - \ln N_{1+,t}\right)^2\right) \tag{3.14}$$

where:

$N_{1+,t}^{\text{obs}}$ is the survey estimate of 1+ abundance for year t;

$N_{1+,t}$ is the model estimate of 1+ abundance for year t;

$CV_{\text{add-1}}$ is the extent of additional error about the abundance estimates, and;

σ_t is the standard deviation of the logarithm of $N_{1+,t}^{\text{obs}}$ (approximated by the CV of the untransformed abundance estimate).

Calf estimates

The residuals about the model fit to the calf estimates were also assumed to be independent and identically log-normally distributed. Following previous approaches which fit the calf estimates using a deterministic population dynamics model (Wade, 1997; Wade and Perryman, 2002), the reported observation error about the calf estimates was assumed to be subject to some additional observation error as was the case for the abundance estimates. This approach led to the following component of the negative log-likelihood function:

$$L_2 = \sum_t 0.5\left[\ln\left(\underset{\sim}{\sigma}_t^2 + CV_{\text{add-2}}^2\right) + \frac{1}{\underset{\sim}{\sigma}_t^2 + CV_{\text{add-2}}^2}\left(\ln N_{0,t}^{\text{obs}} - \ln N_{0,t}\right)^2\right] \tag{3.15}$$

where:

$N_{0,t}^{\text{obs}}$ is the survey estimate of calf production in year t;

[12] The likelihood components were calculated ignoring constants independent of the parameters of the model.

$N_{0,t}$ is the model estimate of calf production in year t;

$CV_{\text{add-2}}$ is the extent of additional error about the calf estimates, and;

σ_t is the standard deviation of the logarithm of $N_{0,t}^{\text{obs}}$ (approximated by the CV of the untransformed calf production estimate).

Stranding counts

The residuals about the model fit to the indices of number of stranded animals were assumed to be independent and identically log-normally distributed, leading to the following component of the negative log-likelihood function:

$$L_3 = \sum_t 0.5\left[\ln\left(\sigma_M^2\right) + \frac{1}{\sigma_M^2}\left(\ln M_t^{obs} - \ln(\hat{q}\,\hat{M}_t)\right)^2\right] \tag{3.16}$$

where:

$\hat{q}$ is the constant of proportionality between the indices of stranded animals and $\hat{M}_t$;

M_t^{obs} is the observed number of stranded animals (based on data for California, Oregon and Washington), and;

$\hat{M}_t$ is the model-estimate of the number of animals (for all stages and both sexes) dying due to natural causes:

$$\hat{M}_t = (1 - S_{1+,t}^*)[N_t^r + N_t^c] + \sum_a (1 - S_{a,t}^*)[N_{a,t}^i + N_{a,t}^{male}] \tag{3.17}$$

An empirical estimate for the observation error of the stranding counts does not exist (Brownell Jr. *et al.*, 2007). Therefore, reasonable alternative values were chosen (σ_M = 0.10 or 0.20) to assess the sensitivity of the results to the value assumed for this parameter. A value for σ_M of 0.20 implies that the lower 95% limits for the stranding estimates for 1999/2000 do not overlap with the upper 95%

limits for the strandings estimates for any other years, and it is therefore an upper limit for this parameter which would be consistent with those years representing an unusual mortality event.

The value for $\hat{q}$ was set to its maximum likelihood estimate. This is equivalent to integrating over the prior for this parameter when its prior distribution is uniform in log-space (Walters and Ludwig, 1994). It was reasonable to assume that $\hat{q}$ was less than 1.0, because counts of stranding animals were only made along a portion of the migratory route, and further it seems unlikely that all animals that die will wash ashore or that all of those that do will be counted. In addition, an underlying assumption of this method is that $\hat{q}$ was constant through time. This is unlikely to be strictly true. However, given that gray whales migrate (and die) close to the coast, observation effort has been relatively constant through time for the stranding index considered here and that the mortality event of 1999 and 2000 is believed to have been caused by a substantial decrease in survival (as opposed to a higher fraction of carcasses washing ashore due to a change in wind, ocean currents or the like), minor violations of this assumption were unlikely to be consequential to the results.

Environmental impact on demographic rates

In addition to being subjected to process error, the deviations of birth and survival rates about the deterministic relationship each year were also allowed to be related to an environmental index I_t (in this case, the amount of sea-ice covering the Bering Sea , averaged over March and April). It was assumed that I_t was measured subject to observation error (or there was some error in the relationship between the process error deviations, ε_t, and the environmental index). Consequently, I_t was treated as a state variable, similar to the model prediction of population size. The measurements of the environmental index were therefore treated as data and were consequently included as a component of the likelihood function when the model was fit. The expected environmental index in a given year was assumed to be related to process error residuals for that year, such that the observed index was normally distributed about its expectation:

$$I_t^{obs} = \beta\varepsilon_t + \gamma_t \qquad (3.18)$$

where:

I_t^{obs} is the observed value of the environmental index in year *t*;

β is a scaling parameter for the influence of the environment on the process error residuals;

γ_t the difference between the observed and model-predicted amount of sea ice in year *t*, such that $\gamma_t \sim N(0;\sigma_I^2)$, and;

σ_I is the standard deviation of the residual error for the environmental index:

$$\sigma_I = |\beta|\sigma_I^* \qquad (3.19)$$

This formulation takes a fixed input value for σ_I^* (Table 3.1) and scales the expected standard deviation of the fits to the environmental index by the estimated absolute value for β. It was found through preliminary analyses that, simply fixing σ_I to a given fixed input value (ignoring Eqn. 3.19) led to estimates of the process error deviations ε_t which became increasingly small with smaller assumed values of σ_I. Hence, Eqn. 3.19 leads to the desired effect of the process error deviations being more correlated with the environmental index at smaller values of σ_I.

Perryman *et al.* (2002) investigated two different time lags (corresponding to the potential effect of sea-ice on ovulation or pregnancy rates) and concluded that a relationship between sea-ice during a given year and reproductive success would most likely result from an effect on the pregnancy rates in that year. Therefore, the timing of the potential effect of sea-ice variability in a given year was assumed to be related to deviations from expected birth rates in that year as opposed to the previous year (i.e. a potential effect on ovulation rates). Given the estimation framework here, negative values of β correspond with larger values of the sea-ice index having detrimental affects on birth and survival rates (negative process error deviations).

Given the above assumptions, the contribution of the environmental index to the likelihood function was:

$$L_4 = \sum_t \left[\ln(\sigma_I) + \frac{1}{2\sigma_I^2}\left(I_t^{obs} - I_t\right)^2 \right] \tag{3.20}$$

σ_I^* was assumed to be 0.30 for the base case scenario, because preliminary analyses indicated that this value provided a conservative weight for the environmental index during the model fitting (i.e., it led to a reasonable balance between not over-fitting the environmental index, while still allowing for a relatively strong signal in the process error deviations). Analyses were also conducted with σ_I^*= 0.10 and 1.00 to investigate the sensitivity of the results to alternative values. Likewise, two scenarios were considered in which the model was fit only to data for sea-ice pertaining to those years for which it would have had an effect on recent calf production (1993 – 2008). In these scenarios an alternative index of sea-ice was also fit, based on an updated version of the index used by Perryman *et al.* (2002) (Fig. 3.2, left panel; Perryman, *unpublished data*). This was done to assess the impact of the length of the time-series of environmental data on the results, as well as that given for alternative index of sea-ice.

Parameterization and scenarios

The estimable parameters of the population dynamics model are listed in Table 3.2. Rather than treating all of the survival rates by age as estimable parameters, two survival rates were considered: (i) calf survival S_0 and, (ii) the survival rate for animals aged 1 and older S_{1+}. Moreover, calf survival was not treated as an estimable parameter. Instead, the difference, Δ, between adult and calf survival was estimated. This also allowed the constraint that adult survival cannot be less than calf survival to be enforced. All but one of the scenarios in which the calf data were used to fit the model involved setting the level of additional observation error equal to that for the abundance data (i.e. only one CV_{add} was estimated, such that $CV_{\text{add-2}}$= $CV_{\text{add-1}}$).

Table 3.1 outlines the full set of scenarios. The two base case scenarios were: (i) the stochastic model described above ("Full" in Table 3.1), and; (ii) a deterministic version fit only to abundance data following the approach of previous assessments (e.g., Wade, 2002a) ("Deterministic" in Table 3.1). Several alternative scenarios were considered for the full stochastic model to investigate the affects of certain assumptions and data sources on the results. These alternative scenarios involved estimating the maximum likelihood estimates for the parameters (MLE), while the two base cases involved parameter estimation using maximum likelihood as well as a Bayesian framework. The latter facilitated comparison with previous assessments and forms a basis for evaluating the performance of the Gray Whale *SLA*. A parallel set of scenarios involved estimating separate values for ε_{add-1} and ε_{add-2}. This was done to assess the ability of the model to fit the mortality event when the process error deviations were not assumed to be equal for birth and survival rates during the mortality event.

Parameter estimation

The models were developed using AD Model Builder (ADMB, Otter Research, http://otter-rsch.com/admodel.htm). ADMB uses automatic differentiation (Griewank and Corliss, 1991) to efficiently estimate the variance-covariance matrix of model parameters with respect to the likelihood function. Additionally, it allows for Bayesian estimation by sampling from the posterior distribution using Markov Chain Monte Carlo (MCMC), as implemented by the Metropolis-Hastings algorithm (Hastings, 1970; Gelman *et al.*, 2004). The proposal (or "jump") function used by ADMB for the MCMC algorithm is multivariate normal with a variance-covariance matrix based on that estimated for the model parameters.

The Bayesian Output Analysis Program (BOA) for MCMC was used to diagnose the convergence of the MCMC algorithm (Smith, 2007). The Heidelberger and Welch (1983) stationarity and half-width tests, and the Geweke (1992) and the Raftery and Lewis (1992) convergence diagnostics were inspected for signs of non-convergence and used as guidelines for determining an appropriate burn-in and thinning interval for the chain.

3.2 RESULTS

The MCMC algorithm was run for 50 million iterations, saving every 25,000th sample after a 20% burn-in, leading to a final sample size of 1,601 draws from the posterior. This process resulted in diagnostics for the chain that gave no sign of not having converged, as indicated by Figure 3.3.

The model was able to fit the abundance and calf data reasonably well for all scenarios (see Fig. 3.4 for three examples for calf data; Fig. 3.5 upper panels for abundance data for all scenarios). The results were consistent with this stock being at or near carrying capacity, although estimates of carrying capacity differed among scenarios (Fig. 3.6, left panels; Tables 3.3 and 3.4). The scenarios that did not take the strandings data into account (the 'Deterministic' and 'No Strandings Data' scenarios), or did not place much weight on the strandings data (the σ_M = 0.20 scenario) estimated carrying capacity to be in the low 20,000s, and that the population size has been constant at this level since the late-1980s or early 1990s (Fig. 3.4, upper right panel; Fig. 3.5, lower panels). The inability of certain scenarios to fit the 1999-2000 mortality event is indicated by values of ε_{add-2} that are closer to zero in Tables 3.3 and 3.4. The estimates of maximum birth rate and survival rates were similar among the scenarios that were unable to fit the 1999-2000 mortality event, with higher maximum birth rates and somewhat lower survival rates than for the remaining scenarios (Tables 3.3 and 3.4). The "Full" scenario estimated life history parameters more precisely than the "Deterministic" scenario, and also estimated lower maximum birth rates and higher survival rates (Fig. 3.7).

The scenarios which estimated both $CV_{\text{add-1}}$ (abundance) and $CV_{\text{add-2}}$ (calf) resulted in estimates for $CV_{\text{add-1}}$ which were generally equal to those for the other scenarios. However, $CV_{\text{add-2}}$ was estimated to be equal to zero. The results from estimating this additional parameter were generally similar to those for the Full model (Tables 3.3 and 3.4).

In general, the scenarios investigated here were able to capture at least some of the additional mortality during 1999 and 2000, and estimated that the population has since recovered following that event to numbers that equal or possibly exceed those in 1998, but not necessarily to carrying capacity (Fig. 3.4, left and middle panels). Those scenarios which were able to fit the 1999-2000 mortality event also resulted in less precise (and slightly lower) estimates of current depletion (Fig. 3.6, right panels). There was essentially no support for carrying capacity being greater than 40,000 or that the stock size is currently at less than 70% of carrying capacity for any of the scenarios (Fig. 3.5, lower panels; Fig. 3.6, right panels; Tables 3.3 and 3.4).

The "Full" model was able to capture the variability in the calf production estimates quite well (Fig. 3.4; left panels). Even though the "Deterministic" model was not fitted to the calf estimates, the resulting estimates of calf production were consistent with the average observed calf production in recent years, albeit with much more uncertainty around these estimates than the "Full" model (Fig. 3.4; right panels). None of the scenarios considered were fitted to the 1980 and 1981 calf counts as noted above. However, there are model-predictions corresponding to those counts. In general, the predicted numbers of calves in 1980 and 1981 exceeded the observations, more so for the "Deterministic" model (although the observed values were within the 95% probability intervals for this model) (Fig. 3.4).

The "Full" model fit the data nearly equally well irrespective of whether ε_{add-1} and ε_{add-2} were estimated individually (Fig. 3.4 left and centre panels). However, the estimates of ε_{add-2} were quite different between these scenarios (Tables 3.3 and 3.4, second row last two columns). The scenario which estimated both ε_{add-1} and ε_{add-2} resulted in a larger negative value for ε_{add-2} (lower survival) and was better able to fit the strandings data during the years of the mortality event (Fig. 3.4, middle and bottom rows; Tables 3.3 and 3.4).

The parameter that related the sea-ice index to the process error deviations β was estimated to be negative for all but two scenarios (Tables 3.3 and 3.4). Setting σ_I^*=0.30 allowed the model to fit all but the most extreme years of the sea-ice index (e.g., Fig. 3.4, left and middle panels). Consequently, birth and survival rates were lower (i.e. lower calf production and higher numbers of strandings) than expected during years for which the sea-ice index was large. This result was most evident during those years before the first stranding and calf estimates. For example, calf production and survival were estimated to have been less than otherwise expected during the heavy sea-ice years of the 1970's because of negative process error deviations during those years (Fig. 3.4).

Varying the value of σ_I^* did not greatly affect the ability of the model to fit the data other than the sea-ice index itself. The environmental signal in the process error deviations became more pronounced, especially for those years before the strandings and calf data were available, by giving the sea-ice data more weight (i.e., the σ_I^*=0.10 scenario in Tables 3.3 and 3.4). Likewise, the process error deviations were close to zero prior to there being strandings and calf data when the sea-ice data were substantially down-weighted (i.e., the σ_I^*=1.00 scenarios in Tables 3.3 and 3.4). This scenario led to a positive value for the parameter β. However, the estimated value of β for this scenario was essentially irrelevant because the process error deviates were essentially zero prior to the calf and strandings data and because of the lower weight given to the effect of sea-ice on the model fits.

There was essentially no difference between the results for the two scenarios which only fit to recent sea-ice data from 1993-2008 when the additional process error was assumed equal for birth and survival rates during the mortality event ("Recent Ice" and "Perryman *et al.* Ice" in Tables 3.3). However, the estimated values for ε_{add-1} were more negative for those scenarios which estimated both ε_{add-1} and ε_{add-2}, leading again to better fits to the strandings data and higher estimates of the numbers of animals which died during those years ("Natural Mortality '99 + '00" in Table 3.4). It followed that the estimates of current depletion were lower for those scenarios which were only fit to the recent ice data and also estimated both ε_{add-1} and ε_{add-2} (Table 3.4).

The realized standard deviation of the process error residuals (`σ_ε) was similar across all stochastic scenarios and generally equal to about 0.20; with the notable exceptions of those scenarios for which the input value for σ_ε was varied (Tables 3.3 and 3.4). Not surprisingly, varying the value for σ_ε had a direct result on the realized standard deviations of the process error residuals and, as expected, the realized standard deviations were less than the value for σ_ε. For the Full model with $\varepsilon_{add-1} = \varepsilon_{add-2}$, the point estimates for $`\sigma_\varepsilon$ were 0.07, 0.21 and 0.33, given σ_ε = 0.30, 0.50 and 0.70 respectively. The scenarios with σ_ε =0.30 exhibited fairly deterministic dynamics (with the exception of the impact on the ε_{add-1} during the 1999-2000 mortality event). These scenarios also led to estimated values for $CV_{\text{add-1}}$ = 0.18 and 0.20, which were the largest of any of the scenarios considered in these analyses (Tables 3.3 and 3.4). The estimated value for β was positive when σ_ε =0.30 and both ε_{add-1} and ε_{add-2} were estimated individually, but due to the essentially deterministic dynamics (i.e., very small process error deviates), the estimated value of β for this scenario was inconsequential. In general, the effect of increasing the standard deviation of the process errors was similar to that of decreasing the value for σ_I^* (or similarly, only fitting to the sea-ice data for 1993-2008), and vice-versa. That is, the estimated effects of sea-ice became more exaggerated for higher values of σ_ε or lower values for σ_I^* (or longer time series of sea-ice), especially during those years before calf and strandings data became available.

3.3 DISCUSSION

We incorporated an environmental index into a population dynamics modeling framework, and allowed for a hypothesized relationship between sea-ice and gray whale population dynamics when fitting to observations of abundance, sea-ice, strandings and calf production. The incorporation of such a relationship could potentially improve our understanding of cetacean population dynamics and help to determine whether existing management strategies are robust to climate-induced forcing of the population dynamics. However, it should be noted that the goal of this investigation was not to provide evidence for or against a certain hypothesis about how environmental conditions may affect population dynamics. Rather, the primary aim was to develop a tool by which alternative hypotheses may be explicitly taken into account within a population dynamics modeling framework; ultimately, providing a means through which the robustness of management strategies may be evaluated, given such hypotheses and forecasts of future climate change.

The framework allowed for the deviations in birth and survival rates to be related to an index of sea-ice in the Bering Sea, following a plausible hypothesis about how this environmental index might be related to the population dynamics of ENP gray whales. It would be straightforward to substitute an alternative environmental index (e.g., sea-ice in the Chukchi Sea, El Niño/Southern Oscillation etc…), or some weighted combination of multiple indices into the framework developed here, but such analyses were beyond the scope of this chapter. In this study, the environmental index was used as a proxy measure for the variability in birth and survival rates, while observations of calf production and strandings numbers were taken as direct measures of the underlying variability in those life history parameters. During the years for which calf count, strandings and sea-ice data were all available, the effect of sea-ice on the population dynamics was calibrated. Then, during years when the sea-ice data were available, but prior to direct observations of calf production and strandings (i.e., during the 1960s and 1970s), the expected dynamics in birth and survival rates were extrapolated based on the values of the sea-ice index.

However, something extraordinary clearly occurred during 1999 and 2000 in terms of survival rates, as exemplified by the stranding counts (Fig. 3.4), and the ability of the different model configurations to fit the 1999-2000 mortality event had a large influence on the results. Specifically, the results were more optimistic regarding recent stock size relative to carrying capacity for those scenarios which were not able to fit the strandings data during 1999 and 2000. Furthermore, when the strandings data and mortality event were ignored (e.g., the deterministic model), the recovery of the stock since 1930 was attributed to higher calf production during the period of increasing abundance estimates, as opposed to higher survival rates. In contrast, when the stranding data are taken into account, recovery was explained through higher survival rates and lower calf production.

It was not possible to fit the strandings data for the 1999-2000 mortality event without allowing for some additional process error in the survival rates during those years, given the assumptions made regarding the nature of the process error deviations. This additional process error could be modeled in a few different ways in addition to the approach taken in this chapter. For example, Ward *et al.* (2007) estimate the probability of an unusual or 'catastrophic' event by adopting a mixture distribution approach to process error. That is, they estimate if a given year was a catastrophic year, and, depending on that assessment, draw the process error for that year from one of two (regular and catastrophic) distributions (in effect we have assumed an underlying mixture distribution with a step function for 1999 and 2000, where those years are given probability of 1.0 for catastrophe, and other years assigned zero probability). An estimate of the probability of a mortality event would be of great interest when running future projections and testing the Gray Whale *SLA*, whereas the approach taken here is somewhat limited in its predictive ability of future catastrophic events. However, it is not immediately obvious that available data for ENP gray whales would be sufficient to estimate the additional parameters in a mixed model approach.

Observations of recent variability in calf production and the amount of sea-ice covering the early season feeding grounds supports the hypothesis of a relationship between sea-ice and calf production in gray whales. However, it is possible that this relationship (if it exists) is something that has developed or strengthened within the last two decades. For example, the two early (1980s) calf production estimates are nearly equal (Fig. 3.4), yet occurred during years of disparate ice conditions (Fig. 3.2). Therefore, these early calf production data suggest some non-linearity in the relationship between population dynamics and environmental forcing. We have assumed that the relationship between calf production and sea-ice is stationary (and specifically independent of population density), and one result of this assumption was that the model predicts lower than expected calf production during much of the 1960s and 1970s, when there were higher levels of sea-ice in the Bering Sea. Consequently, the estimates of survival were higher for the stochastic than for the deterministic configurations of the model (Fig. 3.7), which allowed the stochastic model to mimic for the observed trend in the abundance data.

Modeling the interaction between population density and the effects of environmental variability on vital rates, and the probability of mortality events is beyond the scope of this chapter. However, as populations increase in density, the impact of density-independent factors on population dynamics probably become more pronounced (e.g., Durant *et al*., 2005) and accounting for density-dependent mortality events may have implications for management strategies (e.g., Wilcox and Eldred, 2003). Therefore, if the framework presented here is used to test management strategies, a plausible set of scenarios for how such environmental affects and the probability of mortality events might change with population density should be identified. It seems unlikely that it will be possible to estimate such relationships given the amount of data available for most cetacean populations, but the approach taken here could be modified to examine different assumptions along these lines (e.g., modifying σ_I^* as a function of depletion).

The assumption that the birth and survival process errors were perfectly correlated was rather simplistic. In reality, there is likely to be some correlation, but it may be imperfect and non-linear (Eberhardt, 1977; Gaillard *et al.*, 2000). The assumption made here was fairly inconsequential during normal stranding years, because the variability in strandings among years is generally low. However, the consequence of this assumption during the 1999-2000 mortality event was substantial. Estimating both ε_{add-1} and ε_{add-2} provided better fits to the observed strandings during this event. These scenarios illustrated the constraint placed on the ability of the model to simultaneously fit the calf and strandings data during the mortality event, when the additional process error during those years was assumed to the same for birth and survival rates. The differences between the estimates of ε_{add-2} (roughly twice as large when estimated individually) could have implications for projections of population dynamics if future mortality events are conditioned on those estimates of ε_{add-2}.

A forecast of future sea-ice conditions will be needed to perform projections of population dynamics within this framework and hence test the Gray Whale *SLA*. Overland and Wang (2007) have provided one such forecast, based on an ensemble mean from a suite of models considered by the Intergovernmental Panel on Climate Change. We plan on including that forecast as input for population projections in the next stage of this research, using the framework presented here as an operating model while testing the Gray Whale *SLA*.

Future work may extend this framework to other cetacean stocks. Several alternative candidates exist for which a relationship between environmental conditions and cetacean population dynamics has been recognized, for example: northeast Atlantic fin whales (Lockyer, 1986); sperm whales off the Galapagos Islands (Whitehead, 1997), and; north and south Atlantic right whales (Green *et al.*, 2003; Leaper *et al.*, 2006). In addition, recent observations suggest a possible relationship between body condition and sea-ice for animals taken in the aboriginal hunt for the Bering-Chukchi-Beaufort Seas stock of bowhead whales (George *et al.*, 2009). Such information, combined with an index of calf production for this stock (Koski *et al.*, 2008), could eventually be included in a framework similar to that presented here, and then applied to testing of the bowhead *SLA* given relevant climate forecasts.

In conclusion, the framework developed here provides a basis for testing management strategies, given a hypothesis about how environmental factors influence population dynamics and climate forecasts. The results indicated that including the environmental index and fitting to the mortality event lead to somewhat different interpretations of the population dynamics of the ENP gray whale when compared to those provided by a deterministic model. Using this framework to test the Gray Whale *SLA* should help to ensure that management is robust to a plausible range of scenarios for how future climate might impact this, and other cetacean populations.

Table 3.1

The scenarios considered in these analyses. Different data sets, parameter values and estimation techniques are outlined. The scenarios labeled 'Deterministic' and 'Full' refer to the base cases, for which a Bayesian estimation framework was adopted as well as maximum likelihood estimation (MLE). A further set of parallel runs were performed for the Full model, but not fitting the calf estimates from 1999 – 2001. The remaining scenarios are variations of the 'Full' base case. The '=' signs denote that a parameter was not estimated but set to the value of another parameter, and 'NA' signifies a variable that is not applicable to a certain scenario (e.g., σ_I^* is not applicable when the sea-ice data are not considered).

Scenario	Abundance Data	Calf Data	Ice Data	Strandings data	$CV_{\text{add-1}}$ (abundance)	$CV_{\text{add-2}}$ (calf)	σ_ε
Deterministic	Yes	No	No	No	Estimated	NA	NA
Full	Yes	Yes	Yes	Yes	Estimated	$= CV_{\text{add-1}}$	0.50
$\sigma_M = 0.20$	Yes	Yes	Yes	Yes	Estimated	$= CV_{\text{add-1}}$	0.50
Recent Ice	Yes	Yes	'93-'08	Yes	Estimated	$= CV_{\text{add-1}}$	0.50
Perryman *et al*. Ice	Yes	Yes	'93-'08	Yes	Estimated	$= CV_{\text{add-1}}$	0.50
$\sigma_I^* = 0.10$	Yes	Yes	Yes	Yes	Estimated	$= CV_{\text{add-1}}$	0.50
$\sigma_I^* = 1.00$	Yes	Yes	Yes	Yes	Estimated	$= CV_{\text{add-1}}$	0.50
$\sigma_\varepsilon = 0.30$	Yes	Yes	Yes	Yes	Estimated	$= CV_{\text{add-1}}$	0.30
$\sigma_\varepsilon = 0.70$	Yes	Yes	Yes	Yes	Estimated	$= CV_{\text{add-1}}$	0.70
$CV_{\text{add-1}}$ & $CV_{\text{add-2}}$	Yes	Yes	Yes	Yes	Estimated	Estimated	0.50

Table 3.2

The parameters and their assumed prior distributions. The abbreviations for the prior distributions include: U [uniform] and N [normal]. Footnotes below describe the sources and reasoning behind these parameter values and distributions.

Parameter	Prior distribution
Maximum non-calf survival rate, S_{1+}	U[0.950, 0.999] [a]
Maximum birth rate, $b_{\max}$	U[0.01, 0.99]
Difference between non-calf and calf survival, $\Delta = S_{1+} - S_0$	U[0.01, 0.25] [b]
Carrying capacity, K_{1+}	U[15 000, 70 000] [b]
Relative population size in 1930, $N_{1+,1930} / K_{1+}$	U[0.050, 0.50] [b]
Process error residuals, ε_t	N[0, σ_ε^2]
Additional process error during '99/'00 mortality event, $\varepsilon_{add\text{-}1}$ and $\varepsilon_{add\text{-}2}$	U[-4.0, 4.0] [b]
Influence of sea-ice on calf production, β	U[-400, 400] [b]

a. Equal to the prior distribution used in recent assessments (IWC, 1998).

b. Preliminary analyses provided no evidence of posterior support for values outside this range.

Table 3.3

Results for the scenarios based on the Full model. The estimates correspond to the mode of the posteriors for the Bayesian analyses, and MLEs are shown for the ML analyses: $\tilde{S}$ is the median stochastic survival rate over all years; $`\sigma_\varepsilon$ is the standard deviation of the realized process errors (after the transformation in Eqns. 3.2 and 3.3), and the combined natural mortality during 1999-2000, corresponding to the total number of whales estimated to have died during the mortality event is also shown. The asterisk on $CV_{add\text{-}2}$ (calf) indicates that this parameter was estimated to be zero.

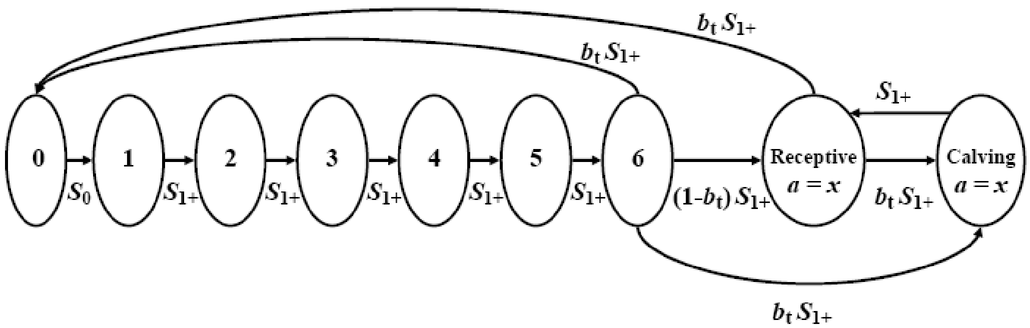

Figure 3.1: Life cycle graph of the model used to track the number of females in each reproductive stage though time. This life cycle refers to the underlying deterministic model, with transition probabilities shown as functions of life history parameters. The survival and birth rates were modified to be stochastic in the all of the analyses presented here (except 'Deterministic'). The arrow from immature to calf arises because some juveniles may mature and give birth (i.e. become pregnant at first estrous) during the projection interval from time *t* to *t*+1.

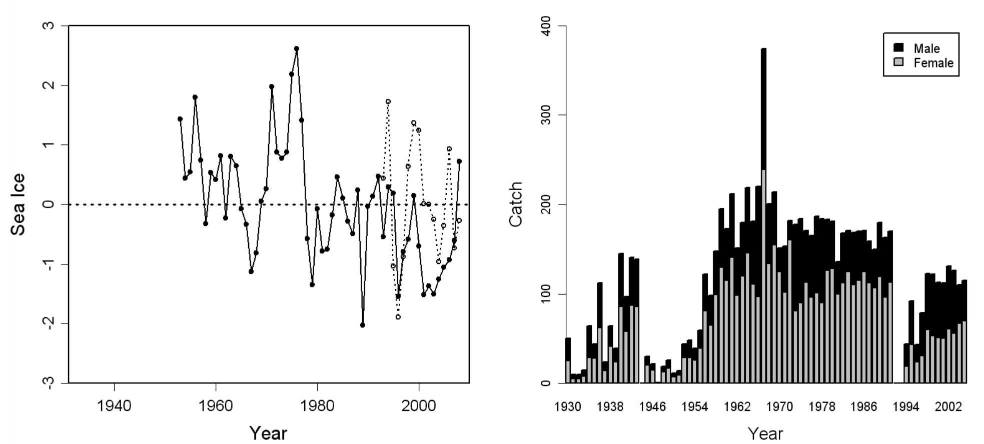

Figure 3.2: (Left panel) The standardized HadSST index for the March-April averaged sea-ice area covering the Bering Sea is shown by the solid line, and the Perryman *et al.* index is shown as the dashed line. Positive values represent years with greater than average spring ice over the time period considered. (Right panel) Catches by individuals and sex: 1930-2006.

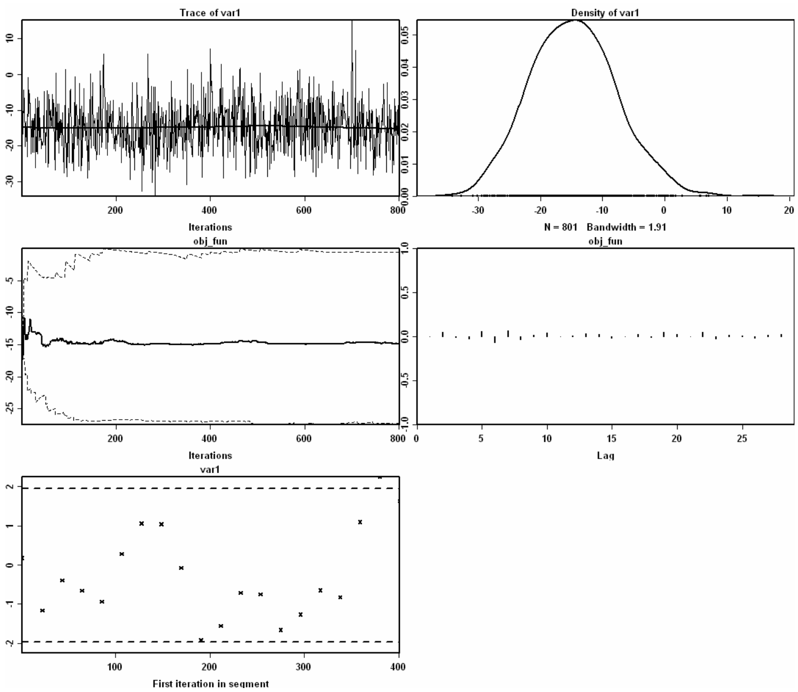

Figure 3.3: Diagnostic plots for the negative log-likelihood function resulting from the MCMC chain for the base-case Full model scenario (all data). Clockwise from upper left: trace, density, autocorrelation, Geweke's z-score, and the cumulative quantile plots showing the evolution of the median (solid line) and 95th percentiles of the chain.

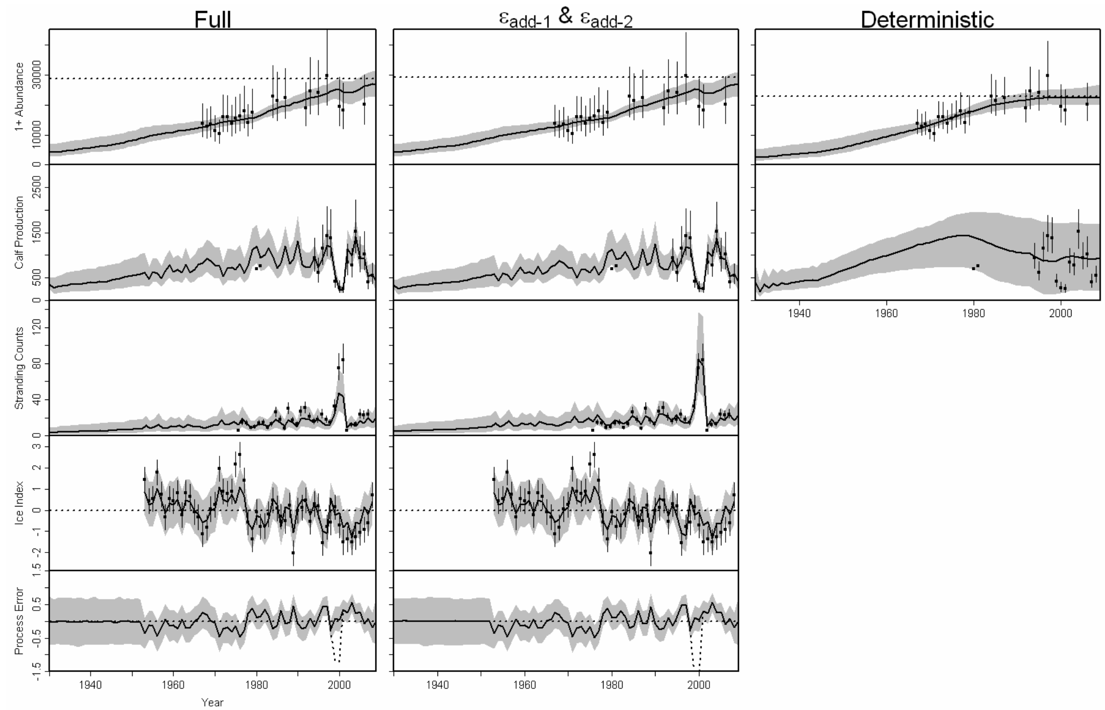

Figure 3.4: Model fits are shown: left column is the Full model; middle column is that model, but estimating ε_{add-1} and ε_{add-2} separately, and; right column is the Deterministic model. From top to bottom: abundance; calf production; strandings; sea-ice, and; estimated process error deviations. The abundance estimates are plotted with the 95% CIs associated with the mode of the posterior distribution for $CV_{\text{add-1}}$. The median of the posterior estimate for carrying capacity is plotted as a horizontal line with the abundance fits. For all plots, the medians and 95% Bayesian credibility intervals are shown as solid lines and shaded areas respectively. The calf estimates for 1980-81 were not fit for the first two scenarios, nor were any of the recent calf estimates fit for the Deterministic model. However, they are plotted for reference. Horizontal dotted lines at zero are plotted in the fits to the sea-ice data and the process error deviation estimates for reference. And the median of the posterior for ε_{add-2} is represented by the more vertical dashed line on the bottom two plots.

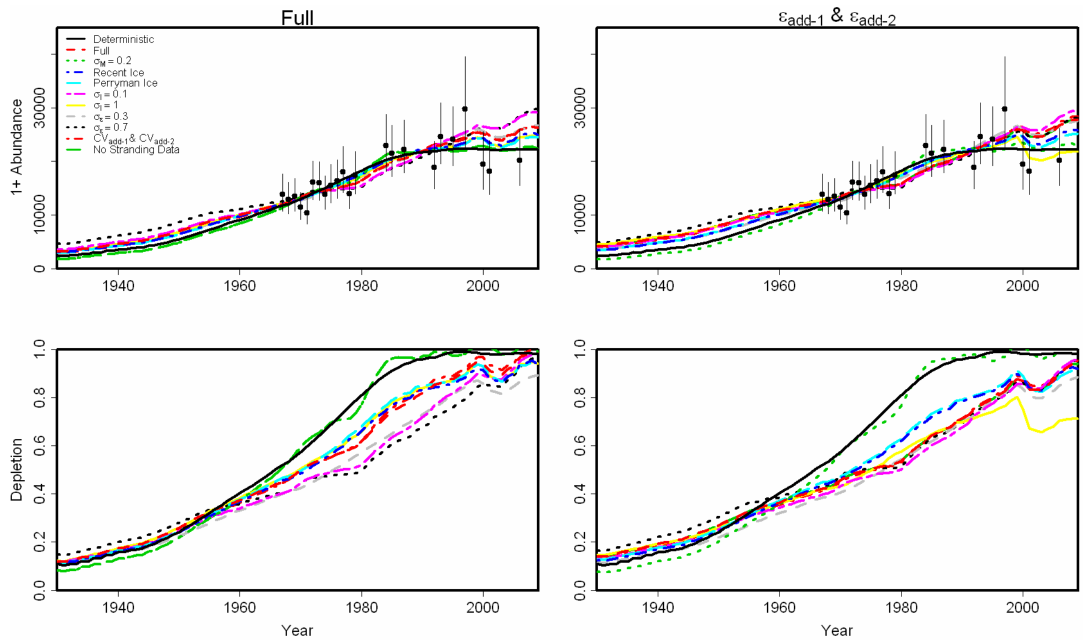

Figure 3.5: Fits to the abundance data based on the maximum likelihood estimates for each scenario (upper panels) and the estimated relative population size ("depletion") through time (bottom panels). The scenarios under the Full model are shown in the left panels, while those that estimated ε_{add-1} and ε_{add-2} are shown in the right panels. The deterministic scenario is plotted as the solid black line. 95% CIs are plotted for the abundance estimates assuming a value for $CV_{\text{add-1}} = 0.10$.

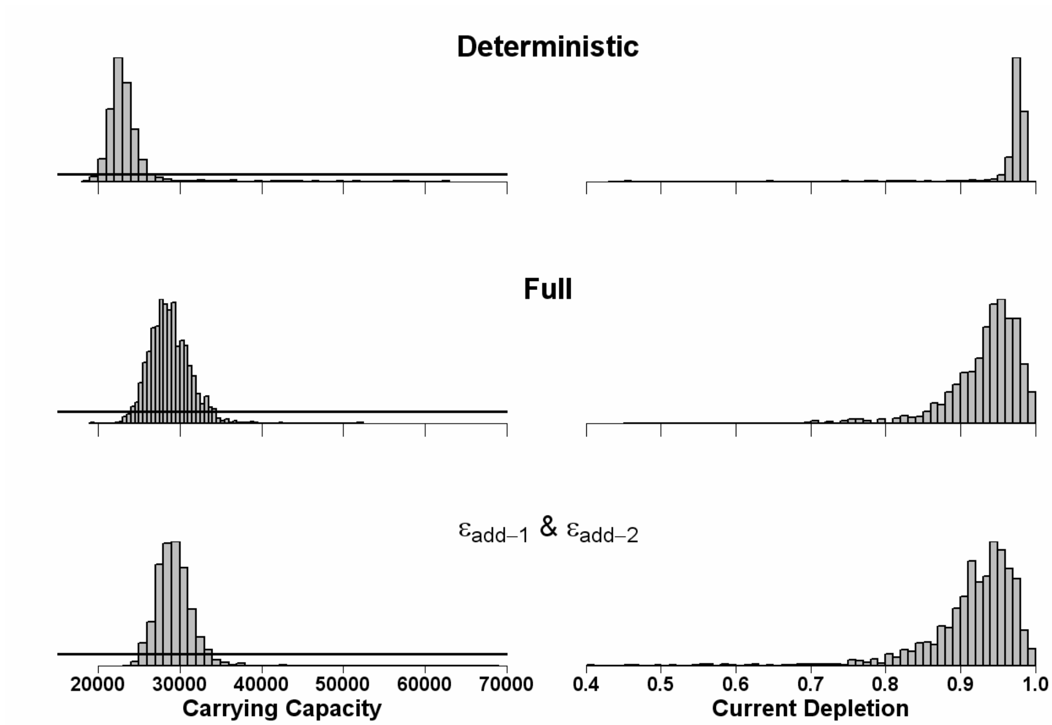

Figure 3.6: Histograms comparing marginal posterior densities (bars). Estimates of carrying capacity (plots on left side) and current depletion (right side) are shown. The upper row shows the samples from the posterior for the deterministic model, the middle rows shows samples from the posteriors for the Full model and the bottom row shows those for the Full model when ε_{add-1} and ε_{add-2} are estimated individually. The uniform prior for carrying capacity is shown as a solid line.

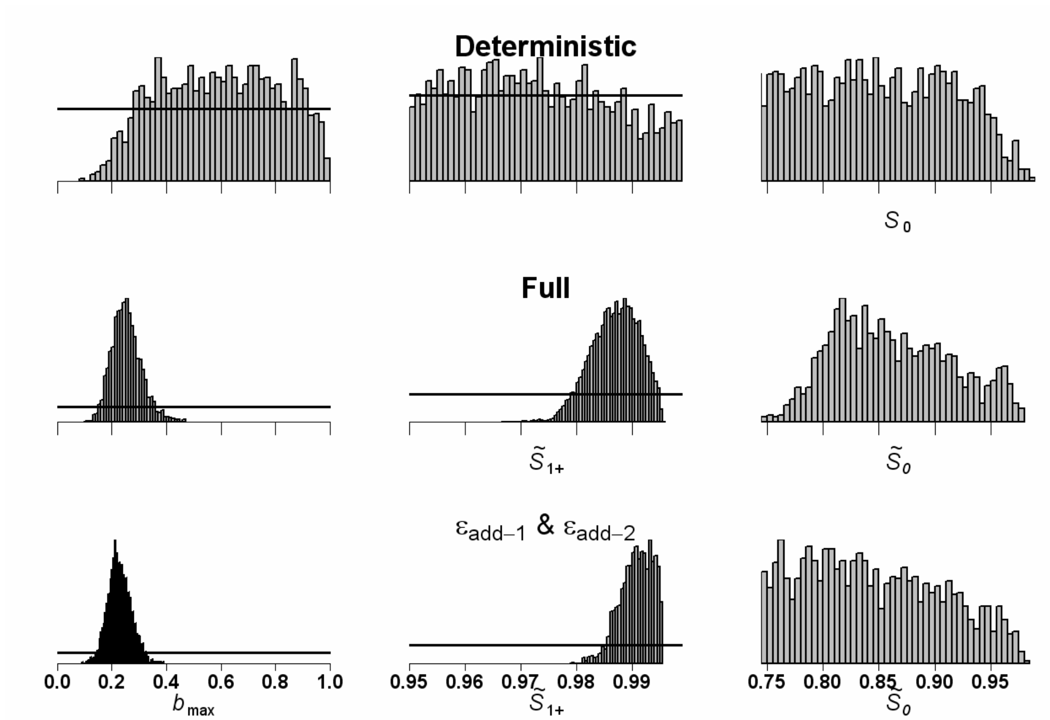

Figure 3.7: Histograms comparing marginal posterior densities (bars). Estimates of the maximum birth rate (in the limit of vanishing population size) (left column), survival rate of non-calves S_{1+} (middle column), and calf survival S_0 (right column) are shown. The upper row shows the samples from the posterior for the deterministic model, the middle rows shows samples from the posteriors for the Full model and the bottom row shows those for the Full model when $\varepsilon_{add\text{-}1}$ and $\varepsilon_{add\text{-}2}$ are estimated individually. The survival rates for the Full model (including those for the $\varepsilon_{add\text{-}1}$ and $\varepsilon_{add\text{-}2}$ scenario) are shown as the medians through time, in order to provide a better comparison with those estimates from the deterministic model. The uniform priors are shown as solid lines.

Chapter 4:

Testing the Gray Whale *SLA*: allowing environmental variability to influence population dynamics

ABSTRACT

The performance of the Gray Whale *SLA* was evaluated based on an operating model which was conditioned on available information, including survey estimates of 1+ abundance, calf counts, strandings data, and the extent of sea-ice in the early season feeding grounds in the Bering Sea. The scenarios considered in the analyses explore the impact of different sources of environmental variation, including scenarios in which future environmental forcing and episodic events are driven by the relationship between extent of sea-ice and reproductive success and survival. A variety of sources of uncertainty are considered, including parameter uncertainty, the uncertainty about the relationship between the extent of sea-ice and population dynamics, and observation error. The impact of these sources of uncertainty on the performance of the Gray Whale *SLA* appears small.

4.1 INTRODUCTION

The eastern North Pacific (ENP) stock of gray whales is currently subject to aboriginal hunting, with recommended strike limits based on the *Gray Whale Strike Limit Algorithm* (*SLA*) under the Aboriginal Subsistence Whaling Management Procedure (AWMP) of the IWC (IWC, 2003). *Implementation Reviews* are scheduled under the AWMP every five years, and that for the Gray Whale *SLA* is currently due. The goal of *Implementation Reviews* is to evaluate new information that has become available since the last *Implementation Review* (or the original *Implementation*) and to determine whether the current state of nature is not outside the realm of plausibility envisioned during the testing of the original *SLA*. If this is the case, additional simulation trials may be conducted to assess whether the performance of the adopted *SLA* remains reasonable, and if not, what changes to the *SLA* are needed.

New or updated sources of information pertaining to the population dynamics of ENP gray whales have become available in recent years and need to be considered during this *Implementation Review*, including: (1) new abundance estimates (Rugh *et al.*, 2008); (2) new estimates of calf production during 1994-2008 from the northbound migration at Point Piedras Blancas, California (Perryman *et al.*, 2002; Perryman, *unpublished data*), and; (3) the number of stranded animals on the coasts of California, Oregon and Washington states, for which a combined annual count is available for 1975-2006 (Brownell Jr. *et al.*, 2007). The latter potentially contains information on the magnitude of the mortality event during 1999/2000 (Gulland *et al.*, 2005). In addition to these data sets, it has been hypothesized that observed variability in the calf counts is a function of the amount of sea-ice covering the early season feeding grounds (Perryman *et al.*, 2002).

Therefore, in this chapter we test the performance of the *SLA* given scenarios for which future population dynamics are subject to environmental forcing and episodic events, using an operating model that integrates these sources of new information and the hypothesis of environmental forcing on the population dynamics (Chapter 3). A forecast of relevant sea-ice conditions based on global climate model output (Overland and Wang, 2007) is used to modify the future stochastic birth and survival rates when testing the *SLA*, given the estimated relationship between observed variations in recent sea-ice (Rayner *et al*., 2003) and calf and strandings data. This approach involves the incorporation of climate-model based forecasts into the operating model; the same basic approach is also is being used to test the performance of alternative management strategies in other fisheries (e.g., Gulf of Alaska walleye Pollock, *Theragra chalcogramma*; A'mar *et al.*, 2009).

Standard summary statistics are provided for the trials investigated here, and these are compared to recent results from the *Evaluation Trials* provided by Punt and Breiwick (2008) to the extent possible. The analyses presented here should help to ensure that the performance of the current *SLA* remains satisfactory (or else provide insight into potential weaknesses), given the new information that has become available since the previous phase of testing and adoption (IWC, 2005a).

4.2 METHODS

Operating model

The population dynamics model developed in Chapter 3 (corresponding to the'Full' scenario) was used as the operating model. This model is sex- and age-based, with an annual time-step. The dynamics includes stochastic birth and survival rates, and explicitly considers the transition between receptive and calving stages for mature females (Fig. 4.1). For consistency, the notation of Chapter 3 is adopted below.

Density dependence was assumed to act through the birth rate according to a Pella-Tomlinson function of 1+ depletion:

$$b_t = \max\left\{0,\ b_{\text{eq}} + (b_{\max} - b_{\text{eq}})\left[1 - \left(\frac{N_{1+,t}}{K_{1+}}\right)^z\right]\right\} \tag{4.1}$$

where:

$b_{\max}$ is the maximum birth rate (in the limit of zero population size);

K_{1+} is the carrying capacity of the 1+ component of the population (all animals aged 1 yr and older);

b_{eq} is the equilibrium birth rate at carrying capacity;

z is the degree of density-dependent compensation (assumed to equal 2.39, which implies maximum sustainable yield at a population size approximately 60% of K_{1+}), and;

$N_{1+,t}$ is the size of the 1+ component of the population (both sexes combined) in year *t*.

Selectivity was assumed to be knife-edged and uniform on ages 5+, and the population trajectories were initialized in 1930.

The operating model was conditioned on available data, including: (1) estimates of population size during 1967-2006 (starting year of survey) from the southbound migration at Granite Canyon, California (Rugh *et al.*, 2005, 2008); (2) estimates of calf production during 1994-2008[13] from the northbound migration at Point Piedras Blancas, California (Perryman *et al.*, 2002; Perryman, *unpublished data*), (3) the number of stranded animals on the coasts of California, Oregon and Washington states, for which a combined annual count is available for 1975-2006 (Brownell Jr. *et al.*, 2007)[14], and; (4) estimated sea-ice area covering the Bering Sea, averaged over March and April during 1953-2008, as calculated by the Hadley Center for their sea ice and sea surface temperature data set version 1 ('HadSST') (Rayner *et al.*, 2003) (Fig. 4.2, left panel).

Deviations from expected birth and survival rates were allowed to be a function of sea-ice variability in the Bering Sea. Thus, the model is an adaptation of the hypothesis that the amount of sea-ice in the Bering Sea early during the feeding season may be related to variability in calf production the following year (Perryman *et al.*, 2002).

[13] The two early estimates of calf production during 1980-1981 (Poole, 1984) were not used in these analyses.
[14] Data on strandings are collected in other locations (e.g. Mexico and Alaska), but the stranding network effort in California, Oregon and Washington has been more consistent through the years.

Future projections

The population was projected forward from the start of 2009. Values for the environmental index were based on an ensemble mean forecast of future sea-ice in the Bering Sea (March-April average) (Overland and Wang, 2007). The trials were based on a 92-year time horizon (*T*=92), because the time series of forecasted sea-ice was only available through 2098. Each simulated trajectory was based on a set of parameter values $\underline{\theta}_i$ (e.g., K_{1+}, $b_{\max}$ etc…) sampled from the joint Bayesian posterior distribution constructed using the MCMC algorithm described in Chapter 3. In a given year, the process error residuals about the expected birth and survival rates were:

$$\varepsilon_t = \left(I_t^{obs} / \beta \right) - \gamma_t \tag{4.2}$$

where:

I_t^{obs} is the forecasted value of the environmental index for year *t* (Fig. 4.2, left panel);

β is a scaling parameter that accounts for the influence of the environment on the process error residuals (sampled from the joint posterior);

γ_t is a generated normal random deviate reflecting error about the sea-ice – process error relationship, such that $\gamma_t \sim N(0; \sigma_I^2)$, and;

σ_I is the standard deviation of the residual error for the environmental index:

$$\sigma_I = |\beta| \sigma_I^* \tag{4.3}$$

This formulation takes a fixed input value for σ_I^* (assumed to be 0.30 for these analyses, corresponding with the 'Full' model described in Chapter 3) and scales the expected standard deviation of the fits to the environmental index by the absolute value sampled from the posterior distribution for β.

Stochastic birth and survival rates

The stochastic survival and birth rates were calculated given the generated process errors for each year. Birth rates were assumed to vary annually about the deterministic value given by Eqn. 4.1. Since this rate must lie between zero and one, its realization in any one year was calculated using a logistic transformation:

$$b_t^* = \left[1 + \exp(-(\Phi^{-1}\left(b_t\right)\sqrt{2.76 + \sigma_\varepsilon^2} + \varepsilon_t + \varepsilon_{\text{add-1},t}))\right]^{-1} \quad (4.4)$$

where:

Φ^{-1} is the inverse standard normal cumulative distribution function;

ε_t is the process error deviation for year t, and;

$\varepsilon_{add-1,t}$ allows for additional process error in the birth rate during years with extraordinary dynamics, such as 1999 and 2000 (in other years, this parameter was set equal to zero).

This formulation of stochastic birth rates ensured that the expected birth rate in a given year was equal to the deterministic value from Eqn. 4.1.

Survival rates were also allowed to vary annually with the same process error residuals as birth rates. It was assumed that these rates were independent of sex and perfectly correlated between ages in a given year, so that:

$$S_{a,t}^* = \left[1 + \exp(-(\Phi^{-1}\left(S_a\right)\sqrt{2.76 + \sigma_\varepsilon^2} + \varepsilon_t + \varepsilon_{add-2,t}))\right]^{-1} \quad (4.5)$$

where:

$S_{a,t}^*$ is the realized age-specific survival rate during year t;

S_a is the expected survival rate from age a to age a+1; and

$\varepsilon_{add-2,t}$ is a parameter which allows for additional process error in survival rates during years with extraordinary dynamics, such as 1999 and 2000 (in other years, this parameter was set equal to zero).

For these analyses, the additional process error in survival rates was assumed to be equal to that for birth rates (i.e., $\varepsilon_{add-1,t} = \varepsilon_{add-2,t} = \varepsilon_{add,t}$).

Data generation

Future abundance estimates were assumed to become available every 10 years. Observation error was assumed to be log-normal:

$$N_{1+,t}^{\text{obs}} = N_{1+,t}\, e^{\phi_t} \tag{4.6}$$

where:

$N_{1+,t}^{\text{obs}}$ is the survey estimate of 1+ abundance for year t;

$N_{1+,t}$ is the 'true' 1+ abundance at the start of year t;

ϕ_t is a normal random deviate ~N(0, σ^2); where $\sigma = \sqrt{\overline{CV}_{est}^2 + CV_{\text{add-1}}^2}$;

$CV_{\text{add-1}}$ is the extent of additional error about the abundance estimates (sampled from the joint posterior), and;

$\overline{CV}_{est}$ is the expected (sampling) standard deviation of the logarithm of $N_{1+,t}^{\text{obs}}$:

$$\overline{CV}_{est} = \sqrt{\frac{1}{Y}\sum_{y=1}^{Y} CV_{\text{y}}^2}, \tag{4.7}$$

where:

y indexes years for which there are survey data up to 2008, and;

Y is the total number of such years.

The estimates of abundance and $\overline{CV}_{est}$ (as opposed to σ) were passed to the *SLA*. No attempt was made to account for further estimation error in the abundance estimates (i.e., mean school size estimation error calculations were ignored).

Need

The annual need Q_t for year *t* was calculated according to the 'need envelope':

$$Q_t = Q_{2009} + \frac{t-2009}{91}\left(Q_{2098} - Q_{2009}\right) \tag{4.8}$$

where:

Q_{2009} (=150) is the present need, and;

Q_{2098} is the final need (in year 2098).

The level of need supplied to the *SLA* was the total (block) need for the 5-year period for which the strike limits were to be set. Two values were assumed for final need (in yr. 2098), corresponding with the 'base case' (Q_{2098}=340) and 'high need' (Q_{2098}=530) trial levels used in previous testing of the *SLA* (IWC, 2003).

Trials

The set of trials is listed in Table 4.1. In addition to the two levels of final need, six scenarios were explored with respect to the future probability (if any) of catastrophic (otherwise known as 'episodic') events and the nature of stochastic (or deterministic) population dynamics: (H0) Deterministic population dynamics with no future catastrophic events[15]; (H1) Environmental stochasticity (as a function of sea-ice) with no future catastrophic events; (H2) Environmental stochasticity (as a function of sea-ice) with probability of future catastrophic events conditioned on the stranding index (corresponding to the percentage of catastrophic years[16] during the time series of stranding counts); (H3) Environmental stochasticity (as a function

[15] The two deterministic trials are most comparable with the base-case operating models in IWC (2004).
[16] The 2 years (1999 and 2000) during the unusual mortality event were considered to be catastrophic.

of sea-ice) with the probability of future catastrophic events p^* conditioned on the percentage of times they occurred during the fitting process when 1+ depletion was greater than 0.40 (Eqn. 4.9; Fig. 4.2 right); (H4) As for H3, but the environmental stochasticity was independent of the sea-ice index, i.e. simply $\varepsilon_t \sim N\left(0, \sigma_\varepsilon^2\right)$, and; (H5) As per H4 but with no future catastrophes.

A depletion of 0.4 represents a level encompassing the full range of trajectories from the posterior (i.e., a small number of those trajectories were estimated to have never recovered to more than 50% of carrying capacity, when carrying capacity was estimated to have been around 50,000 individuals). The probability of future catastrophes p^* conditioned on the percentage of times they occurred during the fitting process when 1+ depletion was greater than 0.40 was then:

$$p^* = 2\left[\left(\sum_{t=1930}^{2008} I(N_{1+,t} / K > 0)\right)^{-1}\right] \tag{4.9}$$

where:

$I()$ is the indicator function.

Performance statistics

The performance statistics were calculated based on future block quotas returned from the standalone version of the 'GUP2' *SLA* (Punt and Breiwick, 2008). All performance statistics were computed in terms of the 1+ component of the population following the standard methods and notation of the AWMP (IWC, 2003). Specifically, four performance statistics were calculated:

1. (D1) Final depletion: $N_{1+,2098} / K_{1+}$;

2. (D8) Rescaled final population size: $N_{1+,2098} / N^*_{1+,2098}$;

where:

$N^*_{1+,2098}$ is the 1+ population size in the final year T, under a scenario of zero future catches.

3. (D10) Relative increase: $N_{1+,2098} / N_{1+,2009}$, and;

4. (N9) Average need satisfaction: $\frac{1}{T}\sum_{t=2009}^{2098}\frac{C_t}{Q_t}$.

where:

C_t is the catch during year *t*, which is determined by the *SLA* through the 5-year block quota system.

4.3 RESULTS

1601 simulations were run for each scenario, corresponding to the number of samples from the posterior provided by the analyses of Chapter 3. In general, the Gray Whale *SLA* was able to satisfy need and maintain a population size near carrying capacity for each of scenarios examined in these analyses. For example, all of the scenarios with base need had an average need satisfaction of 100% and the lowest median final 1+ depletion was 0.874 (Table 4.2). Not surprisingly, those scenarios with higher final need resulted in lower final depletion levels and lower average need satisfaction. However, the differences were not very large (e.g., the lowest median 1+ depletion for the high need scenarios was 0.817). Moreover, none of the scenarios resulted in a lower 5th percentile for the final 1+ depletion less than 0.60. The relative increase statistic (D10) was close to 1 for all scenarios, which indicates stability in the population dynamics. This is, however, not unexpected given the results of Chapter 3, which suggest that this population is close to carrying capacity at present.

The annual probability of future catastrophes for the two 'H2' scenarios was 0.0625, as determined by the number of years for which an episodic event was observed, divided by the total number of years in the strandings index

(2yrs/32yrs)(Brownell *et al.*, 2007). The distribution of probabilities of future catastrophes for the 'H3' and 'H4' scenarios is shown in Fig. 4.2 (right panel). The probability of future catastrophe ranged between 0.025 and 0.222 for those scenarios, with a median of 0.043, which was less than that when conditioned on the stranding index. However, the average difference between these two approaches was relatively small, as evidenced by the nearly identical results between these two assumptions (Table 4.2; Fig. 4.3).

The predicted area of sea-ice on the Bering Sea feeding grounds is forecasted to decrease dramatically, with less than 50% of the average observed area of sea-ice in March-April during future decades (Fig. 4.2, left panel) (Overland and Wang, 2007). The scenarios (H1, H2, and H3) with population dynamics that were a function of this environmental index resulted in the most optimistic outcomes (Table 4.2), with some final depletion levels which were slightly greater than 1.0. On the other hand, the two scenarios that modeled generic environmental stochasticity independent of sea-ice (H4 and H5), resulted in the most pessimistic final depletion levels of any of the scenarios investigated (Table 4.2). Likewise, the trend in process error residuals was very different between these two sets of scenarios. Those scenarios which modeled process error as a function of future sea-ice resulted in an increasing trend in process error deviations, while those scenarios which modeled environmental stochasticity as an independent process resulted in no such trend (Fig. 4.4). However, in terms of the median average need satisfaction, there was essentially no difference between any of the scenarios (Table 4.2).

The results of the "deterministic" trials (H0) were more optimistic than those of the corresponding trials on which the Gray Whale *SLA* was based (GE01 and GE14) (compare table 2 of Punt and Breiwick (2008) with the results for the two H0 trials in table 4.2 of this chapter). However, the differences in the values for the performance statistics are slight, and qualitatively the results of trial H0 and GE01 are identical. The differences in results are attributable to a variety of causes, including differences in the population dynamics models, in the data used to condition the operating model, and in the priors for the parameters of the model.

4.4 DISCUSSION

The analyses incorporated an index of sea-ice variability into an operating model which was used to test the Gray Whale *SLA*, given forecasts for future climate change and a hypothesis regarding the interaction between sea-ice and population dynamics. The trials presented here differ from the standard set designed by the Standing Working Group of the AWMP, in that they were explicitly conditioned on the most recently available data and a hypothesis regarding environmental forcing. For example, deviations in the survival rates during the 1999/2000 mortality event (and resulting population sizes at the start of the future trajectories) were conditioned on observed variability in the strandings data. A set of several alternative trials was also preformed, to compare the results of the environmental forcing scenario to those for which future population dynamics were assumed to be deterministic, or to be subject to random environmental stochasticity (i.e., ignoring sea-ice). For all of the scenarios considered here, the Gray Whale *SLA* was able to maintain stock size and satisfy need at very high levels. Therefore, there is no indication from these analyses that any revisions to the *SLA* are necessary at this time.

It is interesting to note that the assumption that the population dynamics were related to sea-ice led to more optimistic results. This was essentially the result of extrapolating (based on those years for which calf production and strandings data exist) a recent relationship between the environment and population dynamics into the future, under the assumption that such an effect (if it exists) would be constant with respect to time and population density (among other factors). While this is obviously an oversimplification, the framework used here could be modified during the next *Implementation Review* in order to take into account alternative hypotheses with respect to predicted changes in the effect of future environmental variability on population dynamics (e.g., by modifying σ_I^* as a function of depletion).

Table 4.1

The scenarios considered. The trials are denoted by an 'H' followed with the trial number and then 'BN' or 'HN' for base or high final need. Descriptions are given for each scenario in terms of the stochastic or deterministic nature of the population dynamics and the probability of future catastrophes. The extent of future stochasticity σ_ε is equal to 0.50 (for consistency with the 'Full' analyses of Chapter 3) for all except the deterministic scenario.

Trial	Description	σ_ε	Final need	Probability of future catastrophe	Future stochasticity
H0 : BN	Deterministic + no future catastrophes	NA	340	0	None (Deterministic)
H1 : BN	Environmental stochasticity + no future catastrophes	0.5	340	0	Environmental
H2 : BN	Environmental stochasticity + p(future catastrophe)= 0.0625	0.5	340	0.0625	Environmental
H3 : BN	Environmental stochasticity + p(future catastrophe)= *p**	0.5	340	*p** (Eqn. 4.9)	Environmental
H4 : BN	Stochasticity (no sea-ice) + p(future catastrophe)=*p**	0.5	340	*p** (Eqn. 4.9)	Environmental (no sea-ice)
H5 : BN	Stochasticity (no sea-ice) + no future catastrophes	0.5	340	0	Environmental (no sea-ice)
H0 : HN	Deterministic + no future catastrophes	NA	530	0	None (Deterministic)
H1 : HN	Environmental stochasticity + no future catastrophes	0.5	530	0	Environmental
H2 : HN	Environmental stochasticity + p(future catastrophe)= 0.0625	0.5	530	0.0625	Environmental
H3 : HN	Environmental stochasticity + p(future catastrophe)= *p**	0.5	530	*p** (Eqn. 4.9)	Environmental
H4 : HN	Stochasticity (no sea-ice) + p(future catastrophe)= *p**	0.5	530	*p** (Eqn. 4.9)	Environmental (no sea-ice)
H5 : HN	Stochasticity (no sea-ice) + no future catastrophes	0.5	530	0	Environmental (no sea-ice)

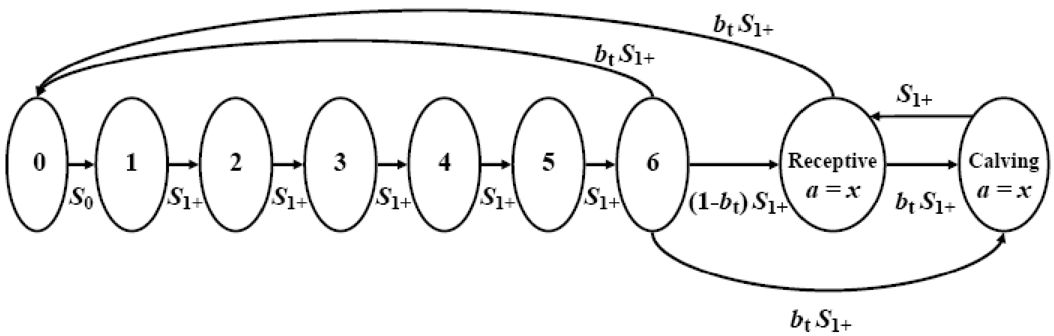

Figure 4.1: Life cycle graph of the model used to track the number of females in each reproductive stage though time. This life cycle refers to the underlying deterministic model, with transition probabilities shown as functions of life history parameters. However, it should be noted that the survival and birth rates were modified to be stochastic in the all analyses except for 'H0'. The arrow from immature to calf arises because some juveniles may mature and give birth (i.e. become pregnant at first estrous) during the projection interval from time t to t+1.

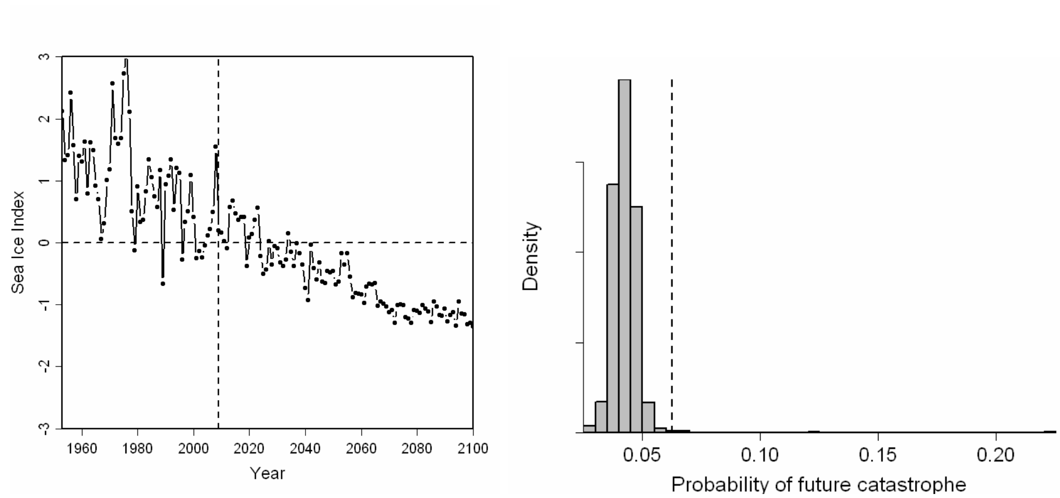

Figure 4.2: (Left panel) The standardized index for the March-April average sea-ice area covering the Bering Sea. The vertical dashed line denotes 2009 and the start of that portion of the time series which is based on the ensemble global climate model mean predictions provided by Overland and Wang (2007). Prior to 2009, the time series is based on the HadSST observations of sea-ice (Rayner *et al.*, 2003). The horizontal dashed line at zero is shown for reference; positive values indicate years with greater than average sea-ice over the entire time period and vice-versa. (Right panel) The distribution for the probability of future catastrophe. This distribution is conditioned on the number of years for which the depletion of each trajectory is greater 0.40 during 1930-2008, divided by 2 (the number of years with observed catastrophes, corresponding to 1999 and 2000). The dashed vertical line denotes the probability as calculated from the strandings index (Brownell *et al.*, 2007)

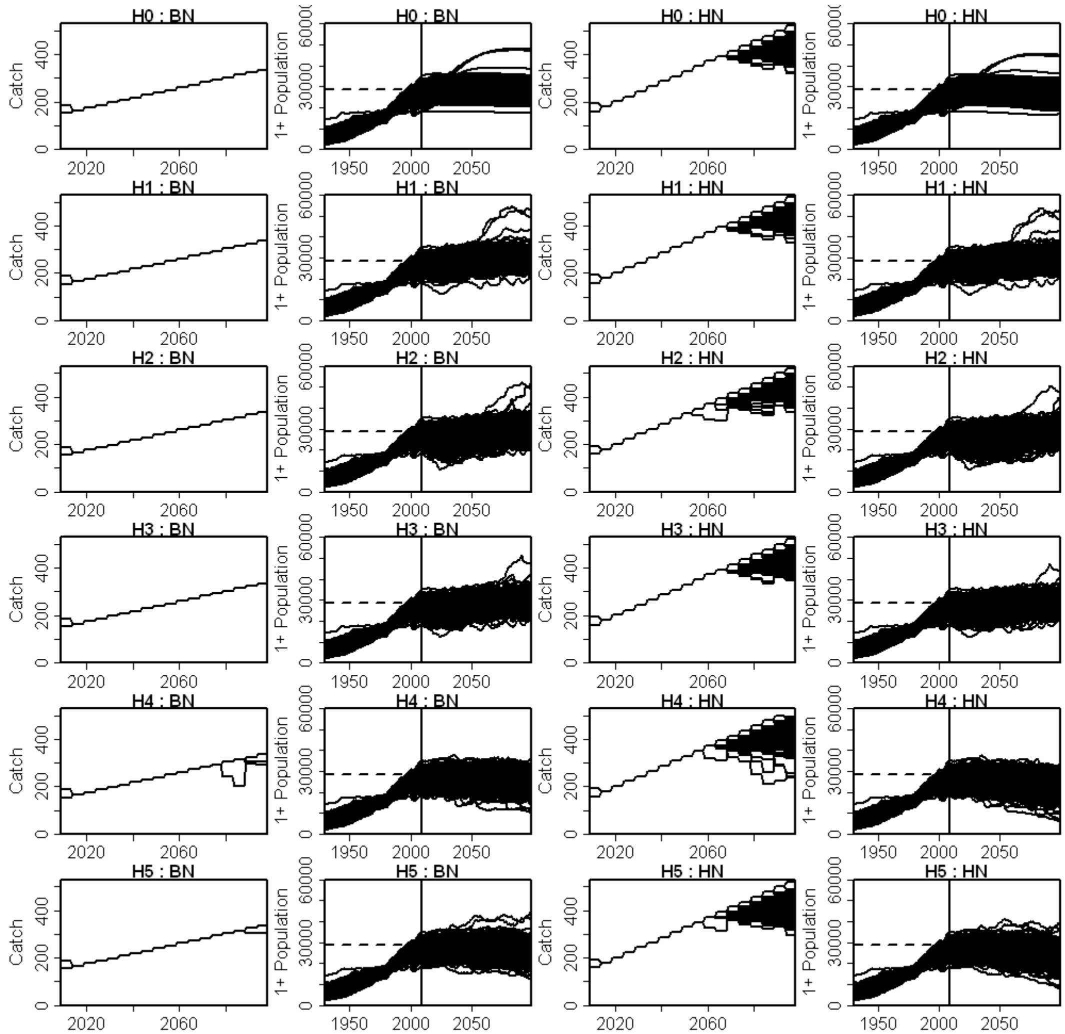

Figure 4.3: Time-trajectories of future catches (first and third columns) and population trajectories from 1930-2098 (second and fourth columns) for the twelve scenarios (Table 4.1). The left and right two columns are respectively for a final need levels of 340 and 530 whales per year. The results for each simulation are plotted as an individual line (e.g., a single visible line for catches represents a series of years where future catches were identical across scenarios).

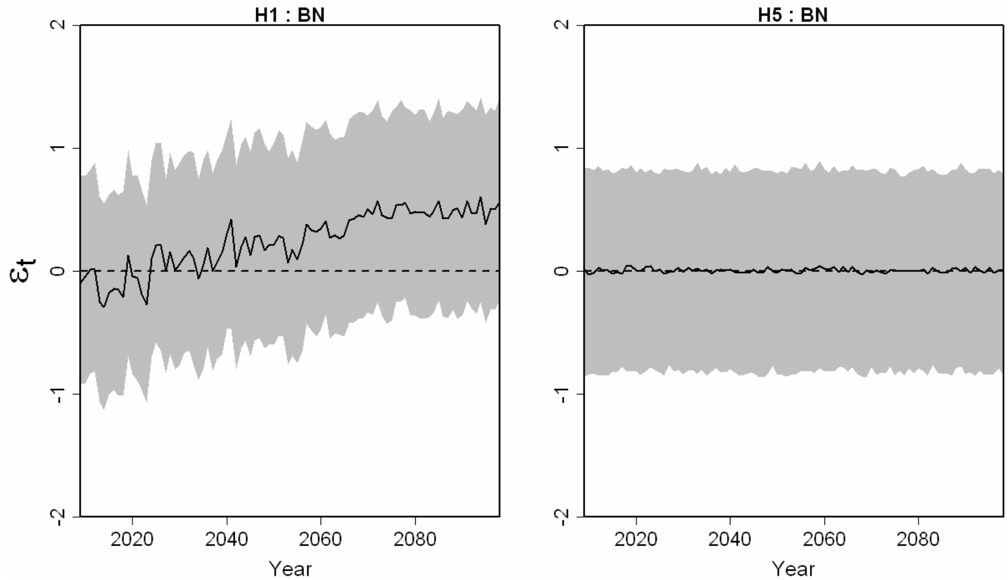

Figure 4.4: The time-trajectories of future process error residuals ε_t for a case where these residuals are a function of future sea-ice (H1:BN; left panel) and where they are independent of the sea-ice index (H5: BN; right panel). The annual median is plotted as the solid line, the 5th and 95th percentiles are shaded in gray and the horizontal dashed line at zero is shown for reference.

CONCLUSIONS

The preceding chapters quantify several key aspects of uncertainty in the context of marine mammal stock assessments. A Bayesian estimation framework was used for each example, which allowed the various dimensions of uncertainty to be integrated in the analyses and provided a logical foundation for calculating the probability that management strategies can achieve their desired objectives. Several case studies were examined, and it was found that existing management strategies are likely to be quite robust to the uncertainties considered when relatively a long time series of abundance estimates is available (i.e., BCB bowheads and ENP gray whales). On the other hand, the results of risk assessments were sensitive to how uncertainty was treated when constructing a coherent joint prior distribution that respects biological realism if abundance data are scarce (EG walrus).

A population dynamics model represents a working hypothesis with respect to the mechanisms that lead to changes in abundance. In common with all hypotheses, these models are based on underlying assumptions about the processes that drive the dynamics of the population. Therefore, model uncertainty can be thought of as uncertainty in which processes are most important in determining the population dynamics. Model selection methods are analogous to hypothesis testing; certain models may be rejected if they are not consistent with observations. However, given the relatively low growth rates of marine mammal populations and the inherent difficulties in estimating abundance for most populations of marine mammals, it is likely that a range of plausible models and assumptions will be consistent with the observed data. That is, available data may not provide much power to reject alternative hypotheses about the population dynamics. In Chapter 1, the assessment of the BCB stock of bowhead whales represented a situation for which alternative models were able to fit the data nearly equally well, but resulted in quite different estimates of stock status and sustainable catch levels. Each model represented a variation on an underlying set of assumptions with respect to the historical catch record, carrying capacity and density dependence. Given available data, there was no evidence for rejecting the different assumptions underlying each model. Therefore, Bayesian model averaging was used to take this uncertainty into account, while also integrating parameter uncertainty and providing a weighted average of the model results based on their respective abilities to fit the data.

By using Bayesian model averaging, the assessment results presented in this case were able to incorporate uncertainty regarding assumptions such as the historical catch history is known without error and that the carrying capacity of the environment has remained unchanged since the middle of the 19^{th} century for BCB bowheads. While taking into account the uncertainty in these assumptions is likely an improvement over previous approaches for this assessment which ignored such uncertainty, care must be given when considering the set of alternative models which are considered. If the candidate models are not biologically plausible or otherwise inappropriate, then the resulting estimates of management quantities may also be misleading, even if model uncertainty is taken into account. Munch *et al*. (2005) address this concern and provide a promising development in the treatment of model uncertainty based on Bayesian nonparametric modeling and using fishery stock-recruitment models as an example. This approach is similar to Bayesian model averaging in that alternative models are weighted by their ability to fit available data, but provides a framework which integrates model uncertainty over a continuous range of models spanning the biologically plausible stock-recruitment model space. This approach could potentially be incorporated into stock assessment frameworks to take into account model uncertainty (e.g., uncertainty in the assumed form of density dependence) while also accounting for parameter and observation uncertainty. Further, as fisheries management continues to move towards an ecosystem approach based on inherently complex models, the need to account for model uncertainty is likely to become increasingly important (Hill *et al.*, 2007).

Bayesian methods have become progressively more popular in fishery science because they provide a natural framework for integrating and quantifying multiple sources of uncertainty. As discussed above, model uncertainty is one potentially important level in this hierarchy. Another fundamental level of uncertainty is expressed by the joint prior distribution for model parameters, which represents the uncertainty in those quantities prior to observing available data. Chapter 2 explored a subtle, but potentially important, aspect of constructing a coherent joint prior distribution, given an imposed constraint which ensured biological realism for the functionally related parameters in age-structured population dynamics models. It is evident from the results of this research that uncertainties resulting from alternative approaches for constructing the joint prior are unlikely to affect the results of assessments when informative time series of abundance estimates are available. In contrast, the results of a risk assessment for a data-poor stock were shown to be sensitive to the alternative approaches for creating the joint prior distribution. Unfortunately, there are no objective criteria on which to base a recommendation for adopting one approach to constructing a coherent joint prior over another. However, the results of Chapter 2 serve as a reminder that, when information on the trend in abundance is lacking (as is the case for many stocks of marine mammals), age-structured models are not necessarily the best approach for providing management advice. Instead, alternative methods should be considered for calculating sustainable limits of human-caused mortality. For example, the 'Potential Biological Removal' (PBR) rule adopted by the U.S. National Marine Fisheries Service (Wade, 1998) may be a better candidate than data-intensive age-structured models for determining precautionary catch limits for EG walrus. Indeed, the lack of sufficient data to inform more complex models for many stocks of marine mammals was exactly the motivation that led to the development of the

PBR as a simple, yet robust, method for assessing the appropriateness of removal levels (Taylor *et al.*, 2000).

Constructing coherent joint prior distributions which respect biological realism is a challenge that is not unique to marine mammal stock assessments. For example, Punt and Hilborn (1997) provide an example of how an incoherent distribution results from placing priors on both unexploited biomass and depletion (the ratio of current to unexploited biomass) in a biomass dynamics model for the western stock of New Zealand hoki (*Macruronus novaezelandiae*). Indeed, specifying contradictory priors is a potential pitfall during the development of any Bayesian analysis. While care must be taken in constructing a coherent joint prior, the real challenge is more likely to involve the necessary imposition of constraints on parameter space to ensure biologically realistic parameter values. This is a challenge which extends beyond marine mammal stock assessments and even the broader realm of fisheries models. It is a consideration for any application in the general arena of natural resource modeling whenever biological constraints on parameter values form part of the prior knowledge about the system in question.

Although walrus and many other marine mammals are extremely difficult to survey because they are distributed widely over large areas in relatively inaccessible habitats, some populations have been successfully monitored for long time periods e.g. the ENP gray whale. In Chapter 3, a modeling framework was developed for this stock, which allowed for the incorporation of a hypothesized relationship between sea-ice and population dynamics while also taking into account the mortality event in 1999 and 2000. This research represented the first time that the extent of this mortality event was quantified and integrated into a stock assessment. In this case, given the uncertainty in the magnitude of the mortality event and the availability of relevant data on fluctuations in birth and death rates (i.e., calf production and strandings data), the stochastic modeling framework developed in Chapter 3 is an appropriate and necessary approach for providing estimates of stock status, because failure to take the mortality event into account is likely to lead to overly optimistic estimates of stock status. Therefore, the framework developed in Chapter 3 should be considered in addition to standard deterministic models during future assessments of this population.

The role of environmental variability on population dynamics is an area of special concern for management of marine mammals which are found in the Arctic, because forecasted climate change and anticipated changes in sea-ice are expected to be dramatic in this region. In Chapter 4, the modeling framework developed in Chapter 3 was used as an operating model in order to test the Gray Whale *SLA* of the IWC, given future predictions of annual sea-ice area on the Bering Sea feeding grounds. The estimated relationship between sea-ice and calf production was used to extrapolate future population dynamics based on the forecasted decrease in sea-ice. Future catches were determined by the *SLA* under different levels of future aboriginal subsistence need and account was taken of observation error in future estimates of abundance as generated using the operating model. While the *SLA* performed very well under the scenarios considered in these analyses, there is still much uncertainty about how changes in sea-ice (or other environmental conditions) will affect future population dynamics. At present, the level of information about the affects of environmental variability on population dynamics is largely correlative in nature. That is, the underlying mechanisms responsible for fluctuations in birth and survival rates are not well understood. Although a plausible explanation has been hypothesized (i.e., that sea-ice may act as a physical barrier to prime feeding habitat), it is not straightforward to predict how other likely changes in the environment resulting from reductions in sea-ice will interact with the mechanisms that are currently in force. Therefore, while the results of Chapter 4 indicate that the Gray Whale *SLA* is robust to predicted changes in arctic sea-ice, this conclusion must be tempered by uncertainty in the underlying assumption that current ecological processes will remain unchanged in the future, especially when so many other fundamental changes in ecosystems are expected as a result of climate change.

As continuing research provides more insight into the mechanisms underlying the impacts of environmental variability on population dynamics of ENP gray whales, the modeling framework developed here will provide a good basis for integrating such information into assessments and management strategy evaluations. One of the appealing attributes of this framework for incorporating environmental data is its flexibility. For example, it is simple to substitute alternative environmental data during the model fitting process. Likewise, this framework can be applied to other stocks for which environmental fluctuations are hypothesized to be an important determinant of variability in population dynamics or behavior, and could prove to be useful in modeling changes in the availability of animals with respect to surveys or fishery catches. Additionally, it would be relatively straightforward to take into account hypothesized changes in the interaction between environmental variability and population dynamics in future projections (e.g., a loss of sea-ice might be beneficial for the ENP gray whales until the point at which the loss of sea-ice might result in negative effects owing to other impacts on the ecosystem).

Such considerations bring the research presented here full-circle. That is, the underlying uncertainty in the assumption that a certain index of environmental conditions is related to population dynamics and that if such a relationship exists, that current processes will remain unchanged in the future, are really manifestations of model uncertainty. Further, instead of assuming that current relationships will persist independently of other ecological changes, it may be preferable to enforce constraints on the degree to which future environmental conditions may affect population dynamics to respect biological realism. Explicitly accounting for this last point is beyond the scope of this dissertation, but does illustrate how the various issues dealt with in this research are potentially inter-related in the broader context of providing management advice in the face of scientific uncertainty.

In summary, this dissertation explores several notable categories of uncertainty in marine mammal stock assessments. This research serves to improve the current understanding of population dynamics by incorporating and quantifying these various sources of uncertainty, and hence it also aims to ensure that resulting management advice is robust to these issues. In addition, the methods developed for incorporating environmental variability as well as the issues of model uncertainty and constructing coherent joint prior distributions which respect biological realism, are matters likely relevant to a large range of ecological modeling efforts. Therefore, the methods applied here are broadly applicable, and also serve as a basis for providing the best available management advice for marine mammals as well as other exploited natural resources.

Appendix A:
DERIVATION OF EQNS. 3.2 AND 3.3

In a given year, the realized stochastic birth rate can be written as a logistic function of a parameter related to the expected birth rate μ_t and process error ε_t that year:

$$b_t^* = \left[1+\exp(-(\mu_t+\varepsilon_t))\right]^{-1} \qquad \text{where:} \qquad \varepsilon_t \sim N(0,\sigma_\varepsilon^2) \qquad \text{A.1}$$

Further, let $\mu_t^* = \mu_t + \varepsilon_t$ where $\mu_t^* \sim N(\mu_t, \sigma_\varepsilon^2)$. Now, given a random variable generated from some underlying distribution $X \sim f(x)$ and a function of this random variable $Z = h(X)$, the expectation of the function can be written:

$$E[Z] = \int_{-\infty}^{\infty} h(x) f(x) dx \qquad \text{A.2}$$

It is necessary to define the expectation of the stochastic birth rates as equal to the deterministic value from the Pella-Tomlinson model (Eqn. 3.1), i.e. $E[b_t^*] = b_t$ to model density dependence acting solely through the stochastic birth rate. Proceeding from the form of the expectation above, while noting that $b_t^* = h(\mu_t^*) = \left[1+\exp(-\mu_t^*)\right]^{-1}$ and likewise, given its additive nature, that $\mu_t^* \sim N(\mu_t, \sigma_\varepsilon^2)$, substitute for *h(x)* and *f(x)* in equation A.2 and write the analytical expectation of the stochastic birth rates (Punt, 2008):

$$E[b_t^*] = \int_{-\infty}^{\infty} \left[1+\exp(-\mu_t^*)\right]^{-1} \left[\frac{1}{\sigma_\varepsilon\sqrt{2\pi}} \exp\left(\frac{-\left(\mu_t^* - \mu_t\right)^2}{2\sigma_\varepsilon^2}\right)\right] d\mu_t^* \qquad \text{A.3}$$

It was found through numerical methods that, the integral on the right side is well approximated by:

$$\approx \Phi\left(\frac{\mu_t}{\sqrt{2.76+\sigma_\varepsilon^2}}\right) \qquad \text{A.4}$$

where:

Φ is the standard normal cumulative distribution function; and
2.76 is a value found through numerical minimization, which approximates this expectation.

Setting the expectation of the stochastic birth rates equal to the deterministic density dependent rate:

$$\Phi\left(\frac{\mu_t}{\sqrt{2.76+\sigma_\varepsilon^2}}\right)=b_t \qquad \text{A.5}$$

And finally, rearranging to solve this equation for μ_t and substituting back into equation A.1 yields Eqns. 3.2 and 3.3. Of course, for those years with added process error, the stochastic expectation will not necessarily be equal to the deterministic value.

VITA

John was born in Sacramento, California in 1976. He was raised in Davis with his younger brother, Patrick. His parents, John and Dorothy, introduced him to science through their respective involvements in the entomology and botany departments at UC Davis. He graduated from Davis High School in 1994. In 1998 he received his B.S. in Biology from UC San Diego, where he also captained the men's soccer team and spent the off-season in the ocean, surfing. He was hired during his senior year by Dr. Tim Gerrodette at the SWFSC of the NMFS, to assist in research of dolphin populations and the eastern tropical Pacific tuna fishery. During his 3 years as an employee of the SWFSC he became increasingly interested in the application of quantitative methods in conservation biology, and was also introduced to marine mammal surveys through field work in the eastern tropical Pacific and various locations along the west coast of the U.S. After traveling around the world by himself for a year, to surf and fly-fish in the southern hemisphere, he moved to Seattle for graduate school to study quantitative fisheries methods. Before enrolling at the UW, he worked as a marine mammal observer on aerial and ship-based surveys in the Arctic, and in the Aleutian Islands. Since that time, he has also been a marine mammal observer on surveys in the western Atlantic and the Yangtze River in China. Much of his dissertation research has been conducted for the International Whaling Commission, where John has been an Invited Participant during recent Scientific Committee meetings. He received his Ph.D. from the University of Washington, School of Aquatic and Fishery Sciences in 2009.

Testing the *Gray Whale* Strike Limit Algorithm (*SLA*): allowing environmental variability to influence population dynamics

JOHN R. BRANDON AND ANDRÉ E. PUNT

School of Aquatic and Fisheries Sciences, Box 35020, University of Washington, Seattle, WA 98195-5020, USA

Contact e-mail: jbrandon@u.washington.edu

ABSTRACT

The performance of the *Gray Whale SLA* is evaluated based on an operating model conditioned on available information for the eastern North Pacific stock of gray whales including: survey estimates of 1+ abundance; calf counts; strandings data; and the extent of sea-ice in the feeding grounds in the Bering Sea in the early season. Multiple scenarios are considered in the analyses to explore the impact of different sources of environmental variation, including scenarios in which future environmental forcing and episodic events are driven by the relationships between reproductive success and survival to sea ice. A variety of sources of uncertainty are considered, including parameter uncertainty, the uncertainty about the relationship between the extent of sea-ice and population dynamics, and observation error. The impact of these sources of uncertainty on the performance of the *Gray Whale SLA* is small. For all scenarios considered in the simulations, application of the *SLA* results in the stock being at or near carrying capacity at the end of a 92 year projection period for which sea-ice cover forecasts are available, while still satisfying the needs of aboriginal whalers.

KEYWORDS: BIRTH RATE; CLIMATE CHANGE; ICE; MANAGEMENT PROCEDURE; MODELLING; MORTALITY RATE; WHALING–ABORIGINAL; GRAY WHALE

INTRODUCTION

The IWC has established a procedure (an '*Implementation*') to provide scientific advice on catch limits for different whale stocks (e.g. IWC, 2012). The eastern North Pacific (ENP) population of gray whales is currently subject to aboriginal hunting, with recommended strike limits based on the *Gray Whale Strike Limit Algorithm* (*Gray Whale SLA*) under the Aboriginal Subsistence Whaling Management Procedure (AWMP) of the IWC (IWC, 2003). *Implementation Reviews* are scheduled under the AWMP every five years. The goal of *Implementation Reviews* is to evaluate new information that has become available since the last *Implementation Review* (or the original *Implementation*), *inter alia* to determine whether the current state of nature is outside the realm of plausibility envisioned during the simulation testing of the original *SLA*. If this is the case, additional simulation trials may be conducted to assess whether the anticipated performance of the *SLA* adopted remains reasonable, and if not, what changes to the *SLA* are needed.

New or updated sources of information pertaining to the population dynamics of ENP gray whales have become available in recent years, including: (1) new abundance estimates (Rugh *et. al.,* 2008); (2) new estimates of calf production during 1994–2008 from the northbound migration at Point Piedras Blancas, California (Perryman *et al.*, 2002; Perryman, unpublished data); and (3) the number of stranded animals on the coasts of California, Oregon and Washington states, for which a combined annual count is available for 1975–2006 (Brownell *et al.*, 2007). The last data source potentially contains information on the magnitude of the mortality event during 1999/2000 (Gulland *et al.*, 2005). In addition to these data sets, it has been hypothesised that observed variability in the calf counts is a function of the amount of sea-ice covering the feeding grounds in the Bering Sea in the early season (Perryman *et al.*, 2002).

Accordingly, in this paper the performance of the *Gray Whale SLA* is tested given scenarios when future population dynamics are subject to environmental forcing and episodic events, using an operating model that integrates these sources of new information and the hypothesis of environmental forcing on the population dynamics (Brandon and Punt, 2009). A forecast of relevant sea-ice conditions based on global climate model output (Overland and Wang, 2007) is used to modify the future stochastic birth and survival rates generated when testing the *SLA*, given the estimated relationships of calf production and strandings data to observed variations in recent sea-ice. This technique involves the incorporation of climate-model-based forecasts into the operating model. The same basic framework is also being used to test the performance of alternative management approaches in other fisheries (e.g. Gulf of Alaska and Eastern Bering Sea walleye pollock, *Theragra chalcogramma*; A'mar *et al.*, 2009; Ianelli *et al.*, 2011).

Standard summary statistics are provided for the trials investigated here, and these are compared to results from the *Evaluation Trials* provided by Punt and Breiwick (2008) to the extent possible. The analyses presented here should help to ensure that the anticipated performance of the current *Gray Whale SLA* remains satisfactory (or else provide insight into potential weaknesses), given the new information that has become available since the phase of testing and adoption reported in IWC (2005a).

METHODS

Operating model

The population dynamics model developed by Brandon and Punt (2009) (corresponding to their 'Full' scenario) was used as the operating model. This model is sex- and age-based,

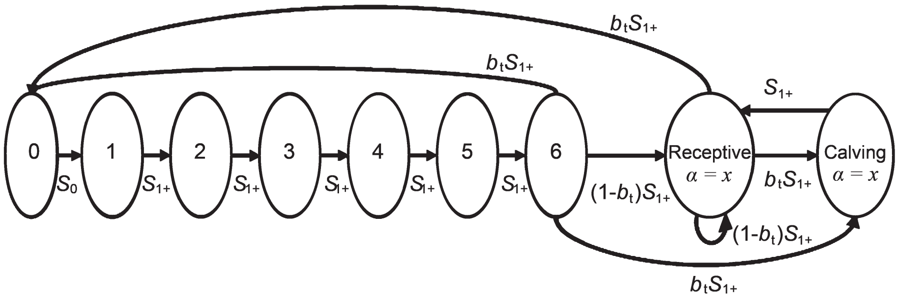

Fig. 1. Life cycle graph of the model used to track the number of females in each reproductive stage though time. This life cycle refers to the underlying deterministic model, with transition probabilities shown as functions of life history parameters. However, it should be noted that the birth and survival rates were modified to be stochastic in the all analyses except for 'H0'. The arrow from immature to calf arises because some immatures may mature and give birth (i.e. become pregnant at first estrous) during the projection interval from time *t* to *t*+1.

with an annual time-step. The dynamics include stochastic birth and survival rates, and explicitly consider the transition between receptive and calving stages for mature females (Fig. 1). For consistency, the notation of Brandon and Punt (2009) is adopted below.

Density dependence was assumed to act through the birth rate according to a Pella-Tomlinson function of 1+ depletion:

$$b_t = max\left\{0,\ b_{eq} + (b_{max} - b_{eq})\left[1 - \left(\frac{N_{1+,t}}{K_{1+}}\right)^{z}\right]\right\} N_{1+,t} \quad (1)$$

where b_{max} is the maximum birth rate (in the limit of zero population size); K_1 is the carrying capacity in terms of the 1+ component of the population (all animals aged 1 year and older)[1]; b_{eq} is the equilibrium birth rate at carrying capacity; z is the degree of density-dependent compensation (assumed to equal 2.39, which implies maximum sustainable yield at a population size approximately 60% of K_1, the conventional value for MSYL assumed for whale populations, e.g. IWC, 2005a); and $N_{1+,t}$ is the size of the 1+ component of the population (both sexes combined) at the start of year *t*.

Selectivity was assumed to be knife-edged and uniform for ages 5+, catches were assumed to be taken at the start of the year, before natural mortality, and the population trajectories were initialised in 1930, under the assumption of a stable-age-distribution given some level of hunting mortality in 1930 (as in Brandon and Punt, 2009). Process error after 1930 ensures that the age-structure by the time data are available is non-equilibrium.

Deviations from expected birth and survival rates were allowed to be functions of sea-ice variability in the Bering Sea. Thus, the operating model is an adaptation of the hypothesis that the variability in calf production the following year may be related to the amount of sea-ice in the Bering Sea early during the feeding season (Perryman *et al.*, 2002). Birth rates were assumed to vary annually about the deterministic value given by Equation (1). Since this rate must lie between zero and one, its realisation in any one year was calculated using a logistic transformation:

[1] Strictly, K_{1+} is only the carrying capacity in the deterministic case (no fluctuations in birth rate and no catastrophic events). It should be interpreted here as a parameter which relates to stochastic carrying capacity. The latter could be defined as the average long-term population size in the absence of catches.

$$b_t^* = \left[1 + \exp(-(\Phi^{-1}\left(b_t\right)\sqrt{2.76+\sigma_\varepsilon^2} + \varepsilon_t + \varepsilon_{add}))\right]^{-1} \quad (2)$$

Where Φ^{-1} is the inverse standard normal cumulative distribution function; ε_t is the process error deviation for year t, $\varepsilon_t \sim N(0;\sigma_\varepsilon^2)$, σ_ε is a measure of the extent of variability in process error and; allows for additional process error in the birth (and survival) rate during years with extraordinary dynamics, such as 1999 and 2000 (in other years before 2009, this parameter was set equal to zero; see below for how future catastrophic events are generated). This formulation of stochastic birth rates (e.g. the 2.76 factor) ensures that the expected birth rate in a given year equals the deterministic value from Equation (1) (see Appendix A of Brandon and Punt, 2009). The form of Equation (2) (and (3)) is such that 'positive' catastrophic events can lead to very high survival and birth rates (where the maximum birth rate is bounded by 0.99). However, it should be noted that Equation (2) only applies to receptive females and that a high birth rate in one year will result in a decrease in receptive females and hence a lower pregnancy rate the following year (Fig. 1).

Survival rates were also allowed to vary annually with the same process error deviations as birth rates to reflect the assumption that survival and birth rate covary. The effects of process error on survival and birth rate are assumed to be the same in the absence of data to distinguish these sources of process error. It was assumed that process error in survival rates were independent of sex and perfectly correlated between ages in a given year, so that:

$$S_{a,t}^* = \left[1 + \exp(-(\Phi^{-1}\left(S_a\right)\sqrt{2.76+\sigma_\varepsilon^2} + \varepsilon_t + \varepsilon_{add}))\right]^{-1} \quad (3)$$

where $S_{a,t}^*$ is the realised age-specific survival rate during year t; and S_a is the expected survival rate from age a to age a+1.

Conditioning

The operating model was conditioned on available data, including: (1) estimates of population size during 1967–2006 (covering the years of surveys) from the southbound migration at Granite Canyon, California (Rugh *et al.*, 2005; 2008); (2) estimates of calf production during 1994–2008[2] from the northbound migration at Point Piedras Blancas,

[2] The two early estimates of calf production during 1980–1981 (Poole, 1984) were not used in these analyses.

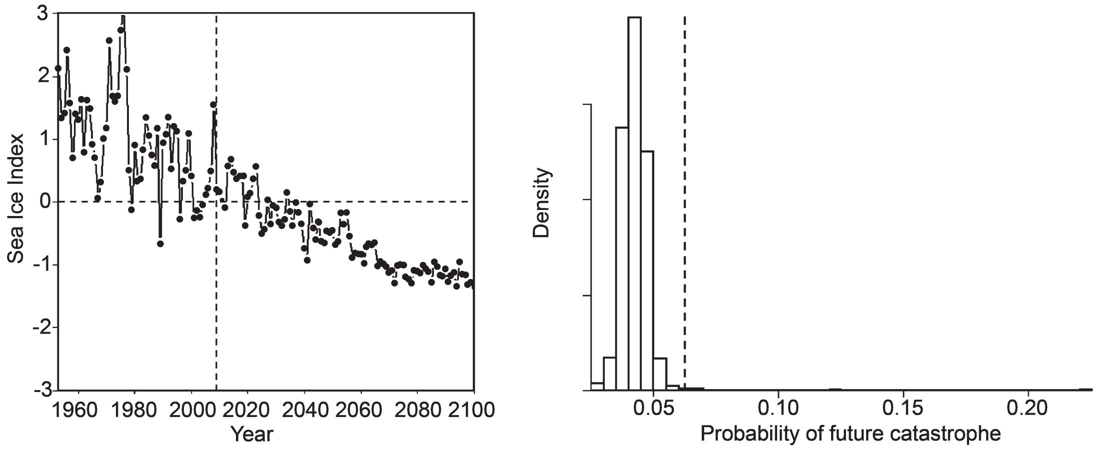

Fig. 2. Left panel: The standardised index for the March–April average sea-ice area covering the Bering Sea. The vertical dashed line denotes 2009 and the start of that portion of the time series which is based on the ensemble global climate model mean predictions provided by Overland and Wang (2007). Prior to 2009, the time series is based on the HadSST observations of sea-ice (Rayner *et al*., 2003). The horizontal dashed line at zero is shown for reference; positive values indicate years with greater than average sea-ice over the entire time period and *vice versa*. Right panel: The distribution for the probability of a future catastrophe in any one year. This distribution is conditioned on the number of years for which the depletion of each trajectory is greater 0.40 during 1930–2008, divided by 2 (the number of years with observed catastrophes, corresponding to 1999 and 2000) (Brandon and Punt, 2009). The dashed vertical line denotes the probability as calculated from the strandings index (Brownell, *et al*., 2007).

California (Perryman *et al*., 2002; Perryman, unpublished data); (3) the number of stranded animals on the coasts of California, Oregon and Washington states, for which a combined annual count is available for 1975–2006 (Brownell *et al*., 2007)[3]; and (4) estimated sea-ice area cover in the Bering Sea, averaged over March and April during 1953–2008, as calculated by the Hadley Center for their sea ice and sea surface temperature data set version 1 (‘HadSST’) (Rayner *et al*., 2003) (see Fig. 2, left panel). The conditioning process involves fitting the operating model to the data and estimating posterior distributions from the basis for probabilistic projections of future population dynamics.

The deviations of birth and survival rates about the deterministic relationship each year were allowed to be related to an environmental index I_t (the amount of sea-ice covering the Bering Sea) during the conditioning. It was assumed that I_t was measured subject to observation error (or there was some error in the relationship between the process error deviations and the environmental index). Consequently, I_t was a state variable, like the model prediction of population size. Hence, the measurements of the environmental index were treated as data and were consequently included as a component of the likelihood function when the model was fit. The expected environmental index in a given year was assumed to be related to process error residuals for that year, such that the observed index was normally distributed about its expectation:

$$I_t^{obs} = \beta \varepsilon_t + \gamma_t \tag{4}$$

where I_t^{obs} is the observed value of the environmental index in year t; β is a scaling parameter for the influence of the environment on the process error residuals; γ_t the difference between the observed and model-predicted amount of sea ice in year t, such that $\gamma_t \sim N(0;\sigma_I^2)$; and σ_I is the standard deviation of the residual error for the environmental index:

$$\sigma_I = |\beta| \sigma_I^* \tag{5}$$

This formulation takes a fixed input value for (assumed to be 0.30 for these analyses, corresponding to the ‘Full’ model of Brandon and Punt, 2009) and scales the expected standard deviation of the fits to the environmental index by the estimated absolute value for β.

Future projections

Once the operating model was conditioned on the available data, it was possible to project simulated population trajectories into the future. Each forward projection was initialised in 2009, based on the estimated status of the simulated population and the parameter values (e.g. K_{1+}, b_{max} etc…) for a given trajectory from the joint Bayesian posterior distribution. The posterior was constructed using the MCMC algorithm during the conditioning phase (Brandon and Punt, 2009).

Future values for the sea-ice index were based on an ensemble mean forecast of sea-ice in the Bering Sea (March–April average) (Overland and Wang, 2007). The trials were based on a 92-year time horizon (T = 92), because the time series of forecasted sea-ice was only available until 2098. In a given year, the process error deviations about the expected birth and survival rates were a function of forecasted sea-ice according to:

$$\varepsilon_t = \left(I_t^{obs} / \beta \right) - \gamma_t \tag{6}$$

where I_t^{obs} is the forecasted value of the sea-ice index for year t (Fig. 2, left panel); and $\gamma_t \sim N(0;\sigma_I^2)$

Future abundance estimates were assumed to become available every 10 years. Observation error was assumed to be log-normal:

$$N_{1+,t}^{\text{obs}} = N_{1+,t} \, e^{\phi_t} \tag{7}$$

[3] Data on strandings are collected in other locations (e.g. Mexico and Alaska), but the stranding network effort in California, Oregon and Washington has been more consistent over time.

where $I^{obs}_{1+,t}$ is the survey estimate of 1+ abundance for year t; $N_{1+,t}$ is the 'true' 1+ abundance at the start of year t; $\phi_t \sim N(0;\sigma^2)$; where $\sigma = \sqrt{\overline{CV}^2_{est} + CV^2_{addA}}$; CV_{addA} is the extent of additional error about the abundance estimates (sampled from the joint posterior), and; $\overline{CV}_{est}$ is the expected (sampling) standard deviation of the logarithm of $N^{obs}_{1+,t}$:

$$\overline{CV}_{est} = \sqrt{\tfrac{1}{Y}\sum_{y=1}^{Y} CV_y^2} \tag{8}$$

where y indexes years for which there are survey data up to 2008; CV_y is the sampling CV associated with the abundance estimate for year y; and Y is the total number of years with past surveys. The estimates of abundance and $\overline{CV}_{est}$ (as distinct from σ) were passed to the *SLA*. No attempt was made to account for further estimation error in the abundance estimates (i.e. mean school size estimation error calculations were ignored).

Need[4]

The annual need Q_t for year t was calculated according to the 'need envelope':

$$Q_t = Q_{2009} + \frac{t-2009}{91}\left(Q_{2098} - Q_{2009}\right) \tag{9}$$

where Q_{2009} (= 150) is the present need; and Q_{2098} is the final need (in year 2098). The level of need supplied to the *SLA* was the total (block) need for the 5-year period for which the strike limits were to be set. Two values were assumed for final need (in year 2098), corresponding to the 'base case' (Q_{2098} = 340) and 'high need' (Q_{2098} = 530) trial levels used in previous testing of the *SLA* (IWC, 2003).

Trials

The set of trials is listed in Table 1. In addition to the two levels of final need, six scenarios were explored with respect to p^*, the future probability (if any) of catastrophic (otherwise known as 'episodic') events, and the nature of stochastic (or deterministic) population dynamics.

(1) (H0) Deterministic population dynamics with no future catastrophic events[5];

(2) (H1) Environmental stochasticity (as a function of sea-ice) with no future catastrophic events;

(3) (H2) Environmental stochasticity (as a function of sea-ice), with probability of future catastrophic events conditioned on the stranding index (0.0625, the proportion of years for which an episodic event was observed, divided by the total number of years in the strandings index (2yr/32yr) (Brownell *et al.*, 2007));

(4) (H3) Environmental stochasticity (as a function of sea-ice) with the probability of future catastrophic events conditioned on the percentage of times they occurred during the fitting process when 1+ depletion was greater than 0.40 (Eqn. 9; Fig. 2 right);

(5) (H4) As for H3, but the environmental stochasticity was independent of the sea-ice index, i.e. simply $\varepsilon_t \sim N(0,\sigma^2_\varepsilon)$; and

(6) (H5) As for H4 but with no future catastrophes.

A depletion level of 0.40 during the conditioning phase was used for calculating the probability of future episodic events for scenarios H3 and H4 because the population almost always recovers to 40% of carrying capacity by when the catastrophes occur. The probability of future catastrophes p^* conditioned on the percentage of times they occurred during the fitting process when 1+ depletion was greater than 0.40 was then:

$$p^* = 2\left[\left(\sum_{t=1930}^{2008} I(N_{1+,t}/K > 0.4)\right)^{-1}\right] \tag{10}$$

where $I()$ is the indicator function. Hence, a future year was determined to be either normal ($\varepsilon_{add} = 0$) or catastrophic by drawing a random variate from a Bernoulli distribution with probability p^* for these scenarios if the 1+ depletion was greater than 0.40. Future catastrophic years were modelled through the inclusion of the estimated ε_{add} parameter into Eqn. 2 and 3 for birth and survival rates during those years (Fig. 2, right).

No attempt was made to model correlation between years with catastrophes, i.e. the probability of a catastrophe occurring did not depend on the whether or not there was one the previous year.

Performance statistics

The performance statistics were calculated based on future block quotas returned from the standalone version of the 'GUP2' *SLA* (IWC, 2005b; Punt and Breiwick, 2008). All performance statistics were computed in terms of the age 1+ component of the population following the standard methods and notation of the AWMP (IWC, 2003). Specifically, four performance statistics were calculated:

(1) (D1) Final depletion: $N_{1+,2098}/K_{1+}$;

(2) (D8) Rescaled final population size: $N_{1+,2098}/N^*_{1+,2098}$, where $N_{1+,2098}$ is the 1+ population size in 2098, under a scenario of zero future catches;

(3) (D10) Relative increase: $N_{1+,2098}/N_{1+,2009}$; and

(4) (N9) Average need satisfaction: $\frac{1}{T}\sum_{t=2009}^{2098}\frac{C_t}{Q_t}$

where T is the number of years in the projection period; and C_t is the catch during year t, which is determined by the *SLA* through the 5-year block quota system.

RESULTS

1,601 simulations were run for each scenario, corresponding to the number of samples from the posterior provided by Brandon and Punt (2009). In general, the *Gray Whale SLA* was able to satisfy need and maintain a population size near carrying capacity for all of scenarios examined in these analyses. For example, all of the scenarios with base need had an average need satisfaction of 100% and the lowest median final 1+ depletion was 0.874 (Table 2). Not

[4] This is the number of whales a country or the Commission specifies is required to satisfy cultural and subsistence 'needs' before taking the conservation situation into account

[5] The two deterministic trials are most comparable with the base case operating models in IWC (2004).

Table 1

The scenarios considered. The trials are denoted by an 'H' followed with the trial number and then 'BN' or 'HN' for base or high final need. Descriptions are given for each scenario in terms of the stochastic or deterministic nature of the population dynamics and the probability of future catastrophes.

Trial	Description	σ_ε	Final need	Probability of future catastrophe	Future stochasticity
H0:BN	Deterministic + no future catastrophes	N/A	340	0	None (deterministic)
H1:BN	Environmental stochasticity + no future catastrophes	0.5	340	0	Environmental
H2:BN	Environmental stochasticity + *p*(future catastrophe) = 0.0625	0.5	340	0.0625	Environmental
H3:BN	Environmental stochasticity + *p*(future catastrophe) = *p**	0.5	340	*p** (Eqn. 10)	Environmental
H4:BN	Stochasticity (no sea-ice) + *p*(future catastrophe) = *p**	0.5	340	*p** (Eqn. 10)	Environmental (no sea-ice)
H5:BN	Stochasticity (no sea-ice) + no future catastrophes	0.5	340	0	Environmental (no sea-ice)
H0:HN	Deterministic + no future catastrophes	N/A	530	0	None (deterministic)
H1:HN	Environmental stochasticity + no future catastrophes	0.5	530	0	Environmental
H2:HN	Environmental stochasticity + *p*(future catastrophe) = 0.0625	0.5	530	0.0625	Environmental
H3:HN	Environmental stochasticity + *p*(future catastrophe) = *p**	0.5	530	*p** (Eqn. 10)	Environmental
H4:HN	Stochasticity (no sea-ice) + *p*(future catastrophe) = *p**	0.5	530	*p** (Eqn. 10)	Environmental (no sea-ice)
H5:HN	Stochasticity (no sea-ice) + no future catastrophes	0.5	530	0	Environmental (no sea-ice)

surprisingly, those scenarios based on higher final need resulted in lower final depletion levels and lower average need satisfaction. However, the differences were not large (e.g. the lowest median 1+ depletion for the high need scenarios was 0.817). Moreover, none of the scenarios resulted in a lower 5th percentile for the final 1+ depletion less than 0.60. The relative increase statistic (D10) was close to 1 for all scenarios. The increase in population size is somewhat constrained because even under decreases in ice cover, Eqn. 1 still imposes an upper bound on abundance.

The distribution of probabilities of future catastrophes for the 'H3' and 'H4' scenarios is shown in Fig. 2 (right panel). The probability of future catastrophe ranged between 0.025 and 0.222 for those scenarios, with a median of 0.043, which was less than that when conditioned on the stranding index. However, the average difference between these two approaches was relatively small, as evidenced by the nearly identical results for these two assumptions (Table 2; Fig. 3).

The predicted area of sea-ice on the Bering Sea feeding grounds is forecast to decrease dramatically, with less than 50% of the average observed area of sea-ice in March–April during future decades (Fig. 2, left panel; Overland and Wang, 2007). The scenarios H1, H2, and H3 with population dynamics that are a function of this sea-ice index resulted in the most optimistic outcomes (Table 2), with some final depletion levels slightly greater than 1.0. On the other hand, the two scenarios that modelled generic environmental stochasticity independent of sea-ice (H4 and H5) resulted in the most pessimistic final depletion levels of any of the scenarios investigated (Table 2). Likewise, the trend in process error deviations was very different between these two sets of scenarios. Those scenarios which modelled

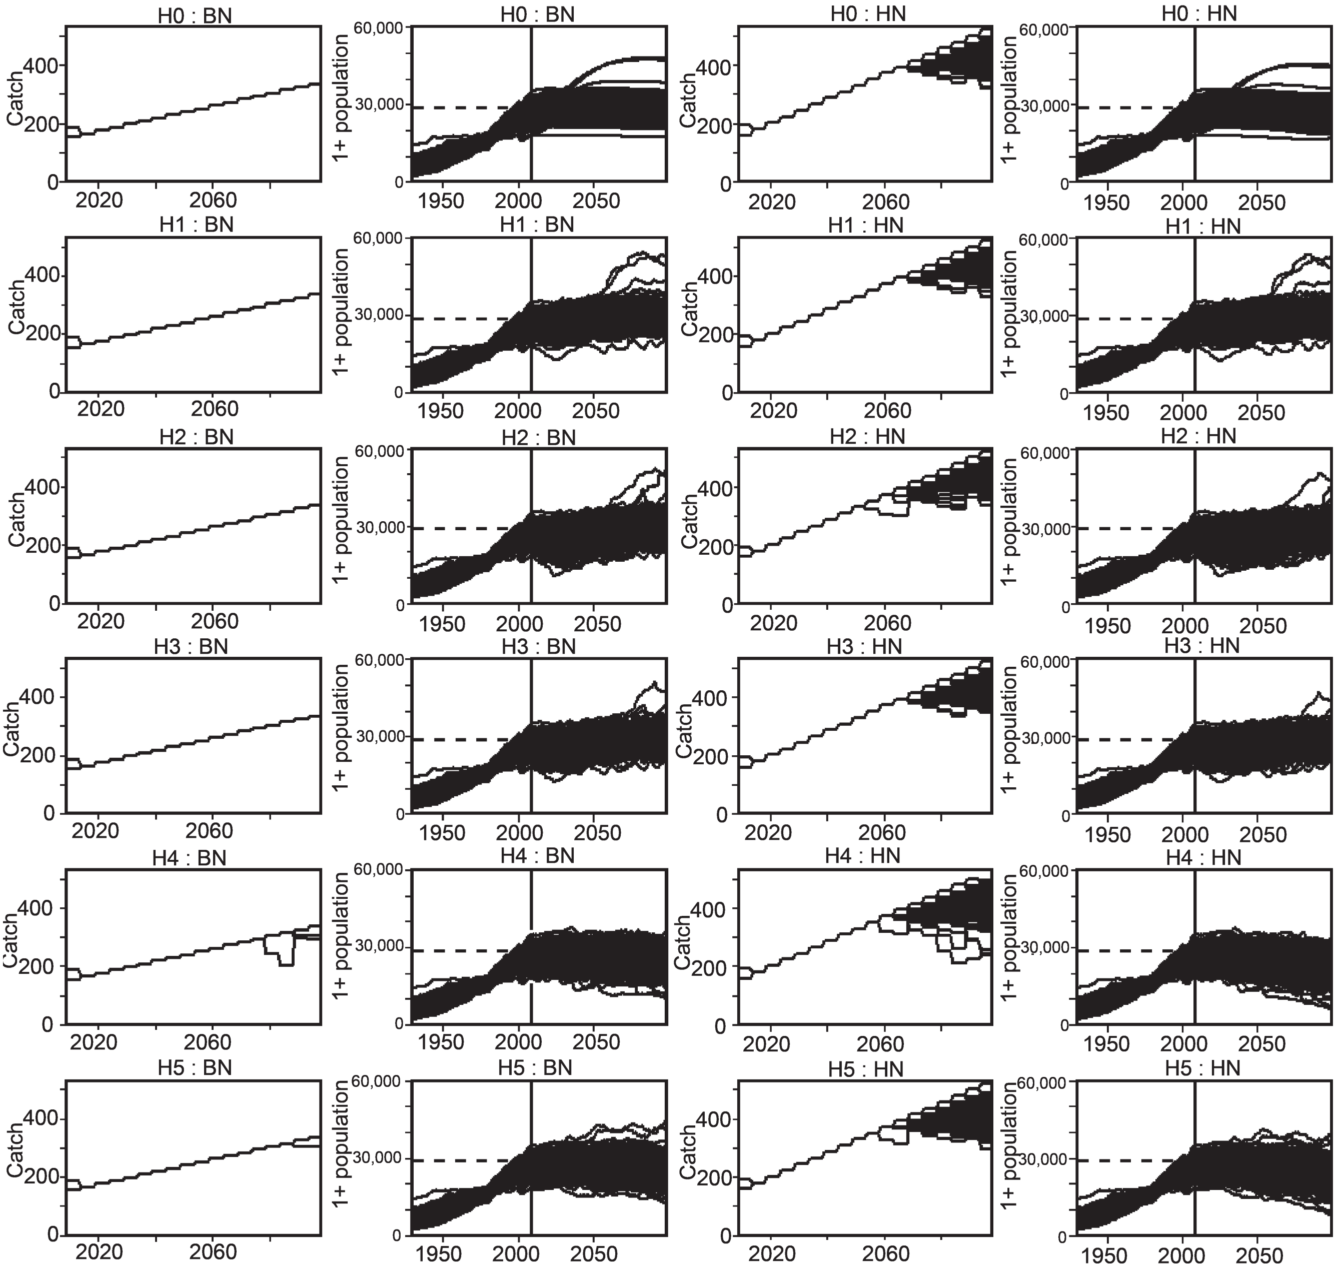

Fig. 3. Time-trajectories of future catches (first and third columns) and population trajectories from 1930–2098 (second and fourth columns) for the twelve scenarios (Table 1). The left and right pairs of columns are respectively for a final need levels of 340 and 530 whales per year. The results for each simulation are plotted as an individual line (thus a single visible line for catches represents a series of years where future catches were identical across scenarios).

process error as a function of future sea-ice resulted in an increasing trend in the size of process error deviations, while those scenarios which modelled environmental stochasticity as an independent process led to no such trend (Fig. 4). However, in terms of the median average need satisfaction, there was essentially no difference amongst all the scenarios; the *SLA* was able to achieve high need satisfaction for all of those examined here (Table 2).

The results of the 'deterministic' trials (H0) were more optimistic than those of the corresponding trials on which the *Gray Whale SLA* was based (GE01 and GE14) (compare table 2 of Breiwick *et al.* (2009) with the results for the two H0 trials in Table 2 of this paper). However, the differences in the values for the performance statistics are slight, and qualitatively the results of trial H0 and GE01 are identical. The differences in results are attributable to a variety of causes, including differences in the population dynamics models, in the data used to condition the operating model, and in the priors for the parameters of that model.

DISCUSSION

The approach taken here allows a forecast for an index of environmental variability to be incorporated into an operating model, which can be used to test management approaches given hypothesized interactions between the environment and population dynamics. These trials differ slightly from the standard set designed by the Standing Working Group of the AWMP during the original *Implementation* of the *Gray Whale SLA* (IWC, 2005a) in that they are conditioned on updated and newly available data, as well as a hypothesis regarding the effect of sea-ice on deviations in demographic rates. Hence, these analyses serve

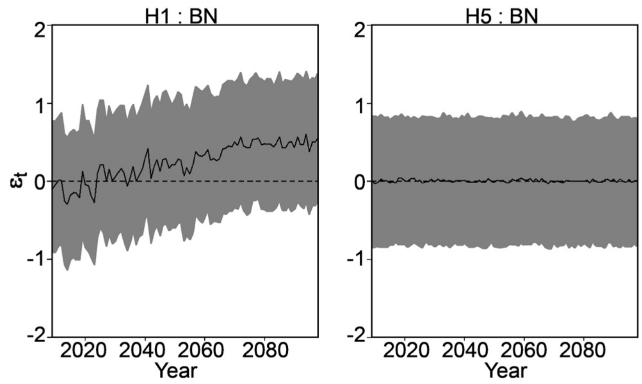

Fig. 4. The time-trajectories of future process error deviations for a case where these deviations are a function of future sea-ice (H1:BN; left panel) and where they are independent of the sea-ice index (H5: BN; right panel). The annual median is plotted as the solid line, the 90% probability interval envelope is shaded in gray, and the horizontal dashed line at zero is shown for reference.

to take account of new information that has become available since the original *Implementation*. The results provide evidence that the current state of nature is not outside the realm of plausibility envisioned during the simulation testing of the original *SLA*.

The magnitude of future additional mortality events was assigned in an *ad hoc* manner during the original *Implementation* of the *Gray Whale SLA*, i.e. future events were assumed to result in 20% declines in abundance (a likely large value, chosen to test the robustness of the *SLA*). In these analyses however, the operating model is conditioned in part on the strandings data, which allows the deviations in survival rates during the 1999/2000 mortality event and the resulting population size at the start of the future trajectories to be estimated directly. Likewise, the observed frequency and magnitude of those mortality events determined when conditioning are used to model the potential impact of future events. A set of several alternative trials was also preformed, to compare the results of the environmental forcing scenario to those for which future population dynamics were assumed to be deterministic, or to be subject to random environmental stochasticity (i.e. ignoring possible sea-ice impacts). For all of the scenarios considered here, the *Gray Whale SLA* was able to maintain stock size and satisfy need at higher levels. Therefore, there is no indication from these analyses that any revisions to the *SLA* are necessary.

While the *SLA* performed well under the scenarios considered in these analyses, there is still considerable uncertainty about how changes in sea-ice (or other environmental conditions) will affect future population dynamics. At present, the available information about the affects of environmental variability on cetacean population dynamics is largely correlative in nature, with the underlying mechanisms responsible for fluctuations in birth and survival rates not well understood. Although a plausible explanation has been hypothesised for ENP gray whales (i.e. that sea-ice may act as a physical barrier to prime feeding habitat), it is not straightforward to predict how other changes resulting from reductions in sea-ice will interact with the mechanisms that are currently influencing the dynamics of this population. Therefore, the conclusion that the *Gray Whale SLA* is robust to predicted changes in sea-ice should be tempered by uncertainty regarding the underlying assumption that current ecological processes will remain unchanged in the future, especially when so many other fundamental changes in ecosystems are expected as a result of climate change. Indeed, this one is one of the reasons *Implementation Reviews* are mandatory.

The assumption that the population dynamics were related to sea-ice led to more optimistic results. This was essentially the result of extrapolating (based on those years for which calf production and strandings data exist) a recent relationship between the environment and population dynamics into the future, under the assumption that such an effect (if it exists) would be invariant over time and independent of population density, among other factors. While more optimistic results would have been expected given the nature of the relationship between calf production and sea-ice cover, the magnitude of the effect could not be determined *a priori*. In addition, it was possible that the impact of trends in birth rate and survival could have 'confused' the *SLA* and led to poorer performance (e.g. the models underlying the *SLA*s could have concluded that the stock was depleted rather than close to carrying capacity) and reduced the strike limit.

The operating model used here could be modified to take into account alternative hypotheses with respect to predicted changes in the relationship between future environmental variability and population dynamics. For example, it would be relatively straightforward to model a change-point in the relationship between deviations in demographic rates and sea-ice, such that a loss of sea-ice might be beneficial up to some future time, after which the continued loss of sea-ice results in negative effects on population dynamics (e.g. by changing the sign of β after some future year). The operating model could then be used to test the performance of the *SLA* under such scenarios. A disadvantage of this approach would be that there are no data to determine the magnitude of negative effects, so any results would be speculative.

One of the appealing attributes of the framework for incorporating environmental data is its flexibility. As continuing research provides more insight into the mechanisms underlying the impacts of environmental variability on the population dynamics of ENP gray whales, the basic operating model used here can provide a basis for integrating this new information into assessments and evaluating alternative management approaches. For example, alternative environmental data (e.g. an index of El Niño/Southern Oscillation, a sea-ice index on the Chukchi Seas feeding grounds, or some weighted combination of different indices) could be substituted during the model fitting process to take alternative hypothesised relationships between environmental variability and population dynamics into account. Likewise, the framework could, with some modification, be applied to other populations of cetaceans for which environmental fluctuations are hypothesised to be an important determinant of population dynamics. Therefore, this framework should help to ensure that management strategies are robust to hypothesised impacts of future environmental variability on cetacean population dynamics.

ACKNOWLEDGEMENTS

Support for JB was provided by a grant from the IWC. Wayne Perryman (SWFSC), Cherry Allison (IWC), Muyin Wang (NOAA/PMEL) and Robert Brownell, Jr (SWFSC) kindly provided (respectively) unpublished estimates of calf production, the most recent catch history records, global climate model forecasts of sea-ice and the strandings data. Feedback from Sue Moore, Bill Koski, Doug Butterworth, and an anonymous reviewer improved an earlier version of this paper. Finally, we acknowledge the many people who have been responsible for collecting the data analysed here.

Brandon, J. R., Punt, A. E., Moreno, P. and Reeves, R. R. Toward a tier system approach for calculating limits on human-caused mortality of marine mammals. – ICES Journal of Marine Science, 74: 877–887.

Received 17 January 2016; revised 2 July 2016; accepted 7 July 2016; advance access publication 22 December 2016.

The Potential Biological Removal (PBR) management strategy is used for the assessment, relative to management objectives, of human-caused mortality of marine mammal stocks. PBR has been used to provide scientific advice on limits on human-caused mortality of marine mammals as well as other long-lived marine vertebrates worldwide. Current values for the parameters of this reference limit were obtained using a Management Strategy Evaluation (MSE) approach, where computer simulation is used to model a range of scenarios representing different scientific uncertainties. An assumption underlying the current management strategy, as originally evaluated, is that only the single most recent estimate of abundance is used to calculate PBR. We extend the original MSE and introduce a tiered hierarchy of data availability, from data-rich to data-poor. Alternative approaches for deriving values used to calculate PBR in each tier (e.g. incorporating multiple abundance estimates for data-rich stocks) are evaluated relative to the management objectives of the United States Marine Mammal Protection Act. A PBR tier system would allow the best available information to be used for each stock, recognizing the different types and levels of uncertainty that exist among stocks. It is shown that if the sex ratio of human caused mortality is not one, PBR may not perform as expected. Likewise, an alternative value for the N_{MIN} percentile could be adopted when survey estimates are imprecise and multiple abundance estimates are available. The standard approach, using only a single abundance estimate, is less flexible in this regard. Additionally, incorporating multiple abundance estimates for data-rich stocks can lead to increased stability of calculated values for PBR through time. Reduction in variability could reduce regulatory uncertainty that may be associated with some human activities managed according to PBR. Therefore, including multiple abundance estimates, when possible, into the calculation of PBR may prove desirable.

Keywords: marine mammals, management strategy evaluation, population dynamics, potential biological removal, tier system.

Introduction

Marine mammals are typically highly mobile and range over large areas. This can lead to estimates of abundance that are imprecise or incomplete, limiting the ability to detect trends and assess population characteristics relative to management reference points. The 1994 amendments to the US Marine Mammal Protection Act (MMPA, originally enacted in 1972) contain provisions intended to limit annual levels of human-caused mortality and serious injury experienced by stocks of marine mammals (note that hereafter human-caused "mortality" is understood to encompass both outright deaths and serious injuries). Although assessment reports for some US marine mammal stocks include information on and estimates of human-caused mortality from sources other than commercial fisheries (e.g. ship strikes, subsistence harvest), most of the information and estimates pertain to mortality in fisheries, which is the only sector for which PBR is applied in management.

Specifically, as part of the stock assessment framework, the MMPA prescribes that a "Potential Biological Removal" (PBR) limit to human-caused mortality be set for each stock. Further, the MMPA mandates that this limit be calculated using a harvest control rule (or in this context a removal control rule) that is the product of three values: (i) a minimum estimate of abundance that "provides reasonable assurance that the stock size is equal to or greater than the estimate"; (ii) one-half of the maximum intrinsic rate of population growth; and (iii) a recovery factor between 0.1 and 1.0. PBR can therefore be written as the equation:

$$\text{PBR} = N_{\text{MIN}} 0.50 R_{\text{MAX}} F_{\text{R}} \quad (1)$$

One of the primary management objectives of the MMPA is to allow stocks of marine mammals to be maintained at or above their "optimum sustainable population" (OSP) level (MMPA, 1972). OSP is defined by the US National Marine Fisheries Service (NMFS) as a level between the maximum net productivity level (MNPL) of the population and its carrying capacity (Wade, 1998; Taylor *et al.*, 2000). MNPL is the population level relative to carrying capacity that corresponds to the maximum net rate of population growth. MNPL is thought to occur between 50 and 85% of carrying capacity for marine mammals (e.g. Taylor and DeMaster, 1993).

The PBR approach to managing human-caused mortality has been shown through performance testing to be fit for its designed purpose. Alternative approaches for setting limits to human-caused mortality have been debated (e.g. IWC, 2003, 2005; Lonergan, 2011; Cooke *et al.*, 2012), and the PBR management scheme has limitations when stock-level abundance data are lacking (e.g. Robards *et al.*, 2009). Nevertheless, PBR is well established within the U.S. regulatory context where it has been applied for more than 20 years. Additionally, the basic principles of PBR have been used to provide scientific advice on limits of human-caused mortality of marine mammals as well as other long-lived marine vertebrates in other countries. For example, reference limits based on PBR have been considered for seals in Canada (e.g. Hammill and Stenson, 2007; Stenson *et al.*, 2012) and the United Kingdom (Butler *et al.*, 2008); pilot whales (*Globicephala macrorhynchus*) in Japan (Kanaji *et al.*, 2011); dugongs (*Dugong dugon*) in Torres Strait, between Australia and Papua New Guinea (Marsh *et al.*, 2004); and sea-birds (Dillingham and Fletcher, 2011), sea-lions (*Phocarctos hookeri;* Maunder *et al.*, 2000), and dolphins (*Cephalorhynchus hectori*) in New Zealand (Slooten and Dawson, 2008; Slooten, 2013). A generalization of the PBR framework has also been developed to estimate the combined direct and indirect effects of fishing on cetaceans in US waters (Moore, 2013). Among the features that make PBR appealing to managers is that it is easily understood, inherently precautionary, and simple to apply.

The amount of data (number, frequency, and precision of estimates of abundance) differs among marine mammal populations, making some species or populations "data-rich" while others can be considered "data-poor". However, the PBR formula as evaluated by Wade (1998) makes use of only the most recent estimate of abundance, irrespective of its precision or the number of estimates available. Stocks with different amounts of data are common in fisheries. One solution to this problem, apart from collecting more data for the data-poor stocks, which is often impractical or infeasible, is to develop tier systems of harvest control rules. Such tier systems assign species or populations to different tiers based on the availability and quality of data or on the quality of the assessments that use the data (Dichmont *et al.*, in press).

No formal tier system currently exists for marine mammal stocks in the United States. However, for stocks with multiple abundance estimates (e.g. the California/Oregon/Washington stocks of Dall's porpoise and Pacific white-sided dolphins; Carretta *et al.*, 2015), the US NMFS has provided guidelines for calculating N_{MIN} as an arithmetic average, within an eight-year window, weighted by the precision of each estimate (NMFS, 2005). Wade and DeMaster (1999) demonstrated that averaging abundance (and mortality) estimates using this method can lead to a lower rate of classifying human-caused mortality as greater than PBR when it is not (i.e. averaging can lower the rate of false positives—the rate of classifying situations as in need of management measures when such measures are not actually warranted). That analysis did not quantitatively explore how combining multiple estimates of abundance might affect the value used to calculate N_{MIN}.

Ultimately, a tier system approach would enable better use of all available data. We therefore investigate one alternative tier system that could help move toward this goal following an MSE approach. Various aspects of the PBR calculation could be considered for a tier system. We focus on the availability of abundance estimates and the calculation of N_{MIN} as a case study for how a tier system might be implemented. This article provides a comparison between the standard PBR approach (single estimate of abundance) and two alternative approaches for combining multiple abundance estimates, depending on data availability (e.g. survey frequency). As the amount of information available to calculate N_{MIN} increases, it might be expected that the precision of the minimum abundance estimate would increase as well. Additionally, we provide an evaluation of alternative approaches across multiple performance metrics, e.g. meeting the OSP management objective of the MMPA while simultaneously reducing temporal variability in PBR. This could make the overall management process more stable without compromising its conservation effectiveness.

Brief history of development and testing of PBR decision rules

Although the MMPA stipulates that PBR must be calculated as the product of three terms, it does not provide explicit values for those terms. Rules for setting the values have been established largely based on the results of a management strategy evaluation (MSE) conducted by Wade (1998), who expanded on a previous simulation study (Taylor, 1993). MSE is the use of simulation modelling to evaluate the performance of candidate management strategies, where a management strategy relates to specifications for the data to be collected and how those data are used in a feedback loop involving management actions (in the case of US marine mammal stocks, the PBR). MSE has been used extensively to evaluate the ability of potential management strategies related to commercial and aboriginal subsistence whaling to satisfy the management objectives of the International Whaling Commission (IWC) (Punt and Donovan, 2007). MSE involves several steps: (i) developing a model of the system, which represents the "truth" for the purposes of simulation (the "operating model"); (ii) specifying the range of uncertainties to be considered and thereby which "trials" will be undertaken; (iii) defining performance metrics that quantify the management objectives; (iv) selecting the candidate management strategies; (v) conducting projections of each management strategy for each operating model; and (vi) providing the results to decision makers (Punt *et al.*, in press). The trials conducted by Wade (1998) and here capture uncertainties about the "true" state of nature (e.g. uncertainties in the actual underlying abundance or human-caused mortality levels).

In common with many MSEs, Wade (1998) defined a set of "base case" trials, along with a set of robustness trials. Wade's (1998) base-case trials involved estimates of abundance that were unbiased, albeit with two different levels of precision, to find the percentile of the sampling distribution for the most recent abundance estimate (i.e. N_{MIN}) that results in meeting the OSP management objective of the MMPA when F_R is set equal to 1, i.e. after 100 years, 95% of the simulations lead to population sizes greater than MNPL (Figure 1). The assumptions of the "base case" trials include: R_{MAX} is 0.04 for cetaceans and 0.12 for pinnipeds; MNPL is 50% of carrying capacity (K); and the initial population size is 30% of K. Under those scenarios, the value of N_{MIN} is the lower 20th percentile of the sampling distribution for the most recent abundance estimate (Wade, 1998).

Wade (1998) then set N_{MIN} to the lower 20th percentile of the most recent abundance estimate and found the value of F_R that results in at least 95% of the simulations meeting the OSP objective for the remaining trials (Figure 1). The results of Wade's simulation testing form the basis for the parameter values currently used by the US NMFS to calculate PBR for stocks of marine mammals (NMFS, 2005).

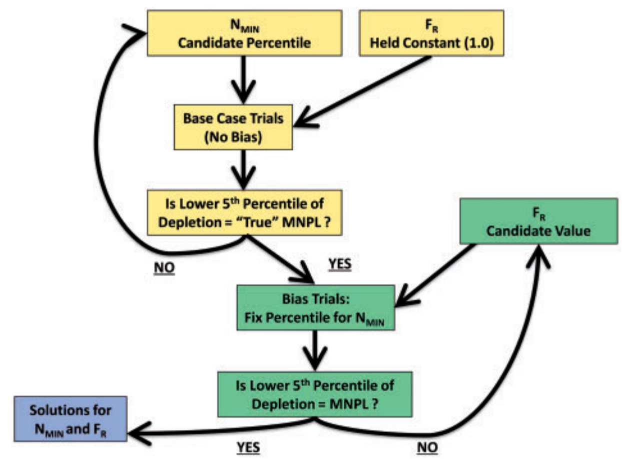

Figure 1. Flow diagram of Wade's (1998) procedure for solving for values of N_{MIN} and F_R that meet the OSP management objective of the MMPA.

Methods

The model for the underlying population dynamics and data generation for the simulations (i.e. the operating model) is provided in Appendix A (The Fortran code for the operating model and calculating PBR for the data tiers is free, open-source, and available from: https://github.com/John-Brandon/PBR-Tier-System. R code to analyse and visualize output is available in the same repository.). The operating model of the Appendix differs from that of previous simulation studies of PBR (Taylor, 1993; Wade, 1998; Wade and DeMaster, 1999), which were based on an age-aggregated population dynamics model. An age-structured model allows the performance of PBR to be evaluated over a wider range of uncertainties (e.g. different patterns of vulnerability to human-caused mortality across sexes and ages).

Parameterization and trials

Values for life history parameters were assumed to be: adult survival (S_{adult}) = 0.95; maximum birth rate (b_{max}) = 0.5; age at transition to adult survival (a_T) = age at first partuition (a_p) = the age from which life history parameters remain constant (age x) = 11 years (Appendix A). These values were chosen to approximate the life-history pattern of humpback whales *Megaptera novaeangliae* (e.g. Zerbini *et al.*, 2010). In order to make the results comparable with previous PBR simulation research, the trials were identical to those performed by Wade (1998) (Table 1).

Selectivity-at-age was assumed to be uniform across all ages and the sex ratio of human-caused mortality was assumed to be 50:50. The sensitivity of the results to the assumption of uniform selectivity-at-age was explored by running the base case trials (Table 1; $CV_N = 0.2$) with selectivity-at-age being knife edged on the plus group (age x); Appendix A). The age x-plus group corresponded with the reproductive component of the population, given the assumed life history. The relative vulnerability of females to males with respect to human-caused mortality was allowed to vary in sensitivity evaluations at the increments: 0.001, 0.01, 0.1, 0.5, 1, 2, 10, 100, and 1000. A value of 0.5 means that females are half as vulnerable to human-caused mortality as males, a value of 1 represents equal vulnerabilities of the sexes, and a value of 2 means that females are twice as vulnerable as males (Equation A.8). The sensitivity trials for relative vulnerability by sex were also run for the base case specifications with $CV_N = 0.2$ (Table 1). In common with previous evaluations of PBR, no attempt is made here to specify the source(s) of human-caused mortality. However, it is assumed that the mortality of interest can be constrained by management. Therefore, the evaluations in this article pertain most closely to the PBR approach as applied in the United States to marine mammal stocks subject to mortality in commercial fisheries.

A PBR tier system

Three alternative tiers for calculating PBR were investigated:

Tier 1: Using only the most recent estimate of abundance, and setting N_{MIN} to the 20th percentile of a log-normal distribution, following Wade (1998);

Tier 2: Using a weighted arithmetic mean and variance of available abundance estimates over the last eight years (NMFS, 2005). The weights (w_s) were equal to the inverse of the variances of the abundance estimates, such that:

$$\bar{N}' = \sum_s w_s \hat{N}_s; \quad w_s = \frac{1/\mathrm{var}\left(\hat{N}_s\right)}{\sum_s 1/\mathrm{var}\left(N_s\right)}; \qquad \mathrm{CV}(\bar{N}) = \frac{\sqrt{\sum_s w_s^2 var\left(\hat{N}_s\right)}}{\bar{N}} \tag{2}$$

where $\bar{N}'$ is the weighted arithmetic mean abundance, $\mathrm{CV}(\bar{N})$ is the coefficient of variation of the weighted arithmetic mean, and s denotes a survey year. The summations are taken over available survey estimates within the last 8 years, following the US.NMFS guidelines (NMFS, 2005).

Table 1. Trials considered in evaluating the performance of alternative approaches to incorporating abundance estimates in the calculation of PBR.

Trial	Description	R_{MAX}	CV_N	CV_M	Abundance Bias	Initial Depletion	Mortality ~ Normal (μ, σ^2)	Abundance survey interval (years)	θ
0A	Base Case	0.04	0.20	0.30	1	0.30	μ = PBR, σ = CV_M *PBR	4	1.0
0B		–	0.80	–	–	–	–	–	–
1A	Biased mortality	–	0.20	–	–	–	**μ = 2 * PBR**	–	–
1B		–	0.80	–	–	–	**μ = 2 * PBR**	–	–
2A	Biased abundance	–	0.20	–	**2.00**	–	–	–	–
2B		–	0.80	–	**2.00**	–	–	–	–
3A	Biased R_{MAX}	**0.02**	0.20	–	–	–	–	–	–
3B		**0.02**	0.80	–	–	–	–	–	–
4A	Bias in CV_N	–	**0.80**	–	–	–	–	–	–
4B		–	**1.60**	–	–	–	–	–	–
5A	Bias in CV_M	–	0.20	**1.20**	–	–	–	–	–
5B		–	0.80	**1.20**	–	–	–	–	–
6A	Survey every 8 years	–	0.20	–	–	–	–	**8**	–
6B		–	0.80	–	–	–	–	**8**	–
7A	MNPL = 0.45 * K	–	0.20	–	–	–	–	–	**0.53**
7B		–	0.80	–	–	–	–	–	**0.53**
8A	Biased mortality and MNPL = 0.70 * K	–	0.20	–	–	–	**μ = 2 * PBR**	–	**5.04**
8B		–	0.80	–	–	–	**μ = 2 * PBR**	–	**5.04**

These trials follow those considered by Wade (1998). The default R_{MAX} for cetaceans is shown. Dashes represent parameter values that are the same as those for the base-case scenario. Parameter values that differ from the base-case scenario are denoted in bold. CV_N and CV_M are the coefficients of variation about the estimates of abundance and mortality respectively. "~" denotes "distributed as", and θ is the shape parameter for density dependence (Equation A.5). A value of 1.0 under "Abundance Bias" means the abundance estimates are unbiased, whereas a value of 0.50 means that true abundance is one-half of the estimated value. All animals irrespective of age and sex are equally vulnerable to being killed.

Tier 3: A weighted average by time and precision. This approach has been investigated by the Scientific Committee of the IWC for calculating strike limits for aboriginal subsistence whaling (e.g. Brandão and Butterworth, 2014):

$$\bar{N}' = \exp\left[\sum_s \frac{\gamma^{t_s}\ln(N_s)}{CV_s^2} \left(\sum_s \frac{\gamma^{t_s}}{CV_s^2}\right)^{-1}\right]; \qquad CV(\bar{N}') = \sqrt{\sum_s \frac{\gamma^{2t_s}}{CV_s^2} \Big/ \sum_s \frac{\gamma^{t_s}}{CV_s^2}}; \tag{3}$$

where $\bar{N}'$ is the weighted average abundance by time and precision, $CV(\bar{N}')$ is the coefficient of variation of the weighted average by time and precision, and t_s is the number of years between year s and the year for which an estimate of abundance is needed. Abundance estimates were weighted by time through the γ parameter, which was set equal to 0.9 in this case. This value allows for the majority of the weight to be placed on the most recent estimates, while still allowing for some weight to be placed on older estimates as well.

The minimum abundance estimate for each approach was calculated following the assumption of log-normal sampling error:

$$N_{MIN} = \frac{N'}{\exp\left(z\sqrt{\ln\left(1 + CV(N')^2\right)}\right)}$$

where $\bar{N}'$ is either the most recent estimate of abundance $\hat{N}_t$, or the estimate of abundance resulting from one of the averaging approaches (N′ from Eqn 2 or 3), and z is a standard normal variate (e.g. $z = 0.842$ corresponds with the 20th percentile of the log-normally distributed abundance estimate).

Performance metrics

Two thousand simulations were run for each trial. Preliminary analyses indicated that this number of simulations was sufficient to achieve stable results. Two performance metrics were calculated for the MSE: (1) the fifth percentile across simulations of depletion (N_{1+}/K_{1+}) at the end of 100 years, and (2) variation in the calculated values for PBR through time. Variation in PBR was calculated as a performance metric because, all else being equal, lower variation in PBR should equate with a more robust management scheme, i.e. one that simultaneously reduces the probability of conservation risk (under-protection) and the economic loss to stakeholders through unnecessary regulation of human activities (over-protection). The value for PBR was updated after every new survey. The average inter-survey variation (AISV) statistic was used to measure the average absolute difference in PBR between surveys:

$$AISV = \sum_{ts=1}^{T} |PBR_{ts+1} - PBR_{ts}| \Big/ \sum_{ts=1}^{T} PBR_{ts} \tag{4}$$

where ts indexes each time the PBR is calculated and T is the final survey year in the simulated time series.

Depletion (the number of 1+ animals relative to carrying capacity) after 100 years was the main performance metric investigated by Wade (1998) and was used in this study to determine whether the OSP management objective of the MMPA had been met.

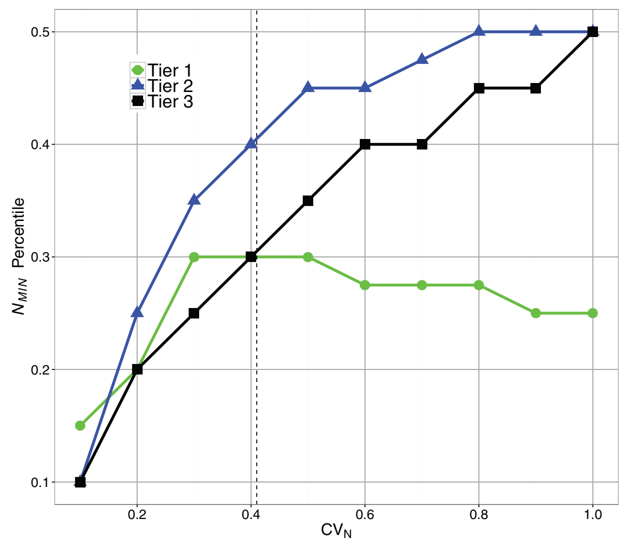

Figure 2. The percentile used to calculate N_{MIN} that meets the OSP management objective of the MMPA, given CV_N for each data availability tier and approach to calculating N_{MIN}. The dashed vertical line represents the median CV_N across stocks in the 2014 US assessment reports (http://www.nmfs.noaa.gov/pr/sars/region.htm).

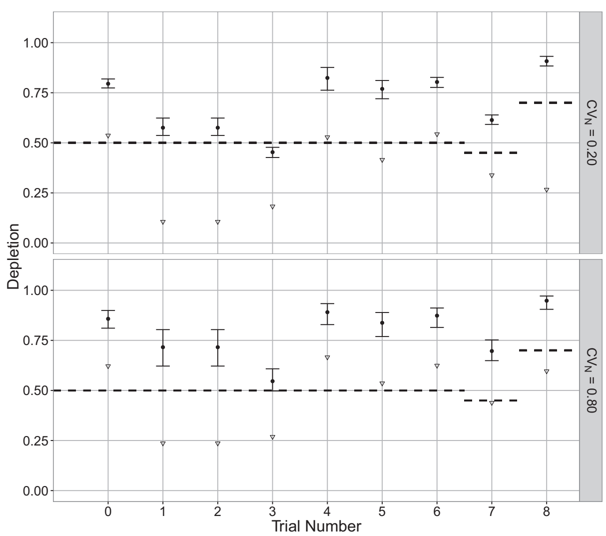

Figure 3. Final depletion when $F_R = 0.50$, and the Tier 3 approach is used to calculate the PBR. Median values are plotted as dots, and error bars represent the inner 90% of the simulations (i.e. the range between the 5th and 95th percentiles). The horizontal dashed lines represent MNPL for a given trial. Triangles show the fifth percentile for simulations when $F_R = 1.0$. The results for the other two approaches to calculating PBR follow the same pattern as shown here (albeit with the N_{MIN} percentile held constant at 0.25 for the Tier 2 approach).

Results

Specifying the value of N_{MIN}

The age-structured operating model was able to mimic the results of the age-aggregated model used by Wade (1998) given the assumption that all animals were equally vulnerable to human-caused mortality. For example, the 20th percentile of the abundance estimates used to calculate N_{MIN} resulted in the lower fifth percentile of simulations being at MNPL under the base case trial with $CV_N = 0.20$ (Figure 2). The NMFS (2005) approach for averaging abundance estimates (Tier 2) resulted in a slightly higher value (0.25) for the N_{MIN} percentile given the OSP management objective (Figure 2). The N_{MIN} percentile for the weighted by time and precision approach (Tier 3) was ~0.20, conditional on the assumption that CV_N for the abundance estimates was not any greater than 0.20 (Figure 2). When abundance estimates are relatively precise (e.g. $CV_N = 0.2$), the percentiles across data tiers are similar (0.2–0.25). As the uncertainty in abundance estimates (CV_N) increases, the percentiles between data tiers diverge. For the standard approach to calculating PBR (Tier 1), the percentile for N_{MIN} only varies between 0.2 and 0.3 (Figure 2). The approach using only the single most recent abundance estimate is hence less affected by the precision of the survey estimates than are the alternative approaches that incorporate more information.

The N_{MIN} percentile was held constant at 0.20 for the standard single abundance estimate and the weighted average approaches, and at 0.25 for the arithmetic averaging approach in subsequent analyses.

Selecting the value for F_R

Setting the N_{MIN} percentile equal to 0.20 (Tier 1 standard approach; Tier 3 weighted by time and precision) or 0.25 (Tier 2 arithmetic averaging approach), and running the remaining trials (Table 1), resulted in a value for $F_R = 0.50$ that met the management objective of depletion only to a level at or above MNPL after 100 years (Figure 3 shows the results for Tier 3). The one exception was trial 3, which involved a bias in R_{MAX} (i.e. true R_{MAX} was 0.02, but the default value of 0.04 was assumed when calculating PBR; in other words, population growth was overestimated). The results of this trial were less satisfactory than those reported by Wade (1998). Those results were based on the assumption that the true R_{MAX} for this trial was equal to the default value (e.g. 0.04), whereas the value assumed to calculate PBR was twice the true value (e.g. 0.08) (P. Wade, NMFS, *pers comm.*). The assumption made here is that the value used to calculate PBR is the default (e.g. 0.04), and the true value is one-half of that (e.g. 0.02). The difference between assumptions made by Wade (1998) and the assumptions made here regarding the true R_{MAX} values explains the discrepancy in the results for final depletion. This trial failed to meet the OSP management objective for the approaches to calculating PBR examined here (Supplementary Figures S.1 and S.2 show the results for Tier 1 and 2, respectively).

The fifth percentile of depletion for each trial was generally consistent between tiers when abundance estimates were relatively precise ($CV_N = 0.2$); however, when abundance estimates were less precise ($CV_N = 0.8$), the lower fifth percentiles of depletion were higher for those tiers that calculated PBR using multiple abundance estimates compared with Tier 1 (e.g. compare the lower panels of Supplementary Figure S.1 and S.2).

Variability in PBR

The AISV was noticeably lower for Tiers 2 and 3. Averaging across abundance estimates resulted in fewer years with more extreme values for PBR than the standard approach of using only

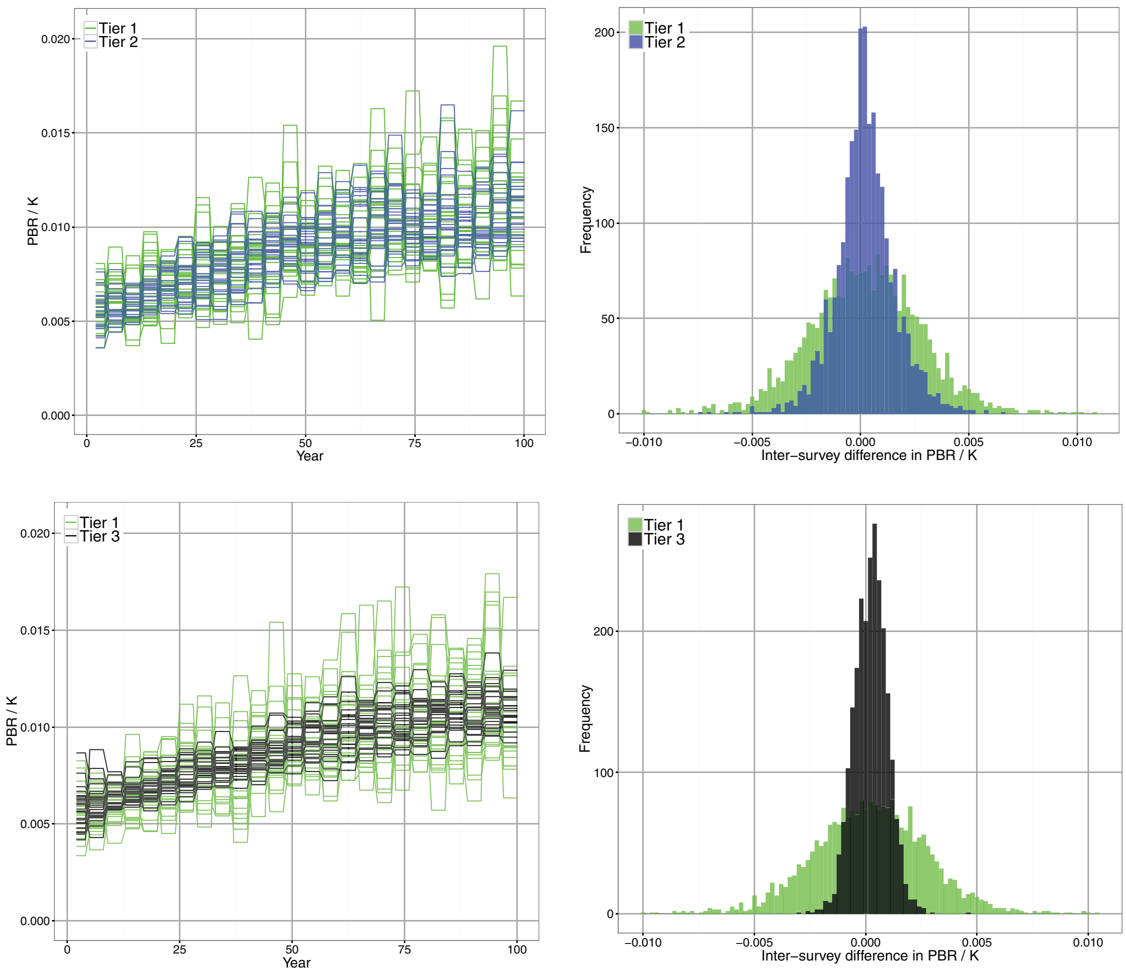

Figure 4. Time series of PBR values (relative to carrying capacity K) for the Tier 1 (Wade, 1998) and Tier 2 (NMFS, 2005) approaches (upper left panel). 30 randomly selected simulations are shown for each tier. The upper right panel shows the distributions of the AISV statistic (relative to carrying capacity *K*) for the Tier 1 approach and for the Tier 2 approach. The bottom two panels show the same comparisons between Tiers 1 and 3. Results are shown for the base-case trial where $CV_N = 0.2$.

Table 2. Results for the AISV in PBR are shown for the three approaches evaluated given a $CV_N = 0.2$ (results are shown for $CV_N = 0.8$ in parentheses).

BASE CASE: $N_{MIN} = 0.2$; $F_R = 1$			**BIAS TRIALS: N_{MIN} selected; $F_R = 0.5$**		
	Lower fifth percentile of of final depletion	**AISV**	**Lower percentile for N_{MIN}**	**MIN lower fifth percentile of final depletion**	**MAX AISV across trials**
Tier 1	0.5	0.22 (0.77)	0.2	0.43	0.76 (1.13)
			% Difference from Tier 1		
Tier 2	104	50 (54)	125	100	53 (57)
Tier 3	99	32 (29)	100	98	29 (31)

The percentage difference under Tiers 2 and 3 is equal to the value for those tiers divided by the value for Tier 1.

the most recent estimate of abundance (Figure 4). This result was consistent across all trials in Table 1. For the base case trial, Tier 2 resulted in an AISV that was roughly one-half (50% for $CV_N = 0.2$; 54% for $CV_N = 0.8$) of that for the Tier 1 approach. This variability was even further reduced under Tier 3; the AISV was roughly one-third of that for the Tier 1 approach (32% for $CV_N = 0.2$; 29% for $CV_N = 0.8$; Table 2).

For the robustness trials, the maximum AISV across trials was used for comparison. The trial with a survey interval of 8 years was excluded from this comparison because Tier 2 performs exactly as Tier 1 in this case, i.e. only one estimate of abundance is available within an 8-year window, and hence averaging is not an option. The Tier 2 and 3 approaches resulted in AISVs for the robustness trials, relative to those from Tier 1, which compared

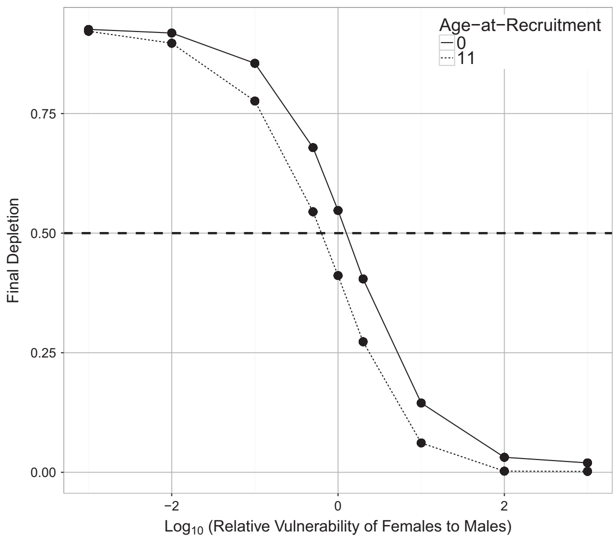

Figure 5. The fifth percentiles of final depletion (circles) as a function of the relative vulnerability of females to males for the Tier 1 base-case trial with $CV_N = 0.2$. The solid line represents a scenario where all animals are equally vulnerable. The relative vulnerability is plotted in Log_{10} space, i.e. a value of 0 represents equal vulnerability, a value of 1 represents a case where females are 10 times more vulnerable than males, etc. The dotted line represents a scenario where only the reproductively mature component of the population is subject to human-caused mortality. The dashed horizontal line represents the OSP management objective of the US MMPA.

favourably with the results of the base case trial. Tier 2 resulted in a maximum AISV across robustness trials that was roughly one-half (53% for $CV_N = 0.2$; 57% for $CV_N = 0.8$) of that from the Tier 1 approach. Again, this variability was even further reduced under Tier 3; the AISV was roughly one-third of that from the Tier 1 approach (29% for $CV_N = 0.2$; 31% for $CV_N = 0.8$; Table 2).

Reduction in temporal variability in PBR limits did not come at the expense of increasing the conservation risk, i.e. the lower fifth percentiles of final depletion were nearly equal across Tiers (Table 2). For example, for the base case trial, Tier 3 resulted in a fifth percentile for final depletion that was 99% of that from Tier 1 (0.495 vs. 0.5).

Selectivity-at-age and sex

The relative vulnerability of females, in contrast to the age at which animals become vulnerable to human-caused mortality, had a large effect on whether or not the PBR approach met the OSP management objective of the US MMPA. This pattern was similar across tiers (Figure 5 shows the base case for Tier 1). In general, the results were more optimistic with respect to meeting the OSP management objective when females were less vulnerable than males. In the case where females were twice as vulnerable to human-caused mortality as males, the fifth percentile of final depletion indicated that stocks would be depleted to below the OSP management objective after 100 years (Figure 5). This analysis also indicated that PBR might be overly conservative (i.e. overly risk-averse or precautionary) if human-caused mortality was predominately males.

Discussion

Data on population age structure and sex structure are important when providing management advice (Figure 5). If selectivity is skewed with respect to age or sex, our results indicate that the performance the PBR management approach (Wade, 1998) may over- or under-protect stocks, depending on the nature of the skew in selectivity. If human-caused mortality consists predominately of young animals and/or of males, PBR will likely be overly conservative. Conversely, PBR may not be sufficiently precautionary if human-caused mortality consists predominately of mature females (Figure 5) or if R_{MAX} is over-estimated (Figure 3).

Empirical estimates of R_{MAX} are generally limited to stocks that have been monitored during recovery from exploitation (e.g. Punt and Wade, 2012). The majority of stocks in the United States have been assigned default values for this parameter (0.04 for cetaceans, 0.12 for pinnipeds). If the default value for this parameter is not accurate, PBR may be biased and management objectives may not be met (Figure 3; Trial 3). Alternative methods for estimating R_{MAX}, based on allometric and life table models, have been developed for other marine vertebrates (e.g. Dillingham *et al.*, 2016), and could provide a complimentary approach to assigning values to this important parameter for marine mammals.

The implications of biased sex ratios have been recognized in the past. Consequently, e.g. IWC catch limits are reduced when females are more vulnerable to capture than males (IWC, 2012). Information on the age and sex structure of fishery bycatch should be collected, when possible, to investigate if selectivity is non-uniform. Quantitative approaches to adjusting F_R for such cases (e.g. when the sex ratio is not one) could be assessed through a future MSE.

The results of this study also highlight two effects that the incorporation of multiple estimates of abundance can have on the calculation of PBR. The first involves the value for the N_{MIN} percentile that meets the OSP management objective of the MMPA. If abundance estimates are relatively precise (e.g. $CV_N \leq 0.2$), the difference between N_{MIN} percentiles is small across the data tiers investigated here. Additionally, for the standard approach (Tier 1), the solution for the N_{MIN} percentile is relatively insensitive to the precision of the abundance estimate. Over a range of CVs from 0.2 to 1.0, the N_{MIN} percentile for Tier 1 only varies between 0.2 and 0.3 (Figure 2).

The value for the N_{MIN} percentile increases as the precision of the estimates of abundance decreases when multiple estimates are used to calculate PBR (Tiers 2 and 3). For these tiers, if the precision of the abundance estimates is low, the 20th percentile of the resulting confidence limit results in a value for PBR that is more conservative (i.e. lower) than would be necessary to meet the OSP management objective of the MMPA. The results from these simulations indicate that for $CV_N \geq 0.6$, the 40th percentile of the confidence limit for either Tier 2 or Tier 3 would be appropriate (Figure 2).

To understand how this difference influences the calculated value of PBR, consider a scenario where the survey interval is 4 years, estimates of abundance have a $CV_N = 0.6$, and the point estimates are assumed to be equal between the last two surveys. Under Tier 2 (NMFS, 2005), there would be a 38% increase in the calculated value of PBR if the 40th percentile of the confidence limit were used, relative to PBR based on the standard 20th percentile. For this hypothetical scenario, averaging two point estimates of 1500 individuals would result in a PBR of 13.0 (N_{MIN} = 40th percentile) vs. 9.4 (N_{MIN} = 20th percentile). The management implications for such differences are likely to be stock-specific, and may be limited to those stocks for which estimates of human-caused mortality are nearly equal to the calculated value of PBR based on the standard approach (Tier 1).

The second effect of incorporating multiple abundance estimates in the calculation of PBR is a reduction in the temporal variability of calculated PBR values. Including only a single estimate of abundance in the calculation of PBR results in variability at least two times greater than that resulting from the approaches where multiple estimates are averaged (Figure 4; Table 2). The reduction in variability from incorporating multiple abundance estimates does not come at the expense of increasing the conservation risk (Table 2). Given this risk equivalency, strategies that decrease the variability in the calculated value for PBR may be worth considering. For example, temporal variability in the calculated PBR value can cause economic uncertainty for commercial fisheries that have interactions with marine mammals. Incorporating multiple abundance estimates in the calculation of PBR could lessen unnecessary impacts on human activities while still meeting conservation objectives, e.g. the OSP management objective of the MMPA. Such an approach would be consistent with MMPA recommendations to consider economic factors in implementing regulations with respect to the taking of marine mammals (MMPA, 1972).

The PBR tier system evaluated here represents an extension of the current US management scheme. This tier system could be considered for calculating PBR under a management scheme that has the same objective as the US MMPA. Stocks could be assigned to a tier based on the number of available abundance estimates. Nevertheless, there are several assumptions that should be considered before any such tier system was put into practice, including (but not limited to): (i) The set of trials adequately spans the range of plausible uncertainties; (ii) The value used for R_{MAX} is not biased, and; (iii) Selectivity is not skewed disproportionally towards females. Additionally, different guidelines may be in effect in different jurisdictions (e.g. whether older abundance estimates age out of consideration, or not). Therefore, a tier system like this one may be appropriate in one instance but not another. Likewise, reference limits and management objectives in different jurisdictions are not always identical. Hence future MSEs in such cases would need to be adjusted accordingly.

Advancements have been made recently in analytical approaches to calculating abundance and trends for marine mammal populations using relatively long time series. For example, Moore and Barlow (2014) used hierarchical Bayesian modelling to estimate trends in abundance and N_{MIN} from six abundance estimates of eastern North Pacific sperm whales *Physeter macrocephalus* based on surveys during 1991–2008. Similar methods have been applied to fin whales *Balaenoptera physalus* and beaked whales (family Ziphiidae) (Moore and Barlow, 2011, 2013). A MSE incorporating more sophisticated model fitting of abundance data is outside the scope of this research, although in principle it would be possible. Additionally, future MSEs could investigate methods for incorporating trend estimates into the calculation of PBR. For example, quantitative approaches could be evaluated for calculating F_R as a function of the estimated rate of change in abundance and its standard error (perhaps contingent on the stock's status, e.g. listed as endangered, threatened, etc.). Methods to incorporate trend information have been evaluated by the IWC for aboriginal subsistence whaling strike limits (e.g. Brandão and Butterworth, 2014), and these could form the basis for evaluations of a PBR tier management scheme for stocks with multiple estimates of abundance.

Abundance estimates are imprecise for many stocks of marine mammals (e.g. Taylor *et al.*, 2007). The median CV estimates across stocks in the 2014 US marine mammal stock assessment reports was 0.41 (Carretta *et al.*, 2015). If survey estimates are imprecise, and a stock falls within either Tier 2 or Tier 3, an alternative value for the N_{MIN} percentile could be adopted from the results presented here (Figure 2). Incorporating multiple abundance estimates for data-rich stocks can lead to more stability through time for calculated values of PBR, while simultaneously meeting conservation objectives such as the OSP objective of the MMPA. Therefore, including multiple abundance estimates into the calculation of PBR, when possible, may prove desirable.

APPENDIX A

The operating model and data generation

The basic population dynamics were:

$$N^s_{t+1,a} = \begin{cases} 0.5b_{t+1}P_{t+1} & \text{if } a = 0 \\ (N^s_{t,a-1} - M^s_{t,a-1})S_{a-1} & \text{if } 1 \leq a < x \\ (N^s_{t,x} - M^s_{t,x})S_x + (N^s_{t,x-1} - M^s_{t,x-1})S_{x-1} & \text{if } a = x \end{cases} \quad \text{(A.1)}$$

where $N^s_{t,a}$ is the number of animals of age a and sex s (m/f), at the start of year t, b_t is the birth rate (the proportion of females that have reached parturition and given birth) in year t (Equation A.5), P_t is the number of females that have reached the age of first parturition (a_p) at the start of year t:

$$P_t = \sum_{a'=a_p}^{x} N^f_{t,a'} \quad \text{(A.2)}$$

S_a is the annual survival rate of animals of age a, determined by the age at transition to adult survival (a_T):

$$S_a = \begin{cases} S_{juv} & \text{if } a < a_T \\ S_{adult} & \text{if } a \geq a_T \end{cases} \quad \text{(A.3)}$$

$M^s_{t,a}$ is the human-caused (anthropogenic) mortality of animals of age a and sex s, during year t.

It was assumed that the values for the population dynamics parameters, including human-caused mortality rates, were the same from a certain age onwards (denoted as age "x"). Age x was assumed equal for males and females. Senescence in birth and mortality rates was not modelled. Males were assumed to be a non-limiting factor in reproduction.

Initial conditions

A numbers-per-recruit approach is taken to initialize the age-structure in the first year of the projections. This is represented by a stable age distribution, in year $t = 0$, given a fixed initial anthropogenic exploitation rate denoted E:

$$\tilde{N}^s_a = \begin{cases} 0.5 & \text{if } a = 0 \\ [\tilde{N}^s_{a-1}(E)]S_{a-1}(1 - V^s_{a-1}E) & \text{if } 1 \leq a < x \\ [\tilde{N}^s_{x-1}(E)]S_{x-1}(1 - V^s_{x-1}E)/ & \\ \quad [1 - S_x(1 - V^s_x E)] & \text{if } a = x \end{cases} \quad \text{(A.4)}$$

where E is the anthropogenic exploitation rate prior to implementation of the PBR management strategy, V^s_a is the relative vulnerability of animals of age a and sex s to anthropogenic mortality (assumed for most analyses to be 1 for all ages and both sexes), $\tilde{N}^s_a(E)$ is the number of animals of age a and sex s, as a function of a fixed anthropogenic exploitation rate (E). The subscript for time t is dropped in Equation (A.4) for clarity. The value for E that resulted in a given depletion level with a stable age structure is solved for using Brent's method (Brent, 1973; Press *et al.*, 1992). The numbers per female recruit were rescaled so that abundance at the start of the first year corresponded to the initial depletion level in terms of the age 1+ component (ages one year and older).

Intrinsic rate of population growth (R_{MAX})

The intrinsic rate of population growth, or maximum net recruitment rate, for an age-structured population dynamics model can be solved for from the characteristic equation of the projection matrix (e.g. Punt, 1999; Caswell, 2001). The projection matrix corresponds to Eqn A.1, where maximum fecundity (female calves per female) is substituted for the birth rate (i.e. maximum fecundity $= 0.5b_{max}$, assuming a 50:50 sex ratio at birth). b_{max} is the maximum birth rate, which corresponds with R_{MAX}, i.e. the birth rate in the absence of any density dependence.

The base-case R_{MAX} is set to 0.04 for cetaceans to make the results comparable to those of Wade (1998). This is implemented by solving for the juvenile survival rate S_{juv} that resulted in a projection matrix with a dominant real eigenvalue $\lambda_{MAX} = R_{MAX} + 1$. λ_{MAX} was calculated numerically using the Fortran 90 LAPACK (Linear Algebra PACKage) libraries (Available from: www.netlib.org.) (Anderson *et al.*, 1999). Brent's method (Brent, 1973; Press *et al.*, 1992) was used to solve for the juvenile survival rate S_{juv} that resulted in the target value for R_{MAX}.

Density dependence

Density dependence was assumed to act through the birth rate, according to the Pella-Tomlinson model:

$$b_t = \max\{0, b_{eq} + (b_{max} - b_{eq})[1 - (N_{t,1+}/K_{1+})^\theta]\} \quad \text{(A.5)}$$

where θ is the shape parameter, assumed for the base-case trials to equal 1.0 (or MNPL of ~50% of K_{1+}, the carrying capacity in terms of the component of the stock that is age 1 year and older). Likewise $N_{t,1+} = \sum_{s'}\sum_{a'=1}^{x} N^{s'}_{t,a'}$.

For an age-structured model, if the carrying capacity is modelled in terms of the total population (including calves), the resulting system of equations becomes essentially intractable. Hence, carrying capacity is modelled in terms of age 1+ abundance.

The equilibrium birth rate b_{eq}(i.e. the birth rate at carrying capacity in the absence of anthropogenic mortality) is given by:

$$b_{eq} = \left(\sum_{a'=a_p}^{x} \tilde{N}^f_{a'}(E = 0)\right)^{-1} \quad \text{(A.6)}$$

Data generation

The sampling error about the survey estimates was assumed to be log-normal.

$$\hat{N}_t = \beta \exp\left[\ln\left(\frac{N_t}{\sqrt{1+CV_N^2}}\right) + x\sqrt{\ln\left(1+CV_N^2\right)}\right] \quad (A.7)$$

where N_t is the true underlying abundance, and β is the extent of bias in the abundance estimate. If the abundance estimates are unbiased then $\beta = 1.0$. Values of $\beta > 1.0$ represent abundance estimates that are positively biased (i.e., surveys over-estimate true abundance on average). CV_N is the coefficient of variation about the true abundance, and, x is a standard normal random variate (mean = 0, variance = 1).

The total human-caused mortality each year is: $M_t = \sum_{s'} \sum_{a'=0}^{x} M_{t,a'}^{s'}$ where

$$M_{t,a}^{s} = M_t \delta^s V_a^s N_{t,a}^s / \sum_{s'} \sum_{a'=0}^{x} \delta^{s'} V_{a'}^{s'} N_{t,a'}^{s'} \quad (A.8)$$

where δ^{female} is the relative vulnerability of females relative to males, given $\delta^{male} = 1$. M_t was assumed to be normally distributed, with an expectation equal to PBR, and a pre-specified coefficient of variation CV_M (base-case value 0.3). M_t was set to zero if the generated human-caused mortality was less than zero. These assumptions about the estimated human-caused mortality were made to be consistent with the approach taken by Wade (1998).

Additional *SLA* variants to further evaluate the proposed Makah hunt

John R. Brandon* and Jonathan Scordino#
Contact email: jonathan.scordino@makah.com

ABSTRACT
At the 2012 Annual Scientific Committee meeting, the Implementation Review for eastern North Pacific gray whales with a focus on the proposed Makah hunt and the Pacific Coast Feeding Group (PCFG) was completed. Two variants of the proposed hunt (one with research provisions) were agreed by the Committee to meet the conservation objectives of the Commission. However, the Committee also noted that neither of these variants exactly mimicked the proposed hunt and expressed concern that the actual conservation outcome of the proposed hunt had not been tested. The reason that an exact variant was not tested was because there is a temporal rule in the proposed hunt, such that all struck and lost whales from December through April are not counted against the Allowable PCFG Limit (APL), whereas any struck and lost whales in May are counted against the APL. There are insufficient data however, to determine the proportion of strikes that would occur in May or prior to May, and hence the two variants of the hunt were developed to bracket the range of possible strikes by month. Following the Committee's request for an exact evaluation of the proposed hunt management plan, six additional variants were identified intersessionally. In combination, these eight variants span the full range of possible strikes that could occur in May or prior to May, and hence provide a means of more precise evaluation. A broad comparison is provided here of this set of variants across all evaluation and robustness trials, and more detailed results are presented for trials identified as of interest during the Implementation Review. Perhaps not surprisingly, the conservation performance of the six additional variants is found to be in-between the two previously evaluated variants. The central questions remaining for management advice would then seem to pertain to whether the photo-ID research provision might be required for any (or all) of the additional variants presented here, and moreover, whether the research provision should apply to the proposed hunt management plan as a whole.

KEYWORDS: ABORIGINAL WHALING; MANAGEMENT PROCEDURE; NORTH PACIFIC; GRAY WHALES

INTRODUCTION

During the 2012 Scientific Committee meeting, the Implementation Review for eastern North Pacific gray whales was completed (IWC/64/Rep1 Annex E). The focus of that Implementation Review was on the proposed Makah hunt and the Pacific Coast Feeding Group (PCFG) of gray whales. Several variants of the proposed Makah hunt were examined (see SC/64/Rep3 Annex D), and the Scientific Committee agreed that two of these variants (one with research provisions – see below) performed acceptably in terms of meeting the aboriginal subsistence and conservation objectives of the Commission.

However, the Scientific Committee also noted that these two variants did not exactly mimic the proposed Makah hunt, and agreed that the Standing Working Group of the AWMP should develop and test an exact variant intersessionally, in order for the Scientific Committee to evaluate the results at this year's meeting.

During the AWMP intersessional meeting, the Standing Working Group reviewed a set of six

* *Greeneridge Sciences, Inc., San Francisco, California, USA*
# *Makah Fisheries Management, Makah Tribe, Neah Bay, Washington, USA*

additional variants suggested by Brandon and Scordino (2012), and agreed these were appropriate and sufficient to achieve the Scientific Committee's goal (SC/65a/Rep02).

Background and rationale for why a set of variants (rather than a single management variant) has been suggested in order to satisfy the Scientific Committee's request is outlined below. As described in the Scientific Committee's report (IWC/64/Rep1):

> *"In order to minimise the risk of taking PCFG whales, the management plan developed by the Makah Tribe restricts the hunt both temporally (to the migratory season for gray whales i.e. 1 December – 31 May) and geographically (to the Pacific Ocean region i.e. the Makah U&A[1] except the Strait of Juan de Fuca). Some PCFG whales are present during the migratory season and thus the plan proposes an allowable PCFG limit (APL) during hunts that are targeting eastern North Pacific migrating whales with the aim of ensuring that accidental takes of PCFG whales do not deplete the PCFG. Whales struck in May might have a higher probability of being PCFG whales since they feed in this area in June. The management plan thus proposes an additional requirement that all animals struck-and lost in May are assumed to be PCFG whales (i.e. count against the APL), whereas whales struck between December and April are not.*
>
> *Weather conditions and availability of whales makes it likely that most hunting will occur in May. However, there are insufficient data to assess the number of strikes by month. Thus, it is not possible to reliably estimate the proportion of struck-and-lost whales that would count towards the APL. Given this uncertainty about how the plan would respond to failing to take into account struck-and-lost PCFG whales, the Tribe had proposed two SLA variants (1 and 2) spanning the options as to when the hunt might occur.*
>
> *SLA variant 1 proposes that struck-and-lost whales do not count towards the APL i.e., there is no management response to PCFG whales struck but not landed. SLA variant 2 proposes that all struck-and-lost whales count to the APL irrespective of hunting month. i.e., the number of whales counted towards the APL may exceed the actual number of PCFG whales struck."*

Hence, the two agreed acceptable *SLA* variants (1 and 2) differ in their categorical assignment of struck and lost whales to the APL, and therefore each variant corresponds to the hunt taking place during two different time periods.

Variant 1 was agreed to have performed acceptably for all trials deemed most plausible[2] during the Implementation Review, except that is, for two related trials where it was deemed to have marginal performance. Those two trials in question assume that the PCFG $MSYR_{1+}$ = 2% and further that the probability of striking a PCFG whale is double the observed proportion of PCFG whales in the available photo-identification studies during the proposed hunting season. Because the ratio of PCFG whales to migratory whales can be monitored through photo-identification studies during the proposed hunting season, variant 1 was agreed to meet the Commission's conservation objectives under the provision that annual photo-identification research be undertaken and results reported to the Scientific Committee for evaluation. Given the assumption that no struck and lost whales belong to the PCFG, variant 1 corresponds to the proposed hunt occurring entirely during Dec – Apr.

---

[1] Usual and accustomed fishing grounds

[2] Generally, the most challenging trials were agreed by the Committee to have low plausibility (*e.g.,* see the discussion regarding MSYR = 1% being at the lower bound of plausibility in IWC/64/Rep1 Annex E), and hence if a variant did not meet conservation criteria for those challenging lower plausibility trials, it was not judged that the variant performed unacceptably.

Variant 2, on the other hand, assumes all struck and lost whales belong to the PCFG, and as such counts all struck and lost whales against the APL. This variant performed acceptably for all trials deemed most plausible by the Scientific Committee (*i.e.*, it was agreed acceptable with no such research provision). Under the proposed hunting rules outlined above, variant 2 corresponds to hunting during May only.

Essentially then, the aspect of the proposed hunt that was not evaluated during the Implementation Review is the interaction between the actual number of strikes-per-month over the entire hunting season (Dec – May) and the time-varying assumption of whether a struck and lost whale belongs to the PCFG (*i.e.*, counts against the APL).

At present, there is no reliable way to predict the exact number (or model the probability) of strikes that may occur during a given month. However, one strategy to address this challenge is to evaluate a variant for each possible outcome of the number of strikes by month. To simplify this approach, months can be divided into two categories (May, or prior to May), given the assumption of whether or not struck and lost whales are counted against the APL during those time periods. This leads to the six additional variants suggested by Brandon and Scordino (2012). Variants 1 (all strikes prior to May) and 2 (all strikes in May) are logical bounds on the range of possible strikes by time period. Following the recommendation of the Scientific Committee, a comparison of the results of all eight variants (including *SLA* variants 1 and 2) is presented here to further evaluate the proposed Makah hunt management plan.

METHODS

The additional variants are labeled alphabetically (A-F) to avoid confusion with previously evaluated variants that were assigned numbers during the 2012 Implementation Review. The full range of variants considered in these analyses, including variants 1 and 2, is shown in Table 1. Note that the maximum strike limit per year in the proposed Makah hunt management plan is seven (SC/64/Rep3).

Table 1

Variant *SLAs* covering the range of possible strikes by time period (prior to May or during May), given the categorical assignment of struck and lost whales to the APL in the proposed Makah hunt management plan. Accordingly, the proposed management plan assumes that all whales struck and lost prior to May are migrants belonging to the greater northern feeding group, whereas it assumes that all whales struck and lost in May belong to the PCFG.

Variant	Description
1.	All strikes prior to May.
A.	Allow up to six strikes prior to May.
B.	“ ” five strikes prior to May.
C.	“ ” four strikes prior to May.
D.	“ ” three strikes prior to May.
E.	“ ” two strikes prior to May.
F.	“ ” one strike prior to May.
2.	All strikes in May.

Allocation of strikes by month

Variants D – F are outlined below as examples illustrating how the set of additional variants is modeled. Note that there are additional rules in the proposed management plan that could preclude hunting, even if the APL for a given year has not been reached (*i.e.*, the limit of 20 whales landed per five year quota, the maximum of five whales landed in any calendar year, and the maximum of three struck and lost whales in any calendar year; SC/64/Rep3). For the purposes of these illustrative examples, those additional rules are not included in the outline below but they are nevertheless an active component of the simulated hunt (exactly as they were during the Implementation Review).

Variant D: Allow up to 3 strikes prior to May, remaining (max of 4) strikes in May
1. Compute the APL.
2. If hunting is allowed under the APL, the first strike of the season occurs prior to May.
3. If the first whale is struck and lost, it does not count against the APL.
4. If a second strike is allowed under the APL, the second strike occurs prior to May.
5. If the second whale is struck and lost, it does not count against the APL.
6. If a third strike is allowed under the APL, the third strike occurs prior to May.
7. If the third whale is struck and lost, it does not count against the APL.
8. If subsequent strikes are allowed under the APL, they occur in May. If any of these are struck and lost, they are assumed to be PCFG whales and those strikes apply to the APL.

Variant E: Allow up to 2 strikes prior to May, remaining (max of 5) strikes in May
1. Compute the APL.
2. If hunting is allowed under the APL, the first strike of the season occurs prior to May.
3. If the first whale is struck and lost, it does not count against the APL.
4. If a subsequent strike is allowed under the APL, the second strike occurs prior to May.
5. If the second whale is struck and lost, it does not count against the APL.
6. If subsequent strikes are allowed under the APL, they occur in May. If any of these are struck and lost, they are assumed to be PCFG whales and those strikes apply to the APL.

Variant F: Allow up to 1 strike prior to May, remaining (max of 6) strikes in May
1. Compute the APL.
2. If hunting is allowed under the APL, the first strike of the season occurs prior to May.
3. If the whale is struck and lost, it does not count against the APL.
4. If any subsequent strikes are allowed under the APL, they occur in May. If any of these are struck and lost, they are assumed to be PCFG whales and those strikes apply to the APL.

Variants A-C proceed accordingly, and all other parameters of the operating model and trials are identical to those used during the Implementation Review (SC/64/Rep3 Annex F).

Further, as recommended by the Standing Working Group (SC/65a/Rep02), all of the additional variants were run across all of the evaluation and robustness trials examined during the 2012 Implementation Review, and the results compared with *SLA* variants 1 and 2.

RESULTS

Figure 1 shows the lower 5^{th} percentile (5%ile) of (a) final PCFG (age 1+) depletion, and; (b) rescaled (age 1+) PCFG depletion for all evaluation and robustness trials given the range of possible maximum strikes prior to May (including *SLAs* 1 and 2 for comparison).

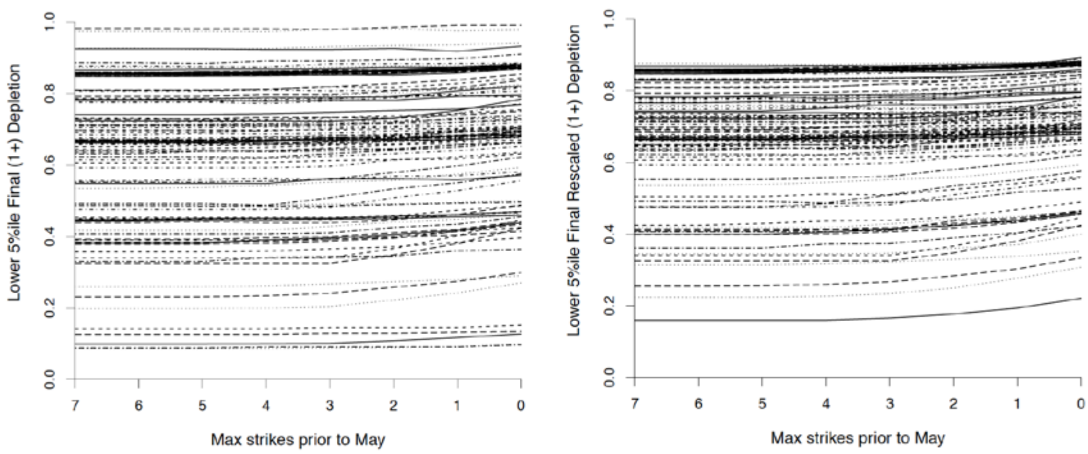

Fig. 1. The lower 5th percentile (5%ile) of PCFG final depletion (left panel) and rescaled (1+) depletion (right panel) are shown as a function of the maximum number of strikes prior to May for all evaluation and robustness trials. The lines connect the results for a single trial across variants. *SLA* variant 1 corresponds to all (maximum of seven) strikes prior May, *SLA* variant 2 corresponds to zero strikes prior to May (*i.e.*, all strikes occur in May), and variants A-F correspond with the intermediate number of (maximum) strikes prior to May (Table 1).

There are several note-worthy patterns that emerge from these results across all trials: (1) the additional variants (A-F) have intermediate conservation performance between *SLAs* 1 and 2; (2) any trend that exists in conservation performance between variants for a given trial is best described as a monotonically increasing function of the number of strikes that occur during May (*i.e.*, there is no pattern of convexity or concavity in conservation performance across variants), and; (3) there appears to be a saturation point (dependent on the trial), after which the number of allowable strikes prior to May does not lead to a decrease in conservation performance.

We did also investigate the output for the other conservation statistics of interest for all trials (e.g. minimum number of mature females) and found the same patterns hold true as shown in Fig. 1. Due to considerations of space, we have not presented results for every performance statistic for each trial across all variants, but these have been provided to the Secretariat and are on file for reference.

Given the fundamental result that variants A-F are intermediate in conservation performance across all evaluation and robustness trials, only the subset of trials identified as having questionable conservation performance during the 2012 Implementation Review is considered further here. The lower 5th percentile and median of the final and rescaled final depletion statistics are shown in Table 2 for those trials.

In the more detailed presentation of results across variants provided in Table 2, variants A through F can again be seen to result in conservation performance that is in-between variants 1 and 2 (excepting the rare cases of apparent monte-carlo sampling error in the third decimal). Likewise, as the number of strikes prior to May decreases, conservation performance can also be seen to increase.

Of the set of trials in Table 2, GB10B and GP10B are of particular interest because the conservation performance of *SLA* 1 was found to have been marginal for these two trials during the Implementation Review. The Zeh plots for these two trials are provided in Fig. 2 across all eight variants. These plots display the trade-off between conservation performance and need satisfaction across the range of possible strikes by month.

Table 2

Final and rescaled final depletion statistics for the eight *SLA* variants for the trials with $MSYR_{1+}$=1% and the trials with $MSYR_{1+}$=2% for which conservation performance might be considered to be questionable given the results of the 2012 Implementation Review.

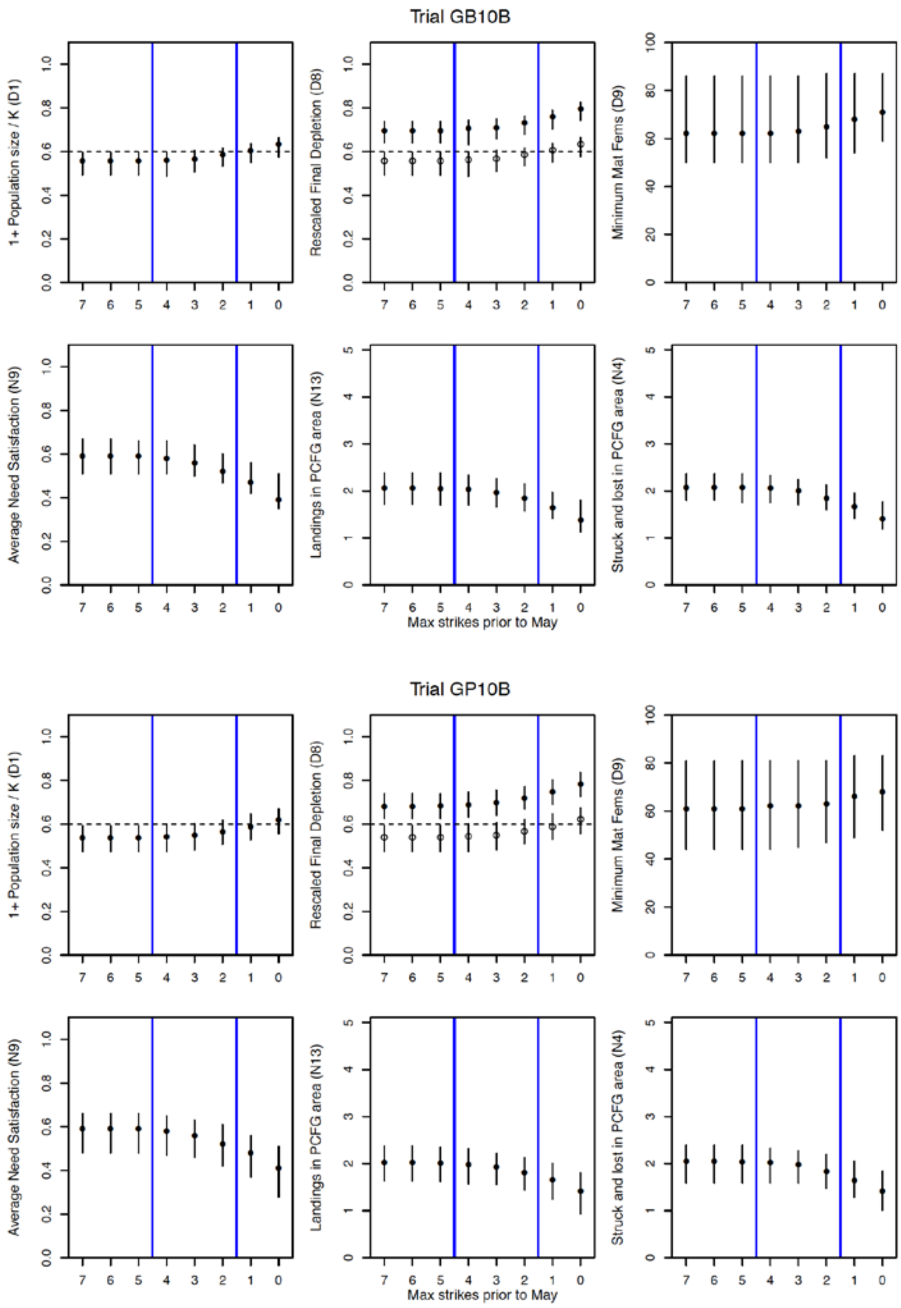

Fig. 2. Zeh plots for the two trials (GB10B upper panel, and GP10B lower panel) that assume that PCFG $MSYR_{1+}$ = 2% and that the probability of striking a PCFG whale is double the proportion of PCFG whales observed in the photo-ID data during the proposed hunting season. The conservation performance for variant 1 (all strikes prior to May) was found to be marginal for these trials during the Implementation Review. The maximum number of strikes that could occur prior to May for each variant is indicated along the x-axis, and the depletion plots (upper left two panels for each trial) are shown with a dashed horizontal line at 0.60 for reference.

DISCUSSION

The result that variants A - F achieve conservation performance that is intermediate between variants 1 and 2 is perhaps not surprising, given the original design that variants 1 and 2 should bracket the expected performance of the proposed Makah whaling management plan.

Variant 1 is less conservative with respect to the resource than variant 2 because it does not make the assumption that struck and lost whales belong to the PCFG. In other words, if a struck and lost whale is indeed a PCFG whale, variant 1 does not count this strike against the APL, and it is therefore possible under variant 1 to strike more PCFG whales before the hunt would be stopped (*e.g.*, because the APL was reached) than it is under variant 2.

Mechanically, variants A-F are bounded by variants 1 and 2 in terms of conservation performance because the percentage of strikes assumed to be PCFG can not be less than none (variant 1) or greater than all (variant 2). This logically leads to a transitive relationship of inequality with respect to conservation performance under the APL. In other words, variants A-F can only perform equal to or greater than variant 1 (and no better than variant 2). This relationship is evident in Figs. 1 and 2, and Table 2.

Given the relationship across these variants (*i.e.*, the number of strikes allotted by monthly time period), if variant 1 performed acceptably for a certain trial during the Implementation Review, then variants A-F (and variant 2) would be expected to perform acceptably for that trial as well. Hence, we propose that it is redundant to re-visit in detail the results of variants A-F for any trials except those for which variant 1 was deemed to have performed unacceptably.

The trials in Table 2 were identified during the Implementation Review as those for which either variants 1 or 2 had questionable performance. However, of those trials, only the results from GB10B and GP10B were considered further. The associated marginal conservation performance of variant 1 for GB10B and GP10B lead to the recommended research provision to hedge against the risk identified in those two trials. The other trials in Table 2 were deemed to have low plausibility.

Given the recommendations from the 2012 Implementation Review with respect to the two extremes of when strikes might occur (variants 1 and 2) -- and the results of the additional variants presented here which provide a finer resolution on this issue -- it seems that the central questions remaining for management advice pertain to whether the photo-ID research provision might be required for any (or all) of the additional variants (A-F), and moreover whether the research provision should apply for the proposed hunt management plan as a whole.

ACKNOWLEDGEMENTS
Dr. Punt kindly coded, ran and provided output for the additional variants; No small task, for most anyone else at least. We extend our thanks.

ABSTRACT

The distribution and abundance of harbor seals (*Phoca vitulina richardii*) in Oregon were monitored from 1977 to 2003 by aerial photographic surveys. Harbor seals on shore were counted each year during the reproductive period. Mean annual counts of non-pups (adults and subadults) were used as an index of population size and the trend in the counts was modeled using exponential (density-independent) and generalized logistic (density-dependent) growth models. Models were fit using maximum likelihood and evaluated using Akaike's Information Criterion. The population dynamics of harbor seals in Oregon were best described by the generalized logistic model. The population grew following protection under the Marine Mammal Protection Act of 1972 until stabilizing in the early 1990s. The estimated absolute abundance of harbor seals (all age classes) during the 2002 reproductive period was 10,087 individuals (95% confidence interval was 8,445–12,046 individuals). The current predicted population size for harbor seals in Oregon is above its estimated maximum net productivity level and hence within its optimum sustainable population range. We speculate that recent increases in ocean productivity in the eastern Pacific Ocean may lead to an increase in carrying capacity and renewed growth in Oregon's harbor seal population.

Key words: harbor seal, *Phoca vitulina*, Oregon, generalized logistic, optimum sustainable population, maximum net productivity level, carrying capacity, trend, status.

Trends in the abundance of Pacific harbor seals (*Phoca vitulina richardii*) along much of the west coast of North America suggest that harbor seal numbers may be approaching, or may have reached, current carrying capacity. Research suggesting that harbor seals populations have undergone density-dependent growth includes work from southern (Stewart and Yochem 1994) and central (Sydeman and Allen 1999) California, coastal and inland Washington (Jeffries *et al.* 2003), and British Columbia (Olesiuk 1999). However, in Alaska trends have been more varied; evidence there suggests that while some populations have increased or stabilized (Small *et al.* 2003), others may have declined (Pitcher 1990, Frost *et al.* 1999).

In Oregon, harbor seals are currently the most abundant and ubiquitous pinniped species found in coastal marine and estuarine waters. They can be found year-round on nearshore reefs and islands, along shore, and on tidally exposed sand and mud flats in most estuaries. Throughout the early 1900s harbor seals were viewed as significant predators of marine fishery resources and were subject to indiscriminate killing through state-funded bounty programs. No estimates of abundance are available for this period. By the late 1960s, Pearson and Verts (1970) estimated that fewer than 500 seals existed in Oregon's coastal waters and perhaps less than 100 in the Columbia River. Although it is not clear if they visited many of the areas where harbor seals are found today, they did note that seals only "occasionally entered estuaries for short periods."

Shortly after implementation of the Marine Mammal Protection Act (MMPA; 16 U.S.C. 1361) in 1972, harbor seals began to occupy many of Oregon's estuaries and the population size appeared to increase. This was most likely in response to the protection provided under the federal law (cessation of hunting and harassment), as well as increased pup survival and access to prey in newly available estuarine habitat. Harvey *et al.* (1990) first reported this increased use of estuaries concurrent with an increase in seal numbers. They found that harbor seal counts at 14 major trend sites statewide increased at an average annual rate of 8.1%, and the proportion of seals found in estuaries increased from 47% of the total count in 1975 to 61% in 1983.

The recovery of a depressed population such as harbor seals in Oregon could be considered a primary objective of the MMPA since it was intended that marine mammal populations should reach and be maintained within their optimum sustainable population (OSP) range. As defined, OSP is the range of population sizes between the maximum net productivity level (MNPL) and the carrying capacity of the species' environment (Federal Register, 21 December 1976, 41FR55536).

This paper presents an analysis of aerial survey counts of harbor seals in Oregon from 1977–2003. Our objectives were to: (1) model the trend in harbor seal survey counts; (2) determine whether or not seals in Oregon were within their OSP range; and (3) estimate the absolute size of the current population.

Methods

Aerial Surveys

We conducted annual aerial surveys along the Oregon coast during the mid-May to mid-June reproductive period. The coast was divided into two survey regions (Fig. 1), each of which could be flown during a 4-h survey. Haul-outs south of Hunters Island (42.31°N) were not included in the trend analysis because surveys did not occur there until 1984. We attempted to count each haul-out at least two times per year (*i.e.,* two replicates per region per year). The first and second survey windows typically occurred in late May and early June, respectively.

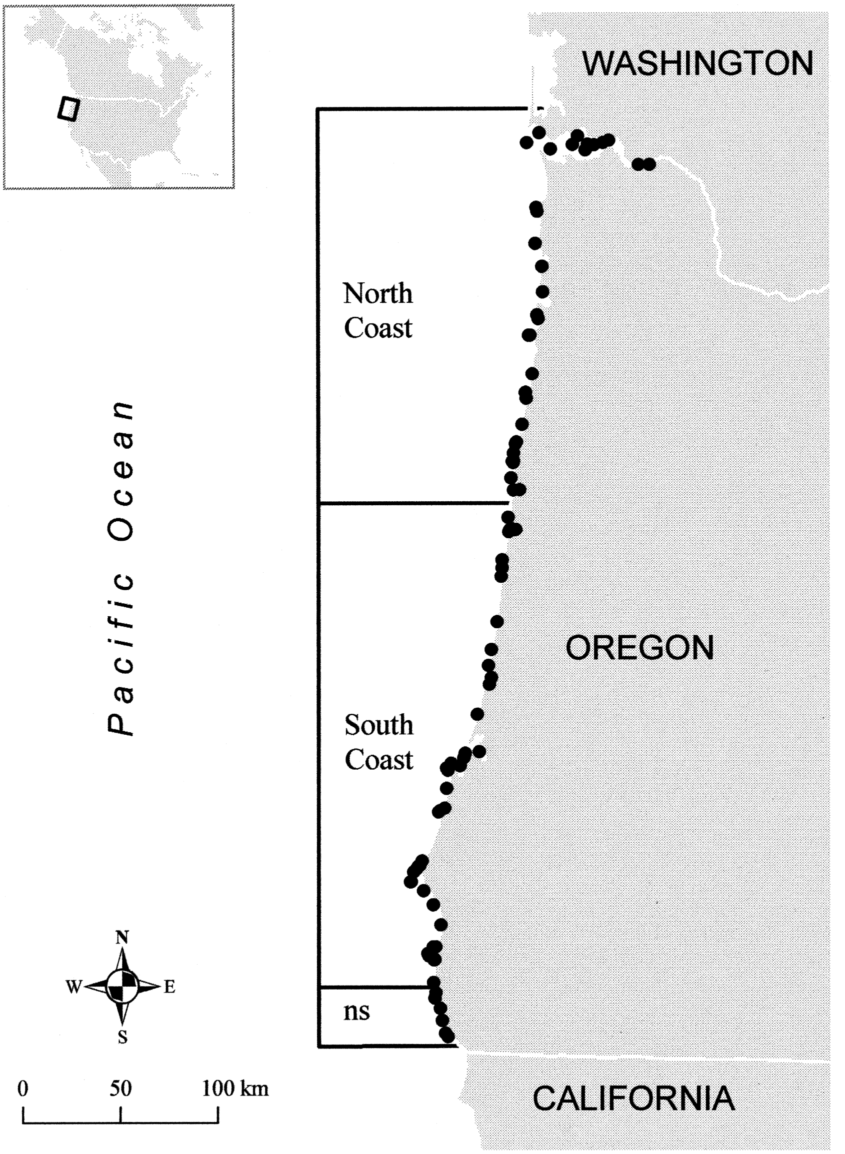

Figure 1. Map of harbor seal haul-out sites and survey regions in Oregon. Haul-outs on the southernmost coast were not surveyed (ns) prior to 1984 and were therefore not included in the trend analysis; counts from these haul-outs, however, were included when estimating absolute abundance for the 2002 reproductive period.

We conducted surveys from a single-engine, high-wing aircraft at altitudes of between 180 and 300 m. Surveys were flown within 2 h of the predicted morning low tide under good visibility and weather conditions (no fog, little or no precipitation, 300 m minimum ceiling). Data collected during surveys included date, time, location, weather conditions, and an estimate of the number of harbor seals at each site. Photographs of animals were taken obliquely through a side window of the aircraft using a hand-held 35-mm SLR camera, with a 70–210 mm zoom lens, and high speed (400 ASA) color slide film. These photographs were projected onto a white surface and the image of each animal was marked with a pen to prevent overcounting or undercounting. During the last two survey years (2002 and 2003), we used a digital SLR camera in conjunction with a GIS system to obtain harbor seal counts. Seals in the water were not counted. Although we counted both pups and non-pups, only the latter were used in the trend analysis.

Surveys were often cancelled due to poor weather (primarily fog), which resulted in some years having only one survey per region. In addition, some surveys were considered incomplete if either photographs or accurate counts could not be obtained for one or more haul-outs within the region. The two most common reasons for an incomplete survey were fog and human disturbance. Surveys with more than one missing haul-out were discarded; if only one haul-out was missing, the count was estimated either from field notes or by using the mean count from replicate surveys from the same year. In the case of the Columbia River, some missing counts were obtained from the Washington Department of Fish and Wildlife (Jeffries, unpublished data).[1]

Population Growth Models

We analyzed our aerial survey count data based on the methods in Jeffries *et al.* (2003) (also see Wade 1999). Our approach assumed that the average proportion of seals hauled out and counted during a survey was constant over space and time. The following statistical model was used to represent the count data:

$$C_{t_{ij}} = N_{t_{ij}} + \varepsilon_{t_{ij}}, \tag{1}$$

where $C_{t_{ij}}$ is the observed count of non-pup harbor seals ashore during survey i, in region j and year t; $N_{t_{ij}}$ is the estimated non-pup population size ashore as predicted by a population growth model; and $\varepsilon_{t_{ij}}$ are independent and normally distributed errors with an expectation of zero and a constant coefficient of variation.

Population growth was modeled using exponential and generalized logistic difference equations. These are non-age and non-sex-structured, deterministic, discrete-time models where the annual time-step represents the pupping season. The exponential model assumes density-independent growth at an annually constant rate ($R_{\max}$):

$$N_{t_{ij}} = N_{t_{ij}-1} + N_{t_{ij}-1} R_{\max}. \tag{2}$$

The generalized logistic model assumes density-dependent growth where the rate of increase depends on the population size relative to the carrying capacity K:

$$N_{t_{ij}} = N_{t_{ij}-1} + N_{t_{ij}-1}\left[1 - \left(\frac{N_{t_{ij}-1}}{K}\right)^{z}\right]. \tag{3}$$

The shape parameter z determines the inflection point of the growth curve and hence the timing of the density-dependent effect relative to K. The intercept in both growth models is the abundance N_0 at an arbitrary starting time $t = 0$ (we chose 1968 since

[1] Personal communication from S. Jeffries, Washington Department of Fish and Wildlife, 7801 Phillips Road S.W., Tacoma, WA 98498, U.S.A., January, 2004.

estimates of statewide harbor seal abundance were available from the literature for that year).

Model Selection

Following Jeffries *et al.* (2003), we fit a total of six versions of the above models to our data: two exponential growth models and four generalized logistic growth models. The two exponential models differed by whether the parameter $R_{\max}$ was allowed to vary by region. Similarly, the four generalized logistic models differed by whether $R_{\max}$ and z varied by region. (N_0 and K were both assumed to vary by region.)

We used information-theoretic methods to evaluate our candidate models (Burnham and Anderson 1998). We first ranked our models according to the small sample version of Akaike's Information Criterion:

$$\mathrm{AIC}_{c_i} = -2\log(L_i) + 2m_i + \frac{2m_i(m_i+1)}{(n-m_i-1)}. \tag{4}$$

where L_i is the likelihood of model i, m is the number of parameters in the model (including the nuisance parameter), and n is the total number of surveys. We rescaled AIC_c values by subtracting the minimum from each value:

$$\Delta_i = \mathrm{AIC}_{c_i} - \min\mathrm{AIC}_c. \tag{5}$$

These rescaled values provided a ranking from best to worst where the larger the difference, the less plausible the model. Lastly, we calculated normalized Akaike weights for each of the M models, which can be interpreted as the "weight of evidence" in favor of model i:

$$w_i = \frac{\exp\left(-\frac{1}{2}\Delta_i\right)}{\sum_{i=1}^{M}\exp\left(-\frac{1}{2}\Delta_i\right)}. \tag{6}$$

Goodness of fit of the global model (generalized logistic with regionally varying $R_{\max}$ and z) was tested using a Kolmogorov-Smirnov (KS) test to assess whether the standardized residuals were normally distributed.

Parameter Estimation

Parameter estimates for N_0, $R_{\max}$, K, and z were obtained by maximum likelihood (Jeffries *et al.* 2003). This was carried out using an optimization search algorithm in a Fortran program. The optimization was constrained such that the predicted population size was not allowed to exceed K (*i.e.,* over-shooting and oscillation about K was considered noise) and $z \geq 1$ (*i.e.,* density-dependence was restricted to occur at or above $K/2$).

We based our inferences on the single "best" approximating model as identified by the Akaike weights. We estimated the conditional variance of model parameters *via* parametric bootstrapping (Efron and Tibshirani 1993, Jeffries *et al.* 2003). Parametric bootstraps were generated using the maximum likelihood estimates from the best model to generate a "true" population growth curve. Noise was then added to the data in the form of normally distributed residuals from the assumed statistical model. The model was then refit to this new data and a set of new maximum likelihood estimates were generated and stored. We did this 10,000 times and computed the mean, standard error and percentile confidence limits for the 2.5 and 97.5 percentiles for each parameter (*i.e.,* N_0, R_{max}, K, and z).

OSP Determination

We determined whether harbor seals were within their OSP range by comparing the most recent predicted index of population size ($\hat{N}_{2003}$) with MNPL (Gerrodette and DeMaster 1990), where MNPL was estimated based on an approximation in Polachek (1982):

$$\text{MNPL} \approx K(z+1)^{(-1/z)}. \qquad (7)$$

For each parametric bootstrap we computed the ratio $\hat{N}_{2003}$/MNPL. If the lower bound of the 95% confidence interval for the ratio did not include one, then we concluded the population was within its OSP range.

Absolute Abundance Estimation

We estimated the absolute abundance of the 2002 statewide harbor seal population in Oregon by multiplying the mean harbor seal count for that year by a correction factor of 1.53 (Huber *et al.* 2001). The correction factor, developed from aerial surveys of radio-tagged seals in Oregon and Washington, adjusts the observed count of seals upwards to account for animals in the water. We included pups in our mean count since the correction factor is based on an assumed sex and age distribution that included pups. Furthermore, since we wanted a statewide estimate, we included all known haul-outs in our count, not just those used for the trend analysis described above. (The 2002 surveys were used instead of the 2003 survey because fog prevented counts of some of the southernmost haul-outs in 2003.)

Results

Trends in Relative Abundance

From 1977 to 2003 observed counts of non-pup harbor seals ashore nearly doubled in the southern survey region and increased by a factor of four in the north (Table 1, Fig. 2). Of the two types of growth models considered, the generalized logistic models clearly approximated the observed count data better than the exponential models ($\Delta_i \geq 41.78$; Table 2), thus providing evidence for density-dependent growth. Although AIC_c values for all four generalized logistic models suggested they were plausible ($\Delta_i \leq 2.12$; Table 2), we based our inferences on the single best approximating model ($w_i = 0.457$; Table 2). This model suggested that maximum growth rates differed between regions but the inflection points of the growth curves were equal (Table 3). We found no evidence of a lack of fit for our global model ($KS = 0.06$, $P = 0.5$).

OSP Determination

Given that the best approximating model suggested that z was constant between regions, we pooled our regional estimates of K to compute MNPL (as well as other

Table 1. Average annual counts of non-pup harbor seals ashore for two survey regions in Oregon, 1977–2003.

	Average count (n surveys)		
Year	North coast	South coast	Total
1977	616 (1)		
1978		1,749 (1)	
1979

1985	1,115 (2)	2,641 (2)	3,756
1986	991 (3)	2,341 (1)	3,332
1987	1,463 (1)	2,523 (2)	3,986
1988	1,564 (2)	2,916 (2)	4,480
1989	1,907 (2)	3,137 (3)	5,044
1990	1,880 (1)	2,945 (1)	4,825
1991	1,676 (1)	2,917 (2)	4,593
1992	2,501 (2)	3,007 (4)	5,508
1993	2,330 (1)	2,872 (1)	5,202
1994	2,185 (1)	2,496 (1)	4,681
1995	1,907 (1)	2,338 (1)	4,245
1996	2,159 (3)	2,471 (3)	4,630
1997		2,849 (1)	
1998	2,513 (1)	2,816 (1)	5,329
1999	1,780 (1)	2,627 (2)	4,407
2000	1,644 (1)	2,916 (1)	4,560
2001	1,652 (2)	2,827 (2)	4,479
2002	2,155 (2)	3,103 (2)	5,258
2003	2,436 (2)	3,055 (2)	5,491

parameters) (Table 4). None of the bootstrap replicates for $\hat{N}_{2003}$ were below MNPL which is consistent with the hypothesis that harbor seals in Oregon, as indexed by non-pups counted ashore, were within their OSP range. Harbor seals were estimated to be nearly at their estimated carrying capacity (99% of K, Table 4).

Absolute Abundance

The mean coastwide count of harbor seals (pups and non-pups) in Oregon during May–June 2002 was 6,607 animals (SE = 295.7; 5,505 non-pups and 1,102 pups). Multiplying the mean count by the correction factor of 1.53 (SE = 0.1; Huber *et al.* 2001) to account for the number of seals in the water yielded an estimated total of 10,087 animals (95% CI: 8,445–12,046).

Discussion

While the Pacific harbor seal is distributed from Baja California, Mexico, northward to Alaska, for management purposes the U.S. National Marine Fisheries

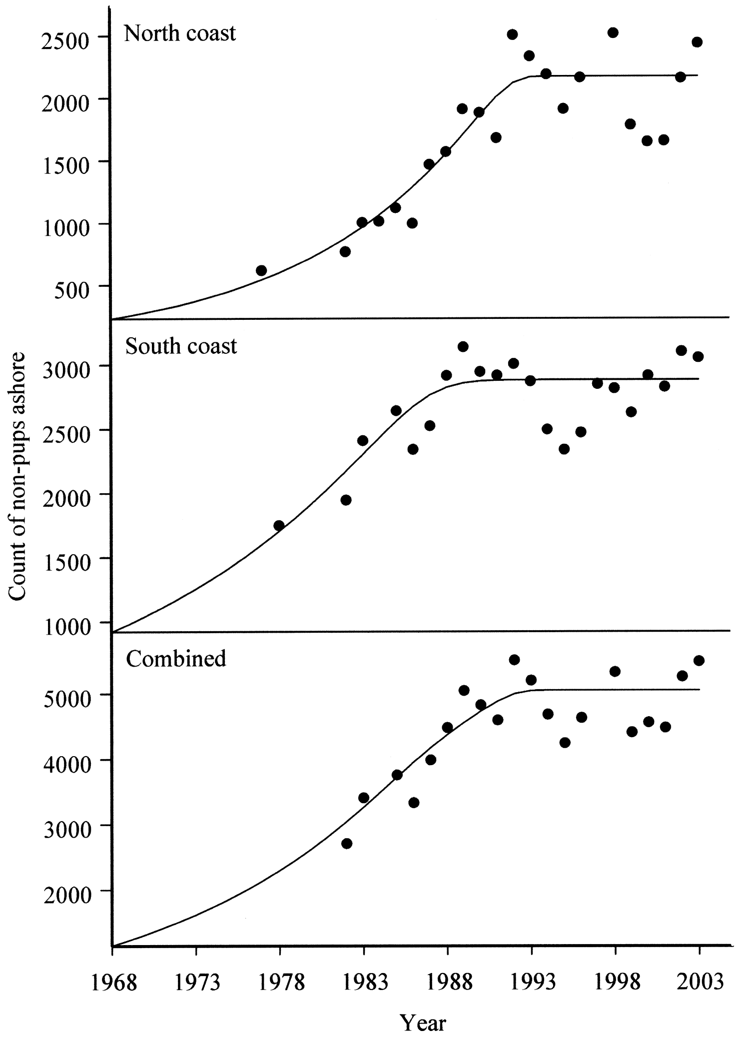

Figure 2. Average (circles) and predicted (line) counts of non-pup harbor seals ashore for two survey regions in Oregon. The combined total represents the sum of the regional averages and predicted values.

Service (NMFS) divides the population into different stocks based on various criteria including genetics, movements, pupping dates, and fishery interactions (Angliss and Lodge 2004, Carretta *et al.* 2004). Harbor seals in Oregon are considered to be part of the Oregon/Washington coast stock, which extends from the California-Oregon border north to Cape Flattery, Washington. While there is strong evidence for separation between the Washington inland waters stock and the Oregon/Washington coast stock, the separation between the Oregon/Washington coast stock and the California stock is largely a "political/jurisdictional convenience" (Carretta *et al.* 2004). Additional information (*e.g.*, new genetic

Table 2. Model selection results for exponential and generalized logistic growth models fit to counts of non-pup harbor seals ashore in Oregon, 1977–2003.

Model	R_{max}	z	Log L	m	AIC_c	Δ_i	w_i
Generalized logistic	Regional	Constant	24.44	9	−28.04	0	0.457

analyses) will be needed to more appropriately characterize harbor seal stock structure in the southern Oregon and northern California region. Nonetheless, we believe that the results of our trend analysis, when considered with those of Jeffries *et al.* (2003), provide evidence that the Oregon/Washington coast stock is currently above its MNPL and within its OSP range. This conclusion, however, rests upon at least several other considerations which are discussed below.

Trend Counts

Environmental covariates such as tide (Terhune and Almon 1983), time of day (Thompson and Harwood 1990), weather (Watts 1992), and date (Frost *et al.* 1999) have been shown to affect the number of seals hauled out at given times and locations. Harbor seal monitoring programs have sought to control for these environmental factors either before data are collected through study design (Jeffries *et al*. 2003) and/or after data are collected through analysis (Frost *et al.* 1999, Boveng *et al.* 2003, Small *et al.* 2003). We chose the former approach.

In the model formulation we used, it was assumed that the average proportion of the population that was hauled out during our surveys was constant. Conceptually, this proportion represents a detection probability (p) which can be thought of more

Table 3. Parameter estimates from generalized logistic growth model with regional growth rates (R_{max}) and a constant shape parameter (z). Point estimates are maximum likelihood estimates (MLE); standard errors and percentile confidence intervals (10,000 replicates) are from parametric bootstraps based on MLEs from the selected model.

Parameter	Region	Estimate	SE	95% confidence interval: Lower	95% confidence interval: Upper

broadly as all the factors influencing the probability of whether an animal is encountered or detected (Buckland *et al.* 2001). If p varied randomly among surveys, then this could be expected to manifest itself in an increased variation in counts and increased variance in the parameter estimates. If p changed systematically over time, then this would result in a biased estimate of population trend.

Sources of variation in p include observer effects, environmental conditions, and attributes of the animal itself (Anderson 2001, Buckland *et al.* 2001). Observers, for example, may differ in their ability to detect animals (while flying and/or counting) based on their training, experience, interest, and fatigue. Likewise, environmental conditions such as season, time of day, tide, and weather may affect whether a seal is hauled out and hence available for detection. Finally, attributes such as the size and coloration of an animal that might make it more or less conspicuous than other individuals may affect its detectability. We sought to minimize these sources of variation by (1) having the majority of the surveys flown (and photographs counted) by the same people, (2) only flying under a specific set of environmental conditions (see methods), and (3) only including non-pups in our trend analysis (which we believed had a more constant probability of detection than pups).

Despite our efforts, survey counts were likely affected to some degree by uncontrolled sources of variation. We were not overly concerned, however, since the effect size we were measuring was large (2–4 fold observed increases), our time series was long (27 yr), and our study design held many covariates relatively constant (*e.g.,* observers, tidal stage, time of day). Frost *et al.* (1999) noted that under this set of circumstances, it may be possible to evaluate population trends without concern for covariate effects. We acknowledge, however, that the precision of our estimates might be increased by using a covariate adjustment approach, as well as by increasing the number of replicate flights flown per year.

More worrisome than random variation in p would be a case in which there was a systematic trend in p over time (Anderson 2001). In this situation, an apparent trend in abundance would be confounded with a trend in detectability. Jeffries *et al.* (2003) noted that one plausible scenario for a time-trending p would be if there was an inverse relationship between seal population density and time spent ashore due to increased intraspecific competition for food resources. They examined this scenario by comparing the proportion of seals ashore in Oregon and Washington in 1991–1992 *versus* those ashore in 1999–2000 (Washington only) and found that while some small decreases in p did occur, they were not inconsistent with their conclusions that seal numbers in Washington had stabilized. We did not conduct a similar comparison and therefore must assume that, as in Washington, no trend in the proportion of seals hauled out occurred in Oregon during our time series.

Population Dynamics

One axiom of population biology is that populations do not increase indefinitely (Williams *et al.* 2002). For large mammals, a basic assumption has been that their populations increase until they are in equilibrium with the environment, and that this equilibrium is achieved through a density-dependent response in population growth that occurs near carrying capacity (Fowler 1981, 1987). This assumption was inherent in the MMPA and in the definitions of OSP and MNPL (Taylor and DeMaster 1993, Ragen 1995, Wade 1998, Taylor *et al.* 2000). In reality, however, it is unlikely that populations have a fixed equilibrium point (Wolda 1989, Harwood and Rohani 1996; but also see Koetsier *et al.* 1990, Turchin 1995). Instead, population regulation and limitation processes likely produce a "stationary distribution of population densities" (Dennis and Taper 1994). Furthermore, there are likely to be multiple "densities" at which a population moves between as environmental conditions and limiting factors change (Williams *et al.* 2002). For example, Hucke-Gaete *et al.* (2004) studied the recovery of Antarctic fur seals (*Arctocephalus gazella*) in the South Shetland Archipelago and proposed that the carrying capacity had declined by an order of magnitude over the past two centuries. Small *et al.* (2003) suggested that the carrying capacity for pinnipeds in the Gulf of Alaska had declined following a climate-regime shift in 1977. In contrast, Bowen *et al.* (2003) reported on the sustained exponential growth of Sable Island (Nova Scotia) grey seal pup production over nearly 40 years in spite of considerable environmental variability.

Gerrodette and DeMaster (1990) noted the implications to the MMPA of changes to carrying capacity when they stated: "whether current or historical carrying capacity is to be used when making an OSP determination is presently an unresolved issue in marine mammal management [in the U.S.]." While we do not know what historic carrying capacity for harbor seals in Oregon might have been, we speculate that carrying capacity may have recently increased as a result of a reversal in the Pacific Decadal Oscillation. This reversal marked a shift in coastal ocean conditions off the west coast of the contiguous United States from a warmer, inhibited productivity period (Pearcy 1992, Hare and Mantua 2000) to a colder, enhanced productivity period (Emmett 2002, Peterson and Schwing 2003). Interestingly, much of the observed increase in harbor seal abundance reported here occurred during the warmer, inhibited productivity period (perhaps as a result of initial low abundance). In Oregon, improved ocean conditions have resulted in increased salmonid (*Oncorhynchus* spp.) survival and increased densities of zooplankton (Peterson and Schwing 2003) and forage fishes (Emmett 2002, Emmett[2]).

Although the harbor seal population in Oregon appeared to stabilize in the 1990s, we do not know the underlying regulatory mechanisms that limited its continued growth. However, since no evidence of unusual disease-related mortality was observed, and many additional areas with apparently suitable habitat remained unused, we suspect that one limiting factor may have been food supply. If so, the

[2] Personal communication from R. Emmett, National Marine Fisheries Service, Hatfield Marine Science Center, Newport, OR 97365, U.S.A., March, 2004.

recently improved ocean conditions may remove food as a limiting factor and hence result in an increase in carrying capacity for seals in this region. Whether this turns out to be the case or not, we nonetheless conclude that, when viewed within the existing MMPA framework, our results support the conclusion that the Oregon/ Washington coast stock is currently above its MNPL and within its OSP range.

Acknowledgments

Many people contributed to collecting the harbor seal abundance data presented here. Several of the earliest surveys were directed and piloted by Bruce Mate at Oregon State University with the assistance of the lead author of this paper. Others that participated in planning, conducting, counting, and summarizing surveys included: James Harvey, Steven Jeffries, Janet Stein, Harriet Huber, and Stephan Kohlmann. Additional guidance and support were provided by Robert Delong, Joe Scordino, Dale Snow, and Neal Coenen. Maria Wright, Rebecca Goggans, and two anonymous reviewers provided many helpful comments which improved this paper. Wayne Moreland, J. P. McLaughlin, and Jim York skillfully piloted a large percentage of the survey flights. Lisa Buswell and Salem Air Center were a constant source of service and professionalism. Many thanks to all of the other individuals, companies, and agencies that provided aircraft and pilot services over these 27 yr. Funding for this work came from numerous sources including Oregon Department of Fish and Wildlife and NMFS (Northwest Region Office and National Marine Mammal Laboratory). We thank the USFWS Coastal Refuges Office in Newport for providing Special Use Permits to conduct flyovers of Oregon refuge islands. These surveys were conducted under NMFS Marine Mammal Research Permit Nos. 419, 499, 835, and 782-1446.

Why a management procedure approach? Some positives and negatives

Doug S. Butterworth

Butterworth, D. S. 2007. Why a management procedure approach? Some positives and negatives. – ICES Journal of Marine Science, 64: 613–617.

The origin of the management procedure (MP) approach (sometimes termed management strategy evaluation), with its simulation testing of feedback-control algorithms as a necessary and structured basis for dealing with the inevitable uncertainties associated with fisheries assessments, is briefly reviewed. Also discussed are the advantages that overcome some of the difficulties of the "traditional" approach of coupling an annual "best" assessment to some harvest control rule, such as a failure to consider longer-term trade-offs properly. The MP approach does, however, also have disadvantages, such as the length of time typically required for its development and an argued inflexibility after implementation. Solutions that have been developed to overcome some of these difficulties are discussed.

Keywords: assessment, management procedure, operating model, precautionary approach, risk, simulation testing, trade-offs, uncertainty.

Introduction

This topic is most readily addressed by comparing the management procedure (MP) approach with what might be termed the "traditional" approach (TA) to the provision of scientific recommendations for management measures [such as total allowable catches (TACs) or allowable effort levels] for fishing marine resources.

Typically, the TA involves developing a "best assessment" of the resource, i.e. a mathematical evaluation that integrates all available data for and understanding of the resource to provide estimates of, in particular, past and present resource abundance and productivity. This is then augmented in some manner to translate these results into, say, a TAC recommendation, e.g. by the application of a reference-point-based harvest control rule or consideration of resource trends predicted under future alternative constant-catch scenarios. In many cases, this process is repeated as frequently as annually.

An MP is formally a formula to provide, say, a TAC recommendation, where the inputs to the formula (essentially resource monitoring data) have been pre-specified. To that extent, it seems no different from the TA. However, the core difference is that this formula has been tested by simulation to confirm that it can be expected to get reasonably close to concurrently achieving appropriate trade-offs among the mutually conflicting objectives of maximizing catches, minimizing interannual catch variability in the interests of industrial stability, and minimizing the risk of substantial depletion of the population that could put future use of the resource in jeopardy. Importantly, though, it must also be shown to be able to achieve this even if the current best assessment of the resource is in error (at least to a degree that is within the bounds of plausibility). Therefore, it is by design compatible with the precautionary approach (PA), by making appropriate allowance for scientific uncertainties. Crucially, it relies on the mechanism of feedback control to adjust for inevitable errors in current perceptions about the resource (the "uncertainties").

The MP approach was first developed by the Scientific Committee of the International Whaling Commission (IWC) during the late 1980s. In 1974, the "New Management Procedure" (NMP) had been adopted as a basis to provide advice on catch limits (IWC, 1976; Punt and Donovan, 2007), a typical example of the TA. However, a decade later, the approach was seen to have failed for two main reasons: (i) the NMP proved unable to meet its intended role of facilitating scientific agreement on catch-limit recommendations, because debate simply moved from what might be an appropriate catch-control law to arguments about parameter (such as maximum sustainable yield (MSY)) values, when implementing that law for a particular case, and (ii) even if agreement could have been reached about the best estimates of those parameters, arguments then developed about how the inevitable scientific uncertainty about those values should be taken into account. The process of developing the IWC "Revised Management Procedure" (RMP) (IWC, 1989; Kirkwood, 1992), initiated by the pioneering work of de la Mare (1986) and with its eventual product accepted by the IWC Scientific Committee in 1991 (IWC, 1992), deliberately focused on resolving these two problems and did so by the process set out above, which is now taken to define an MP.

At about that same time, the desirability of adopting a PA in the management of renewable natural resources was gaining general acceptance, following broad statements to this end adopted by UNCED in Rio de Janeiro in 1992, but it was unclear how to put the PA into effect operationally. The FAO (1995) Technical Consultation on the Precautionary Approach to Capture Fisheries, held in Lysekil, was organized to address this very point. The report of that meeting implicitly endorsed the MP approach developed by IWC by expressing the need for "management plans" involving "decision rules" to be developed, in conjunction with a directive that "a management plan should not be accepted until it has been shown to perform effectively in terms of its ability to avoid undesirable outcomes". Note that the evaluation of such "performance" necessarily implies some simulation testing.

After summarizing major difficulties (primarily in implementation) with the TA in fisheries management, the main advantages of the MP approach are listed below, emphasizing how they resolve those TA problems. However, the MP approach introduces some new difficulties, and I conclude by explaining those and suggesting how they can be addressed. The presentation is framed in terms of providing advice on TACs, but the comments made would apply similarly to management under effort limitation.

Difficulties with the TA

Variability in "best assessments" from year to year, and hence in associated TAC recommendations

This type of variability can arise for three reasons: new data becoming available, primarily from resource-monitoring sources such as surveys and commercial catch per unit effort (cpue); modified methods to refine such data for inputs into stock assessment (e.g. standardization through generalized linear modelling of cpue series); and (supposed) improvements to the assessment methodology. As a consequence, the recommended TAC can vary independently of the true population dynamic processes, for example, as a result of estimation error in the first case or even change in the opposite direction to trends in resource indices in the other two cases.

Inability to consider longer-term trade-offs properly

An evaluation of the trade-off between long-term catches and risk to the resource is fundamental to sound fisheries management. However, risk can be properly evaluated only based on simulating repeated application of a decision rule because, except for short-lived species, no immediate threat to the resource arises from taking catches somewhat in excess of sustainable levels. The common TA of making catch projections based on a best assessment (even if taking account of estimation error and uncertainty about future recruitment) can overestimate risk appreciably, because the management responses that would follow given future resource monitoring data are not considered. For example, if these provided firm evidence of deteriorating stock status, a recommendation to reduce the TAC would undoubtedly follow and adjust the risk downwards.

Lengthy haggling

Even in nominally objective scientific gatherings, discussions during the process of selecting a singular TAC recommendation can become wastefully protracted through attempts (perhaps linked to interest-group agendas) to squeeze agreement to small changes (up or down). These may be based on argued improvements that would arise from minor modifications to data choices or methods used. Generally, however, such changes reflect only noise, rather than improved detection of resource trends from noisy data, and they add no real value to the advice generated.

What if the "best assessment" is wrong?

The TA does not include any formal basis to make proper allowance for uncertainties, which means that the best assessment at any particular time could be considerably in error. Simple approaches to address such uncertainties, such as basing decisions on the most conservative assessment alone (see critique in Butterworth *et al.*, 1996) or on a lower 95% confidence bound on an estimated TAC, can be wasteful of the resource by setting catches much lower than is needed to avoid real risks of unintended depletion of the population.

Default decisions of "no change"

In the numerous instances of assessment uncertainty that occur in practice, management agencies frequently fall back on the default decision of no change as the easiest path to take. In international fora, where change requires a consensus among participating parties, this problem is particularly acute. The ensuant procrastination usually results in whatever action is eventually taken as being too little, too late.

Advantages of the MP approach

Less time spent haggling to little long-term benefit

The flaw in the IWC's NMP was that it stopped with the specification of the catch-control law. A true MP also needs pre-specification of the data to be used, together with a pre-specified estimation method. The latter transforms the input data into the information required for the computation of a TAC in accordance with the control law. This pre-specification (i.e. before any implementation) of both the formule used and their inputs eliminates room to discuss and modify these each year, which can save considerable time. A classic example of this benefit has been provided by the experiences of the South African Rock Lobster Scientific Working Group when converting from a TA to an MP approach: the total of 40 meetings needed in the previous year to finalize the TAC recommendation was reduced to only four in 1997 when an MP was first implemented for the fishery for *Jasus lalandii*.

Haggling time saved can be put to better use

An important byproduct of the MP development process is the identification of those scientific uncertainties that cause the greatest difficulties in meeting risk-related performance criteria. This in turn clarifies the focus areas for longer-term research to help resolve such uncertainties, and perhaps thereby allow for enhanced harvests with the same perceived risk. Reducing haggling time, and the pressure to address short-term issues, creates the opportunity to focus more on longer-term research efforts designed to resolve these more important uncertainties in assessments.

Proper evaluation of risk

Using medium-term projections, the simulation testing framework provides the appropriate basis for an evaluation of risk. Importantly, it generates new resource-monitoring data for each new year, then re-applies the MP formula, so that allowance is made for feedback effects primarily using the updated trend information to self-correct (at least to some extent) for earlier errors made in TAC recommendations.

Providing a sound basis to put limits on interannual TAC variability

Orderly industrial development requires fairly steady TACs. Under the TA, it is impossible to judge what externally imposed constraint on the extent to which the TAC can be allowed to vary from year to year might be set without jeopardizing resource status. In contrast, evaluation of the implications of alternative levels for such constraints is readily achieved through the MP-testing framework. For the short-lived pelagic species dominating the South African purse-seine fishery, the capability to address this desirable feature for management of the fishery in an objective way has proved particularly advantageous, with industry showing particular interest in plots showing the trade-off between bigger catches and lesser TAC stability. This trade-off arises because, if limitations are set on the rate at which a TAC may be reduced, the TAC cannot be allowed to increase to too high a level either; otherwise, it may become impossible to reduce the TAC fast enough to counter drops in abundance arising, perhaps, from some years of environmentally driven poor recruitment.

Consistency with the PA

As the MP simulation testing framework includes not only the best assessment, but also robustness tests to reflect the scientific uncertainties of this assessment, consistency with the PA is ensured.

Providing a framework for interactions with stakeholders, particularly regarding objectives

The MP approach enforces consideration of the long-term as well as the short-term developments. Because many of the objectives of sound management pertain to the former, this prompts clearer thinking among stakeholders. Moreover, the process of scientists neutrally reporting the range of trade-offs available, from within which it is for stakeholders to make the choice, facilitates enhanced interactions among all players. This in turn promotes those players' buy-in to the MP selected and to the TAC recommendations, which it subsequently provides.

Providing a default

Some haggling may nevertheless be unavoidable, particularly in international settings where member states tend to accord primary priority to maintaining their recent catches. In national situations, the state, which ultimately decides the TAC, is distinct from the potential beneficiaries of that decision (the fishing companies), so the decision may reflect broader objectives than the typical emphasis on shorter-term priorities of such companies. However, in international settings, the states become the beneficiaries while still remaining the decision-makers, which in turn creates additional pressure for a no change decision as the only one that can achieve consensus. An important role for an MP in this situation is to output a "default" TAC calculation as the fall-back position, to replace the current no change default that may expose the harvested population to undue risk.

Disadvantages of the MP approach and how they can be addressed

Lengthy development time

The development and review of an MP for a fishery requires more time (at least a number of months) than TA assessments to arrive at a TAC recommendation (typically in 1 or 2 weeks in scientific committees of regional organizations). However, once the MP is in place, non-productive scientific and political haggling time in later years is greatly diminished. Experience has emphasized the importance of avoiding "backtracking" during the extended development/review process, i.e. once a certain stage of the process has been reached, such as specification of the set of models of resource dynamics for simulation testing, the next stage must be undertaken without allowing new hypotheses or information to be placed on the table to take the process back towards its beginning in a potentially infinite loop. As elaborated in Punt and Donovan (2007), the IWC (2005a) set down a schedule to complete the development or review process for selecting which variant of its RMP to apply to a specific species and region over five meetings within a 2-y time frame. This was not to abort new insights developed after such deadlines; rather the place for their consideration was accepted to be the next MP review. Reviews are planned at intervals of 5 y in the IWC framework, but for shorter-lived species, shorter intervals may prove more appropriate.

An overly rigid framework

Decision-makers sometimes desire flexibility to have the "wriggle" room required by the political process, which may have to take heed of the socio-economic realities of the moment. This can be addressed by designing MPs which output a range of TAC options, rather than a single number. The simplest version of such an approach is a "block quota" awarded for a number of years, with a specified maximum amount (somewhat higher than the annual average for the period) that can be taken each year if the block quota is not exceeded over the full period. However, such extensions require that the MP evaluation process include a model of how the choice within the available range is to be made each year. Necessary robustness to possible choices that lead to more negative impacts on the population introduces a cost to such flexibility. This is likely by way of either lower future TACs on average or higher interannual TAC variability, if the perceived risk is to be kept unchanged. As discussed below, the MP review process also provides a mechanism that allows participants to address argued needs for flexibility.

Trusting an autopilot?

An MP is analogous to an autopilot, with the associated advantages. However, this does not mean that the aircraft should be left without a pilot. The pilot must remain on board to look out for unexpected major course deviations that may not have been factored into the design, including appreciable changes in scientific perceptions concerning the resource. Therefore, the MP under consideration for southern bluefin tuna (*Thunnus maccoyii*) includes provisions for updated assessments at regular intervals to ensure that the resource has not moved outside the range over which the MP was designed to operate (CCSBT, 2005). Similar provisions are being adopted for South African fisheries managed under MPs (MCM, 2006). If compelling evidence becomes available, planned reviews at wider time intervals can be brought forward.

Such reviews also provide the opportunity to assess whether the objectives originally chosen, and which the control parameters of the selected MP were "tuned" to achieve, remain appropriate under possibly changed socio-economic circumstances. Importantly, though, decisions to change objectives, or to bring reviews forward, must first ensure that the rationale offered is indeed compelling. Otherwise, such mechanisms can degenerate into surrogates to tinker with outputs each year in a manner that frustrates the advantages that the MP approach seeks to achieve—genuinely appreciable changes in scientific perceptions about a resource are typically not annual events.

Non-availability of, or "poor", data inputs

Care needs to be taken in designing MPs that the future monitoring data assumed to become available for input to the TAC-computing algorithm are indeed likely to eventuate. Nevertheless, the design process needs to consider the possibility that such data either are occasionally not collected or are deemed inadequate for use (e.g. because a small sample size raises questions of whether such data are representative). Simple ways of dealing with occasional gaps in data (e.g. use the same value as for the previous year) need to be pre-specified, with their adequate performance confirmed in robustness trials. If such gaps develop more regularly, however, it may become necessary to consider bringing the regular MP review forward (see provisions in MCM, 2006). Another possible mechanism to consider would be an appropriate adaptation of the IWC RMP, which stipulates a period over which a TAC is phased down to zero, if an abundance survey anticipated in the testing process within a certain period fails to materialize (IWC, 1994). This provides an incentive to encourage continuation of the necessary resource monitoring.

Reference case selection

Evaluation of the achievement of specified quantitative objectives, such as resource recovery by a certain amount within a specified time frame, is dependent on, and can be quite sensitive to, the choice of the "reference case" operating model (or plausibility-weighted "reference set" of such models over which performance statistics are integrated; Plagányi *et al.*, 2007; Rademeyer *et al.*, 2007) that is used for such computations in the testing and tuning process. In other words, the MP approach does not fully escape, in its fullest sense, the difficulties of selecting a best assessment. Naturally, the TA has exactly this same problem, but the MP approach has the advantage of having tested for the adequacy of feedback to correct for any errors, which can to some extent compensate for a poor initial choice of a reference case.

A related problem can arise if such a quantitative, risk-related objective is framed in terms of the probability of not having abundance decrease below a certain level. Even if it is agreed that "low" plausibility scenarios be excluded from consideration (IWC, 2004), arguments can ensue about whether or not certain hypotheses are sufficiently plausible to merit retention, particularly if they are perceived to influence the conclusion as to whether the objective is met. Hypotheses about more complex stock structure in particular tend to raise difficulties because of Type II error problems: the absence of significant evidence from, for example, genetic data to support such hypotheses is not necessarily sufficient to classify them as implausible. Punt and Donovan (2007) outline an innovative "research-conditional" approach adopted by the IWC Scientific Committee to address this problem (Donovan and Hammond, 2004; IWC, 2005b).

Conclusion

The MP approach can solve most, though not all, of the problems of the traditional "best assessment + control rule" approach. Although it does introduce additional difficulties, these can largely be resolved by operating in accordance with sound protocols (IWC, 2005a; MCM, 2006). The greatest advantages are probably: (i) a sound basis to limit the extent of future TAC variations without compromising resource status and (ii) the proper way of addressing concerns about scientific uncertainty through simulation testing to ensure that feedback secures reasonably robust performance across a range of plausible alternative resource dynamics.

As an afterthought, three decades ago, the major issue in global fisheries management was the collapse of several large fisheries for small pelagic species (e.g. Peruvian anchoveta, *Engraulis ringens*; Namibian sardine, *Sardinops sagax*), primarily as a result of over-exploitation to which the management response had come too late. The primary lesson from these events was summarized by Alec MacCall in a speech around 1980 (subsequently reflected in MacCall, 1996) as: "agree beforehand what remedial action to take if negative signals are forthcoming from the resource, rather than risk socio-economic arguments being advanced to delay action in tandem with wishful thinking that the situation will rectify itself." MacCall's invocation is no more than the theme underlying the MP approach: all stakeholders (industry, conservationists, scientists, and managers) need to agree the rules before a fisheries management game is played.

Acknowledgements

The thoughts expressed here follow from rewarding interactions about Management Procedures over a considerable period with many colleagues, particularly in South Africa and on the Scientific Committees of the IWC and the Commission for the Conservation of Southern Bluefin Tuna. Although too numerous to list individually, I must nevertheless mention Geoff Kirkwood and Kjartan Magnusson in the light of their sad passing shortly before the ICES Symposium at which this paper was presented. Beth Fulton is thanked for her comments on an earlier version of the paper.

Abundance and population structure of seasonal gray whales in the Pacific Northwest, 1998-2008

(SC/62/BRG32)

John Calambokidis, Jeffrey L. Laake, Amber Klimek

Abstract

The existence of a small number of eastern North Pacific gray whales that spend the spring, summer and fall feeding in coastal waters of the Pacific Northwest has been known for some time and localized and short-term studies have examined aspects of the natural history of these animals. We report the results of an 11-year (1998-2008) collaborative study examining the abundance and the population structure of these animals conducted over a number of regions from Northern California to British Columbia using photographic identification. Some 12,679 identifications representing 872 unique gray whales were obtained. Gray whales seen after 1 June (after the northward migration) were more likely to be seen repeatedly and in multiple regions and years and 1 June was used as the seasonal start date for the data included in the abundance estimates. Gray whales using the Pacific Northwest in summer and fall include two groups: 1) whales that return frequently and account for the majority of the sightings and 2) apparent stragglers from the migration seen in only one year, generally for shorter periods and in more limited areas. Abundance estimates for whales present in summer and fall using three different methods and different geographic scales revealed the abundance of animals to be at most a few hundred individuals. The proportion of calves documented was generally low but varied dramatically among years and may have been biased downward by weaning of calves prior to much of the seasonal effort. Observations of calves returning to the Pacific Northwest in subsequent years documents one possible mechanism for recruitment. The results we present will be valuable in assessing the impacts of potential resumption of a gray whale hunt by the Makah Tribe, currently proposed to target migrating whales by hunting prior to 1 June.

1 Introduction

Although most gray whales in the Eastern North Pacific stock migrate each spring from calving lagoons in Baja Mexico to feeding grounds in the arctic, the existence of gray whales that spend the spring, summer and fall feeding in coastal waters of the Pacific Northwest has been known for some time. Starting in the 1970s, photographic identification demonstrated that some whales returned regularly to feed off the west coast of Vancouver Island (Darling 1984). The proximity of these whales to the traditional whale hunting grounds of the Makah Tribe coupled with the Tribe's interest in resuming gray whale hunts in the 1990s made determination of the status and number of these whales of greater importance to management.

Beginning in 1998, a collaborative effort among a number of research groups was initiated to conduct a range-wide photographic identification study of gray whales in the Pacific Northwest (Calambokidis et al. 2000, 002b). An initial publication of findings from 1998 demonstrated there was considerable movement of individual whales among sub-areas from northern California to southeastern Alaska (which we broadly refer to as the Pacific Northwest) and also provided initial estimates of the abundance of whales within that geographical area (Calambokidis et al. 002a). The ability to look at movements and employ more sophisticated capture-recapture models, however, was restricted by the lack of multiple years of data with broad geographic coverage. A subsequent report by Calambokidis et al. (2004) characterized the group of whales feeding in these survey areas during the summer-fall period as a "Pacific Coast Feeding Aggregation" (PCFA). They proposed that a smaller area within the PCFA survey areas – from Oregon to Southern Vancouver Island (OR-SVI) – was the most appropriate area for abundance estimation for managing a Makah gray whale hunt (Calambokidis et al. 2004).

The collaborative effort to collect photographic identifications of gray whales from California to Alaska has continued since 1998 and these data now cover 11 years (1998-2008) and span fifteen survey regions along the coast from Southern California to Kodiak, Alaska (Figure 1). We provide estimates of abundance for the summer-fall seasons (1 June to 30 November) for survey regions comprising different combinations of subareas within this range.

2 Methods

Gray whales were photographed during small boat surveys conducted from California to Alaska by Cascadia Research, National Marine Mammal Laboratory and collaborating researchers between 1998 and 2008. Gray whale identifications were divided into the following regions (Figure 1): 1) SCA: Southern California, 2) CCA: Central California, 3) NCA: Northern California, 4) SOR: Southern Oregon, 5) OR: central Oregon, 6) GH+: Gray's Harbor and the surrounding coastal waters, 7) NWA: Northern Washington coast, 8) SJF: Strait of Juan de Fuca, 9) NPS: Northern Puget Sound, 10) PS: which includes southern Puget Sound, Hood Canal (HC), Boundary Bay (BB) and San Juan Islands (SJ), 11) SVI: Southern Vancouver Island, 12) WVI: West Vancouver Island, 13) NBC: Northern Vancouver Island and coastal areas of British Columbia, 14) SEAK: Southeast Alaska, and 15) KAK: Kodiak, Alaska. The NWA and SJF survey areas together make up the Makah Usual and Accustomed grounds (MUA). With some exceptions, research groups work primarily in one or two regions. Details of identifications obtained by the different research groups are briefly summarized below and are listed in Tables 1-2.

o National Marine Mammal Laboratory: NMML obtained identification photographs of 1159 gray whales representing 336 unique individuals sampling all years from 1998 to 2008 (except for 2004) from a variety of locations from northern California to Kodiak, Alaska. Identification photographs were mostly taken while conducting dedicated surveys for gray whales.

o Cascadia Research Collective: Cascadia obtained identifications photographs of gray whales on 1306 occasions representing 372 unique individuals. Surveys were conducted in all years using 5.3 m rigid hull inflatable boat at a wide range of locations from California to Southeast Alaska.

o Humboldt State University: HSU conducted surveys primarily off northern California from 1998 to 2002 and in 2008 and obtained 360 identifications of 156 unique whales.

o Brian Gisborne, Juan de Fuca Express: Brian Gisborne obtained identification photographs every year from 1998 to 2008 primarily along the West Coast trail of southern Vancouver Island during daily trips of this region. He obtained 5318 identifications of 297 unique whales.

o Jim Darling, West Coast Whale Research Foundation: Jim Darling provided identification photographs obtained during surveys along the west coast of Vancouver Island primarily from Clayoquot Sound to Barkley Sound in 1998, 2001, and 2002. These yielded 99 identifications of 59 unique whales.

o Coastal Ecosystems Research Foundation: CERF conducted regular surveys from 1998 to 2008 off British Columbia north of Vancouver Island primarily in the vicinity of Cape Caution. Identification photographs were obtained on 2289 occasions representing 107 unique individuals.

o University of Victoria: UVIC obtained identifications photographs from Clayoquot Sound north along the west side of Vancouver Island every year from 1998 to 2002 except 2001. Identification photographs were obtained on 760 occasions of 137 unique individuals.

o Volker Deecke, independent researcher: Obtained identification photographs of gray whales from 1998 to 2001 and 2006 off British Columbia and in Southeast Alaska including 170 photographs of 74 unique animals.

o Wendy Szanislo, independent researcher: Wendy Szanislo obtained identification photographs of gray whales from 2005 to 2008 along the west coast of Vancouver Island. She obtained 407 identification photographs of 101 unique whales.

o Makah: Makah tribal biologists conducted surveys along the coast of Northern Washington and into the Strait of Juan de Fuca from 2004 to 2008. They obtained 575 photos of 121 unique individuals.

o Other: Various independent researchers that have contributed photographs and related information.

Each year from 1998 to 2008, between 545 and 1490 identifications were obtained of gray whales totaling 12679 photos of 872 unique gray whales for the entire period (Table 1). These were conducted from March through November with most effort from June to September. Surveys were most numerous in British Columbia, along the south and west coasts of Vancouver Island and just north of Vancouver Island (Table 2).

2.1 Photographic Identification Procedures

Procedures during surveys by different groups varied somewhat but were similar in identification procedures. When a gray whale was found, the time, position, number of animals, and behaviors were recorded. Whales were generally approached to within 40-100 m and followed through several dive sequences until suitable identification photographs could be obtained.

For photographic identification of gray whales, both left and right sides of the dorsal region around the dorsal hump were photographed when possible. Most identification photographs were obtained with 35mm cameras most often with large 300mm lenses. We also photographed the ventral surface of the flukes for identification when possible. The latter method was not as reliable as the sides of the whale because the gray whales did not always raise their flukes out of the water. Markings used to distinguish whales included pigmentation of the skin, mottling, and scarring, which varied among individuals. These markings have provided a reliable means of identifying gray whales (Darling 1984). We also identified gray whales using the relative spacing between the knuckles along the ridge of the back behind the dorsal hump. The size and spacing of these bumps varies among whales and does not change over the years we have tracked whales. Figure 2 shows typical photographs and features used in making gray whale identifications.

Comparisons of whale photographs were made in a series of steps. All photographs of gray whales were examined and the best photograph of the right and left sides of each whale (for each sighting) were selected and printed (7 x 2.5 inch). To determine the number of whales seen during the year, the prints were then compared to one another to identify whales seen multiple days. Finally a comparison was made to the CRC catalog of whales seen in past years. Whale photographs that were deemed of suitable quality but did not match our existing catalog (compared by two independent persons) were considered "unique" identifications and assigned a new identification number and added to the catalog.

2.2 Data Analysis

The abundance of gray whales was estimated with open and closed population models for four nested spatial scales consisting of contiguous survey regions (Figure 1; Table3) 1) NCA-SEAK: the survey regions from Northern California (NCA) through Southeast Alaska (SEAK), 2) OR-NBC: survey regions from southern Oregon through Northern Vancouver Island/British Columbia (NBC), 3) OR-SVI: survey regions from southern Oregon through Southern Vancouver Island (SVI), and 4) MUA-SVI: the survey regions from MUA which includes Northern Washington coast (NWA) and Strait of Juan de Fuca (SJF) and SVI . The proposed hunt by the Makah Tribe would be in NWA. Gray whales photographed and identified anytime during the period between 1 June and 30 November (hereafter referred to as the "sampling period") within the defined region were considered to be "captured" or "recaptured". For each unique gray whale photographed, a capture history was constructed using the eleven years of data from 1998-2008. For example, the capture history 01001001000 could represent a gray whale photographed in 1999, 2002 and 2005 in the PCFA. The same gray whale may have had a capture history 01001000000 for a smaller spatial scale such as OR-SVI or may not have been seen at all (00000000000) and would not be used for the smaller spatial scale.

Multiple "detections" of a single whale within the sampling period were not treated differently than a single detection. A "1" in the capture history meant that it was detected on at least one day during the sampling period. However, multiple detections in the same year were used to construct an observed minimum tenure (MT) for each whale. MT was defined as the number of days between the earliest and latest date the whale was photographed with a minimum of one day for any whale seen.

2.2.1 Abundance using closed population models

Closed models for capture-recapture assume that the population is both geographically and demographically closed with no losses or gains. Due to births/immigration and mortality/emigration, closure would not be a reasonable assumption for the 11 year period but previous analysis has assumed closure for two consecutive years (e.g., Calambokidis et al. 2004). For those abundance estimates, a Lincoln-Petersen (LP) estimator (Seber 1982) was used in which each of the consecutive years (June-November) was a sampling occasion. Thus, it was assumed that all whales that were available to be photographed from June-November, 1998 were also available to be photographed from June-November 1999 and vice versa. If new whales joined in 1999 or whales from 1998 did not return in 1999, the closure assumption would be violated. A sequence of abundance estimates can be constructed using each consecutive pair of years (e.g., 1998-1999,1999-2000, etc). It is well known that the LP estimator can be unbiased even if there are losses or gains (Seber 1982) but not both (Kendall 1999) except for a completely random movement model. A completely random movement model is unlikely in this case because with more than 20,000 whales there would be few if any matches between years if movement in and out of the area was completely random.

The losses and gains each year are primarily from “transient” whales that are seen in one of the years and are never seen again in any other year. To remove this source of bias, we developed the following ad-hoc approach to remove the transients. For each pair of years in the computation of abundance with the LP estimator, we only used whales that were seen in one or more years other than the years being considered. For example, in computing an abundance estimate for 1999-2000 we only used whales that were also seen in 1998 or at least one year after 2000. This removed any transients that would have only been seen in either 1999 or 2000. It also removes those seen only in both years; while these are technically not transients their removal was unavoidable using this approach. This was done for each year pairing and we have called this estimation method “Limited LP”.

2.2.2 Abundance using open population models

In addition to the closed models, we fitted open population models to the 11 year time series of capture history data for each spatial scale to estimate abundance and survival. Open models allow gains due to births/immigration and losses due to deaths/emigration. Using the RMark interface (Laake and Rexstad 2008) to program MARK (White and Burnham 1999), we fitted a range of models to the data using the POPAN model structure. The POPAN model structure (Schwarz and Arnason 1996) provides a robust parametrization of the Jolly-Seber (JS) model structure in terms of a super population size (N), probability of entry parameters (immigration), capture probability (p), and survival/permanent emigration (φ).

It is essential to consider the population structure and its dynamics to build adequate models. In particular, we know from previous analysis of a subset of these data (Calambokidis et al. 2004) that some whales were seen in only one year between June-November and were never seen again. Transient behavior is a well-known problem in capture-recapture models and it is often addressed using a robust design which involves coordinated multiple capture occasions within each year and typically assumes closure within the sampling period (June-November). Region-wide coordinated surveys may be possible but would be difficult with variation in weather conditions. Also, the closure assumption within the year would be suspect due to variable timing of whales arrivals and departures into the PCFA. We also know from prior analysis that whales newly seen in year (y) were less likely to return (i.e., seen at some year >y) than previously seen whales but also newly seen whales that stayed longer (i.e., longer MT) in the PCFA were more likely to return. Likewise, previously seen whales were more likely to be seen in the following year (y+1), if they stayed longer in year y. Calambokidis et al. (2004) postulated that these observations were consistent with whale behavior that was determined by foraging success/failure.

Transient behavior in which an animal is seen only once can be modeled by including a different "first year" survival (Pradel et al. 1997) for the newly seen animals. Survival in the time interval after being first seen is dominated by permanent emigration rather than true mortality. Survival in subsequent time intervals represents true survival under the assumption that animals do not permanently emigrate except in their first year. To accommodate the "transient" effect, the whales were divided into cohorts based on the year in which they were first seen. Each cohort's first year survival was allowed to vary from subsequent survivals. "Newly seen" is not a particularly useful concept for the first year of the study (1998), because all whales are being seen for the first time. Thus, we also considered a model that allowed for a different first year survival and effect of MT for 1998 than for 1999-2007 and another model in which each cohort had a different first year survival. We also considered models that allowed a different first-year survival for whales identified as calves under the presumption that their true survival might be lower but that there probability of returning to the PCFA might be higher. In total we considered 8 models for survival (Table 5).

A cohort-specific super-population size was estimated for each cohort. These sizes were estimates of the number of whales that used the PCFA (or subset) during the sampling period for their first time. The estimated population size will be as large or larger than the number of whales newly seen during the year. This was a departure from Calambokidis et al. (2004) who assumed that all whales that were in the PCFA (or subset) were never missed and that capture probability reflected temporary emigration. In effect, Calambokidis et al. (2004) assumed each cohort super-population size was the number that were observed. The accidental discovery of a large number of whales in an area far offshore of Oregon in 2007 (Oleson et al. 2009; Calambokidis et al. 009b) made it particularly clear that this was a poor assumption. Thus, here we have not made this restrictive assumption and have chosen to use the standard assumption in JS models that newly seen whales have the same capture probability as previously seen whales. Lacking broad-scale data from a prior year, to estimate a cohort size for 1998 we had to assume that detection probability in 1998 was the same as in 1999 to make the former parameter estimable. We fitted 3 models for capture probability that varied by time (year) and/or varied by MT in the previous year (Table 5).

We used the individual covariate MT which was both whale and time-specific but we don't know those values for whales that were not caught. Thus, to fit these models we assumed that the covariate values for missed whales was the same as the average covariate value of captured whales. This was accommodated by centering the covariate values in each year such that the median was 0. Missed whales ("0" in the capture history) were assigned a value MT=0 and abundance estimation for each year was based on the median MT (centered 0 value).

We used Test 2 and Test 3 results from the Cormack-Jolly-Seber structure (Lebreton et al. 1992) as a general goodness of fit for the global model and as a measure of possible over-dispersion creating the lack of fit. We fitted each combination of models for S (survival) and p (capture probability) and used AICc (Burnham and Anderson 2002) to select the most parsimonious model of the 18 fitted models. Model averaging was used for all 18 models to compute estimates and unconditional standard errors and confidence intervals.

3 Results

The database from all eleven years (1998-2008) contains 12679 records; however 1930 are replicate identifications of whales on the same day. The database contains photographs of 872 unique whales seen from Southern California to Kodiak, Alaska with an average of 12.3 sightings/whale (range: 1- 202) where a "sighting" is one or more photographs on a day. Only 51.9% of the whales were seen on more than one day but many of these identifications are from early in the season during the migration as well as from peripheral areas such as Kodiak, Alaska (Table 6).

3.1 Seasonality

Whales have been photographed in every month of the year (Table 6) but with very few during December-February when most of the whales are in or migrating to Mexico and survey effort is reduced. Previous analysis of these data have always used 1 June - 30 November as the sampling period to describe the whales in the PCFA because whales seen prior to 1 June are more likely to be whales that are migrating through the region. The separation between May and June is clearly supported by the data. For example, of the 872 unique whales, 204 whales were only seen before 1 June and 84.3% of those were only sighted once. In comparison, of the 668 whales sighted between June and November, 40% were only sighted once. If sightings in Alaska are excluded, then only 32.7% of the 566 were seen only once.

The break between May and June is apparent in various measures such as proportion of whales sighted more than once, sighted in more than one region, and sighted in more than one year (Figure 3). However, the break is more apparent if the identifications are divided into subsets of survey regions (Figure 4). In particular, the difference across months is not as strong for regions such as the inland waters of Washington and British Columbia (NPS, SJF) because these are whales that have diverted from the migration and are either more likely to remain after 1 June or demonstrate high year-to-year fidelity during spring such as with NPS. The pattern across months is also weaker for Southern Vancouver Island

(SVI) which is in the main migration corridor; however, that is due to sampling efforts being focused on the spring herring spawn in Barkley Sound (effectively an inland waterway) and therefore undersampling passing migrant whales (Brian Gisborne, pers. comm.). The break between May and June is much more apparent for NWA and the other areas in the migration corridor. These observations are consistent with the northbound migration of gray whales proceeding past Washington through May. Resighting rates of whales seen after 1 June remained high through November.

The proposed Makah gray whale hunt will occur in NWA after 30 November and prior to 1 June. There have been 74 whale sightings in NWA prior to 1 June of which 20.3% (15) were of whales that were seen in the PCFA after 1 June at some time. All of those whales were sighted after 1 June in SVI and over 80% (12 whales) were seen in MUA (Figure 5). Of those 12 whales, 11 were seen in NWA, 9 were seen in SJF and only 1 whale was seen in SJF that was not seen in NWA. In comparison, 23 whale sightings were in SJF prior to 1 June of which 82.6% (19) were of whales that were seen in the PCFA after 1 June at sometime, emphasizing the importance of restricting a hunt to coastal waters of the MUA (i.e., the NWA) to limit the take of whales from the PCFA. Therefore, with a proposed hunt in the winter/spring in NWA, an assessment of impact on whales in the PCFA needs to consider a target population of whales contained in MUA and SVI after 1 June because all or most of the whales seen in the NWA before 1 June and seen after 1 June in the PCFA are likely to be found in the MUA and SVI.

3.2 Regional Sighting Patterns

There is considerable variation in the annual regional distribution of numbers of whales photographed during the sampling period (Table 7) which is in part due to variation in effort. Although not a true measure of effort, the number of days whales were seen (Table 8) does reflect the amount of effort as well as abundance of whales. In particular, in comparison to other regions, the large number of sightings in SVI partly reflects large numbers of sampling days by Brian Gisborne who has routinely sampled SVI 2-3 days a week. On the other hand, the decline in sightings in SVI during 2007 was not due to reduced effort but to the distribution of whales with many of the whales having moved to waters off Oregon and Washington (Calambokidis et al. 009b).

Whales were sighted across various survey regions and the interchange of whales (Table 9) between survey regions during 1 June - 30 November depends on proximity of the regions (Calambokidis et al. 2004). Of the whales sighted in regions from SOR to NBC, depending on the region, from 57-73% of the whales were seen at some point within MUA-SVI (Figure 6). However, whales seen in California or Alaska were much less likely to be seen in MUA-SVI.

If we look at latitudes of sightings of individual whales across the 11 years using whales that have been sighted on at least 6 different days (Figure 7), we see that sightings of some whales are highly clustered; whereas, sightings of other whales are highly dispersed across several regions. We defined each whales primary range by the 75% inner quantile which is the middle of the range that includes 75% of the locations. The length of the 75% inner quantile in nautical miles exceeded 60 nautical miles (or 1 degree of latitude) for 40% of the whales (Figure 8) and it was more than 180 nautical miles for more than 15% of the whales. Thus, it makes little sense to compute an estimate of abundance for any region that spans less than a degree of latitude.

There was a large variation in the frequency of sightings for whales (Table 10). Most whales that were seen during June-November 1998-2008 in the PCFA (NCA to NBC) were only seen in one year and the whales that were seen in more years were sighted more often each year and therefore represented a large proportion of the sightings (Figure 9). Likewise, examination of MT in the first sighting year demonstrates that whales who stay longer in their first year were more likely to be seen in a following year (Figure 10). Whales "first" seen in 1998 includes some whales that were truly new to the PCFA in that year but many were only "new" because it was the first year of the study. This is evident (Figure 10) in the much higher proportions for 1998 than for the other years. These relationships are important in capture-recapture models for abundance estimation. For example, in an open population model, whales that do not return after their first year (a large percentage in this analysis) would appeared to have not survived because they have permanently emigrated (with a small fraction that died).

3.3 Mothers and calves

While a relatively low proportion of calves have been sighted from the summer and fall sightings of gray whales, 33 different gray whales identified as PCFA whales were seen as definite or probable mothers with calves representing 41 likely births, six whales were seen with calves multiple seasons (two or three) (Table 11). Two individuals were sighted with calves in three years, the most we documented, however, in both cases one of these calves was documented outside the 1998 to 2008 primary study period. One individual (ID#81) was observed with a calf in 2001, 2003, and 2009 (not all data from 2009 has been analyzed) and the other individual (ID#67) was seen with a calf in 1995, 2002 and 2004.

Four of the 41 calves occurred outside our primary study period, three prior to 1998 and one known female who was known to have a calf in 2009, leaving 37 or just over three per year during our primary study period 1998-2008 (Table 12). These likely represent a minimum estimate of the births occurring because: 1) collaborators did not always note the presence or absence of calves, 2) as described below, calves weaned from their mothers, making them unidentifiable as calves, as early as June and July. Both these factors would tend to result in underestimates of the presence of calves.

The number of mothers of calves seen varied dramatically by year from 0 to 9 and was concentrated in a four-year period (2001-2004) which accounted for 28 of the 41 sightings. During this 4-year period an average of 7 calves were seen while an average of just over one calf per year was seen in the other seven years (9 calves in 7 years). Even among these known or suspected mothers, the proportion of years they were seen where they had a calf average only 14% although it was 39% and 36% during the peak years of 2001 and 2002, which would be closer to what would be expected if females were getting pregnant almost every other year.

In 18 cases, a calf was seen associated with its mother early in the season and then either the mother or the calf was resighted later in the season apart, suggesting weaning had occurred. The latest a mother was seen associated with its calf was 6 September (CRC 67 with calf CRC 698 in 2002) and there were indications of separation of calves from their mothers as early as June. In two cases either the mother or calf was seen separated in June, however, in neither case was the calf resighted in the future year (although the mother was) suggesting these calves may not have survived. In at least seven cases the weaning had occurred prior to a July sighting (and possibly earlier).

Of the 33 likely mothers documented, 20 had been seen four or more years in the study area (13 had been seen only 1, 2, or 3 years). Even those animals with long sighting histories were seen with calves in only a small proportion of the years but as shown in Table 11, often the initial sighting of these animals was in late August or later, past the period when weaning may have occurred.

Some of these whales commonly seen in the Pacific Northwest were sighted with calves outside of this region and the somewhat atypical locations may suggest they may behave differently in years they have a calf. One mother (ID#281) was regularly sighted in the PCFA area including every years from 1999 to 2007. In only one of those years was she with a calf (2002). In 2008, however, she was seen on 19 April off Santa Barbara, Southern California apparently in the migration with a small calf but neither of them were seen that year in any of our effort farther north from Northern California to Southeast Alaska. Another case not included in our summary because the calf was never seen in the our study area and also there was uncertainty of who was the mother, was an apparent calf (ID 962) sighted off San Miguel Island on 27 July 2006 but which was accompanied by two adults (ID 359 and 718) both of whom were seen in most years from 2002 to 2008 in the Pacific Northwest (Northern California to Southeast Alaska), but not in 2006. Both the mothers and calves from these two sightings were not seen in the Pacific Northwest in their birth year (despite the mothers being seen most other years) and were only opportunistically sighted outside the region, suggesting there may be other calves born to animals that use the Pacific Northwest that perhaps do not come into sampled areas (either within or outside the Pacific Northwest) in their birth year. This would negatively bias estimates of the number of calves born to these animals.

One important question in evaluating the population structure of the gray whales using the Pacific Northwest feeding areas is how animals are recruited to this group. We examined the sighting histories of the identified calves to determine if they tended to be seen in future years. Animals that were not seen in future years could reflect either mortality in the first year of life or animals that did not continue to feed in the Pacific Northwest in future years. There were 39 calves or suspected calves identified with their mothers through 2008 in the study area. Just under half of these (18) had been seen only in the year they were calves and 21 (54%) had been resighted in years after they were calves. Using only the 30 calves seen through 2004 (to allow a follow up period to resight animals, 19 (63%) have been resighted in a later year. The 37% not seen in a following year could be the result of: 1) the calf dying, 2) the calf not returning to the area or not yet resighted during its return, or 3) the calf not being recognized by photo-ID since calves can undergo changes in markings rapidly especially if not seen for several years. Given all these factors the resighting rate of calves does suggest a high proportion of surviving calves appear to become part of the small feeding aggregation that uses the Pacific Northwest.

3.4 Open Population Capture-Recapture Models

If the yearly cohorts were pooled, Test2+Test3 statistics indicated a significant lack of fit for the PCFA and subsets (Table 13) primarily resulting from Test 3. This was expected due to the different "survival" rates of previously seen whales (true survival) and newly seen whales of which many never returned (i.e., permanently emigrated) (Table 14) . By separating the cohorts, survival for each cohort was time-varying and thus each cohort has a separate first year survival. In this case, the goodness of fit test (Test 2 only) did not demonstrate a lack of fit except for OR-NBC and NCA-SEAK. For those regions, we estimated over-dispersion values of $\widehat{c}$=2.11 and $\widehat{c}$=2.28 respectively, to adjust AICc and estimated standard errors. The lack of fit for OR-NBC and NCA-SEAK is probably related to the inclusion of NCA, WVI and NBC which are at the fringes of the PCFA. Effort in NCA and WVI has been less regular than the other survey regions and whales in NBC have a higher degree of interchange with Alaska.

The best fitted model (Table 15) was always model 2 for p. For φ the best model depended on the spatial scale. For MUA-SVI and OR-SVI, model 7 was best with some support for model 8. For OR-NBC and NCA-SEAK, simpler models for φ with fewer parameters were supported due to the assumed over-dispersion. As shown in Calambokidis et al. (2004), the analysis demonstated strong support for the effect of MT on first year survival (Figure 11-12) and capture probability (Figure 13) in the following year for all spatial scales. First year survival estimates were dominated by permanent emigration. For MUA-SVI, the estimates varied from 0.18 to 0.47 for non-calf whales with MT=1 in their first year and from 0.63 to 0.93 for MT>80 in their first year (Figure 11). For calves, they were more variable but generally higher presumably because they were more likely to return in a following year. Survival subsequent to the first year was assumed to be constant and represent true survival assuming there was little permanent emigration after the first year. Those estimates were 0.951 (se=0.0112), 0.95 (se=0.0098), 0.948 (se=0.0123) and 0.945 (se=0.0118)for MUA-SVI, OR-SVI, OR-NBC, NCA-SEAK respectively. For the analysis of MUA-SVI, there was large year to year variation in capture probability from 0.18 to 0.94 depending on the year and value of MT (Figure 13). The lowest values were from 2007 which reflects the temporary emigration of whales from MUA and SVI to waters offshore of Oregon in that year.

3.5 Abundance and Recruitment

For MUA-SVI, OR-SVI, OR-NBC, and NCA-SEAK annual estimates of abundance were constructed with LP, Limited LP and model averaged values for the POPAN models (Figure 14, Tables 16-21). Estimates are only shown for 1999-2008 because with the closed models only 10 estimates can be constructed with the 11 years of data. In general, the estimates from the POPAN models are intermediate between the higher estimates from LP and lower estimates of Limited LP. This was expected because Limited LP estimates the abundance of whales excluding transient whales; whereas, LP attempts to estimate a total abundance which includes transient whales except that it is positively biased because there are losses and gains in each set of years. The POPAN models allow for gains and losses and the estimate of abundance each year includes the estimate of the new whales that entered that year and the number that have survived (i.e., lived and did not permanently emigrate) from whales seen in previous cohorts. The annual abundance estimate from the POPAN models includes some transient "new" whales that will permanently emigrate and thus should be higher than the Limited LP estimate which excludes transients. The abundance estimates from Limited LP for 2008 are biased low because new whales that enter that year have no chance to be re-sighted and thus they excluded even though some may return in the ensuing years. To a lesser degree, the estimates of 2007 and possibly 2006 are influenced in a similar manner because the whales may have been simply not seen yet even though they are returning.

Excluding the LP estimator which will be biased high and the Limited LP estimates for 2008 which will be biased low, the most recent N_{min}values range from 109 (Table 18) to 211 (Table 21) across the four spatial scales. To gain a sense for how these values might be relevant to estimating a possible level of removal (e.g., due to harvest) we ran calculations using the MMPA's Potential Biological Removal (PBR) formula (typically reserved for stock-level assessments). Using the PBR formula, with a default Rmax of 4% and a recovery factor of 1, the PBR for this group of whales would be 2.2 to 4.3. For the smallest region considered (MUA-SVI), the PBR would range from 2.2 to 2.5 whales for the 2007 limited LP (Table 18) and 2008 POPAN estimates (Table 20).

New whales have continually appeared annually and many of these new whales have subsequently returned and been re-sighted (Table 14). In MUA-SVI from 1999-2008, an average of 22.7 (range: 5.0, 56.0) new whales were seen each year. Of these new whales, on average 10.1 (range: 1.0, 19.0) whales returned and were seen in subsequent years. While these numbers vary annually there has been sufficient numbers of newly seen whales to replace a removal of at least 2 whales annually.

4 Discussion

The population structure of gray whales using the Pacific Northwest in summer and fall is complicated and involves two elements. One group of whales return frequently and account for the majority of the sightings in the Pacific Northwest during summer and fall. This group is certainly not homogeneous and even within this group, there is some degree of preference for certain subareas. Despite widespread movement and interchange among areas, some of these gray whales are more likely to be seen returning to the same areas they were seen before. The second group of whales are apparent stragglers encountered in this region after the migration. These animals are seen in only one year, tend to be seen for shorter periods that year, and in more limited areas.

The existence of these two groups in the study area and their dynamics complicate estimating abundance. The various methods we used here for estimating abundance try to deal with this in different ways. The estimates from the unadjusted Lincoln Petersen incorporate whales from both of these groups and the inclusion of the stragglers violates the closure assumption and creates a positive bias. This explains the higher estimate obtained with this method. The Limited Lincoln Petersen estimate specifically excludes the stragglers and only estimates the abundance of whales that return after the year of the initial sighting. It is useful except for the last year in which new whales that may return are excluded because they have not had a chance to return. The Limited Lincoln Petersen estimates were similar or slightly less than the estimates from the Open models because the latter include stragglers that were present in each year. However, the Open models are not biased like the unadjusted Lincoln-Petersen because they include a first year "survival" that is lower for those whales because they are less likely to return. The Open models should provide a better estimate of the annual number of whales that are present.

Despite extensive interchange among subregions in our study area, whales do not move randomly among areas. Abundance estimates were lower when using more limited geographic ranges but these more limited areas do not reflect closed populations. While the use of geographically stratified models can be useful in cases where populations have geographic strata they use (see for example Hilborn 1990), this would be difficult in our case because of the frequent sightings of animals in multiple regions within the same season and these models typically only allow an animal to be sighted in one strata per period. This could be dealt with by assigning animals to only a single region per season but this would be forcing the data into a somewhat inaccurate construct.

Several studies have considered the question of gray whale population structure. There is widespread agreement that at least two populations of gray whales in the North Pacific exist, a western North Pacific population (also called the Korean population) and an eastern North Pacific (ENP) population (sometimes called the California population) (Swartz et al. 2006; Angliss and Outlaw 2008; Rugh et al. 1999). The population structure of the gray whales feeding in the Pacific Northwest has remained in question and only a few studies have examined this. Steeves et al. (2001) did not find mtDNA differences in a preliminary comparison of gray whales from the summer off Vancouver Island and those from the larger ENP population. Ramakrishnan et al. (2001) did not find evidence that the Pacific Northwest whales represented a maternal genetic isolate, although even very low levels of recruitment from the larger overall population would prevent genetic drift. More recently, Frasier et al. (in prep.) have examined mtDNA differences in a larger sample of gray whales from Vancouver Island than tested by Steeves et al. (2001) and found significant differences in the haplotype frequencies between that sample and data reported for the breeding lagoons off Mexico. The Frasier et al. (in prep) study has had some limitations including samples taken from a single primary location off Vancouver Island, comparison to the breeding lagoons (where genetic differences in the lagoons have also been reported), and no verification by microsatelite analysis that whales have not been duplicated. However, Frasier et al. (in prep) provides the strongest evidence to date that the Pacific Northwest whales might be sufficiently isolated to allow maternally inherited mtDNA to differ from the overall ENP population.

Population structure in other large whales has been the subject of recent inquiry and has revealed diverse results for different species. Clapham et al. (2008) examined 11 subpopulations of whales subjected to whaling that were extirpated possibly due to the loss of the cultural memory of that habitat and concluded subpopulations often exist on a smaller spatial scale than had been recognized. Studies of other baleen whales, particularly humpback whales, have shown evidence of maternally directed site fidelity to specific feeding grounds based on photographic identification studies (Calambokidis et al. 1996, 2001, 2008). This high degree of fidelity to specific feeding areas is often discernible genetically. In the North Pacific strong mtDNA differences were found among feeding areas even when there was evidence of low level of interchange from photo-ID (Baker et al. 2008). Similar findings were documented for humpback whales in the North Atlantic which feed in different areas but interbreed primarily on a single breeding ground (Palsboll et al. 1995) like ENP gray whales. In the North Pacific the differences for humpback whales were often dramatic. For example, humpback whales that feed off California have almost no overlap in mtDNA haplotypes with humpback whales feeding in Southeast Alaska (Baker et al. 1990, 1998, 2008). One difference between humpback and gray whales is the coastal migration route of gray whales which means gray whales going to arctic waters to feed would migrate right through the feeding areas to the south. Other species of large whales have not shown as strong site fidelity to specific feeding grounds. Blue whales have undergone an apparent shift in their feeding distribution in the North Pacific apparently due to shifting oceanographic conditions (Calambokidis et al. 009a). Fin whales in the North Pacific have long migrations and while there do not appear to be multiple distinct feeding areas as was the case for humpback whales, there were some distinct and isolated apparently non-migratory populations (Mizroch et al. 2009; Berube et al. 2004).

Even though the population structure of gray whales off the Pacific Northwest remains unresolved, there is a consistent group of animals that use this area and we provide several estimates of their abundance. Different abundance methods and geographic scopes yield varied results but all suggest the annual abundance of animals using the Pacific Northwest for feeding through the summer is at most a few hundred animals depending on the estimating method and how broadly the region is defined geographically.

Acknowledgments

This analysis would not have been possible without the collaborating organizations and individuals contributing identification photographs (the primary contributors are listed in Methods and Tables 1 and 2). Support for the photographic identification reported here, the comparison of gray whale photographs and preparation of this report came primarily from the National Marine Mammal Laboratory. Permission to conduct some portions of this research in U.S. waters was provided by the U.S. National Marine Fisheries Service and the Makah Tribal Nation. Portions of the research in British Columbia were conducted collaboratively with Fisheries and Oceans Canada (thanks to John Ford and Graeme Ellis). Volker Deecke assisted in analysis and matching of identifications from S. Vancouver Island. William McGill coordinated providing sightings and identifications from CERF, Dawn Goley coordinated effort for HSU, Christina Tombach and Dave Duffus coordinated efforts for UVIC, Carrie Newell provided identification photographs from Oregon, Merrill Gosho, Pat Gearin, Nate Pamplin and Jon Scordino provided photos form Washington. Brian Gisborne's diligence and hard work provided an immense amount of data and photographs from Vancouver Island. A number of people assisted in the field effort and in the printing and matching of photographs at Cascadia Research. Erin Falcone and Lisa Schlender helped compile the data from different contributors and conducted some of the photographic matching. Randy Lumper conducted gray whale matching in the early years of this study. Steve Stone, Donna Darm and Jon Scordino provided helpful comments.

Table 3: Survey regions and region subsets used for abundance estimation. Numbers refer to locations on the map in Figure 1.

Survey Region	Region Description	NCA-SEAK	OR-NBC	OR-SVI	MUA-SVI
(1) SCA = Southern California					
(2) CCA = Central California					
(3) NCA = Northern California	Eureka to Oregon border; mostly from Patricks Pt. and Pt. St George	x			
(4) SOR = Southern Oregon		x	x	x	
(5) OR = Oregon Coast	Primarily central coast near Depoe Bay and Newport, OR	x	x	x	
(6) GH+ = Gray's Harbor	Waters inside Grays Harbor and coastal waters along the S Washington coast	x	x	x	
(7) NWA = Northern Washington	Northern outer coast waters with most effort from Cape Alava to Cape Flattery	x	x	x	x
(8) SJF = Strait of Juan de Fuca	US waters east of Cape Flattery extending to Admiralty Inlet (entrance to Puget Sound)	x	x	x	x
(9) NPS = Northern Puget Sound	Inside waters and embayments from Edmonds to the Canadian border				
(10) PS = Puget Sound	Central and southern Puget Sound (S of Edmonds), including Hood Canal, Boundary Bay, and the San Juan Islands				
(11) SVI = Southern Vancouver Island	Canadian waters of the Strait of Juan de Fuca along Vancouver Island from Victoria to Barkley Sound, along West Coast Trail	x	x	x	x
(12) WVI = West Vancouver Island		x	x		
(13) NBC = Northern British Columbia	British Columbia waters north of Vancouver Island, with principal effort around Cape Caution	x	x		
(14) SEAK = Southeast Alaska	Waters of southeastern Alaska with the only effort in the vicinity of Sitka	x			
(15) KAK = Kodiak, Alaska					

Table 5: Model specifications for survival (φ) and capture probability (p) parameters in POPAN models for gray whale photo-identification data. Fy is 1 if it is year the whale was first seen and 0 otherwise. Fc is 1 for 1998 cohort and 0 otherwise. C is 1 if identified as a calf in its first year and 0 otherwise. MT is minimum tenure (centered so median is 0 each year) of a whale in its first year and 0 otherwise. $\beta_{Fy,1999}$ is for cohorts 1999-2007 and $\beta_{Fy,C}$ represents 9 cohort specific parameters for 1999-2007 (for the first year survival). β_{CF} is an adjustment for calf first year survival andβ_{CM} is an adjustment for calves to the slope of MT for survival. For the capture probability models, β_t has 9 levels for t=2000,...2008 and β_0 represents 1998 and 1999 value. Each POPAN model includes 11 parameters for the initial sizes of the 11 year cohorts.

Model	Parameter Logit Formula	Number of parameters
φ		
1	$\beta_0 + \beta_{Fy} Fy$	2
2	$\beta_0 + \beta_{Fy} Fy + \beta_M MT\, Fy$	3
3	$\beta_0 + \beta_{Fy,1998} Fy + \beta_{Fy,1999}(1 - Fc) Fy$	3
4	$\beta_0 + \beta_{Fy,1998} Fy + \beta_{Fy,1999}(1 - Fc) Fy + \beta_M MT\, Fy$	4
5	$\beta_0 + \beta_{Fy,1998}\, Fy + \beta_{Fy,1999}(1 - Fc)\, Fy + \beta_{M,1998} MT\, Fy + \beta_{M,1999}(1 - Fc)\, MT\, Fy$	5
6	$\beta_0 + \beta_{Fy,1998} Fy + \beta_{Fy,C} Fy\,(1 - Fc) + \beta_M MT\, Fy$	12
7	$\beta_0 + \beta_{Fy,1998} Fy + \beta_{Fy,C} Fy\,(1 - Fc) + \beta_M MT\, Fy + \beta_{CF} C\, F_y$	13
8	$\beta_0 + \beta_{Fy,1998} Fy + \beta_{Fy,C} Fy\,(1 - Fc) + \beta_M MT\, Fy + \beta_{CF} C\, F_y + \beta_{CM} C\, MT$	14
p		
1	$\beta_0 + \beta_t$	10
2	$\beta_0 + \beta_t + \beta_M MT$	11
3	$\beta_0 + \beta_M MT$	2

Table 11: History of mothers seen with calves during study. Each year a whale was seen, the first confirmed sighting date is shown for that year. Years where a calf was documented are shown in bold with an asterisk. Total years seen includes 9 sightings of whales during 1984,1988, 1990-1992 that are not shown but no calves were seen in those few cases.

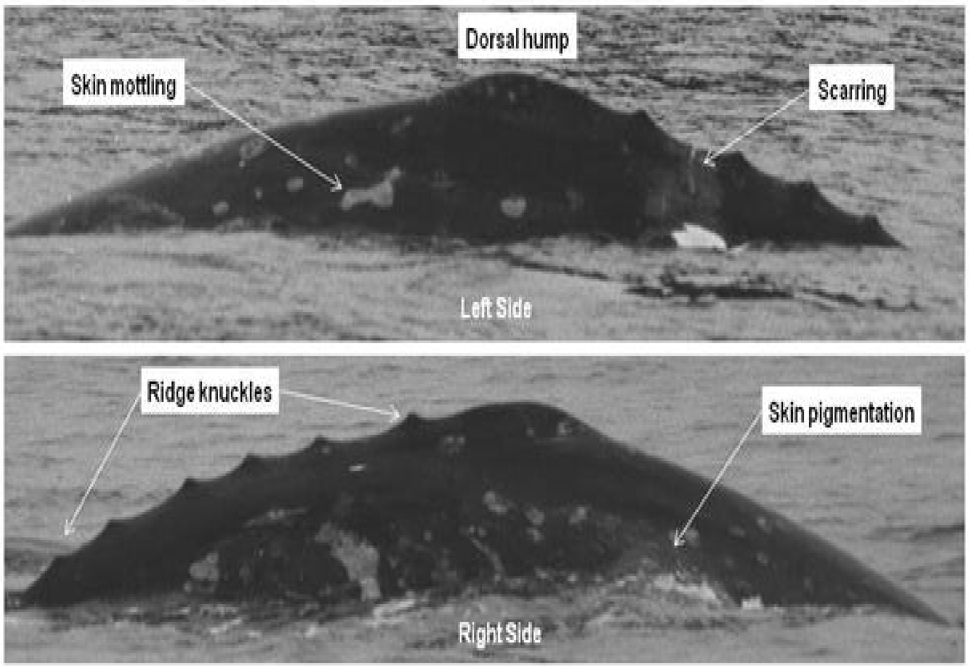

Figure 2: Characteristics used for gray whale photo-identification.

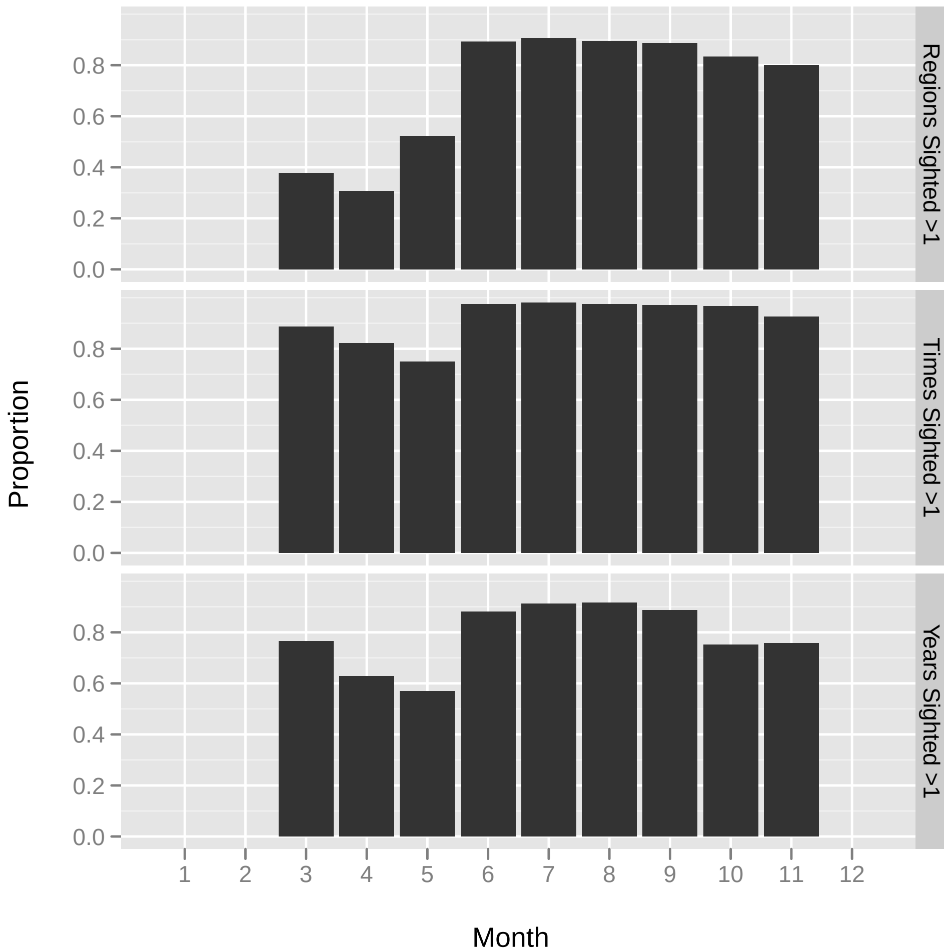

Figure 3: Monthly measures of proportion of whales that were seen in more than one region, seen on more than one day and seen in more than one year. The values include sightings from 1998-2008 in all regions from California to Alaska. Lower values imply whales were simply migrating through the area in a short time frame and were thus less likely to be seen at other times and in other regions. Values are not shown for months with fewer than 20 sightings.

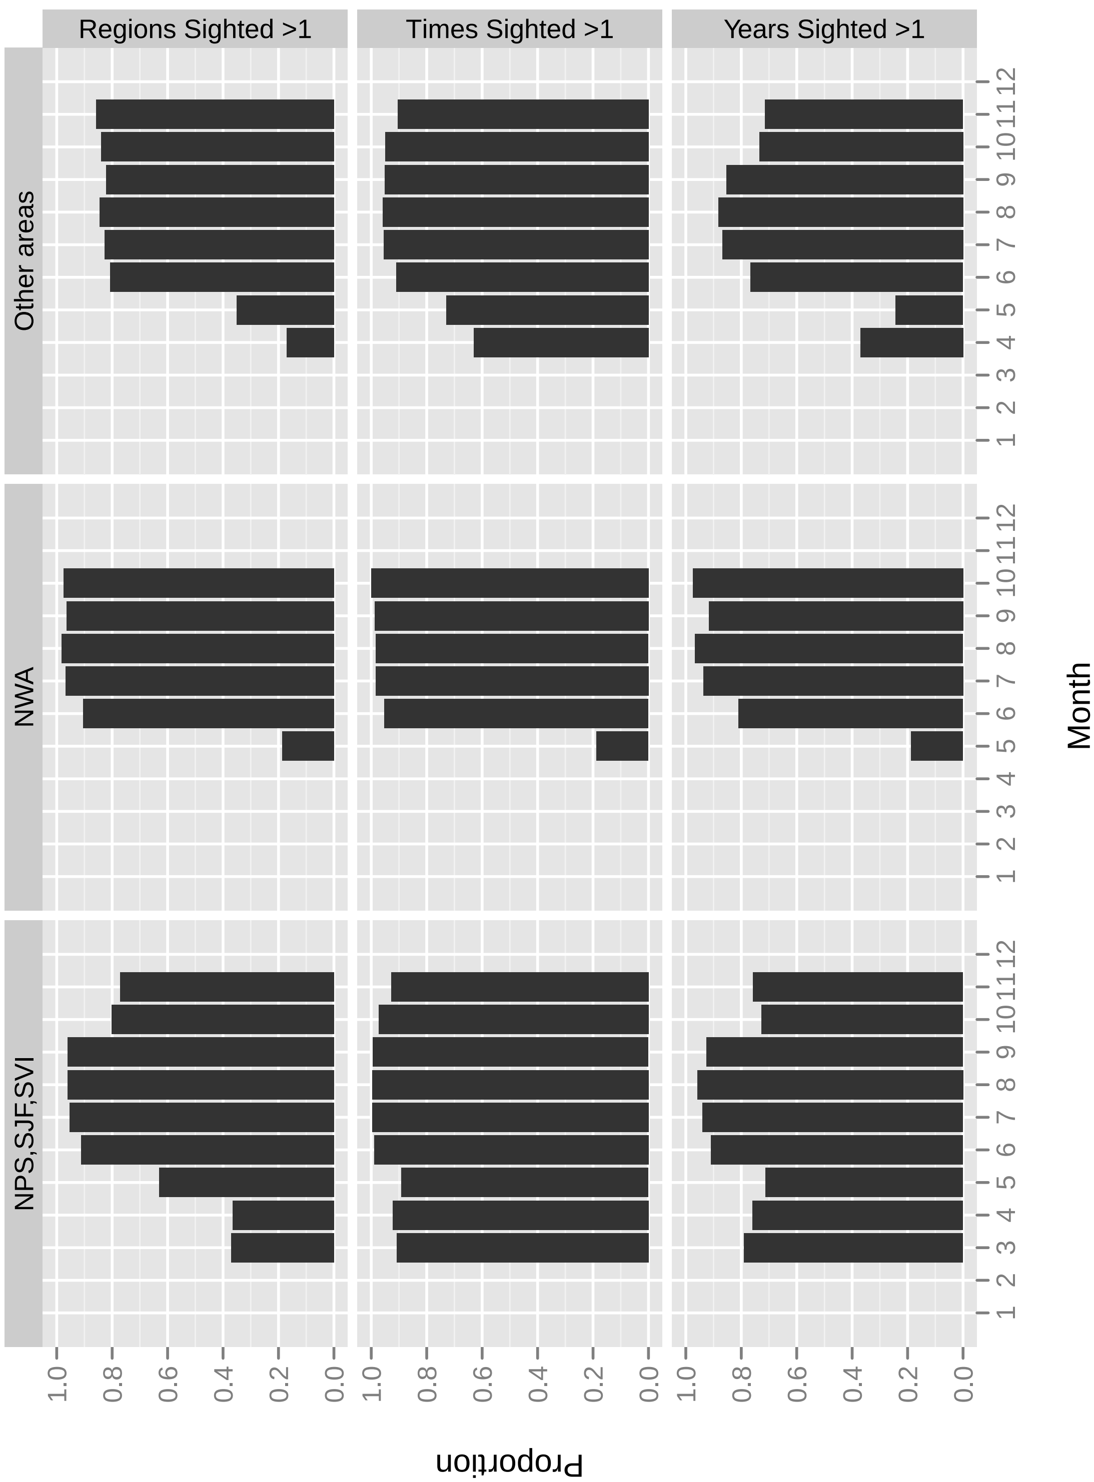

Figure 4: Region and monthly measures of proportion of whales that were seen in more than one region, seen on more than one day and seen in more than one year. The values include sightings from 1998-2008 in all regions from California to Alaska. Lower values imply whales were simply migrating through the area in a short time frame and were thus less likely to be seen at other times and in other regions. Values are not shown for months with fewer than 20 sightings.

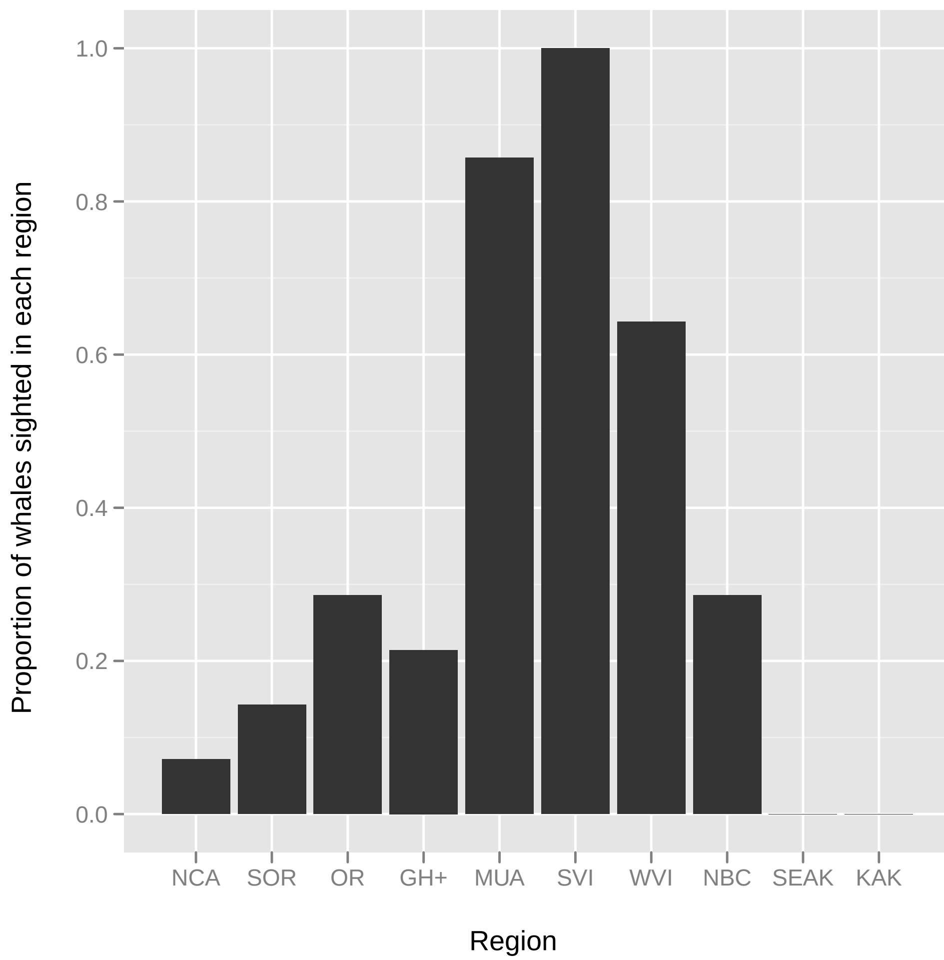

Figure 5: Proportion of the 14 whales seen in NWA during the spring and in the PCFA after 1 June that were seen in each PCFA sub-region after 1 June at least once from 1998-2008.

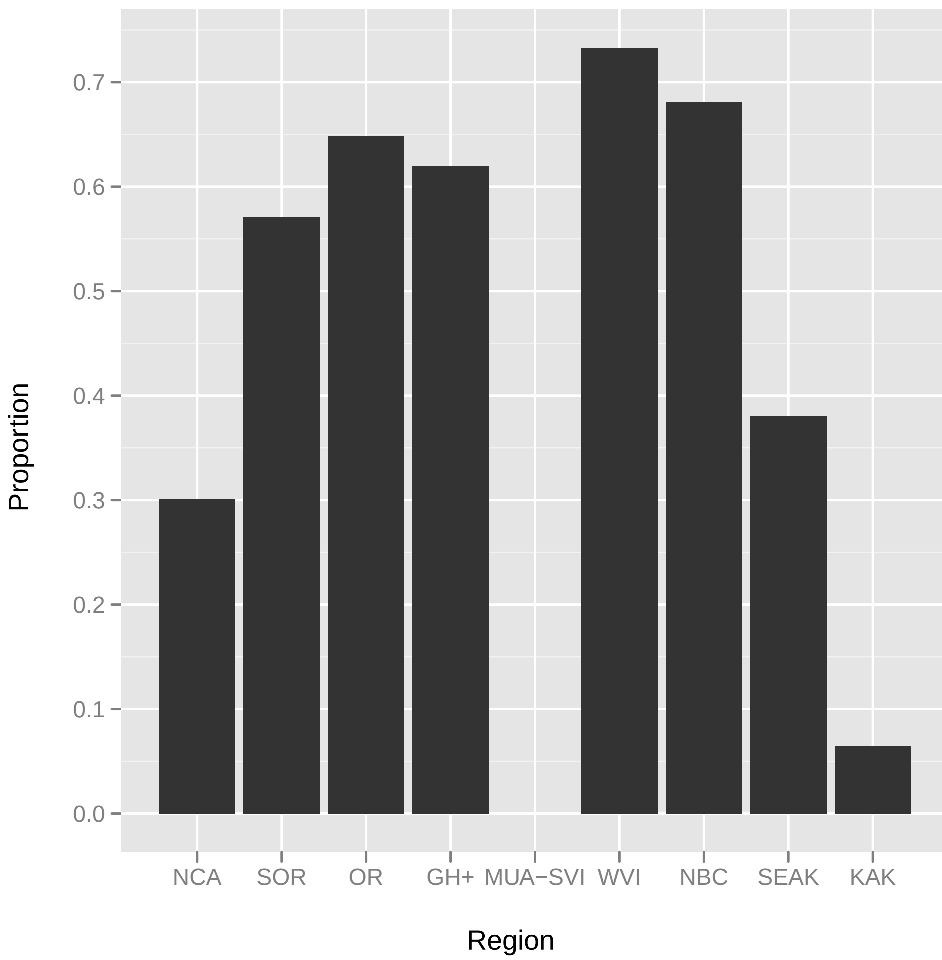

Figure 6: Proportion of whales in PCFA sub-regions that have been seen in the MUA-SVI using sightings after 1 June from 1998-2008.

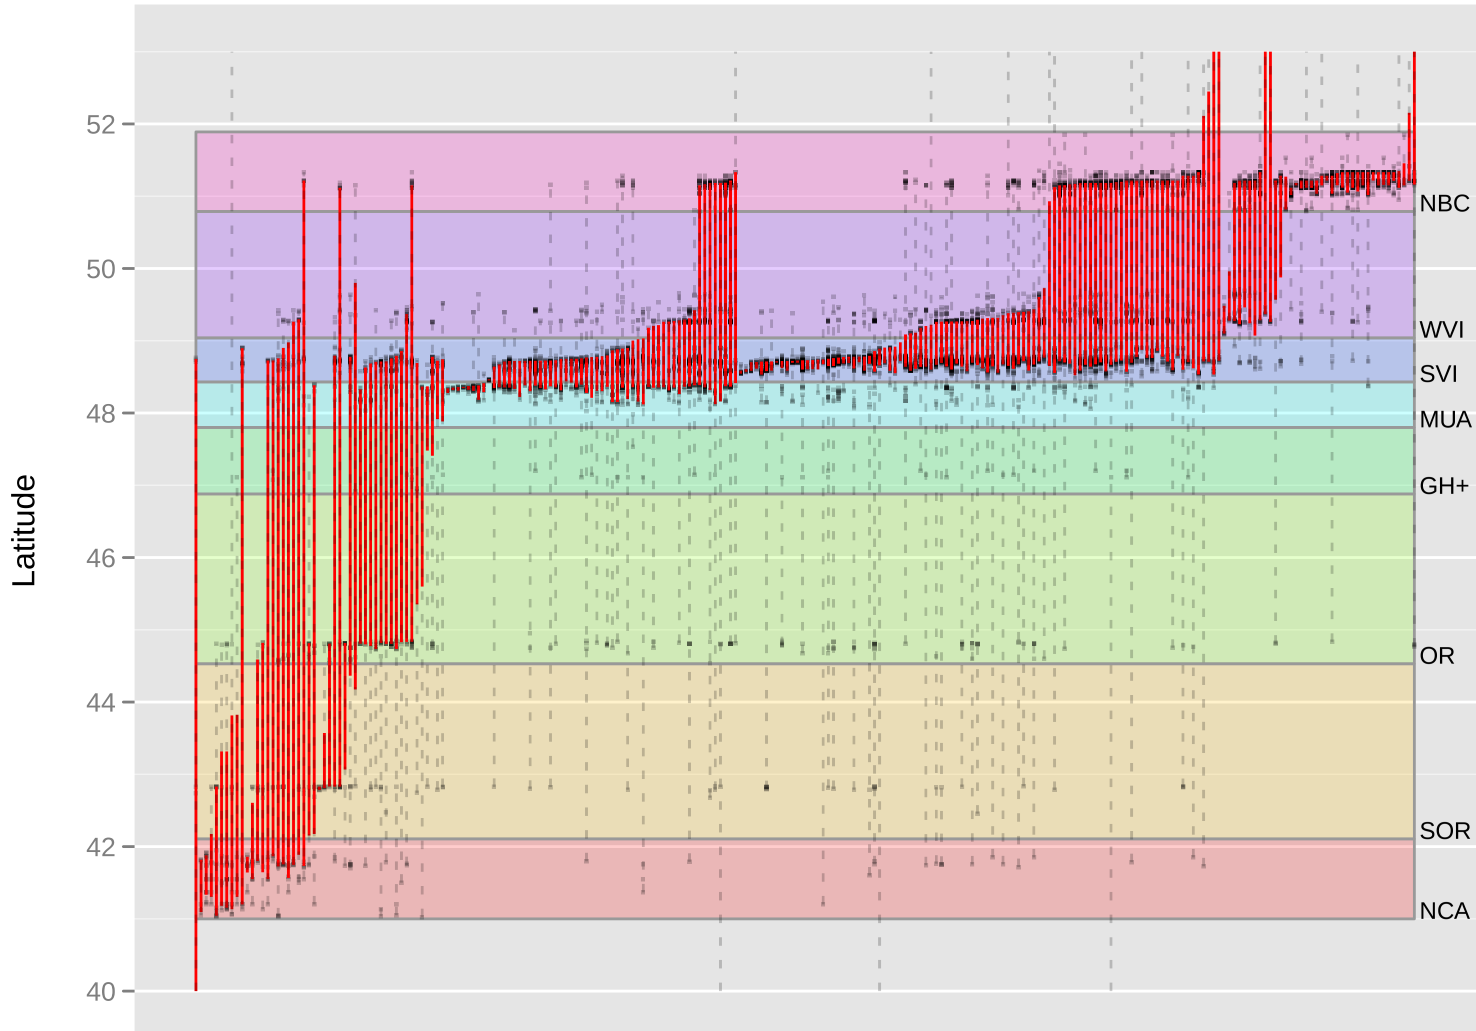

Figure 7: Distribution of latitudes of sightings (points) for whales with 6 or more sightings after 1 June from 1998-2008, the 75% inner quantile (solid thick line), and full range (light dashed line). Each position on the x axis represents an individual whale. Whales have been arranged on the plot by sorting first on the lower bound of the inner quantile (to a half-degree) and then the upper bound of the quantile. This has the effect of sorting from south to north and clusters whales with smaller quantile ranges followed by whales with larger ranges.

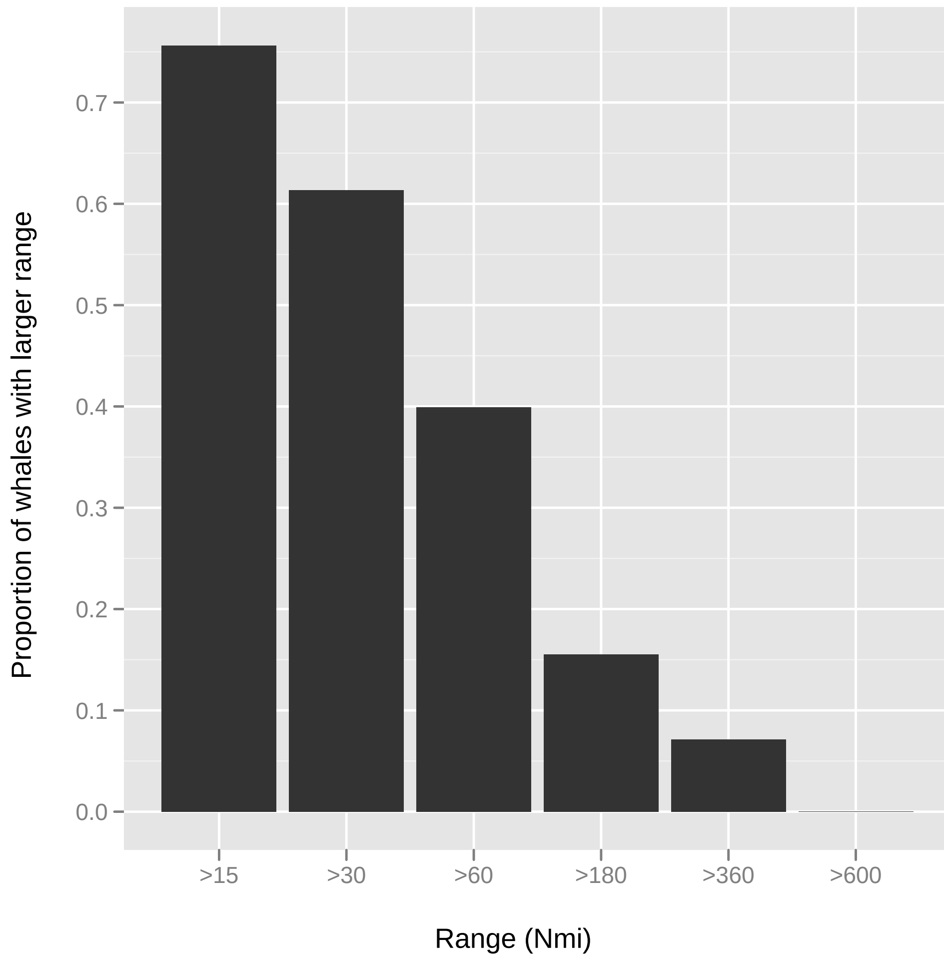

Figure 8: Distribution of ranges of 75% inner quantiles of latitudes expressed in nautical miles for whales sighted on 6 or more days during 1998-2008.

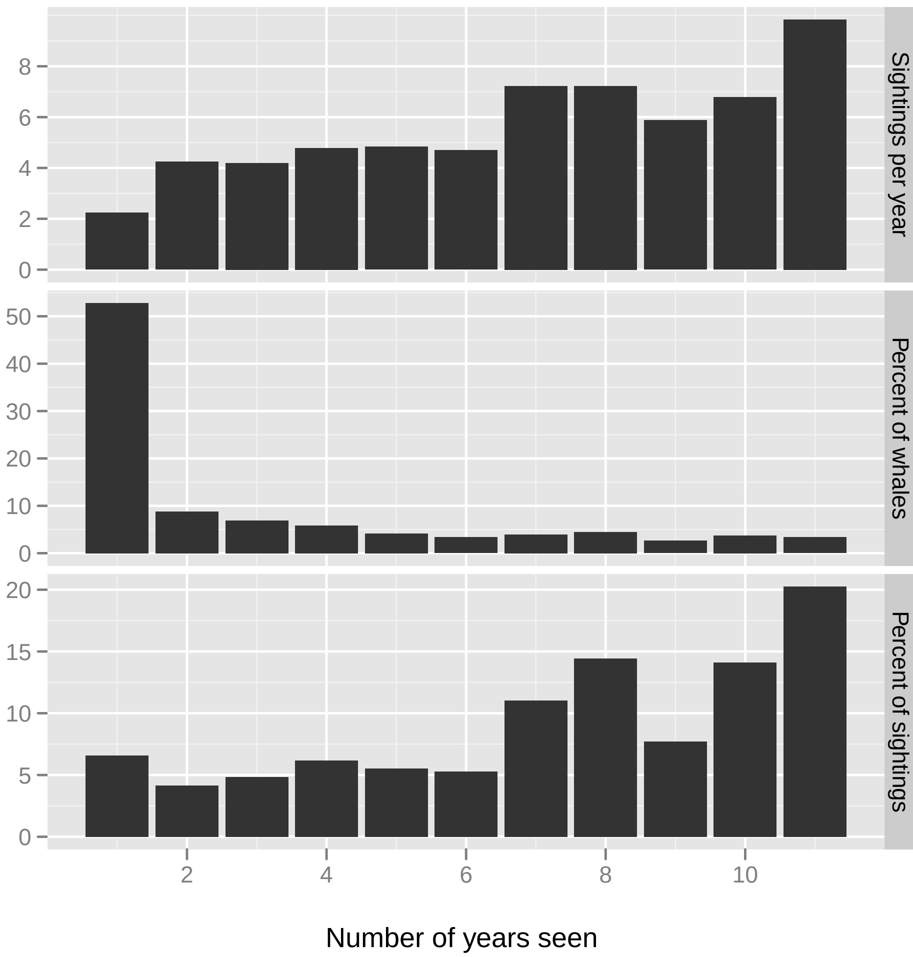

Figure 9: Average number of sightings per year and distribution of whales and numbers of sightings based on numbers of years a whale was seen in NCA-NBC between June-November during 1998-2008.

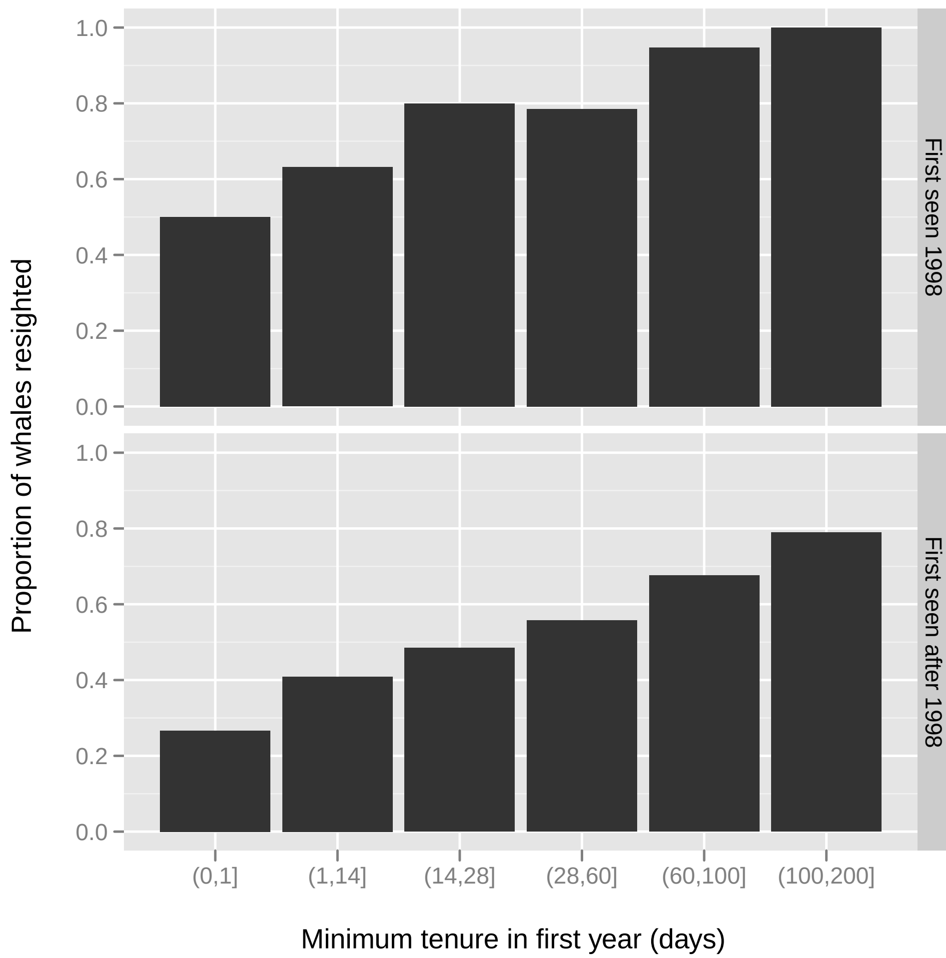

Figure 10: Influence of minimum tenure (MT) in the first year the whale was photographed on the probability it will be re-sighted in one or more following years for whales seen in NCA-NBC for June-November 1998-2008. The bar graphs are divided for 1998 and >1998 because 1998 is the start of the study and it may not be the first year for many of those whales. Re-sightings for 2008 are used but initial sightings for 2008 are excluded because there are no data beyond to evaluate re-sighting probability.

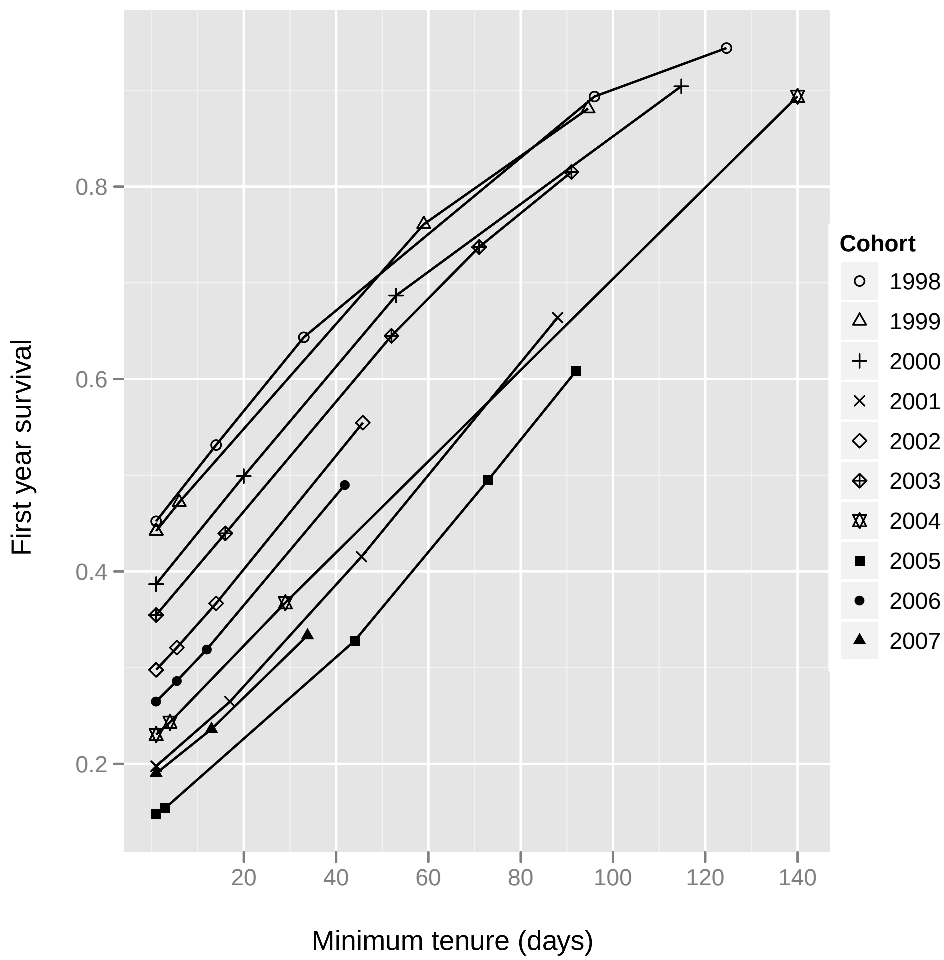

Figure 11: For MUA-SVI analysis of 1998-2008 data, model-averaged estimates of first year survival of non-calves for each cohort at 5%, 25%, 50%, 75%, and 95% quantiles of minimum tenure values for that cohort.

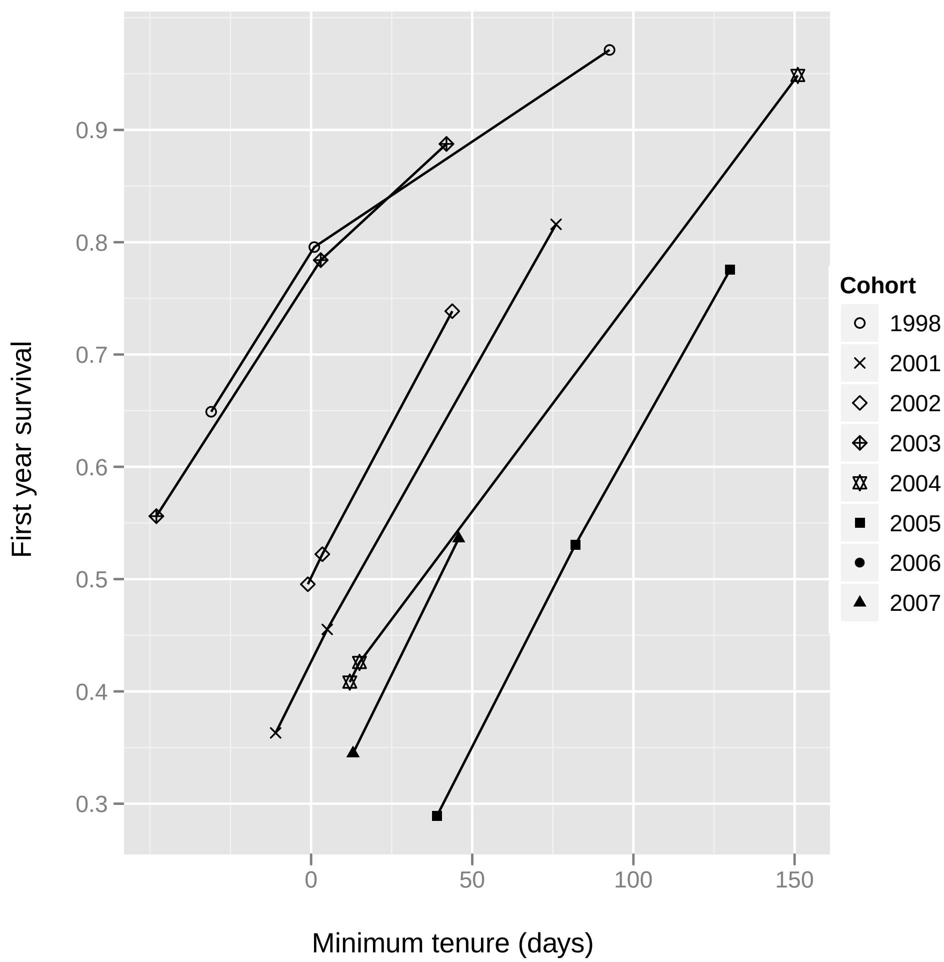

Figure 12: For MUA-SVI analysis of 1998-2008 data, model-averaged estimates of first year survival of calves for each cohort at 5%, 50%, and 95% quantiles of minimum tenure values for that cohort of calves. Cohorts 1999 and 2000 are not shown because no calves were identified in those years.

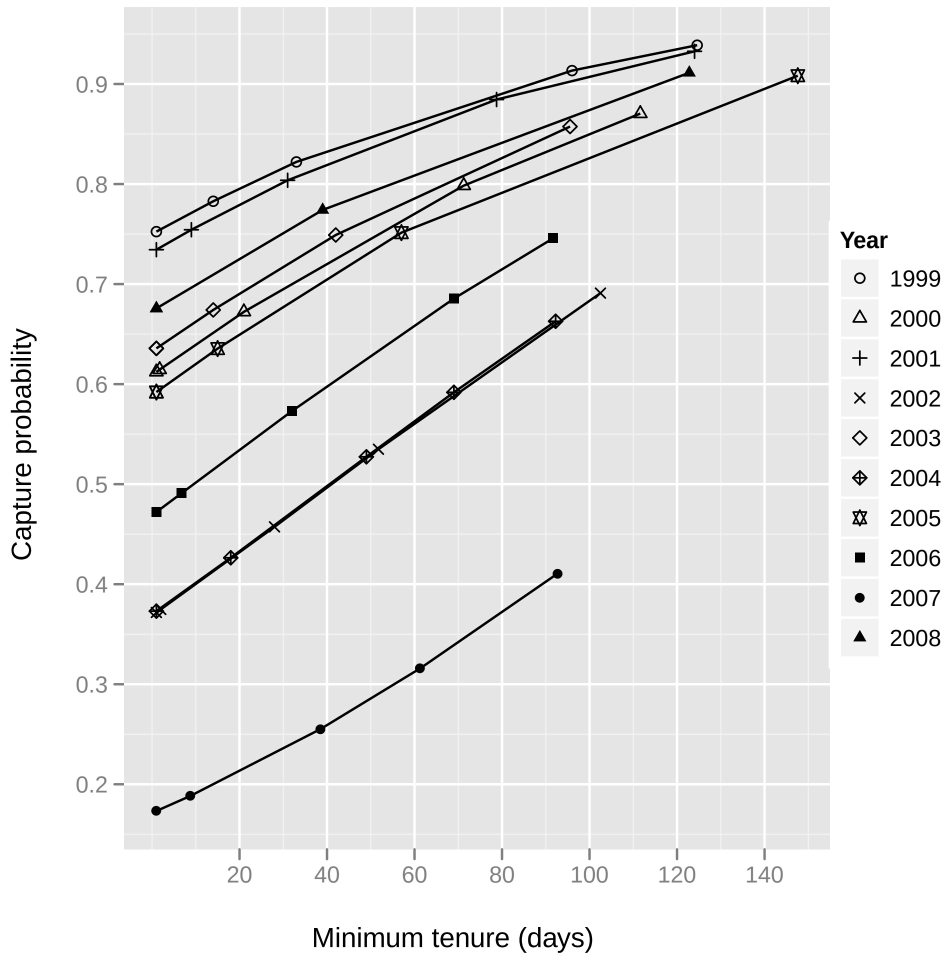

Figure 13: For MUA-SVI analysis of 1998-2008 data, model-averaged estimates of capture probability for each year at 5%, 25%, 50%, 75%, and 95% quantiles of minimum tenure values for whales in the previous year.

Updated analysis of abundance and population structure of seasonal gray whales in the Pacific Northwest, 1996-2015

John Calambokidis, Jeffrey Laake, and Alie Pérez

Abstract

We update the results of a 20-year (1996-2015) collaborative study examining the abundance and the population structure of these animals conducted over a number of regions from Northern California to British Columbia using photographic identification. Some 21235 identifications representing 1638 unique gray whales were obtained during 1996-2015 from Southern California to Kodiak, Alaska. Gray whales seen from 1 June - 30 Nov (after the northward and before southward migrations) were more likely to be seen repeatedly and in multiple regions and years;therefore only whales seen during those data were included in the abundance estimates. Gray whales using the Pacific Northwest in summer and fall include two groups: 1) whales that return frequently and account for the majority of the sightings and 2) transients seen in only one year, generally for shorter periods and in more limited areas. A time series of abundance estimates of the non-transient whales for 1996-2015 was constructed for the region from N. California (NCA) to N. Vancouver Island (NBC). The most recent estimate for 2015 was 243 whales (se=18.9). The estimated abundance increased in the late 1990s and early 2000s during the period when the eastern North Pacific gray whale population was experiencing a high mortality event and this created an apparent influx of whales into the area. The earlier estimates for 1996-1997 are biased low because the survey coverage area was much smaller but those data were included to improve estimates later in the time series. The abundance estimates since the early 2000s has been relatively stable but it has increased in 2013-2015.

1 Introduction

Beginning in 1996, a collaborative effort among a number of research groups was initiated to conduct a range-wide photographic identification study of gray whales in the Pacific Northwest (Calambokidis et al. 2000, 2002b). An initial publication of findings from 1998 demonstrated there was considerable movement of individual whales among sub-areas from northern California to southeastern Alaska (which we broadly refer to as the Pacific Northwest) and also provided initial estimates of the abundance of whales within that geographical area (Calambokidis et al. 2002a). The ability to look at movements and employ more sophisticated capture-recapture models, however, was restricted by the lack of multiple years of data with broad geographic coverage. A subsequent report by Calambokidis et al. (2004) characterized the group of whales feeding in these survey areas during the summer-fall period as a "Pacific Coast Feeding Aggregation" (PCFA). They proposed that a smaller area within the PCFA survey areas – from Oregon to Southern Vancouver Island (OR-SVI) – was the most appropriate area for abundance estimation for managing a Makah gray whale hunt (Calambokidis et al. 2004). Subsequently the IWC has adopted the term PCFG for Pacific Coast Feeding group so we will use PCFG in place of PCFA.

This report updates information through 2015 from a collaborative effort to collect photographic identifications of gray whales from California to Alaska has continued since 1996 and these data now cover 20 years (1996-2015) and span fifteen survey regions along the coast from Southern California to Kodiak, Alaska (Figure 1). We provide estimates of abundance for the summer-fall seasons (1 June to 30 November) during 1996–2015 for survey regions between Northern California and Northern British Columbia (NCA-NBC), the region chosen by the IWC to represent the PCFG. For the National Marine Fisheries Service development of an Environmental Impact Statement, we also provide estimates for the smaller regions between Oregon and Southern Vancouver Island (OR-SVI) and Makah Usual and Accustomed area (MUA) which includes the outer coastal area of the Olympic Peninsula (NWA) and the Strait of Juan de Fuca (SJF), even though this area is quite small relative to the observed movements of whales within the PCFG.

2 Methods

Gray whales were photographed during small boat surveys conducted from California to Alaska by collaborating researchers (Table 1) between 1996 and 2015. Gray whale identifications were divided into the following regions (Figure 1): 1) SCA: Southern California, 2) CCA: Central California, 3) NCA: Northern California, 4) SOR: Southern Oregon, 5) OR: central Oregon, 6) GH+: Gray's Harbor and the surrounding coastal waters, 7) NWA: Northern Washington coast, 8) SJF: Strait of Juan de Fuca, 9) NPS: Northern Puget Sound, 10) PS: which includes southern Puget Sound, Hood Canal (HC), Boundary Bay (BB) and San Juan Islands (SJ), 11) SVI: Southern Vancouver Island, 12) WVI: West Vancouver Island, 13) NBC: Northern Vancouver Island and coastal areas of British Columbia, 14) SEAK: Southeast Alaska, and 15) KAK: Kodiak, Alaska. With some exceptions, research groups work primarily in one or two regions. Details of identifications obtained by the different research groups are are summarized in Tables 1-2.

2.1 Photographic Identification Procedures

Procedures during surveys by different research groups varied somewhat but were similar to one another in identification procedures. When a gray whale was sighted, the time, position, number of animals, and behaviors were recorded. Whales were generally approached to within 40-100 m and followed through several dive sequences until suitable identification photographs and associated field notes could be obtained.

For photographic identification of gray whales, both left and right sides of the dorsal region around the dorsal hump were photographed when possible. Most identification photographs were obtained with were obtained with 35mm cameras prior to 2004 and primarily with digital SLR after 2004 with both camera types paired with a telephoto lens (generally 200-300 mm). Researchers also photographed the ventral surface of the flukes for further identification when possible. The latter method was not as reliable since gray whales did not always raise their flukes out of the water. Markings used to distinguish whales included pigmentation of the skin, mottling, and scarring, which varied among individuals. These markings have provided a reliable means of identifying gray whales (Darling 1984). We also identified gray whales using the relative spacing between the knuckles along the ridge of the back behind the dorsal hump. The size and spacing of these bumps varies among whales and has not changed throughout the years these whales have been tracked, except with injury. Figure 2 shows typical photographs and features used in making gray whale identifications.

Comparisons of whale photographs were made in a series of steps. All photographs of gray whales were examined and the best photograph of the right and left sides of each whale (for each sighting) were selected. Identification photographs were initially compared within year to identify resightings and compared to the CRC catalog of whales seen in past years. Whale photographs that were deemed of suitable quality but did not match our existing catalog (compared by two independent persons) were considered "unique" identifications and assigned a new identification number and added to the catalog.

2.2 Data Analysis

The abundance of gray whales was estimated with open population models for three nested spatial scales consisting of contiguous survey regions (Figure 1; Table 3) 1) NCA-NBC: the coastal survey regions from Northern California (NCA) through Northern Vancouver Island/British Columbia (NBC) which matches the IWC definition of the PCFG, 2) OR-SVI: survey regions from southern Oregon through Southern Vancouver Island (SVI) identified in the Makah waiver request, and 3) MUA - survey regions NWA and SJF. Inland waters in WA (other than SJF) and in BC are excluded from the abundance estimates because these are used primarily by transient whales in the northward spring migration.

Gray whales photographed and identified anytime during the period between 1 June and 30 November (hereafter referred to as the "sampling period") within the defined region were considered to be "captured" or "recaptured". For each unique gray whale photographed, a capture history was constructed using 20 years of data from 1996-2015. For example, the capture history 00010010010000000000 could represent a gray whale photographed in 1999, 2002 and 2005 in the PCFG. The same gray whale may have had a capture history 00010010000000000000 for a smaller spatial scale such as OR-SVI or may not have been seen at all (00000000000000000000) and would not be used at the smaller spatial scale.

Multiple "detections" of a single whale within the sampling period were not treated differently than a single detection. A "1" in the capture history meant that it was detected on at least one day during the sampling period. However, multiple detections in the same year were used to construct an observed minimum tenure (MT) for each whale. MT was defined as the number of days between the earliest and latest date the whale was photographed with a minimum of one day for any whale seen.

We fitted open population models to the 20 yearly time series of capture history data for each spatial scale to estimate abundance and survival. Open models allow gains due to births/immigration and losses due to deaths/emigration. Using the RMark interface (Laake and Rexstad 2008) to program MARK (White and Burnham 1999), we fitted a range of models to the data using the POPAN model structure. The POPAN model structure (Schwarz and Arnason 1996) provides a robust parametrization of the Jolly-Seber (JS) model structure in terms of a super population size (N), probability of entry parameters (immigration), capture probability (p), and survival/permanent emigration (φ).

It is essential to consider the population structure and its dynamics to build adequate models. In particular, we know from previous analysis of a subset of these data (Calambokidis et al. 2004) that some whales were seen in only one year between 1 June and 30 November and were never seen again. Transient behavior is a well-known problem in capture-recapture models and it is often addressed using a robust design which involves coordinated multiple capture occasions within each year and typically assumes closure within the sampling period (June-November). Region-wide coordinated surveys may be possible but would be difficult with variation in weather conditions. Also, the closure assumption within the year would be suspect due to variable timing of whales arrivals and departures into the PCFG, so it would require nested open models. We know from prior analysis that whales newly seen in year (y) were less likely to return (i.e., seen at some year >y) than previously seen whales but also newly seen whales that stayed longer during their first year (i.e., longer MT) in the PCFG were more likely to return. Likewise, previously seen whales were more likely to be seen in the following year (y+1), if they had a longer MT in year y. Calambokidis et al. (2004) postulated that these observations were consistent with whale behavior that was determined by foraging success.

Transient behavior in which an animal is seen only once can be modeled by including a different "first year" survival (Pradel et al. 1997) for the newly seen animals. Survival in the time interval after being first seen is dominated by permanent emigration rather than true mortality. Survival in subsequent time intervals represents true survival under the assumption that animals do not permanently emigrate except in their first year. Pradel et al. (1997) were working with release-recapture data (Cormack-Jolly-Seber) where modeling this transient effect on survival is straightforward. For a Jolly-Seber type analysis where the first capture event is also modeled, the inclusion of a transient effect is less easily accommodated.

We divided the whales into cohorts based on the year in which they were first seen ("newly seen"). In the model, their first year survival could differ from subsequent annual survival as in Pradel et al. (1997). "Newly seen" is not a particularly useful concept for the first year of the study (1996), because all whales were being seen for the first time. The survey effort and coverage in 1996 and 1997 were not nearly as expansive as 1998 and later. We considered models that had three different first year survivals (1996&97, 1998, and >1998) and we also considered a model that allowed for a different first year survival for each year (cohort) to allow for different transient proportion in each year. The first year survival was also allowed to vary as a function of MT with a model in which the relationship was constant across years and varied for (1996&97, 1998, and >1998). We also considered models that allowed a different first-year survival for whales identified as calves under the presumption that their true survival might be lower but that their probability of returning to the PCFG might be higher. Discussion at the 2012 intersessional AWMP meeting led to consideration of an additional covariate which split whales into 2 groups for estimation of post-first-year survival. Whales seen initially as calves and any whale newly seen in 1998 or was in the CRC catalog because it had been seen prior to 1998 were put in one group and the remaining whales newly seen in 1999 or later were put in another group. The expectation was that the first group would have higher post-first-year survival because many of the newly seen whales that entered after the stranding event in 1999/2000 might eventually emigrate. When this covariate was included it made such a large improvement that any model without it would have no support. Therefore, it was included in all 10 models for survival (Table 4).

In Calambokidis et al. (2010) we estimated a cohort-specific super-population size for each cohort using the median MT covariate value for unseen whales but during the April 2011 AWMP meeting it became apparent that this may lead to bias in estimating abundance. Therefore, we used the method outlined in the 2011 AWMP report which is similar to the method used by Calambokidis et al. (2004) in that we assume that all whales in the PCFG for the first year are seen so the super-population size for each cohort is the number seen and thus there are no unknown covariate values. We fixed capture probability (p) and probability of entry (pent) to 1 for each cohort in their entry year. We are not interested in the number of transient whales so we used an estimator of abundance for non-transient whales (2011 AWMP report) which is a modification of the Jolly-Seber estimator which for any year can be expressed as:

$$\hat{N} = n/\hat{p} = (u+m)/\hat{p}$$

where $n = u + m$, n is the number seen in a year being composed of new animals (u=unmarked) and previously seen animals (m=marked), and $\hat{p}$ is the capture probability estimate. For the PCFG we are assuming that any new whale is sighted ($p = 1$) and we are only interested in estimating the abundance of whales that will remain part of the PCFG which is the portion of the new whales that do not permanently emigrate from the PCFG. We can modify the estimator for year j as follows:

$$\hat{N}_j = u_j\hat{\phi}_j + m_j/\hat{p}_j$$

where ϕ_j is the first year survival rate of "new" whales. When ϕ and p contain whale specific covariates like minimum tenure (MT) the estimator becomes:

$$\hat{N}_j = \sum_{i=1}^{u_j} \hat{\phi}_{ij} + \sum_{i=1}^{m_j} 1/\hat{p}_{ij}.$$

To obtain an abundance estimate for 2015, we assumed that the parameter for first year survival intercept in that year was the same as in 2014. A variance-covariance matrix for the abundance estimates was constructed using the variance estimator in Borchers et al. (1998) for a Horvitz-Thompson type estimator with an adaptation for the first component of the abundance estimator for prediction of number of new whales that do not permanently emigrate. For the estimated capture probabilities (p) not fixed to 1, we fitted 3 models that varied by time (year) and/or varied by MT in the previous year (Table 4).

We used Test 2 and Test 3 results from the Cormack-Jolly-Seber structure (Lebreton et al. 1992) as a general goodness of fit for the global model and as a measure of possible over-dispersion creating the lack of fit. We fitted each combination of models for S (survival) and p (capture probability) and used AICc (Burnham and Anderson 2002) to select the most parsimonious model of the 30 fitted models. Model averaging was used for all models to compute estimates and unconditional standard errors and confidence intervals.

3 Results

The database contains 25580 records for whales photographed between 1996 to 2015 from California to Kodiak, Alaska; however 4345 are replicate identifications of whales on the same day. We define a sighting as one or more photographs of a whale on a day. The number of sightings varied annually from 131 and 1959 with a total of 21235 sightings of 1638 unique gray whales (Table 1). The average number of sightings/whale was 13 (range: 1-339). Identifications were made throughout the year but with most effort from June to September. Number of sightings were most numerous in NCA, SVI, WVI, and NBC and (Table 2). The number of uniquely identified whales was greatest in NCA, NWA, SVI and WVI (Table 2).

3.1 Seasonal Sighting Patterns

Whales have been photographed in every month of the year (Table 5) but with very few during December-February when most of the whales are in or migrating to Mexico and survey effort is reduced. Previous analysis of these data have always used 1 June - 30 November as the sampling period to describe the whales in the PCFG because whales seen prior to 1 June and after 30 November are more likely to be whales that are migrating through the region. The southbound migration starts in December and the separation between May and June is clearly supported by the data. For example, of the 1638 unique whales sighted from California to Kodiak, Alaska, 666 whales were only seen between 1 Dec - 31 May and 87.2% of those were only sighted once (one day). Of the 972 whales sighted between 1 June -30 November at some time, 38.8% were only sighted once (one day). If sightings in Alaska are excluded, then only 31.7% of the 833 were seen only once (one day).

The break between May and June is apparent in various measures such as proportion of whales sighted more than once, sighted in more than one region, and sighted in more than one year (Figure 3). However, the break is more apparent if we separate out SJF, NPS and SVI from the other survey regions (Figure 4). The difference across months is not as strong for inland waters of Washington and British Columbia (NPS, SJF) because these are whales that have diverted from the migration and are either more likely to remain after 1 June or demonstrate high year-to-year fidelity during spring such as with NPS. Also, even though Southern Vancouver Island (SVI) is in the main migration corridor and not an inland water, the pattern across months is also weaker because the sampling has been focused on the spring herring spawn in Barkley Sound (effectively an inland waterway) and has purposefully undersampled passing migrant whales (Brian Gisborne, pers. comm.).

The break between May and June is much more apparent for NWA and the other areas in the migration corridor which is consistent with the northbound migration of gray whales proceeding past Washington through May. Resighting rates of whales seen after 1 June remained high through November.

A large photo-ID sample of gray whales in the MUA was conducted in 2015 by Makah Tribal biologists. At the time of this report the full comparison of these whales to historical images had not been completed but in the future will provide a better indication of proportion of PCFG whales present prior to 1 June.

Capture (sighting) histories of whales seen at least once in the PCFG from 1 June - 30 November are provided in Appendix Table 1 which show sightings of whales in 1 Mar -31 May only, 1 June - 30 Nov only and in both time periods within a year.

3.2 Regional Sighting Patterns

There is considerable variation in the annual regional distribution of numbers of whales photographed during the sampling period (Table 6) which is in part due to variation in effort. Although not a true measure of effort, the number of days whales were seen (Table 7) does reflect the amount of effort as well as abundance of whales. In particular, in comparison to other regions, the large number of sightings in SVI partly reflects large numbers of sampling days by Brian Gisborne who has routinely sampled SVI from summer through fall on almost a daily basis. On the other hand, the decline in sightings in SVI during 2007 was not due to reduced effort but to the distribution of whales with many of the whales having moved to waters off Oregon and Washington (Calambokidis et al. 2009b). Similarly, there were 40 survey days in SJF in 2010 but only 4 whales were seen on 4 different days (Table 6, Table 7) so this drop relative to other years was not due to lack of effort.

Whales were sighted across various survey regions and the interchange of whales (Table 8) between survey regions during 1 June - 30 November depends on proximity of the regions (Calambokidis et al. 2004). During 1 June-30 November for 1996 to 2015, 793 unique whales were seen in the PCFG range and 68.6% (544 of the 793 whales seen in the PCFG range) were seen within the smaller OR-SVI region and approximately 36.3% (288 of the 793 whales seen in the PCFG range) were seen within the smaller MUA area; however, there is variation in interchange between areas in the PCFG and the MUA. Of the whales sighted in regions from NCA to NBC, from 39.8% to 59.6% of the whales were seen at some point within MUA (Figure 5). If we exclude transients (whales seen in only one year), the interchange rates with MUA are much higher but the pattern is similar (Figure 6) with a range of 47.7% to 77.5%. Appendix Table 2 provides capture histories using data from 1 June - 30 Nov of whales seen in the MUA at least once. For each year, the table shows whether the whale was sighted in PCFG but not in the MUA during that year, only seen in MUA that year, and seen in both MUA and another PCFG area in that year.

Whales seen in the PCFG exhibited a wide range of movement across and within years. The 143 whales seen in 9 or more years provide a useful example. None of those whales was seen exclusively in a single region, and 67.1% were seen in at least 4 of the 9 survey regions from 1996 to 2015. However, whales did regularly visit the same regions across years with 94.4% were seen in at least one of the regions during six or more of the years they were seen and 65.7% were seen in a region two-thirds or more of the years they were seen. SVI was the region with the maximum number of years seen for 65 of the 143 whales, which in part reflects the larger amount of survey effort in SVI (Calambokidis et al. 2004a, Calambokidis et al. 2013). Thus, some whales regularly visit particular regions more often than others, but they are seen across the other regions as well.

Some of the whales not seen in the PCFG in a year were seen in Kodiak and Southeast Alaska (Table 9). Of the 25 whales identified in Southeast Alaska and the 153 whales identified in Kodiak, Alaska, 14 (56%) and 24 (15.7%), respectively have been seen farther south in the PCFG.

If we look at latitudes of sightings of individual whales across the 20 years using whales that have been sighted on at least 6 different days (Figure 7), we see that sightings of some whales are highly clustered; whereas, sightings of other whales are highly dispersed across several regions. We defined each whales primary range by the 75% inner quantile which is the middle of the range that includes 75% of the locations. The length of the 75% inner quantile in nautical miles exceeded 60 nautical miles (or 1 degree of latitude) for 49.0% of the whales (Figure 8) and it was more than 180 nautical miles for more than 29.6% of the whales. Thus, it makes little sense to compute an estimate of abundance for any region that spans less than a degree of latitude.

3.3 Annual Sighting Patterns

The average number of whales identified in any one year was 156, 104, and 37 for the PCFG, OR-SVI, and MUA, respectively (Table 10). However, those numbers do not represent the total numbers of whales that use each of these areas because not all whales using a region in a year are seen, not all whales return to the same region each year, and not all of the whales return to the PCFG region each year. The annual average number of newly seen whales (excluding 1996-1998 when the photo-id effort expanded to cover all survey regions) was 37.2, 25.8, and 13.6 for PCFG, OR-SVI, and MUA, respectively. The annual average number of newly seen whales that were "recruited" (seen in a subsequent year), excluding 1996-1998 and 2015, was 14.9, 12.6, and 6.4 for PCFG, OR-SVI, MUA respectively. Thus, there were a substantial number of new whales seen each year and 40.6, 49.6, and 47 percent of those were seen again in a subsequent year in the 3 regions respectively. The number of newly seen whales and the number newly seen and recruited (i.e., seen in at least one more year after the initial year it was seen) (Table 11) are displayed as discovery curves in Figures 9 and 10.

Of the whales that were seen during June-November 1996-2015 in the PCFG (NCA to NBC) about half were only seen in one year and the whales that were seen in more years were sighted more often each year and therefore represented a large proportion of the sightings (Figure 11). Of the 750 identified whales first seen before 2015 between 1 June and 30 November in the PCFG range (NCA-NBC), 52% were seen in only one year and only represent about 5% of the sightings (Figure 11). Many of the newly seen whales did not return in subsequent years. Some whales were seen in every year with 9.3% that were seen in every year after their initial identification, including 5 whales first seen in 1996 that were seen in all of 20 subsequent years. The remaining 39% were seen more than once but not in every year.

Likewise, examination of MT in the first sighting year demonstrates that whales who stay longer in their first year were more likely to be seen in a following year (Figure 12). Whales "first" seen in the first few years of the study (1996-1998) includes some whales that were truly new to the PCFG in those years but many were only "new" because it was the first year of the study or as the surveyed regions expanded over time. This is evident (Figure 12) in the much higher proportions for 1996-1998 than for the other years. These relationships will be important in the capture-recapture models for abundance estimation because whales that do not return after their first year (a large percentage in this analysis) would appeared to have not survived because they have permanently emigrated (with a small fraction that died).

3.4 Open Population Capture-Recapture Models

If the yearly cohorts were pooled, Test2+Test3 statistics indicated a significant lack of fit for the PCFG and subsets (Table 12) primarily resulting from Test 3. This was expected due to the different "survival" rates of previously seen whales (true survival) and newly seen whales of which many never returned (i.e., permanently emigrated) (Table 13) . By separating the cohorts, survival for each cohort was time-varying and thus each cohort has a separate first year survival. The goodness of fit test (Test 2) demonstrated a lack of fit for NCA-NBC and OR-SVI (Table 12). For those regions, we estimated an over-dispersion values of $\widehat{c}$=2.29 and $\widehat{c}$=1.23 respectively to adjust AICc and estimated standard errors.

For all areas, the best fitted model (Table 14) was model 2 for p with capture probability varying across years and higher when MT was greater in the previous year. Likewise, for φ the best model was model 4 for all areas. Model 9 was the second best model. Both models 4 and 9 included a separate first year survival which depends on MT. Model 9 included a different calf first-year "survival" which gave a higher survival for calves than non-calves the first year seen (redundant for calves) because they are more likely to return. In models 9 and 4, there are 3 intercepts for first year survival (1996&97, 1998, >1998) and in model 9 the slopes for MT differ as well. These results were consistent with Calambokidis et al. (2004) who demonstrated strong support for the effect of MT on first year survival (Figure 13) and capture probability (Figure 15) in the following year. These results differ some from Calambokidis et al. (2010) who used an annual median-centered MT. Use of MT with median centering was necessary to construct open model abundance estimates in the manner described in Calambokidis et al. (2010). However, that was not necessary for JS1 and the use of MT without median-centering resulted in lower AICc values.

There was large year to year variation in capture probability. The values for NCA-NBC ranged from 0.42 to 0.98 depending on the year and value of MT (Figure 15). The lowest values were from 2007 which reflects the temporary emigration of whales from MUA and SVI to waters offshore of Oregon in that year. In contrast, for MUA capture probabilities were much lower ranging from 0.08 to 0.76 depending on the year and value of MT (Figure 16). The lower overall capture probability and weaker relationship between capture probability and MT reflect the transitory behavior of whales in such a small area. The lower estimates of of capture probability in 1999-2004 for MUA was due to decreased effort by NMML which spread their survey effort across MUA to WVI during 1999-2002, lost a vessel in 2002 and had no funding in 2004 (Figure 16).

First year survival estimates were dominated by permanent emigration. For NCA-NBC, the estimates varied from 0.30 to 0.81 for non-calf whales with MT=1 in their first year and from 0.69 to 0.95 for MT>80 in their first year (Figure 13). Calf survival is by definition a first year survival rate and potentially includes permanent emigration from the PCFG. Depending on the value of MT, calf survival estimates ranged from about 0.35 to over 0.90 (Figure 14). The average calf survival estimate was 0.63 (se = 0.090). There was some support for a different first year calf survival with model 9 being the second best model (ϕ in Table 14) because calves are less likely to permanently emigrate. Unfortunately there is no way to separate permanent emigration from mortality with the existing data.

Survival subsequent to the first year was assumed to be constant but was less for non-calf whales that were newly seen in 1999 or later. Post-first-year suvival for calves and whales present in 1998 or earlier presumably represents true survival assuming there was little permanent emigration after the first year. Those estimates were 0.967 (se=0.0062) and 0.967 (se=0.0066) for OR-SVI and NCA-NBC respectively. The post-first-year survival estimates for whales that entered in 1999 or later and not identified as a calf were 0.912 (se=0.0125) and 0.917 (se=0.0142) for OR-SVI and NCA-NBC respectively.

3.5 Abundance and Recruitment

For NCA-NBC, OR-SVI and MUA annual estimates of abundance were constructed with model averaged values for JS1 (Table 15-16). Estimates for NCA-NBC in Figure 17 are only shown for 1998-2015 with the open models $p = 1$ for 1996 so it will certainly be an underestimate and the survey coverage in 1996 and 1997 was not as extensive as the later years.

The value of N_{min} for 2015 is 228 for NCA-NBC (Table 15). To gain a sense for how these values might be relevant to estimating a possible level of removal (e.g., due to harvest) we computed the MMPA's Potential Biological Removal (PBR) (typically reserved for stock-level assessments). Using the PBR formula, with an Rmax of 6.2% and a recovery factor of 0.5 (Caretta et al. 2013), the PBR for NCA-NBC (PCFG) would be 3.5.

New whales that are not identified as calves have appeared annually and many of these new (non-calf) whales have subsequently returned and been re-sighted (Table 13). In NCA-NBC from 1999-2014, an average of 32.1 (range: 8.0, 68.0) new whales not identified as a calf were seen each year. Of these new non-calf whales, on average 11.8 (range: 1.0, 28.0) whales returned and were seen in subsequent years. It is unknown what proportion of the non-calves used the PCFG as a calf but were not seen in that year. Currently recruitment appears to be offset by losses (either mortality or permanent emigration) as the abundance estimates have been fairly stable since 2002 and recently increasing.

4 Discussion

The population structure of gray whales using the Pacific Northwest in summer and fall is complicated and involves two elements. One group of whales return frequently and account for the majority of the sightings in the Pacific Northwest during summer and fall. This group is certainly not homogeneous and even within this group, there is some degree of preference for certain subareas. Despite widespread movement and interchange among areas, some of these gray whales are more likely to be seen returning to the same areas they were seen before. The second group of whales are transients that are seen in only one year, tend to be seen for shorter periods that year, and in more limited areas.

The existence of these two groups in the study area and their dynamics complicate estimating abundance. While the JS1 estimator may not be optimal, it provides a practical way of handling transients in this open population. Excluding 1996-1997, the JS1 sequence of abundance estimates provides the most reliable assessment of trend for the non-transient abundance and the best estimate of current abundance in 2015.

Despite extensive interchange among subregions in our study area, whales do not move randomly among areas. Abundance estimates were lower when using more limited geographic ranges but these more limited areas do not reflect closed populations. While the use of geographically stratified models can be useful in cases where populations have geographic strata they use (see for example Hilborn 1990), this would be difficult in our case because of the frequent sightings of animals in multiple regions within the same season and these models typically only allow an animal to be sighted in one strata per period. This could be dealt with by assigning animals to only a single region per season but this would be forcing the data into a somewhat inaccurate construct.

Several studies have considered the question of gray whale population structure. There is widespread agreement that at least two populations of gray whales in the North Pacific exist, a western North Pacific population (also called the Korean population) and an eastern North Pacific (ENP) population (sometimes called the California population) (Swartz et al. 2006; Angliss and Outlaw 2008; Rugh et al. 1999). The population structure of the gray whales feeding in the Pacific Northwest has remained in question and only a few studies have examined this. Steeves et al. (2001) did not find mtDNA differences in a preliminary comparison of gray whales from the summer off Vancouver Island and those from the larger ENP population. Ramakrishnan et al. (2001) did not find evidence that the Pacific Northwest whales represented a maternal genetic isolate, although even very low levels of recruitment from the larger overall population would prevent genetic drift. More recently, Frasier et al. (2011) generated mtDNA sequences from a larger sample of gray whales from Vancouver Island than tested by Steeves et al. (2001). They found significant differences in the haplotype frequencies between that sample and mtDNA sequence data reported for ENP gray whales, most of which were animals that stranded along the migratory route. The Frasier et al. (2011) samples were from a relatively small area; however, Lang et al. (2011) evaluated biopsy samples from California to southern Vancouver Island in the PCFG and ENP samples from whales sampled north of the Aleutians and also found significant mtDNA halpotype frequency differences. These two studies provide the strongest evidence to date that the Pacific Northwest whales might be sufficiently isolated to allow maternally inherited mtDNA to differ from the overall ENP population.

Population structure in other large whales has been the subject of recent inquiry and has revealed diverse results for different species. Clapham et al. (2008) examined 11 subpopulations of whales subjected to whaling that were extirpated possibly due to the loss of the cultural memory of that habitat and concluded subpopulations often exist on a smaller spatial scale than had been recognized. Studies of other baleen whales, particularly humpback whales, have shown evidence of maternally directed site fidelity to specific feeding grounds based on photographic identification studies (Calambokidis et al. 1996, 2001, 2008). This high degree of fidelity to specific feeding areas is often discernible genetically. In the North Pacific strong mtDNA differences were found among feeding areas even when there was evidence of low level of interchange from photo-ID (Baker et al. 2008). Similar findings were documented for humpback whales in the North Atlantic which feed in different areas but interbreed primarily on a single breeding ground (Palsboll et al. 1995) like ENP gray whales. In the North Pacific the differences for humpback whales were often dramatic. For example, humpback whales that feed off California have almost no overlap in mtDNA haplotypes with humpback whales feeding in Southeast Alaska (Baker et al. 1990, 1998, 2008). One difference between humpback and gray whales is the coastal migration route of gray whales which means gray whales going to arctic waters to feed would migrate right through the feeding areas to the south. Other species of large whales have not shown as strong site fidelity to specific feeding grounds. Blue whales have undergone an apparent shift in their feeding distribution in the North Pacific apparently due to shifting oceanographic conditions (Calambokidis et al. 2009a). Fin whales in the North Pacific have long migrations and while there do not appear to be multiple distinct feeding areas as was the case for humpback whales, there were some distinct and isolated apparently non-migratory populations (Mizroch et al. 2009; Berube et al. 2004).

Even though the population structure of gray whales off the Pacific Northwest remains unresolved, there is a consistent group of animals that use this area and we provide several estimates of their abundance. Different abundance methods and geographic scopes yield varied results but all suggest the annual abundance of animals using the Pacific Northwest for feeding through the summer is at most a couple hundred animals depending on the estimating method and how broadly the region is defined geographically.

The rapid increase in the abundance estimates at the start of this study is in part due to the smaller area of coverage during 1996 and 1997. We included those years to improve the estimate in 1998-1999 and the estimate for 1998 did increase by 7% from previous analysis. The increase from 1998-2000 occurred during a period the overall eastern North Pacific gray whale population was experiencing a high mortality event that included unusually high numbers of gray whales showing up in areas they were not common. The high rate of increase in the late 1990s and early 2000s should be verified with additional data such as compiling photographic identifications for this area from multiple sources to attempt to verify if the abundance of animals prior to the start of our study was as low as suggested by these trends. Even though the rate of increase may be too high, we believe the abundance did increase and now appears to be relatively stable since 2002.

Acknowledgments

This analysis would not have been possible without the collaborating organizations and individuals contributing identification photographs (the primary contributors are listed in Methods and Tables 1 and 2). Support for the photographic identification reported here, the comparison of gray whale photographs and preparation of this report came primarily from the National Marine Mammal Laboratory. Permission to conduct some portions of this research in U.S. waters was provided by the U.S. National Marine Fisheries Service and the Makah Tribe. Portions of the research in British Columbia were conducted collaboratively with Fisheries and Oceans Canada (thanks to John Ford and Graeme Ellis). Volker Deecke assisted in analysis and matching of identifications from S. Vancouver Island. William Megill coordinated providing sightings and identifications from CERF, Dawn Goley and Jeff Jacobsen coordinated effort for HSU, Christina Tombach and Dave Duffus coordinated early efforts for UVIC, Carrie Newell provided identification photographs from Oregon, Merrill Gosho, Pat Gearin, Nate Pamplin and Jonathan Scordino provided photos form Washington. Brian Gisborne's diligence and hard work provided an immense amount of data and photographs from Vancouver Island. A number of people assisted in the field effort and in the printing and matching of photographs at Cascadia Research. Erin Falcone, Lisa Schlender, Jennifer Quan, and Amber Klimek helped compile the data from different contributors and conducted photographic matching. Randy Lumper conducted gray whale matching in the early years of this study. Jonathan Scordino, Steve Stone and Donna Darm provided many helpful comments, suggestions and edits.

Table 2: Regional distribution of numbers of sightings (one or more photographs of a whale per day) and resulting number of uniquely identified whales by reseach group for 1996-2015. Totals for whales are unique whales across all research groups. NPS is northern Puget Sound and PS includes southern Puget Sound, San Juan Islands, Hood Canal and Boundary Bay.

Table 3: Survey regions and region subsets used for abundance estimation. Numbers refer to locations on the map in Figure 1.

Survey Region	Region Description	NCA-NBC	OR-SVI	MUA
(1) SCA = Southern California				
(2) CCA = Central California				
(3) NCA = Northern California	Eureka to Oregon border; mostly from Patricks Pt. and Pt. St George	x		
(4) SOR = Southern Oregon		x	x	
(5) OR = Oregon Coast	Primarily central coast near Depoe Bay and Newport, OR	x	x	
(6) GH+ = Gray's Harbor	Waters inside Grays Harbor and coastal waters along the S Washington coast	x	x	
(7) NWA = Northern Washington	Northern outer coast waters with most effort from Cape Alava (Sea Lion Rock) to Cape Flattery	x	x	x
(8) SJF = Strait of Juan de Fuca	US waters east of Cape Flattery extending to Admiralty Inlet (entrance to Puget Sound) with most effort ending at Sekiu Point	x	x	x
(9) NPS = Northern Puget Sound	Inside waters and embayments from Edmonds to the Canadian border			
(10) PS = Puget Sound	Central and southern Puget Sound (S of Edmonds), including Hood Canal, Boundary Bay, and the San Juan Islands			
(11) SVI = Southern Vancouver Island	Canadian waters of the Strait of Juan de Fuca along Vancouver Island from Victoria to Barkley Sound, along West Coast Trail	x	x	
(12) WVI = West Vancouver Island		x		
(13) NBC = Northern British Columbia	British Columbia waters north of Vancouver Island, with principal effort around Cape Caution	x		
(14) SEAK = Southeast Alaska	Waters of southeastern Alaska with the only effort in the vicinity of Sitka			
(15) KAK = Kodiak, Alaska				

Table 4: Model specifications for survival (φ) and capture probability (p) parameters in POPAN models for gray whale photo-identification data. For survival models, β_0 is the baseline intercept for non-transient survival. Fy is 1 if it is year the whale was first seen and 0 otherwise. A subscript for Fy means that it applies only for that cohort except that Fy_{99}applies to cohorts 1999 and beyond and Fy_c represents each of the cohorts from 1996 to 2015. C is 1 if identified as a calf in its first year and 0 otherwise. R is 1 for calves or any whale seen in 1998 or was already in the catalog prior to 1998 and 0 otherwise. β_r is an adjustment to post-first-year survival. MT is minimum tenure value of a whale and β_M is the estimated slope parameter for φ or p. $\beta_{M,96-97}$ applies to 1996-97, $\beta_{M,98}$ to 1998 and $\beta_{M,99}$ applies to 1999-2014. $\beta_{Fy,96-97}$, $\beta_{Fy,98}$ and $\beta_{Fy,99}$ are the first-year survival intercept adjustments for 1996-97, 1998 and cohorts 1999-2014 respectively and $\beta_{Fy,c}$ represents 19 cohort-specific first year survival parameters for 1996-2014. β_{CF} is an adjustment for calf first year survival and β_{CM} is an adjustment for calves to the slope of MT for survival. For the capture probability models, β_t has 18 levels for t=1998,...2015 and β_0 represents the 1997 value. For 1996 p=1.

Model	Parameter Logit Formula	Number of parameters
φ		
1	$\beta_0 + \beta_{Fy} Fy + \beta_r R(1 - Fy)$	3
2	$\beta_0 + \beta_{Fy} Fy + \beta_M MT\, Fy + \beta_r R(1 - Fy)$	4
3	$\beta_0 + \beta_{Fy,96-97} Fy_{96-97} + \beta_{Fy,98} Fy_{98} + \beta_{Fy,99} Fy_{99} + \beta R(1 - Fy)$	5
4	$\beta_0 + \beta_{Fy,96-97} Fy_{96-97} + \beta_{Fy,98} Fy_{98} + \beta_{Fy,99} Fy_{99} + \beta_M MT\, Fy + \beta_r R(1 - Fy)$	6
5	$\beta_0 + (\beta_{Fy,96-97} + \beta_{M,96-97} MT) Fy_{96-97} + (\beta_{Fy,98} + \beta_{M,98} MT) Fy_{98} + (\beta_{Fy,99} + \beta_{M,99} MT) Fy_{99} + \beta_r R(1 - Fy)$	8
6	$\beta_0 + \beta_{Fy,c} Fy_c + \beta_M MT\, Fy + \beta_r R(1 - Fy)$	22
7	$\beta_0 + \beta_{Fy,c} Fy_c + \beta_M MT\, Fy + \beta_{CF} C\, F_y + \beta_r R(1 - Fy)$	23
8	$\beta_0 + \beta_{Fy,c} Fy_c + \beta_M MT\, Fy + \beta_{CF} C\, F_y + \beta_{CM} C\, MT + \beta_r R(1 - Fy)$	24
9	$\beta_0 + (\beta_{Fy,96-97} + \beta_{M,96-97} MT) Fy_{96-97} + (\beta_{Fy,98} + \beta_{M,98} MT) Fy_{98} + (\beta_{Fy,99} + \beta_{M,99} MT) Fy_{99} + \beta_{CF} C\, F_y + \beta_r R(1 - Fy)$	9
10	$\beta_0 + (\beta_{Fy,96-97} + \beta_{M,96-97} MT) Fy_{96-97} + (\beta_{Fy,98} + \beta_{M,98} MT) Fy_{98} + (\beta_{Fy,99} + \beta_{M,99} MT) Fy_{99} + \beta_{CF} C\, F_y + \beta_{CM} C\, MT + \beta_r R(1 - Fy)$	10

Table 10: Number of unique whales seen by year for MUA, OR-SVI, and PCFG (NCA-NBC) during 1996-2015.

Region	1996	1997	1998	1999	2000	2001	2002	2003	2004	2005	2006	2007	2008	2009	2010	2011	2012	2013	2014	2015	Average
MUA	19	27	37	11	14	32	8	22	26	33	58	20	75	57	26	41	67	66	63	45	37
OR-SVI	30	36	86	71	70	128	103	110	118	107	96	114	123	118	93	91	127	145	151	161	104
PCFG	45	69	132	151	140	173	203	157	179	135	126	120	174	152	144	164	208	232	200	211	156

Table 11: Discovery of new unique whales over years 1996-2015 for PCFG,OR-SVI and MUA. Recruited only means that the whale was seen in at least one more year after the initial year it was seen. The number 'recruited' will usually be greater than the abundance estimate because some whales die and others may permanently emigrate and do not return.

Table 13: Number of whales seen each year, number that were new that year in that region, and number that were new and were seen in a subsequent year for whales seen between June-November 1996-2015 in each region. The year a whale was seen as new can vary across regions and if it differs will be later in the smaller region.

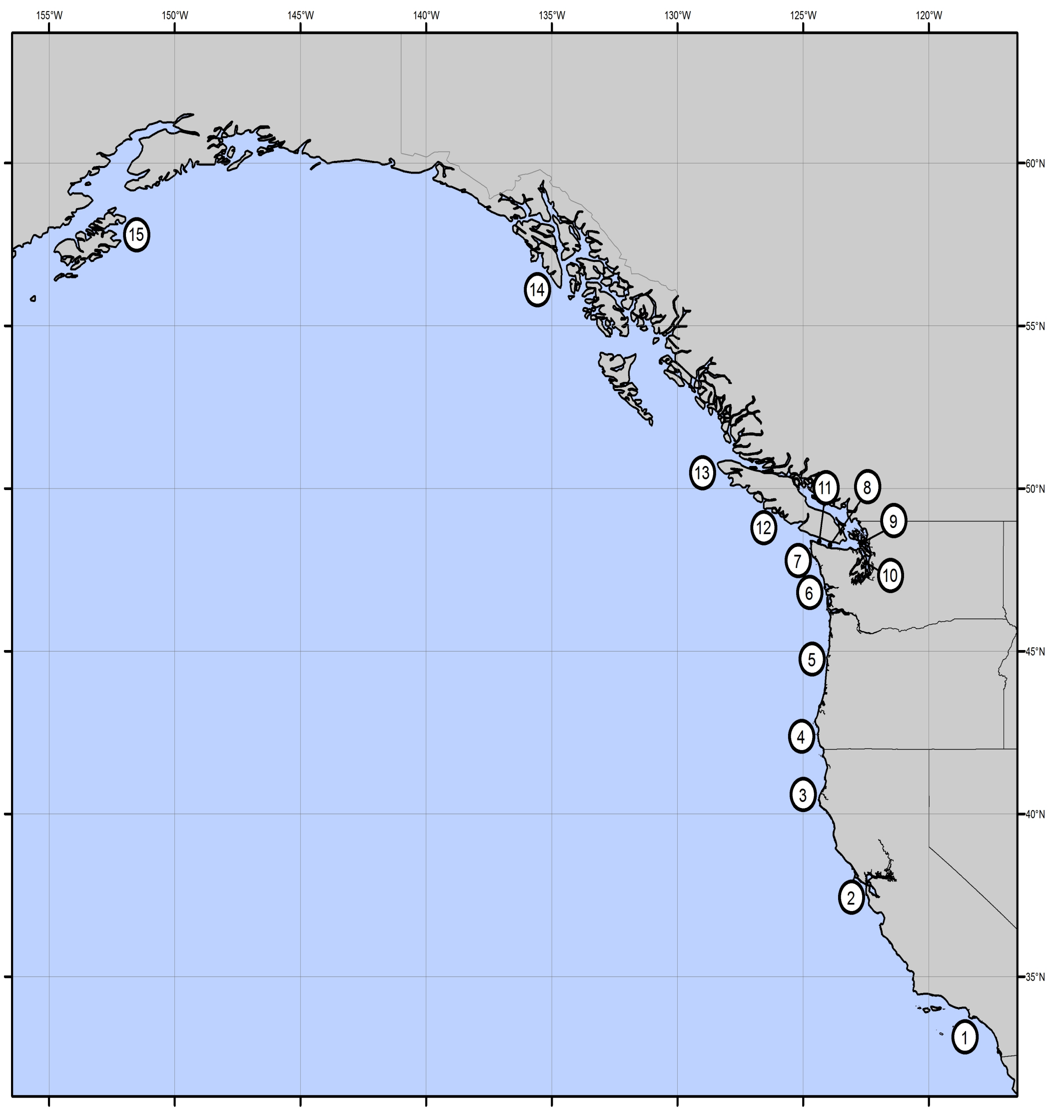

Figure 1: Locations for photo-identifications of gray whales. Numbers refer to values in Table 3.

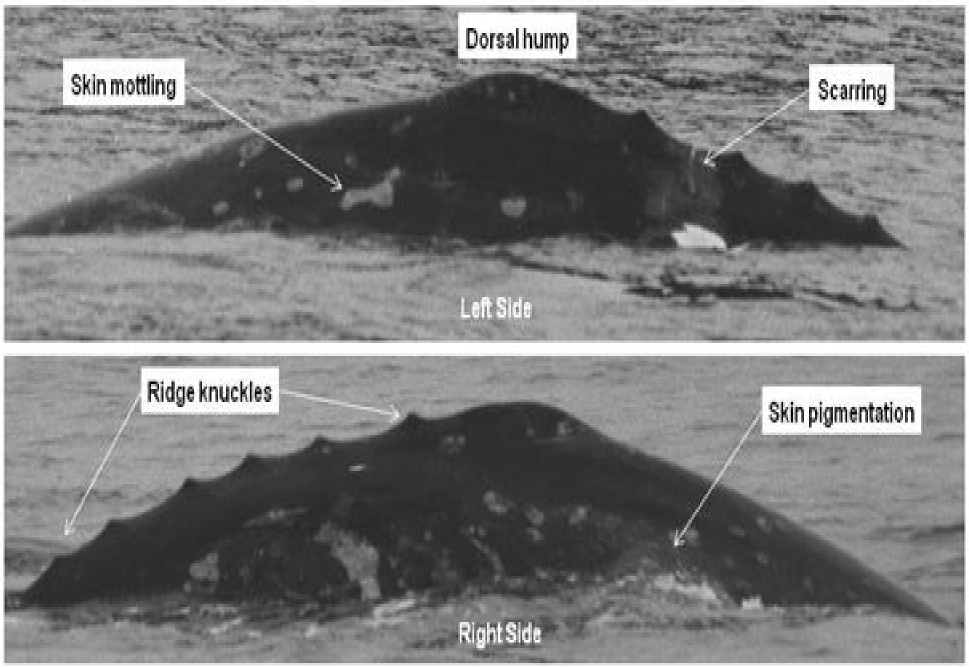

Figure 2: Characteristics used for gray whale photo-identification.

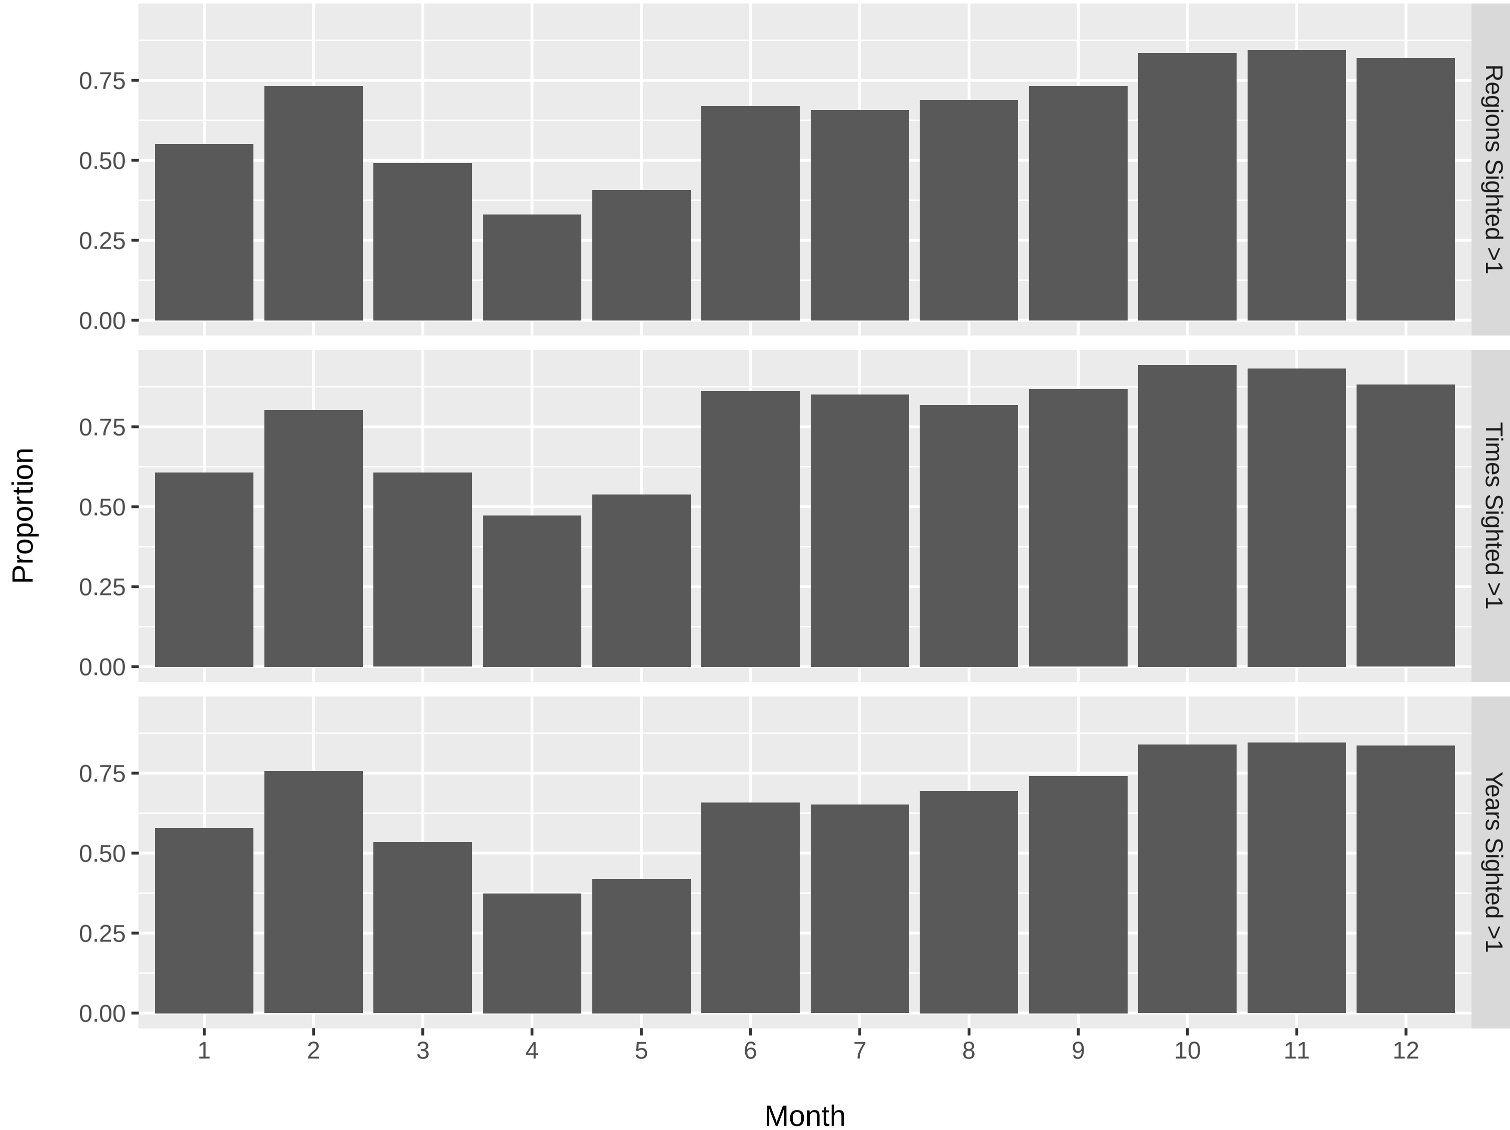

Figure 3: Monthly measures of proportion of whales that were seen in more than one region, seen on more than one day and seen in more than one year. The values include sightings from 1996-2015 in all regions from California to Alaska. Lower values imply whales were simply migrating through the area in a short time frame and were thus less likely to be seen at other times and in other regions. Values are not shown for months with fewer than 20 sightings. Whales seen more often are overrepresented because they are used in each month they were seen. For example a whale seen in June, July and August will be in each summary. Thus, these values may be larger than values computed without splitting by month (e.g., overall proportion of whales seen in more than one year).

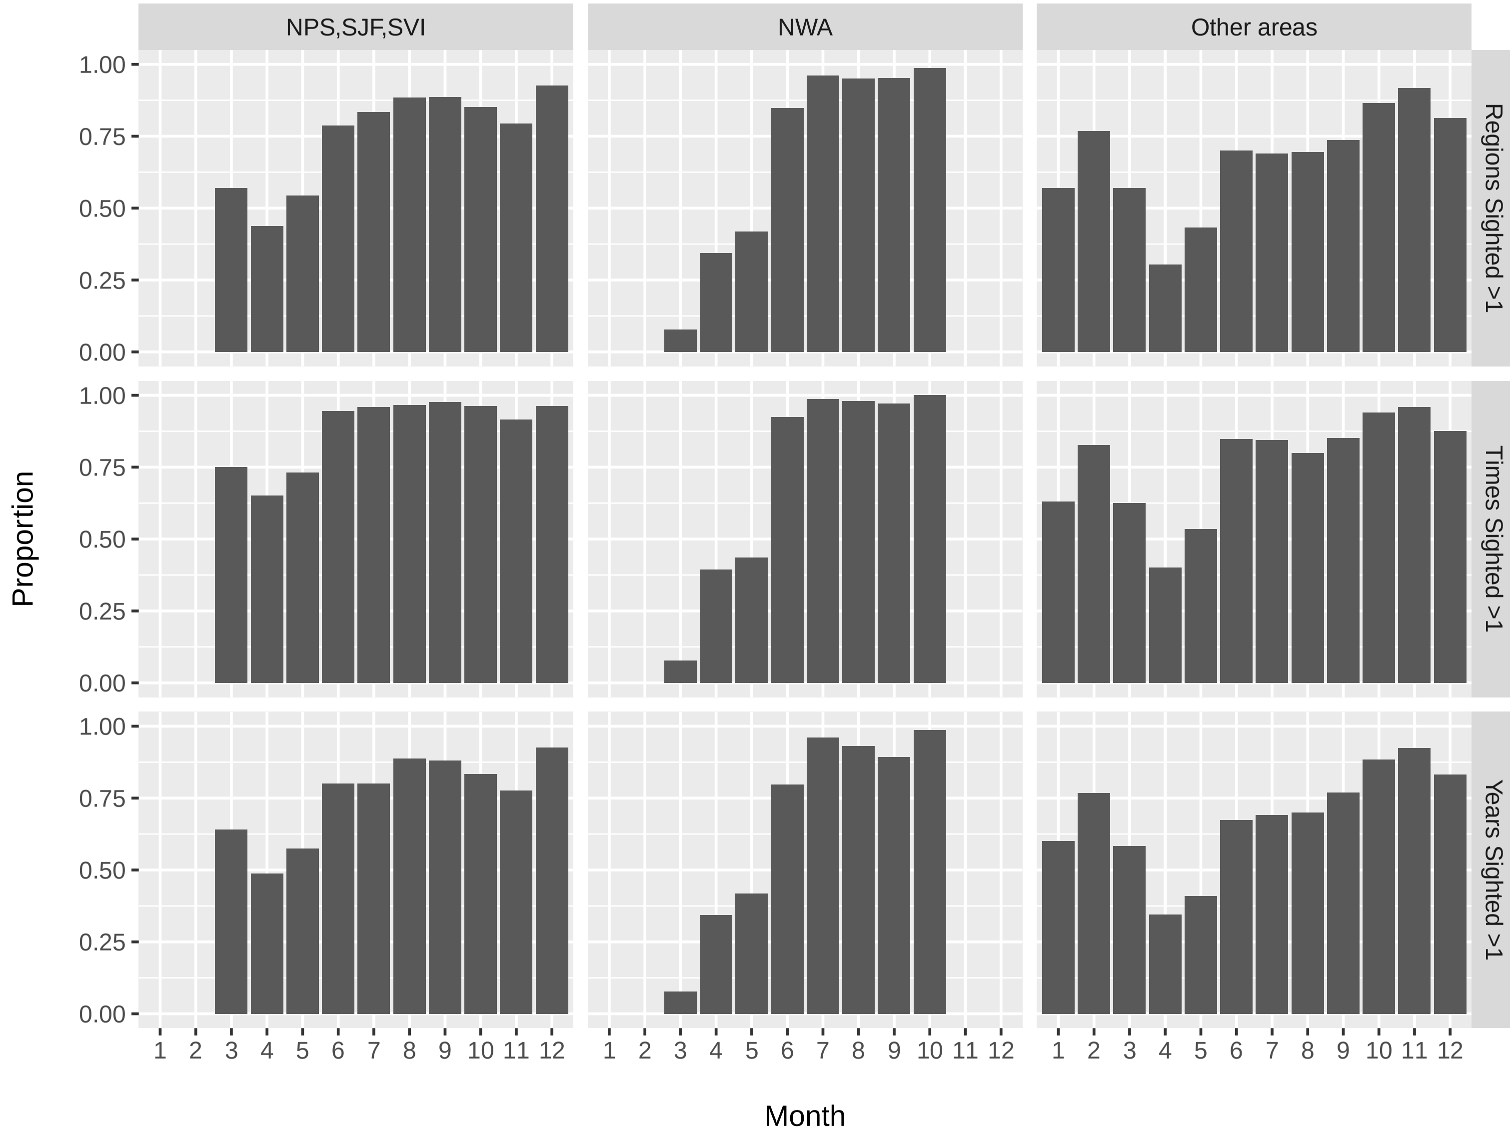

Figure 4: Region and monthly measures of proportion of whales that were seen in more than one region, seen on more than one day and seen in more than one year. The values include sightings from 1996-2015 in all regions from California to Alaska. Lower values imply whales were simply migrating through the area in a short time frame and were thus less likely to be seen at other times and in other regions. Values are not shown for months with fewer than 20 sightings. Whales seen more often are over-represented because they are used in each month they were seen. For example a whale seen in June, July and August will be in each summary. Thus, these values may be larger than values computed without splitting by month (e.g., overall proportion of whales seen in more than one year).

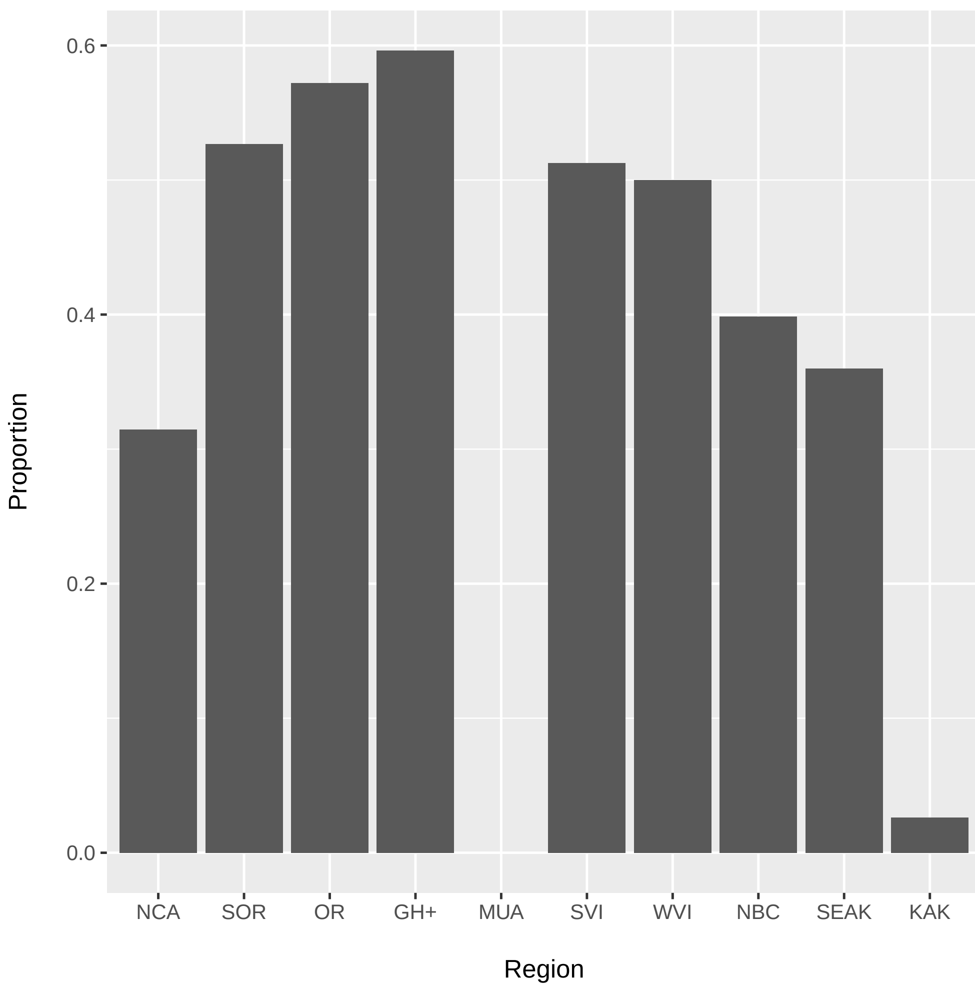

Figure 5: Proportion of whales in sub-regions from NCA to KAK that have been seen in the MUA using sightings after 1 June from 1996-2015.

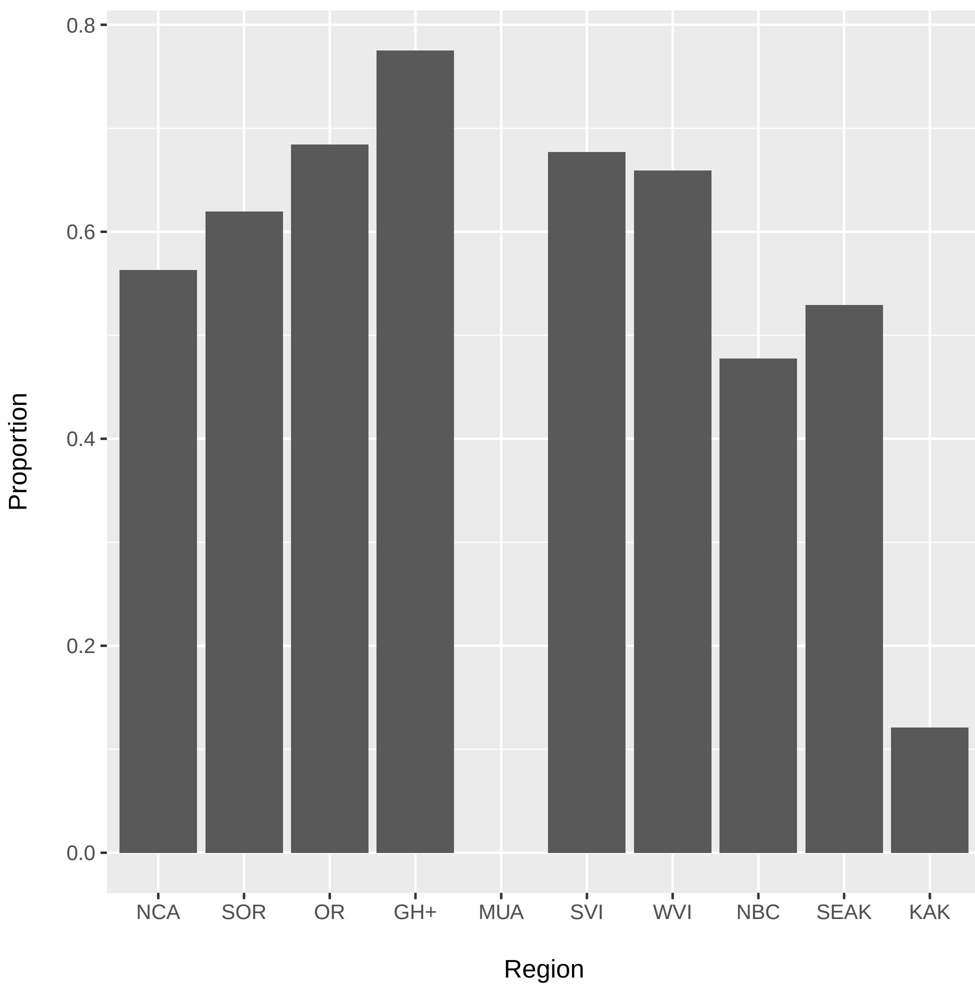

Figure 6: Proportion of whales seen in at least 2 years in sub-regions from NCA to KAK that have been seen in the MUA using sightings after 1 June from 1996-2015.

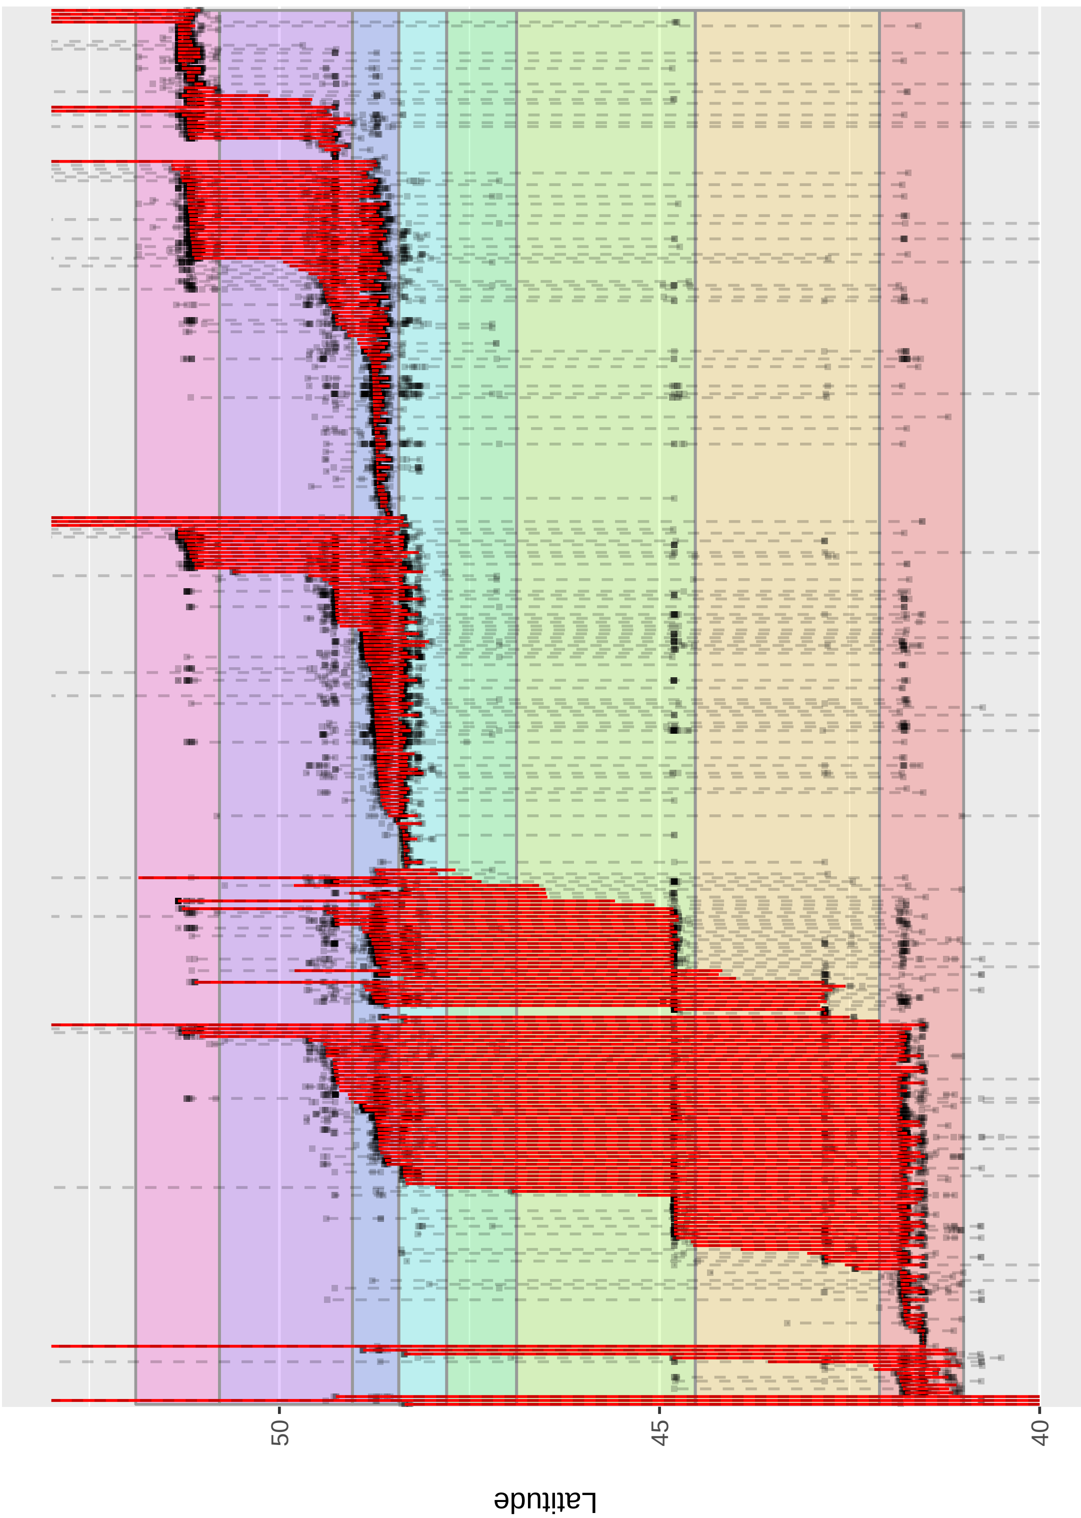

Figure 7: Distribution of latitudes of sightings (points) for whales with 6 or more sightings after 1 June from 1996-2015, the 75% inner quantile (solid thick line), and full range (light dashed line). Each position on the x axis represents an individual whale. Whales have been arranged on the plot by sorting first on the lower bound of the inner quantile (to a half-degree) and then the upper bound of the quantile. This has the effect of sorting from south to north and clusters whales with smaller quantile ranges followed by whales with larger ranges.

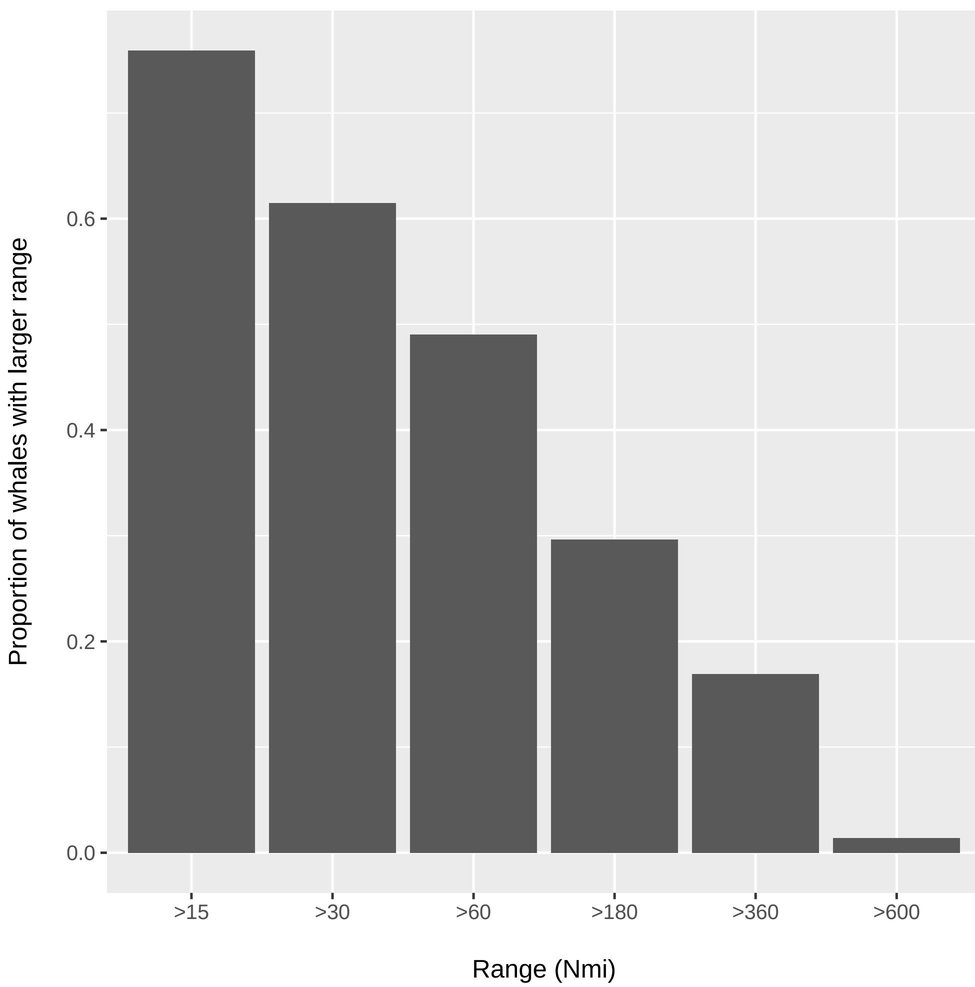

Figure 8: Distribution of ranges of 75% inner quantiles of latitudes expressed in nautical miles for whales sighted on 6 or more days during 1996-2015.

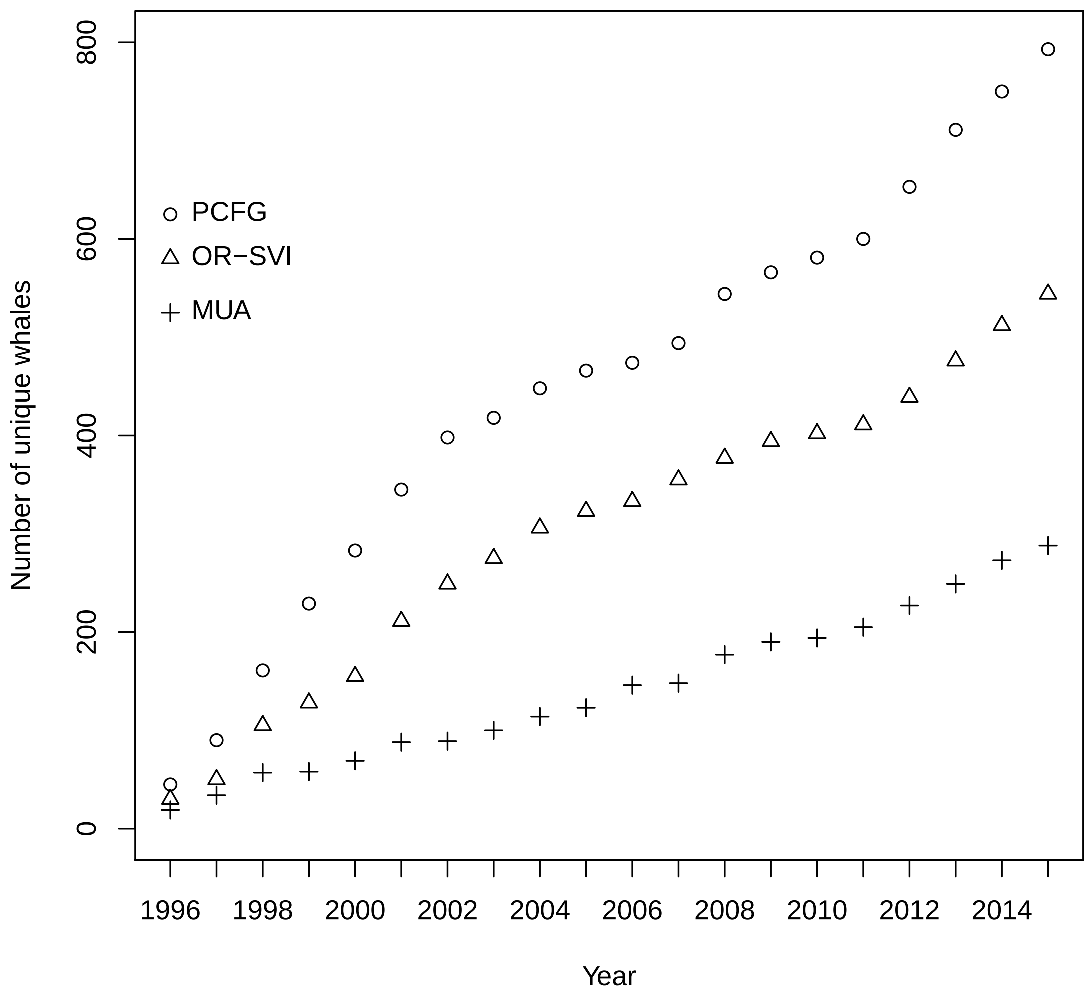

Figure 9: Discovery curves for unique whales seen in PCFG, OR-SVI and MUA for 1996-2015.

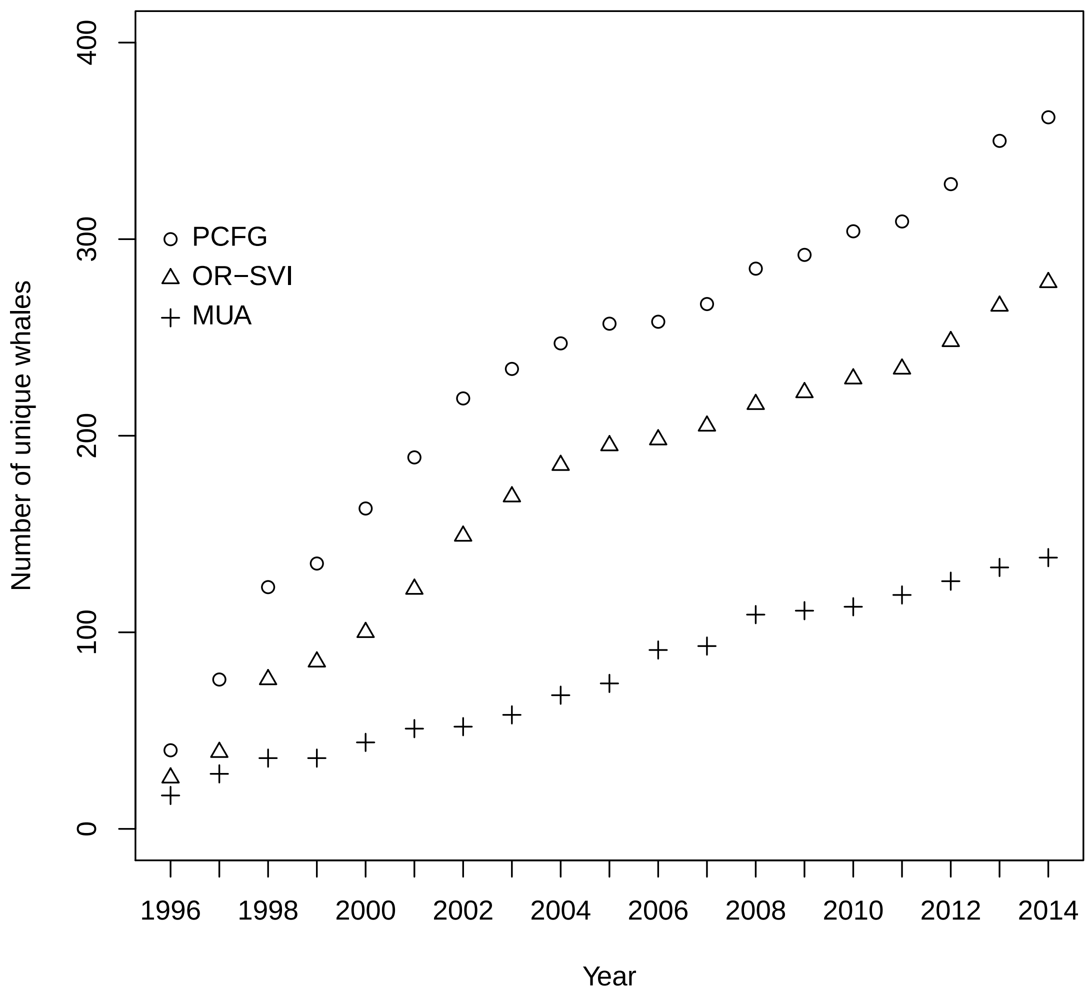

Figure 10: Discovery curves for unique recruited whales seen in PCFG, OR-SVI and MUA for 1996-2015.

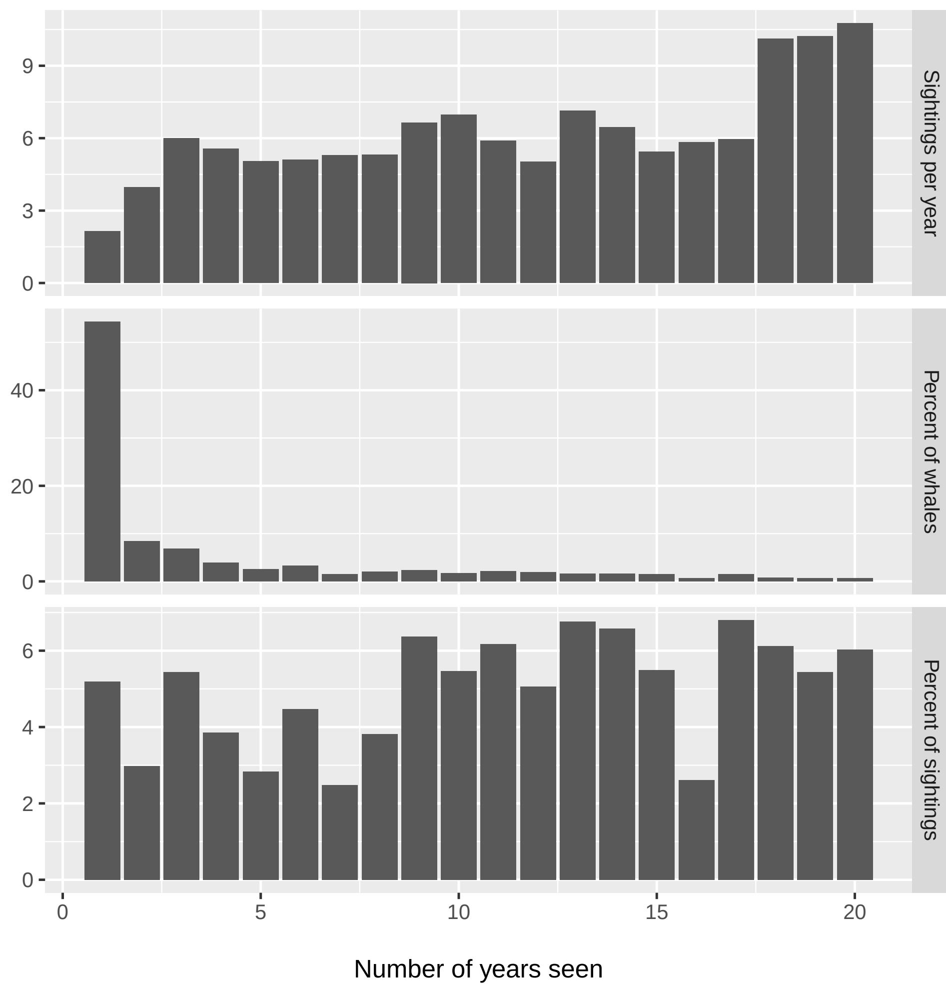

Figure 11: Average number of sightings per year and distribution of whales and numbers of sightings based on numbers of years a whale was seen in NCA-NBC between June-November during 1996-2015.

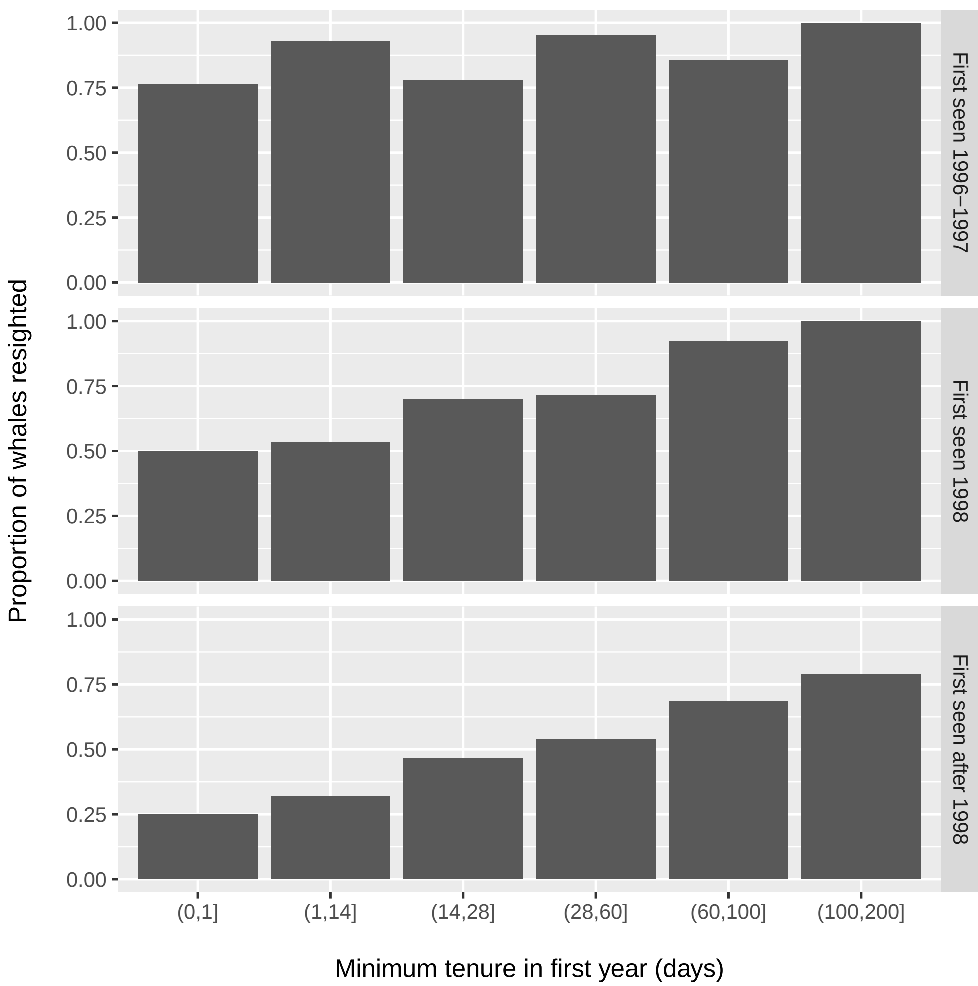

Figure 12: Influence of minimum tenure (MT) in the first year the whale was photographed on the probability it will be re-sighted in one or more following years for whales seen in NCA-NBC for June-November 1996-2015. The bar graphs are divided based on first year in 1996-1997, 1998 and after 1998. Re-sightings for 2015 are used but initial sightings for 2015 are excluded because there are no data beyond to evaluate re-sighting probability.

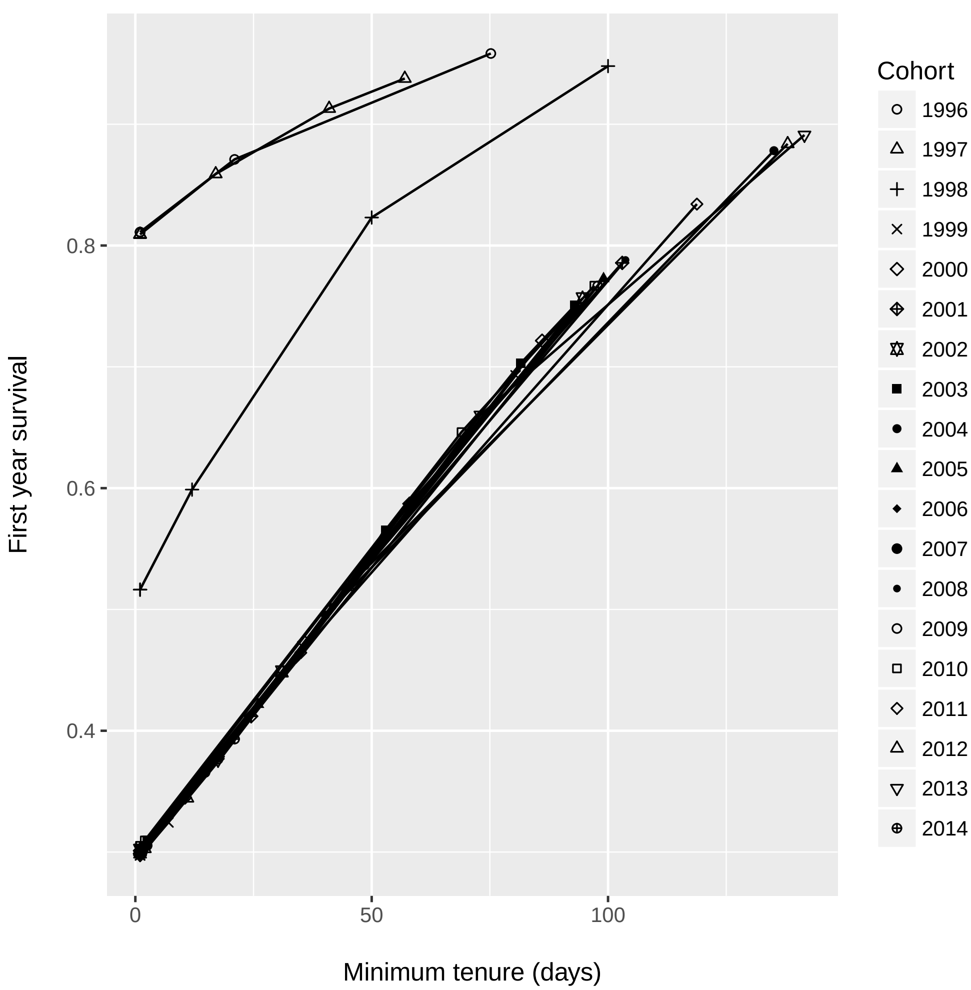

Figure 13: For NCA-NBC analysis of 1996-2015 data, model-averaged estimates of first year survival of non-calves for each cohort at 5%, 25%, 50%, 75%, and 95% quantiles of minimum tenure values for that cohort.

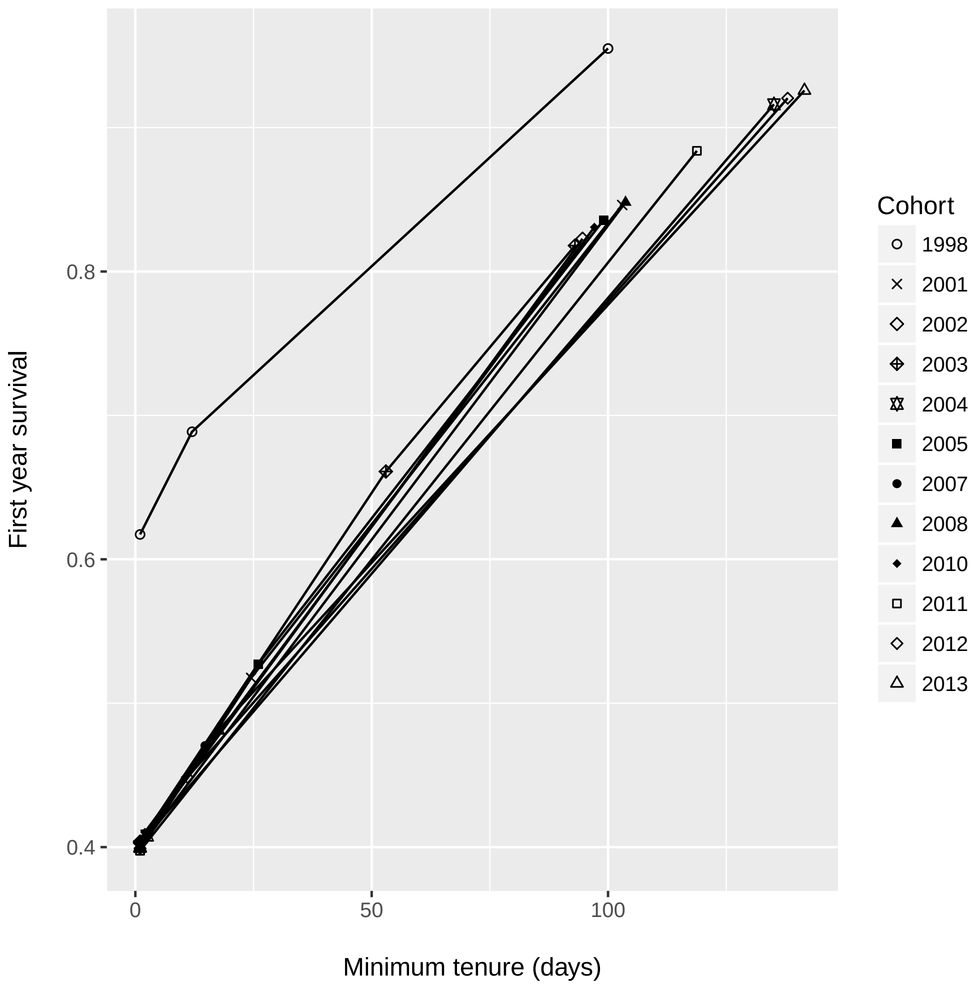

Figure 14: For NCA-NBC analysis of 1996-2015 data, model-averaged estimates of first year survival of calves for each cohort at 5%, 25%, 50%, 75%, and 95% quantiles of minimum tenure values for that cohort.

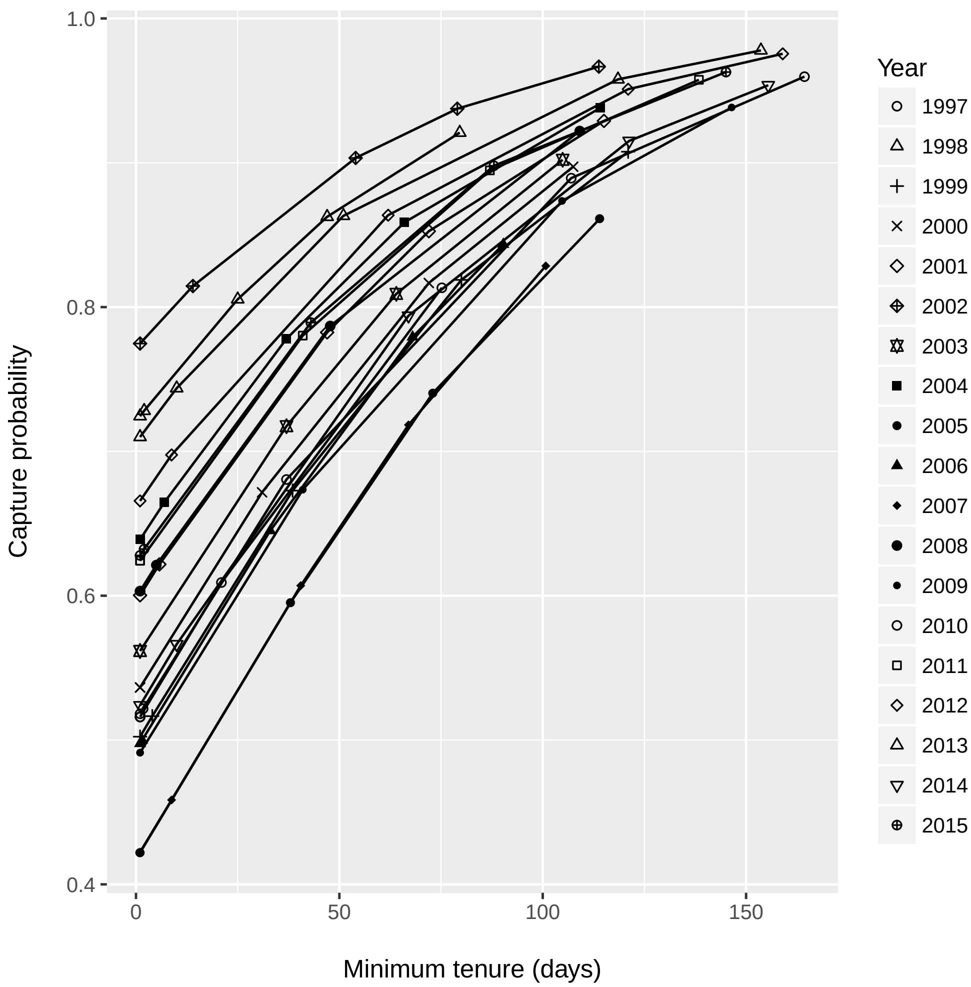

Figure 15: For NCA-NBC analysis of 1996-2015 data, model-averaged estimates of capture probability for each year at 5%, 25%, 50%, 75%, and 95% quantiles of minimum tenure values for whales in the previous year.

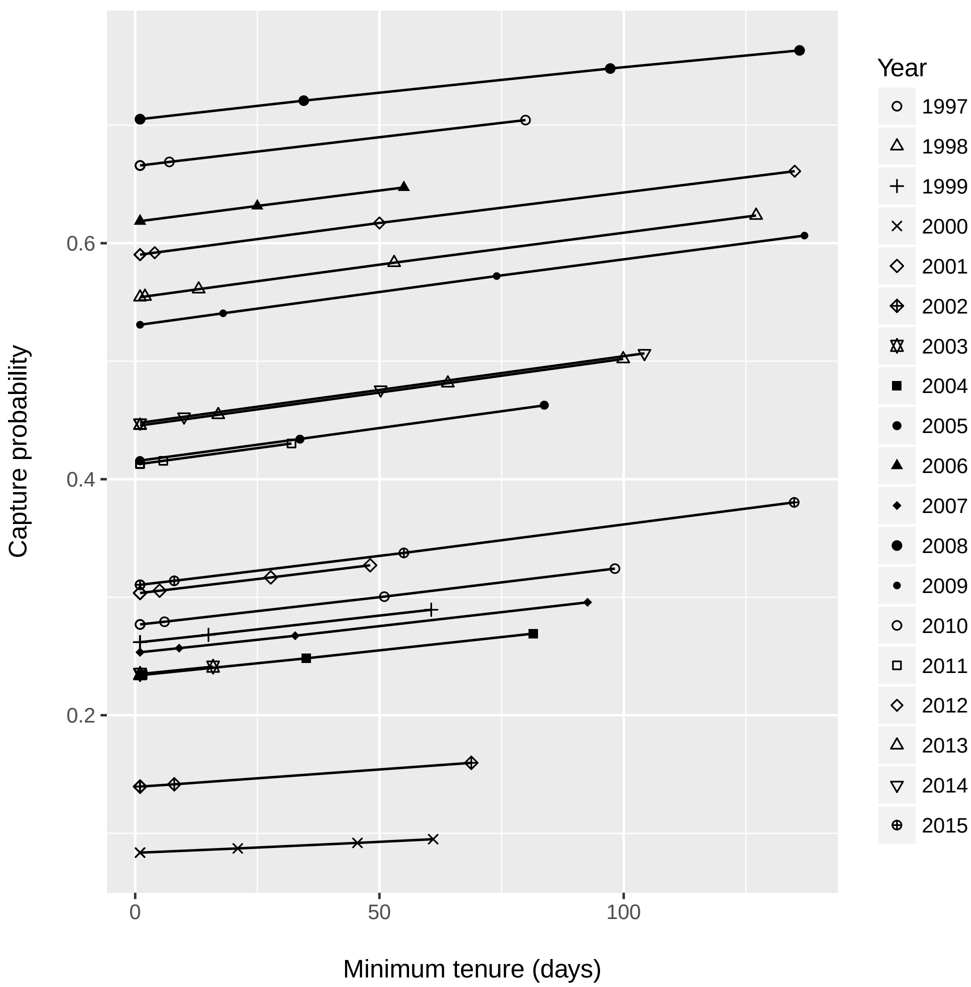

Figure 16: For MUA analysis of 1996-2015 data, model-averaged estimates of capture probability for each year at 5%, 25%, 50%, 75%, and 95% quantiles of minimum tenure values for whales in the previous year.

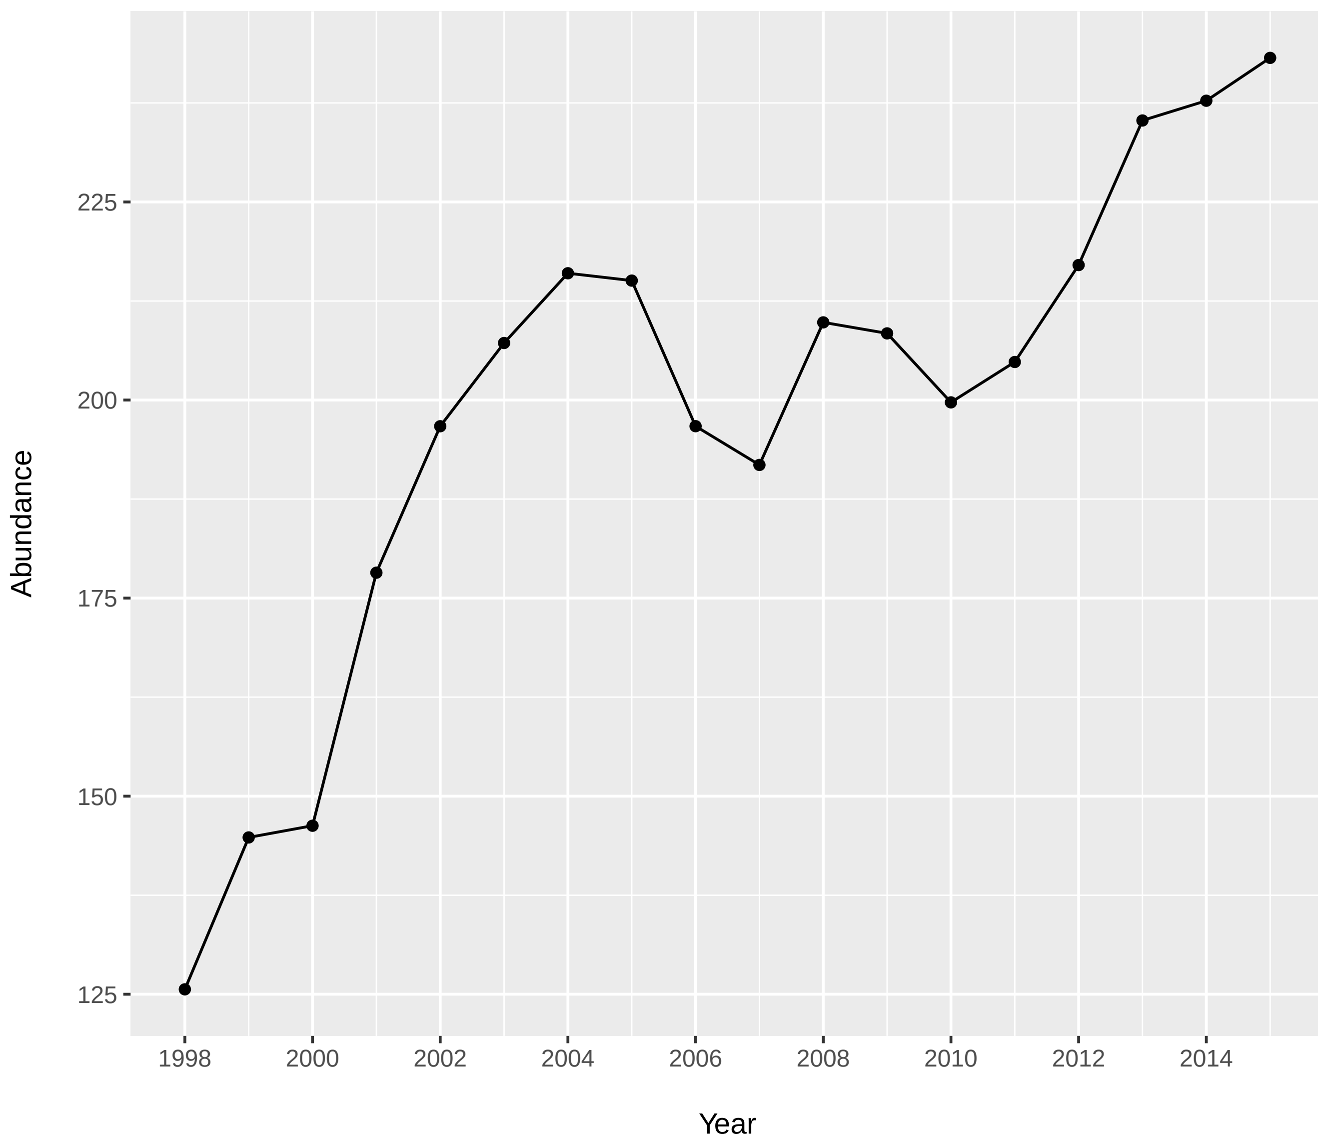

Figure 17: Annual abundance estimates for 1998-2015 in NCA-NBC using the open (Jolly-Seber; POPAN parametrization) population model approach JS1.

Appendix

Table 1 provides capture histories of whales seen in the PCFG at least once from 1 June - 30 November and displays by year, when they were seen only in spring (March-May), only from 1 June - 30 Nov and when they were seen in both time periods. Table 2 provides capture histories using data from 1 June - 30 Nov of whales seen in the MUA at least once. It shows when whales were seen only outside of the MUA but in the PCFG, only in the MUA and both inside the MUA and in the PCFG outside of the MUA

Table 1: Sighting histories of whales seen in the PCFG in at least one year. In year columns, a 1 means the whale was only sighted in the spring (March-May), 2 means it was only seen in June-Nov, and 3 means it was seen in both March-May and June-Nov. The region value is the nunber of years the whale was seen in that region.

Table 1: Sighting histories of whales seen in the PCFG in at least one year. In year columns, a 1 means the whale was only sighted in the spring (March-May), 2 means it was only seen in June-Nov, and 3 means it was seen in both March-May and June-Nov. The region value is the nunber of years the whale was seen in that region.

ABSTRACT

Recovery of cetacean carcasses provides data on levels of human-caused mortality, but represents only a minimum count of impacts. Counts of stranded carcasses are negatively biased by factors that include at-sea scavenging, sinking, drift away from land, stranding in locations where detection is unlikely, and natural removal from beaches due to wave and tidal action prior to detection. We estimate the fraction of carcasses recovered for a population of coastal bottlenose dolphins (*Tursiops truncatus*), using abundance and survival rate data to estimate annual deaths in the population. Observed stranding numbers are compared to expected deaths to estimate the fraction of carcasses recovered. For the California coastal population of bottlenose dolphins, we estimate the fraction of carcasses recovered to be 0.25 (95% CI = 0.20–0.33). During a 12 yr period, 327 animals (95% CI = 253–413) were expected to have died and been available for recovery, but only 83 carcasses attributed to this population were documented. Given the coastal habits of California coastal bottlenose dolphins, it is likely that carcass recovery rates of this population greatly exceed recovery rates of more pelagic dolphin species in the region.

Key words: bottlenose dolphin, *Tursiops truncatus*, strandings, carcass recovery, survival rates, human-caused mortality.

[1]Corresponding author (e-mail: jim.carretta@noaa.gov).

Estimated levels of human-caused mortality and serious injury for cetaceans suffer from negative biases due to incomplete detection and recovery of carcasses. Contributing factors may include scavenging, drift, sinking, decomposition, natural removal from beaches due to wave action, undocumented bycatch, remoteness of cases, carcass removal or burial by municipalities prior to a stranding response, and failure to detect visible carcasses. It follows that documenting *natural* mortality through carcass recovery also suffers from negative bias for many of the same reasons. Previous carcass recovery studies have utilized abundance data, annual survival rates, tagging of carcasses at sea, and stranding numbers to estimate the degree of negative bias. Where reported, the fraction of carcass recovery is quite low, ranging from 0 to 0.062 for Gulf of Mexico cetaceans (Williams *et al.* 2011), <0.01 for North Atlantic harbor porpoises (*Phocoena phocoena*) (Moore and Read 2008), 0.039–0.13 for eastern Pacific gray whales (*Eschrichtius robustus*) (Punt and Wade 2012), 0.17 for north Atlantic right whales (*Eubalaena glacialis*) (Kraus *et al*. 2005), 0.08 for common dolphins (*Delphinus*) off France (Peltier *et al.* 2012), 0.05–0.18 for Brazilian franciscana dolphins (*Pontoporia blainvillei*) (Prado *et al.* 2013), and 0.33 for Sarasota Bay bottlenose dolphins (*Tursiops truncatus*) (Wells *et al*. 2015) (Table 1).

Our goal is to estimate the fraction of carcasses recovered for the "California coastal" population of bottlenose dolphin that occurs along the U.S. west coast and Baja California (Defran *et al*. 1999). This population is a good case study because of factors including habitat preferences, reliability and stability of abundance estimates, and population distinctness. The population has a high degree of nearshore site fidelity, with >99% of all sightings within 500 m of shore (Hanson and Defran 1993, Carretta *et al.* 1998). The population's nearshore distribution suggests that individual California coastal bottlenose dolphins may be the most likely delphinid species to strand in the region, given a mortality event. If stranding probabilities of coastal bottlenose dolphins are indeed higher than other delphinid species in the area, the population serves as an excellent "best case scenario" with respect to carcass recovery.

The range of California coastal bottlenose dolphins is well-known, spanning approximately 1,000 km of coastline from Ensenada, Mexico, to San Francisco, California (Defran *et al.* 1999) (Fig. 1). Rarely, carcasses from this population are found as far north as the states of Oregon and Washington. High rates of photo-identification overlap (percent of identified individuals documented between regions) are documented between Ensenada and Santa Barbara in the southern California Bight (55% to 90%) and between the southern California Bight and Monterey Bay (>50%) (Feinholz 1996, Defran *et al*. 1999, Hwang *et al.* 2014; Fig. 1). Individual animals have traveled nearly 1,000 km between Ensenada and Monterey and rapid movements of 300 km in 5 d between San Diego and Santa Barbara are known (Hwang *et al.* 2014). From this we infer that the area from Ensenada to San Francisco includes one population. Approximately 18% of the stock's range occurs south of the U.S./Mexico border (Carretta *et al.* 2013). Based on mark-recapture movement data, individuals appear to use this entire range and exhibit limited site fidelity to any particular region (Defran *et al*. 1999, Hwang *et al.* 2014). In contrast, only 3% of animals identified near San Quintín, Mexico were also identified in the southern California Bight (Caldwell 1992, Defran *et al*. 2015), suggesting a southern limit of this population somewhere between Ensenada and San Quintín. The coastal stock of bottlenose dolphins is distinct from the offshore stock, based on morphology and genetics (Perrin *et al.* 2011, Lowther-Thielking *et al.* 2015). Of 56 haplotypes found among coastal and offshore bottlenose dolphins in the region, only one is shared by both populations (Perrin *et al.* 2011). Approximately 90% of stranding records of bottlenose dolphins along the mainland coast represent coastal stock animals (Perrin *et al*. 2011; NMFS,

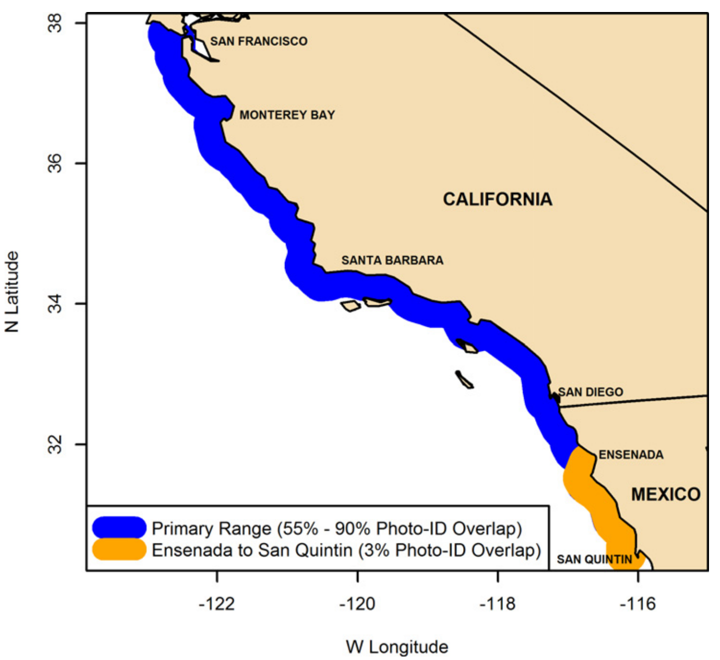

Figure 1. Normal range of California coastal bottlenose dolphins, including estimates of photo-ID match overlap between geographic regions. Photographic mark-recapture evidence indicates that individuals from the population utilize the entire coastal range.

unpublished data), despite the fact that the offshore population is estimated to be 6–7 times more abundant (Barlow 2010, Carretta *et al.* 2013).

Abundance estimates of the coastal stock are based on three different photographic mark-recapture estimates between 1987 and 2005 and appear stable over a 20 yr period, with approximately 300 − 400 marked individuals (Dudzik 1999, Dudzik *et al.* 2006) (Table 2). Such a stable population size facilitates comparison of annual stranding data with expected carcass numbers, in contrast with a population where abundance may be changing rapidly.

Estimation of annual dolphin deaths requires data or assumptions about life history parameters such as annual survival rate. While survival rates for the California coastal population are not currently estimated, other bottlenose dolphin populations (both captive and wild) have been studied, from which published estimates of survival can be used in tandem with abundance data to estimate the number of carcasses available to strand.

Methods

Our analysis focuses on the years 1995–2006, when both reliable abundance estimates and stranding numbers of coastal bottlenose dolphins were available. We reviewed the literature to obtain survival rate estimates for bottlenose dolphins, which are used in combination with abundance data from the California coastal population to estimate the expected number of deaths annually. The number of carcasses recovered annually by stranding networks is compared to the number of expected deaths estimated *via* Monte Carlo simulations and used to estimate the fraction of carcasses recovered.

Strandings

Stranding records of bottlenose dolphins from the U.S. west coast were obtained from several institutions: NOAA Fisheries Southwest Fisheries Science Center, Los Angeles County Museum, Santa Barbara Museum of Natural History, Moss Landing Marine Laboratories, Long Marine Lab (UC Santa Cruz), The Marine Mammal Center, California Academy of Sciences, Oregon State University, Cascadia Research Collective, and the Washington Department of Fish and Wildlife. Stranding records were available as early as 1935, however, we focus on the time period beginning in 1995 for a few reasons. First, 1995 represents the first year that systematic accounting of human-caused mortality for U.S. marine mammal populations was required after 1994 revisions to the Marine Mammal Protection Act (MMPA) (Barlow *et al.* 1995).

Table 2. Estimates of California coastal bottlenose dolphin abundance and coefficients of variation (CV) obtained from photo-ID mark-recapture studies. Estimates represent only marked animals in the population.

Years	Estimated abundance (CV)	Source
1987–1989	354 (0.04)	Dudzik (1999)
1996–1998	356 (0.09)	Dudzik (1999)
2004–2005	323 (0.12)	Dudzik *et al.* (2006)

Second, new field efforts designed to estimate the abundance of the California coastal bottlenose dolphin stock began in 1996 (Dudzik 1999). Third, stranding networks in the region were well-established by this time. Stranding reporting and documentation was much-improved compared with earlier decades and facilitated by increased cell phone use and improved education and outreach efforts with local lifeguards and other coastal authorities compared to earlier periods. In previous decades, it was not uncommon for local municipalities to bury cetacean carcasses or relocate them to landfills before marine mammal experts were contacted. This may still occur on occasion, but public and municipal cooperation is improved, and from a historical perspective, the percentage of strandings reported to biologists today is probably at its highest.

For 1995–2006, we reviewed 92 bottlenose dolphin mainland stranding records from the U.S. west coast from the States of California, Oregon, and Washington. A majority of strandings occurred in California (n = 91), none in Oregon, and one in Washington. We strived to account for all stranding records during this time, but cannot guarantee that records are all-inclusive. Strandings from offshore islands were rare and were not included in this analysis, as stranding response effort there is minimal and opportunistic. Population identity (coastal *vs.* offshore) is not known for every stranding because many lack genetic or skeletal material. Perrin *et al.* (2011) reported finding 56 haplotypes among California coastal and offshore bottlenose dolphin populations, with only one shared haplotype. Of 80 mainland strandings examined by Perrin *et al*. (2011), 73 (91%) were assigned to the coastal population based on having haplotypes known only from coastal reference animals. A larger data set of genetic determinations from strandings along the California, Oregon, and Washington mainland coast between 1953 and 2013 shows that 94% (163/173) of animals have a high probability of being from the coastal population (NMFS, unpublished data). Likewise, during our study period, 54 of 61 (88%) mainland strandings for which genetic material was available were assigned to the coastal population, while the remaining 31 animals were not assigned to any population, usually because genetic material was insufficient or lacking. Based on the historic ratios of bottlenose dolphin carcasses from the mainland that were identified as coastal *vs*. offshore stock animals, we prorated the number of observed mainland strandings by 0.90 to correct for the approximately 10% that represent offshore animals. This implies that of the 92 mainland strandings recorded between 1995 and 2006, approximately 83 animals were from the coastal population.

Dolphin Abundance

We estimate mean dolphin abundance from 1995 to 2006, using the two most recent estimates from Table 2. Our analysis period extends one year before and after field data were collected for those abundance estimates, with the assumption that abundance did not change significantly during the 1 yr periods before and after each field study. Mean abundance for the period is calculated as the geometric mean of the 1996–1998 and 2004–2005 abundance estimates, in the same manner used in Pacific marine mammal stock assessment reports (Carretta *et al.* 2013). The resulting mean estimate (and CV) is 339 animals (CV = 0.07). This estimate represents only *marked* animals in the population (those with distinctive dorsal fins). Dudzik *et al.* (2006) estimated that the fraction of marked animals in the population was 0.63, but did not report a variance for this value. Using the sample sizes of marked (n = 164) and unmarked (n = 97) animals given by Dudzik *et al*. (2006), we assume that the fraction of marked animals in the population is a binomial random variable with mean = 0.63 (see *Simulations* below). This fraction marked represents a correction factor to estimate "true" population size, such that mean abundance is estimated as 339 animals divided by 0.63, or approximately 538 animals.

Annual Survival Rate

Bottlenose dolphins are among the most-studied cetaceans, with long-term studies of small populations yielding a variety of survival rate estimates, including some age- and sex-specific estimates (DeMaster and Drevenak 1988, Hersh *et al.* 1990, Wells and Scott 1990, Small and DeMaster 1995, Stolen and Barlow 2003, Currey *et al*. 2009, Nicholson *et al.* 2012). We reviewed the literature for bottlenose dolphin survival rate estimates, including wild and captive populations. Large differences in annual survival for animals ≤1 yr old (calves) and older animals was apparent from multiple studies, with the lowest annual survival rates found among calves (Table 3).

Simulations

Monte Carlo methods were used to simulate abundance (N_{sim}) and annual survival rate (S) for each year from 1995 to 2006. Annual abundance was modeled as a lognormal random deviate with a mean of 339 animals, a CV = 0.07, and a sample size of 1,000. Simulated annual abundance was divided by the fraction of marked animals in the population (Fr_{marked}), reported as 0.63 by Dudzik *et al.* 2006), to correct for the unmarked portion of the population not reflected in mark-recapture estimates. No estimate of uncertainty was given for Fr_{marked}, but the number of marked (n = 164) and unmarked (n = 97) animals was reported, from which we generated a binomial random variable to represent the fraction of the population marked for each of 1,000 uncorrected annual abundance estimates. The resulting distribution of Fr_{marked} has a mean of 0.63 with an approximate 95% confidence interval of 0.57 to 0.69.

Roughly 18% of the population's range occurs in Mexican waters where we do not have reliable stranding data, thus, all simulated abundances were multiplied by a

Table 3. Published estimates of annual survival rates for captive and wild bottlenose dolphin populations. Only estimates based on wild populations are used in the present study.

Study	Area	Population type	Annual survival rate (age class)
Currey *et al.* (2009)	Doubtful Sound, New Zealand	Wild	0.862 (<1 yr) 0.937 (adults)
DeMaster and Drevenak (1988)	Various display facilities	Captive	0.61 (<1 yr) 0.93 (all ages)
Hersh *et al.* (1990)	Florida	Wild	0.908–0.931 (all ages)
Nicholson *et al.* (2012)	Australia	Wild	0.95 (all ages)
Small and DeMaster (1995)	Various display facilities	Captive	0.666 (<1 yr) 0.948 (adults)
Stolen and Barlow (2003)	Florida	Wild	0.836 (<1 yr) 0.902 (all ages)
Wells and Scott (1990)	Florida	Wild	0.81 (<1 yr) 0.96 (adults)

"range correction factor" ($R_f = 0.82$) to reflect only those carcasses available to strand on U.S. beaches. This is equivalent to assuming that animals are equally likely to utilize areas in southern California and Mexico, which is supported by high resighting rates of individuals between southern California and Mexico (Defran *et al*. 1999, Hwang *et al.* 2014). If on average, more than 18% of the population occurs south of U.S./Mexico border, this approach would overestimate the number of carcasses available to strand on U.S. beaches, which would negatively bias carcass recovery estimates. Insufficient fine-scale and short-term movement data for individual dolphins in this population are available to test this assumption.

Annual survival rate (S) was allowed to vary as a uniform random variable for each of 1,000 N_{sim}, with lower and upper limits taken from the literature (Table 3). Separate survival rates were assumed for two different age classes: animals ≤1 yr old and animals >1 yr. Calf survival (S_{calf}) ranged between 0.81 and 0.862 and adult survival (S_{adult}) ranged between 0.937 and 0.96, based on published values for wild populations only (Table 3).

Use of separate estimates of survival for calves and adults required knowledge about the fraction of calves in the population. Hansen (1990) and Weller (1991) found that calves (defined as animals ≤1 yr old) represented 7% and 11%, respectively, of all individuals photographed in the California coastal population. Values from other coastal bottlenose dolphin populations are similar, with calves representing between 8% and 11% of animals (Würsig 1978, Shane *et al.* 1986, Campbell *et al.* 2002, Stolen and Barlow 2003). The fraction of calves in the population (Fr_{calf}) was based on sampling with replacement from a uniform distribution ranging from 0.07 to 0.11, and was allowed to vary for each of 1,000 values of N_{sim}. The fraction of adult animals (Fr_{adult}) is simply 1 – Fr_{calf}. The expected number of carcasses available to strand each year ($C_{expected}$) is a simulated distribution of 1,000 values derived from $N_{sim,}$ Fr_{calf}, Fr_{adult}, S_{calf}, and S_{adult}, and can be expressed as:

$$C_{expected} = C_{calf} + C_{adult} \tag{1}$$

where

$$C_{calf} = N_{sim}/Fr_{marked} \cdot R_f \cdot (1 - S_{calf}) \cdot Fr_{calf} \tag{2}$$

and

$$C_{adult} = N_{sim}/Fr_{marked} \cdot R_f \cdot (1 - S_{adult}) \cdot Fr_{adult} \tag{3}$$

where $C_{expected}$ = expected dolphin carcasses in year y; C_{calf} = expected calf carcasses in year y; C_{adult} = expected adult carcasses in year y; N_{sim} = simulated abundance in year y, Lognormal(mean = 339, CV = 0.07); Fr_{marked} = fraction of population that is marked, Binomial(mean = 0.63, 95% CI = 0.58–0.69); Fr_{calf} = fraction of calves in the population in year y, Uniform(0.07–0.11); Fr_{adult} = fraction of adults in the population in year y, Uniform(0.89–0.93); S_{calf} = annual calf survival rate in year y, Uniform(0.81–0.862); S_{adult} = annual adult survival rate in year y, Uniform(0.937–0.96); and R_f(0.82) represents the fraction of carcasses assumed to occur in U.S. waters at any one time.

For each year, the estimated fraction of carcasses recovered is simply the observed number of strandings (prorated by 0.90 to account for some animals being of offshore origin) divided by the mean of $C_{expected}$. 95% confidence limits for the fraction of carcasses recovered are calculated as number of stranding events divided by the 2.5th and 97.5th percentiles of C_{expected}.

Results

Over the 12 yr study period, 92 stranded bottlenose dolphin carcasses were documented on the mainland. After prorating for the proportion historically identified as coastal (*vs*. offshore) stock animals, 83 strandings were assumed to originate from the coastal stock. The number of expected deaths for this same period was 327 animals (78 calves and 249 adults). Calves represented 24% of the expected carcasses over the study period, which is less than that documented from long-term stranding data (38%). Estimated carcass recovery for all ages averaged 0.25 (95% CI = 0.20–0.33) over the 12 yr study period (Table 4). Annually, carcass recovery estimates ranged from 0.099 to 0.46 (Table 4), reflecting annual variability in carcass numbers found ashore under an assumption of stable population size. Simulated annual deaths (calves and adults combined) represented 6% of the estimated population size, which is equivalent to an annual all-ages survival rate of 0.94. The mean number of expected deaths each year ($n = 27$) converges towards a single value because we assumed a fixed population size over the study period and simulation sample sizes were sufficient to result in such convergence.

Discussion

With the exception of an embayment population of Florida bottlenose dolphins where carcass recovery was estimated to be 0.33 (Wells *et al.* 2015), carcass recovery estimates for California coastal bottlenose dolphins from this study (0.25) are higher than values found for other cetaceans (Table 1). This is not surprising, considering the coastal habits of the population, the effectiveness of stranding networks, and the high density of human activity along this coast. Our results are case-specific to this particular population and stranding network characteristics, but likely represent a maximum carcass recovery rate for dolphin species along the U.S. west coast. One caveat to our estimates is that they reflect background rates of mortality in the absence of an unusual or mass mortality event, such as those associated with morbillivirus (Lipscomb *et al*. 1994).

Both natural and anthropogenic mortality are represented in strandings, but confirming evidence of anthropogenic mortality is sometimes difficult due to carcass decomposition or the cryptic nature of the evidence (*e.g.*, gill net marks that may not be detected by responders). Our results contain the implicit assumption that stranding probability is equal for natural and anthropogenic mortality, but this may not be true. In a study of harbor porpoise, Moore and Read (2008) suggested that natural mortality involves processes such as predation and starvation that may have lower stranding probabilities than previously healthy gill net-caught animals discarded at sea that are more likely to float. They also found evidence of age-biased mortality for animals caught in gill nets compared to beach strandings representing an unknown mix of natural and anthropogenic mortality. Given the extremely coastal habits of California coastal bottlenose dolphin and infrequent interaction with gill nets that

Table 4. Observed and prorated numbers of strandings, expected carcass numbers, and estimated fraction of carcasses recovered for the period 1995–2006. Prorated strandings may not be whole numbers because observed strandings were prorated by 0.90 to account for some strandings originating from the offshore population.

are fished at least 3 mi (4.8 km) from shore, we believe that any differences in stranding probabilities for natural and anthropogenic mortality are likely to be small.

Levels of uncertainty in carcass recovery estimates are likely underestimated. The fraction of the coastal bottlenose dolphin population that occurs in U.S. waters at any one time is unknown and cannot be estimated without tracking individual dolphin movements. Rather, we assume that 18% of coastal bottlenose dolphin carcasses are unavailable to U.S. west coast stranding networks, based on the fraction of their known range that occurs south of the U.S./Mexico border. Our method of estimating carcass recovery is crude compared with multivariate models that consider factors such as drift, wind, buoyancy, and decomposition (Peltier *et al.* 2012, 2013; Prado *et al.* 2013). However, while it is interesting to know *why* all carcasses are not recovered, we reduce the problem to a simple metric of *how many* carcasses are recovered relative to the expected number, similar to the work of Williams *et al.* (2011). The reasons behind negative biases in carcass recovery are interesting subjects, but are not necessary to develop correction factors for stranding numbers.

Length data for strandings collected during 1995–2006 were available for only 42 of 92 records, so a direct comparison of observed and expected carcass numbers for calves and adults is not possible. Length-at-age data are not available for this population, but two animals from this population as large as 168 cm and 171 cm have been aged at <1 yr (NMFS, unpublished data). By comparison, Read *et al*. (1993) reported a lower-bound length of 171 cm for 1-yr-old bottlenose dolphins in Sarasota Bay. When a larger data set (n = 162) of mainland bottlenose dolphin strandings from 1948 to 2013 is examined, a distinct modal length of 125 cm is apparent, corresponding to high numbers of neonate strandings compared to other age classes (Fig. 2). If animals <1 yr old are assumed to be <170 cm, then approximately 38% of all strandings between 1948 and 2013 represent calves (Fig. 2). From simulations, the fraction of expected calf carcasses is 0.24 (78/327) (Table 4), which is considerably less than the fraction of calves (0.38) observed from long-term stranding data. If we assume that 38% of the 83 strandings attributed to the coastal population between 1995 and 2006 are animals <1 yr old, then 32 calves are represented. The number of expected calves from simulations is 78 over the same period, implying a calf recovery fraction of 0.41. The corresponding estimate of carcass recovery for

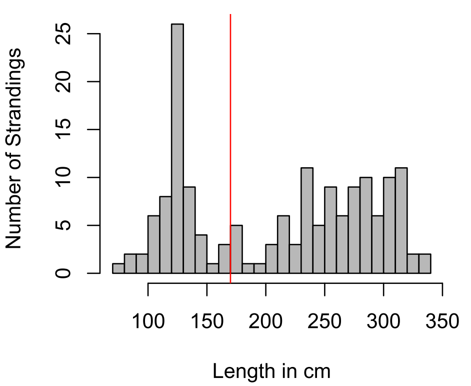

Figure 2. Distribution of dolphin lengths recorded for 162 stranded specimens of *Tursiops truncatus* along the mainland U.S. west coast, 1948–2013. Vertical red line delineates approximate length of animals <1 yr old (≤170 cm).

adults (assuming that 51 of 83 coastal animal strandings were adults) is 51 recovered/249 expected = 0.20. Both observed (38%) and simulated (24%) percentages of calf carcasses are high relative to the percent of calves observed in the population at any one time (7%–11%) (Hansen 1990, Weller 1991), implying that calf recovery rates are relatively high compared to adults. Differences in stranding probabilities by age probably exist, especially if currents and beach conditions favorable to deposition overlap with calving seasonality. For example, the long-term stranding data for 1948–2013 includes 62 strandings <170 cm in length, 48 (77%) of which stranded during the 4 mo spring/summer period of May–August. By comparison, only 46% of "large" carcasses (>170 cm) were collected during this same 4 mo period. These observations imply a seasonal peak in calving, spring/summer ocean conditions conducive to beach deposition of carcasses, or both. Spring and summer are characterized by gentle wave action conducive to deposition, in contrast to autumn and winter conditions more favorable to erosion and removal of objects from beaches. Although newly born calves are seen year-round in this population, calving seasonality is not well-studied. If calving seasonality coincides with summer beach conditions favorable for deposition (and detection due to increased human presence), then high calf recovery levels are not surprising.

Another potential contributing factor to higher calf recovery estimates is that simulated calf survival estimates from wild populations are optimistically high because field researchers fail to detect all births. Wells and Scott (1990) noted that birth rates can be underestimated, especially if field efforts are far enough apart in time such that neonates that die soon after birth have no chance of being counted by researchers unless they strand. Studies of captive calves indicate that a large percentage of neonates die within days of birth (Venn-Watson *et al.* 2011) and this may apply to wild births too. The lower bound of 0.81 for wild calf survival (Wells and Scott 1990) used in our simulations resulted in approximately 6–7 expected calf carcasses annually. Had we included *captive* calf survival estimates in our simulations, annual calf survival could have ranged as low as 0.61 (DeMaster and Drevenak 1988) and the expected number of calf carcasses would have increased to 10–11 annually, representing approximately one-third of annual expected carcasses, which is in close agreement with long-term stranding observations.

Our estimates of carcass recovery (0.25, 95% CI = 0.20–0.33) for an extremely coastal dolphin population suggests that observed anthropogenic mortality values of dolphins in this region derived from strandings should be corrected to account for unobserved mortality. This assumes that the probability of stranding is equal for natural and human-caused deaths, an assumption that is difficult to test. Our estimates have implications for developing carcass recovery correction factors for other more pelagic dolphin species in the region that might be less likely to strand (Perrin *et al.* 2011). Context clues as to the degree of negative bias in carcass recovery for more pelagic dolphins in this region are apparent when abundance and strandings are considered across multiple populations. Perrin *et al.* (2011) noted that a coastal bottlenose dolphin carcass is 50 times more likely to reach shore than an offshore ecotype, based on differences in estimated abundance for each population and assuming similar mortality rates. Danil *et al.* (2010) reported that the more pelagic common dolphin (*Delphinus delphis* and *D. capensis* combined) accounted for 43% of cetacean stranding records in San Diego County, while bottlenose dolphins (largely coastal animals) represented 16% of records. This yields a crude stranding ratio of 2.6 common dolphins for every bottlenose dolphin. In Santa Barbara County, the ratio of common dolphin to bottlenose dolphin strandings is approximately 10:1 (Santa

Barbara Museum of Natural History, unpublished data). Estimates of common dolphin abundance (both species combined) in southern California waters are approximately 400,000 animals (Barlow 2010, Carretta *et al.* 2011), compared with approximately 500–600 animals for coastal bottlenose dolphins. The ratio of common dolphin to bottlenose dolphin abundance is roughly 700:1 and expected stranding ratios should reflect relative abundance if both groups had equal stranding probabilities. Taken in context, abundance and strandings data imply a very low probability of stranding for the extremely abundant, but more pelagic common dolphins.

GRAY WHALE (*Eschrichtius robustus*): Western North Pacific Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Gray whales occur along the eastern and western margins of the North Pacific. In the western North Pacific (WNP), gray whales feed during summer and fall in the Okhotsk Sea off northeast Sakhalin Island, Russia, and off southeastern Kamchatka in the Bering Sea (Weller et al. 1999, 2002; Vertyankin et al. 2004; Tyurneva et al. 2010; Burdin et al. 2013; Figure 1). Some gray whales observed feeding off Sakhalin and Kamchatka migrate during the winter to the west coast of North America in the eastern North Pacific (Mate et al. 2011; Weller et al. 2012; Urbán *et al*. 2013), while others, including at least one whale first identified as a calf off Sakhalin, migrate to areas off Asia in the WNP (Weller et al. 2008; Weller et al. 2013a). Despite the observed movements between the WNP and eastern North Pacific (ENP), genetic comparisons show significant mitochondrial and nuclear genetic differences between whales sampled in the ENP and those sampled on the feeding ground off Sakhalin Island in the WNP (LeDuc et al. 2002; Lang et al. 2011). While a few previously unidentified non-calves are identified annually, a recent population assessment using photo-identification data from 1994 to 2011 fitted to an individually-based model found that whales feeding off Sakhalin Island have been demographically self-contained, at least in recent years, as new recruitment to the population is almost exclusively a result of calves born to mothers from within the group (Cooke et al. 2013).

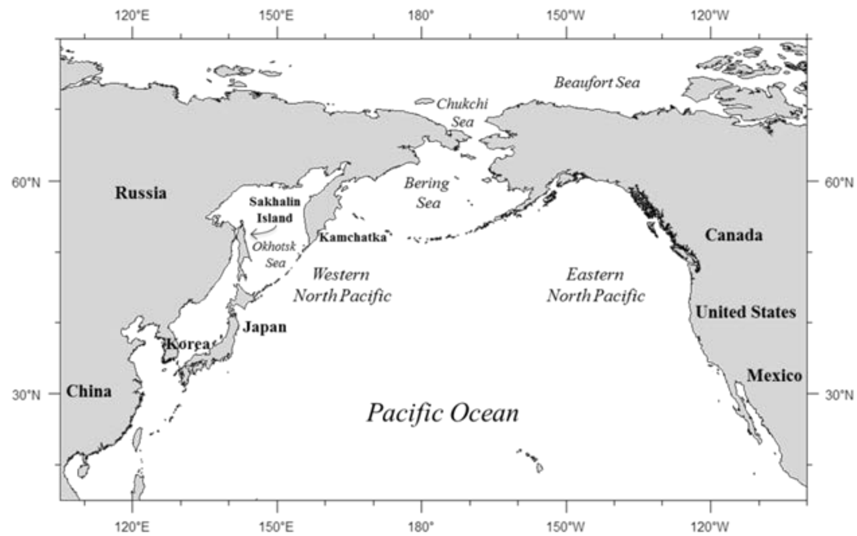

Figure 1. Range map of the Western North Pacific Stock of gray whales, including summering areas off Russia and wintering areas in the western and eastern Pacific.

Historical evidence indicates that the coastal waters of eastern Russia, the Korean Peninsula and Japan were once part of the migratory route in the WNP and that areas in the South China Sea may have been used as wintering grounds (Weller et al. 2002; Weller et al. 2013a). However, contemporary records of gray whales off Asia are rare, with only 13 from Japanese waters between 1990 and 2007 (Nambu *et al*. 2010) and 24 from Chinese waters since 1933 (Wang 1984; Zhu 2002). The last known record of a gray whale off Korea was in 1977 (Park 1995; Kim et al. 2013). While recent observations of gray whales off the coast of Asia are infrequent, they nevertheless continue to occur, including: (1) March/April 2014 - one or possibly two gray whales were sighted and photographed off the Shinano River in Teradomari (Niigata Prefecture) on the Sea of Japan coast of Honshu, Japan (Kato et al. 2014), (2) March 2012 - a gray whale was sighted and photographed in Mikawa Bay (Aichi Prefecture), on the Pacific coast of Honshu, Japan (Kato *et al*. 2012), and (3) November 2011 - a 13 m female gray whale was taken in fishing gear offshore of Baiqingxiang, China, in the Taiwan Strait (Zhu 2012).

Information from tagging, photo-identification and genetic studies show that some whales identified in the WNP off Russia have been observed in the ENP, including coastal waters of Canada, the U.S. and Mexico (Lang 2010; Mate et al. 2011; Weller et al. 2012; Urbán et al. 2013, Mate et al. 2015). In combination, these studies have recorded a total of 27 gray whales observed in both the WNP and ENP. Some whales that feed off Sakhalin Island in summer migrate east across the Pacific to the west coast of North America in winter, while others migrate south to waters off Japan and China. Taken together, these observations indicate that not all gray whales in the WNP share a common wintering ground (Weller et al. 2013a).

In 2012, the National Marine Fisheries Service convened a scientific task force to appraise the currently recognized and emerging stock structure of gray whales in the North Pacific (Weller et al. 2013b). The charge of the task force was to evaluate gray whale stock structure as defined under the Marine Mammal Protection Act (MMPA) and implemented through the National Marine Fisheries Service's Guidelines for Assessing Marine Mammal Stocks (GAMMS; NMFS 2005). Significant differences in both mitochondrial and nuclear DNA between whales sampled off Sakhalin Island (WNP) and whales sampled in the ENP provided convincing evidence that resulted in the task force advising that WNP gray whales should be recognized as a population stock under the MMPA and GAMMS guidelines. Given the interchange of some whales between the WNP and ENP, including seasonal occurrence of WNP whales in U.S. waters, the task force agreed that a stand-alone WNP gray whale population stock assessment report was warranted.

POPULATION SIZE

Photo-identification data collected between 1994 and 2011 on the gray whale summer feeding ground off Sakhalin Island in the WNP were used to calculate an abundance estimate of 140 (SE = ± 6, CV=0.043) whales for the age 1-plus (non-calf) population size in 2012 (Cooke et al. 2013). Some whales (approximately 70 individuals) sighted during the summer off southeastern Kamchatka have not been sighted off Sakhalin Island, but it is as yet unclear whether those whales are part of the WNP stock (IWC 2014).

Minimum Population Estimate

The minimum population estimate (N_{min}) for the WNP stock is calculated from Equation 1 from the PBR Guidelines (Wade and Angliss 1997): $N_{min} = N/\exp(0.842\times[\ln(1+[CV(N)]^2)]^{½})$ and the abundance estimate of 140 (CV=0.043) whales from Cooke et al. (2013), resulting in a minimum population estimate of 135 gray whales on the summer feeding ground off Sakhalin Island in the WNP.

Current Population Trend

The WNP gray whale stock has increased over the last 10 years (2002-2012). The estimated realized average annual rate of population increase during this period is 3.3% per annum (± 0.5%) (Cooke et al. 2013).

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

An analysis of the ENP gray whale population led to an estimate of R_{max} of 0.062, with a 90% probability the value was between 0.032 and 0.088 (Punt and Wade 2012). This value of R_{max} is also applied to WNP gray whales, as it is currently the best estimate of R_{max} available for any gray whale population.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (135), times one-half the estimated maximum annual growth rate for a gray whale population (½ of 6.2% for the Eastern North Pacific Stock, Punt and Wade 2012), times a recovery factor of 0.1 (for an endangered stock with N_{min} < 1,500, Taylor et al. 2003), and also multiplied by estimates for the proportion of the stock that uses U.S. EEZ waters (0.575) and the proportion of the year that those animals are in the U.S. EEZ (3 months, or 0.25 years) (Moore and Weller 2013), resulting in a PBR of 0.06 WNP gray whales per year, or approximately 1 whale every 17 years (if abundance and other parameters in the PBR equation remained constant over that time period).

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Serious Injury Guidelines

NMFS uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to distinguis serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an "injury that is more likely than not to result in mortality".

Fisheries Information

The decline of gray whales in the WNP is attributable to commercial hunting off Korea and Japan between the 1890s and 1960s. The pre-exploitation abundance of WNP gray whales is unknown, but has been estimated to be between 1,500 and 10,000 individuals (Yablokov and Bogoslovskaya 1984). By 1910, after some commercial exploitation had already occurred, it is estimated that only 1,000 to 1,500 gray whales remained in the WNP population (Berzin and Vladimirov 1981). The basis for how these two estimates were derived, however, is not apparent (Weller et al. 2002). By the 1930s, gray whales in the WNP were considered by many to be extinct (Mizue 1951; Bowen 1974).

Today, a significant threat to gray whales in the WNP is incidental catches in coastal net fisheries (Weller et al. 2002; Kato et al. 2012; Weller et al. 2008; Weller et al. 2013a). Between 2005 and 2007, four female gray whales (including one mother-calf pair and one yearling) died in fishing nets on the Pacific coast of Japan. In addition, one adult female gray whale died as a result of a fisheries interaction in November 2011 off Pingtan County, China (Zhu 2012). An analysis of anthropogenic scarring of gray whales photographed off Sakhalin Island found that at least 18.7% (n=28) of 150 individuals identified between 1994 and 2005 had evidence of previous entanglements in fishing gear (Bradford et al. 2009), further highlighting the overall risks coastal fisheries pose to WNP gray whales.

In summer 2013, salmon net fishing was observed for the first time on the gray whale feeding ground off Sakhalin Island. Observations of whales within 100 m of salmon fishing nets have been made and a male gray whale was observed dragging fishing gear (rope), with a related injury on the caudal peduncle at the dorsal insertion point with the flukes (Weller et al. 2014).

Given that some WNP gray whales occur in U.S. waters, there is some probability of WNP gray whales being killed or injured by ship strikes or entangled in fishing gear within U.S. waters.

Subsistence/Native Harvest Information

In 2005, the Makah Indian Tribe requested authorization from NOAA/NMFS, under the Marine Mammal Protection Act of 1972 (MMPA) and the Whaling Convention Act, to resume limited hunting of gray whales for ceremonial and subsistence purposes in the coastal portion of their usual and accustomed (U&A) fishing grounds off Washington State (NOAA 2008). Observations of gray whales moving between the WNP and ENP highlight the need to estimate the probability of a gray whale observed in the WNP being taken during a hunt by the Makah Tribe (Moore and Weller 2013). Given conservation concerns for the WNP population, the Scientific Committee of the International Whaling Commission (IWC) emphasized the need to estimate the probability of a WNP gray whale being struck during aboriginal gray whale hunts (IWC 2012). Additionally, NOAA is required by the National Environmental Policy Act (NEPA) to prepare an Environmental Impact Statement (EIS) pertaining to the Makah's request. The EIS needs to address the likelihood of a WNP whale being taken during the proposed Makah gray whale hunt.

To estimate the probability that a WNP whale might be taken during the proposed Makah gray whale hunt, four alternative models were evaluated. These models made different assumptions about the proportion of WNP whales that would be available for the hunt or utilized different types of data to inform the probability of a WNP whale being taken (Moore and Weller 2013). Based on the preferred model, the probability of striking at least one WNP whale in a single year was estimated to range from 0.006 – 0.012 across different scenarios for the annual number of total gray whales that might be struck. This corresponds to an expectation of ≥ 1 WNP whale strike in one of every 83 to 167 years.

HABITAT CONCERNS

Near shore industrialization and shipping congestion throughout the migratory corridors of the WNP gray whale stock represent risks by increasing the likelihood of exposure to pollutants and ship strikes as well as a general degradation of the habitat. In addition, the summer feeding area off Sakhalin Island is a region rich with offshore oil and gas reserves. Two major offshore oil and gas projects now directly overlap or are in near proximity to this important feeding area, and more development is planned in other parts of the Okhotsk Sea that include the migratory routes of these whales. Operations of this nature have introduced new sources of underwater noise, including seismic surveys, increased shipping traffic, habitat modification, and risks associated with oil spills (Weller et al. 2002). During the past decade, a Western Gray Whale Advisory Panel, convened by the International Union for Conservation of Nature (IUCN), has been providing scientific advice on the matter of anthropogenic threats to gray whales in the WNP (see http://www.iucn.org/wgwap/). Ocean acidification could reduce the abundance of shell-forming organisms (Fabry et al. 2008, Hall-Spencer et al. 2008), many of which are important in the gray whales' diet (Nerini 1984).

STATUS OF STOCK

The WNP stock is listed as "Endangered" under the U.S. Endangered Species Act of 1973 (ESA) and is therefore also considered "strategic" and "depleted" under the MMPA. At the time the ENP stock was delisted, the WNP stock was thought to be geographically isolated from the ENP stock. Recent documentation of some whales moving between the WNP and ENP seems to indicate otherwise (Lang 2010; Mate et al. 2011; Weller et al. 2012; Urbán et al. 2013). Other research findings, however, provide continued support for identifying two separate stocks of North Pacific gray whales, including: (1) significant mitochondrial and nuclear genetic differences between whales that feed in the WNP and those that feed in the ENP (LeDuc et al. 2002; Lang et al. 2011), (2) recruitment into the WNP stock is almost exclusively internal (Cooke et al. 2013), and (3) the abundance of the WNP stock remains low while the abundance of the ENP stock grew steadily following the end of commercial whaling (Cooke et al. 2013). As long as the WNP stock remains listed as endangered under the ESA, it will continue to be considered as depleted under the MMPA.

Southwest Fisheries Science Center

The National Oceanic and Atmospheric Administration (NOAA), organized in 1970, has evolved into an agency that establishes national policies and manages and conserves our oceanic, coastal, and atmospheric resources. An organizational element within NOAA, the Office of Fisheries, is responsible for fisheries policy and the direction of the National Marine Fisheries Service (NMFS).

In addition to its formal publications, NMFS uses the NOAA Technical Memorandum series to issue informal scientific and technical publications when complete formal review and editorial processing are not appropriate or feasible. Documents within this series, however, reflect sound professional work and may be referenced in the formal scientific and technical literature.

SWFSC Technical Memorandums are accessible online at the SWFSC web site (http//swfsc.noaa.gov). Print copies are available from the National Technical Information Service, 5285 Port Royal Road, Springfield, VA 22151 (http://www.ntis.gov).

PREFACE

Under the 1994 amendments to the Marine Mammal Protection Act (MMPA), the National Marine Fisheries Service (NMFS) and the U.S. Fish and Wildlife Service (USFWS) are required to publish Stock Assessment Reports for all stocks of marine mammals within U.S. waters, to review new information every year for strategic stocks and every three years for non-strategic stocks, and to update the stock assessment reports when significant new information becomes available.

Pacific region stock assessments include those studied by the Southwest Fisheries Science Center (SWFSC, La Jolla, CA), the Pacific Islands Fisheries Science Center (PIFSC, Honolulu, HI), the National Marine Mammal Laboratory (NMML, Seattle, WA), and the Northwest Fisheries Science Center (NWFSC, Seattle, WA). The 2016 Pacific marine mammal stock assessments include revised reports for 23 Pacific marine mammal stocks under NMFS jurisdiction, including eight "strategic" stocks: Hawaiian monk seal, Guadalupe fur seal, Southern Resident killer whale, California/Oregon/Washington humpback whale, California/Oregon/Washington fin whale, Eastern North Pacific sei whale, Main Hawaiian Islands Insular false killer whale, and Hawaii Pelagic false killer whale. New abundance estimates are available for 16 U.S. west coast stocks: Guadalupe fur seal, Washington Inland Waters harbor porpoise, California/Oregon/Washington stocks of Dall's porpoise, Pacific white-sided dolphin, Risso's dolphin, coastal and offshore stocks of common bottlenose dolphin, striped dolphin, short- and long-beaked common dolphin, northern right whale dolphin, short-finned pilot whale, pygmy sperm whale, fin whale, Eastern North Pacific sei whale and Southern Resident killer whales. New information on fishery-related serious injury and mortality has been updated for those stocks where possible. Updated estimates of stock abundance are also available for the Hawaiian monk seal.

New abundance estimates for several species along the U.S. west coast are considerably higher than previous estimates (Barlow 2016). This is attributed to two factors: 1) estimates of the trackline detection probability, *g(0)* are lower than in previous surveys, because new Beaufort sea state-specific estimates of *g(0)* have been calculated that better reflect differing probabilities of detection with increasing wind and swell (Barlow 2015); and 2) warm-temperate species such as short-beaked common dolphin, long-beaked common dolphin, and striped dolphin were encountered more frequently during a 2014 line-transect survey compared to previous years, due to anomalous warm-water conditions in the California Current (Barlow 2016, Cavole *et al*. 2016).

Human-caused mortality and injury documentation is often based on stranding data, where raw counts are negatively-biased because only a fraction of carcasses are detected (Williams *et al*. 2011), even for extremely coastal species (Wells *et al*. 2015). Carretta *et al*. (2016a) estimated that only 25% of California coastal bottlenose dolphin carcasses are recovered / documented, and given the extremely coastal habits of the population, Carretta *et al*. (2016a) argue that carcass recovery rates for this population represent a maximum rate, compared to more pelagic dolphin and porpoise species in the region. Therefore, for U.S. west coast stock assessment reports involving dolphins and porpoises, human-related deaths and injuries counted from mainland beach strandings are multiplied by a factor of 4 to account for the non-detection of most carcasses. Species / stocks for which the stranding correction factor has been applied include: California coastal bottlenose dolphin, Washington Inland waters harbor porpoise, Risso's dolphin, striped dolphin, and short-beaked and long-beaked common dolphin. This carcass recovery correction factor has not been applied to large whale serious injuries and mortalities, because the method of detection for most large whale entanglement and vessel strike cases are opportunistic offshore sightings, and it is currently unknown what fraction of injured or dead large whales are detected at sea or ashore.

New estimates of human-caused mortality and serious injury are included for U.S. west coast stocks that interact with the California swordfish drift gillnet fishery (Carretta *et al*. 2016b). Estimates are model-based and are based on inclusion of 25 years of bycatch data, in contrast to previous ratio estimates of bycatch that relied on within-year data only (Carretta *et al*. 2014). The main effects of implementing model-based bycatch estimation are that resulting estimates are less volatile inter-annually, have better precision, and are less prone to biases associated with rare bycatch events and low observer coverage (Carretta and Moore 2014). Model-based estimates also result in positive estimates of bycatch even in years when no bycatch of a particular species is recorded by fishery observers.

This is a working document and individual stock assessment reports will be updated as new information on marine mammal stocks and fisheries becomes available. Background information and guidelines for preparing stock assessment reports are reviewed in Wade and Angliss (1997). The authors solicit any new information or comments which would improve future stock assessment reports.

Draft versions of the 2016 stock assessment reports were reviewed by the Pacific Scientific Review Group at the February 2016 meeting.

These Stock Assessment Reports summarize information from a wide range of original data sources and an extensive bibliography of all sources is given in each report. We recommend users of this

document refer to and cite *original* literature sources cited within the stock assessment reports rather than citing this report or previous Stock Assessment Reports.

CETACEANS – HAWAII & WESTERN PACIFIC

APPENDICES

Revised 6/30/2015

CALIFORNIA SEA LION (*Zalophus californianus*): U.S. Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

The breeding areas of the California sea lion are on islands located in southern California, western Baja California, and the Gulf of California (Figure 1). Mitochondrial DNA analysis identified five genetically distinct geographic populations: (1) Pacific Temperate, (2) Pacific Subtropical, (3) Southern Gulf of California, (4) Central Gulf of California and (5) Northern Gulf of California (Schramm *et al*. 2009). In that study, the Pacific Temperate population included rookeries within U.S. waters and the Coronados Islands just south of U.S./Mexico border. Animals from the Pacific Temperate population range into Canadian waters, and movement of animals between U.S. waters and Baja California waters occurs. Males from western Baja California rookeries may spend most of the year in the United States.

There are no international agreements between the U.S., Mexico, and Canada for joint management of California sea lions, and the number of sea lions at the Coronado Islands is not regularly monitored. Consequently, this stock assessment report considers only the U.S. Stock, i.e. sea lions at rookeries within the U.S. Pup production at the Coronado Islands is minimal (between 12 and 82 pups annually; Lowry and Maravilla-Chavez 2005) and does not represent a significant contribution to the overall size of the Pacific Temperate population.

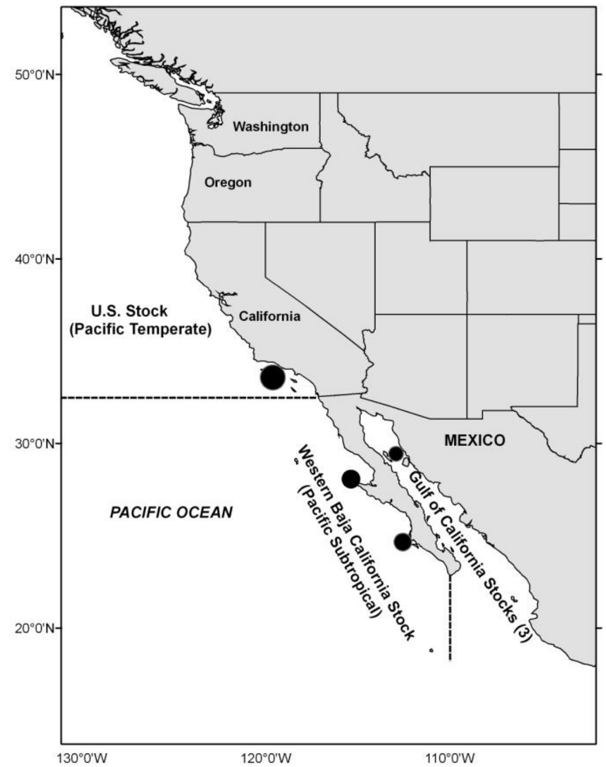

Figure 1. Geographic range of California sea lions showing stock boundaries and locations of major rookeries. The U.S. stock also ranges north into Canadian waters.

POPULATION SIZE

The entire population cannot be counted because all age and sex classes are not ashore at the same time. In lieu of counting all sea lions, pups are counted during the breeding season (because this is the only age class that is ashore in its entirety), and the number of births is estimated from the pup count. Population size is then estimated from the number of births and the proportion of pups in the population. Surveys are conducted in July after all pups have been born. To estimate the number of pups born, the pup count for rookeries in southern California in 2008 (59,774) was adjusted for an estimated 15% pre-census mortality (Boveng 1988; Lowry *et al*. 1992), giving an estimated 68,740 live births in the population. The fraction of newborn pups in the population (23.2%) was estimated from a life table derived for the northern fur seal (*Callorhinus ursinus*) (Boveng 1988, Lowry *et al*. 1992) which was modified to account for the growth rate of this California sea lion population (5.4% yr^{-1}, see below). Multiplying the number of pups born by the inverse of this fraction (4.317) results in a population estimate of 296,750. More recent pup counts made in 2011 totaled 61,943 animals, the highest recorded to date (Figure 2). Estimates of total population size based on these counts are currently being developed, along with new estimates of the fraction of newborn pups in the population.

Minimum Population Estimate

The minimum population size was determined from counts of all age and sex classes that were ashore at all the major rookeries and haulout sites in southern and central California during the 2007 breeding season. The minimum population size of the U.S. stock is 153,337 (NMFS unpubl. data). It includes all California sea lions counted during the July 2007 census at the Channel Islands in southern California and at haulout sites located between Point Conception and Point Reyes, California. An additional unknown number of California sea lions are at sea or hauled out at locations that were not surveyed.

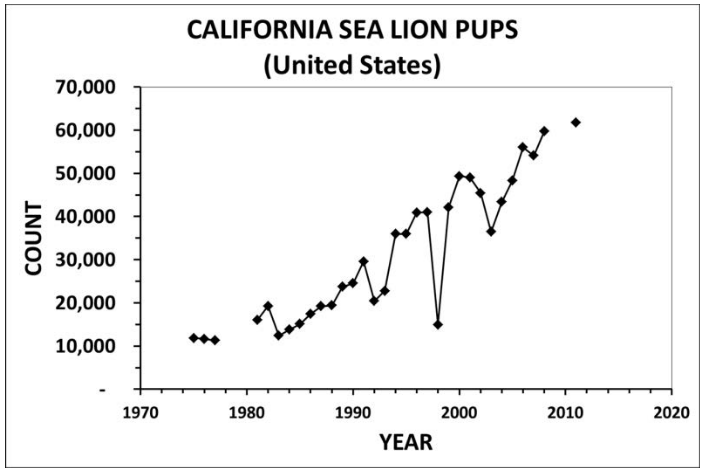

Figure 2. U.S. pup count index for California sea lions (1975-2011). Trends in pup counts from 1975 through 2011 are shown for four rookeries in southern California and for haulouts in central and northern California.

Current Population Trend

Trends in pup counts from 1975 through 2011 are shown in Figure 2 for four rookeries in southern California and for haulouts in central and northern California. The number of pups at rookeries that were not counted were estimated using multiple regression analyses derived from counts of two neighboring rookeries using data from 1975-2000 (Lowry and Maravilla 2005): (1) 1980 at Santa Barbara Is.; (2) 1978-1980 at San Clemente Is.; and (3) 1978 and 1979 at San Nicolas Is. The mean was used when more than one count was available for a given rookery. A regression of the natural logarithm of the pup counts by year indicates that pup counts increased at an annual rate of 5.4% between 1975 and 2008, when pup counts for El Niño years (1983, 1984, 1992, 1993, 1998, and 2003) were removed from the 1975-2005 time series. Using 1975-2008 non-El Niño year data, the coefficient of variation for this average annual growth rate (CV=0.04) was computed via bootstrap sampling of the count data. The 1975-2008 time series of pup counts shows the effect of four El Niño events on the sea lion population (Figure 2). Pup production decreased by 35% in 1983, 27% in 1992, 64% in 1998, and 20% in 2003. After the 1992-93, 1997-98 and 2003 El Niños, pup production rebounded to pre-El Niño levels within two years. In contrast, however, the 1983-1984 El Niño affected adult female survivorship (DeLong *et al*. 1991), which prevented an immediate rebound in pup production because there were fewer adult females available in the population to produce pups (it took five years for pup production to return to the 1982 level). Other characteristics of El Niños are higher pup and juvenile mortality rates (DeLong *et al*. 1991, Lowry and Maravilla-Chavez, 2005) which affect future recruitment into the adult population for the affected cohorts. The 2002 and 2003 decline can be attributed to (1) reduced number of reproductive adult females being incorporated into the population as a result of the 1992-93 and 1997-98 El Niños, (2) domoic acid poisoning (Scholin *et al*. 2000, Lefebvre *et al*. 2000), (3) lower survivorship of pups due to hookworm infestations (Lyons *et al*. 2001), and (4) the 2003 El Niño. Large numbers of emaciated sea lion pups stranded in early 2013 in California and pup weight indices at the San Miguel Island rookery were significantly lower in 2012 compared with previous years (Wells *et al*. 2013). As a result of the large numbers of sea lion strandings in 2013, NOAA declared an unusual mortality event (UME)[1]. Although the exact causes of this UME are unknown, two hypotheses meriting further study include nutritional stress of pups resulting from a lack of forage fish available to lactating mothers and unknown disease agents during that time period.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

We use the default maximum net productivity rate for pinnipeds (12% per year) (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (153,337) <u>times</u> one half the default maximum net growth rate for pinnipeds (½ of 12%) <u>times</u> a recovery factor of

[1] http://www.nmfs.noaa.gov/pr/health/mmume/californiasealions2013.htm

1.0 (for a stock of unknown status that is growing, Wade and Angliss 1997); resulting in a PBR of 9,200 sea lions per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Serious Injury Guidelines

NMFS uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to distinguish serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an "*injury that is more likely than not to result in mortality*".

Historical Depletion

Historic exploitation of California sea lions include harvest for food by native Californians in the Channel Islands 4,000-5,000 years ago (Stewart *et al*. 1993) and for oil and hides in the mid-1800s (Scammon 1874). More recent exploitation of sea lions for pet food, target practice, bounty, trimmings, hides, reduction of fishery depredation, and sport are reviewed in Helling (1984), Cass (1985), Seagers *et al*. (1985), and Howorth (1993). There are few historical records to document the effects of such exploitation on sea lion abundance (Lowry *et al*. 1992).

Fisheries Information

California sea lions are killed in a variety of trawl, purse seine, and gillnet fisheries along the U.S. west coast (Barlow *et al*. 1994, Carretta and Barlow 2011, Carretta *et al*. 2013, Julian and Beeson 1998, Jannot *et al*. 2011, Stewart and Yochem 1987). Those for which recent observations or estimates of bycatch mortality exist are summarized in Table 1. In addition to bycatch estimates from fishery observer programs, information on fishery-related sea lion deaths and serious injuries comes largely from stranding data (Carretta *et al*. 2013). Stranding data represent a minimum number of animals killed or injured, as many entanglements are likely unreported or undetected.

California sea lions are also incidentally killed and injured by hooks from recreational and commercial fisheries. Sea lion deaths due to hook-and-line fisheries are often the result of complications resulting from ingestion of hooks, perforation of body cavities leading to infections, or the inability of the animal to feed. Many of the animals die post-stranding during rehabilitation or are euthanized as a result of their injuries. Between 2008 and 2012, there were 124 California sea lion deaths / serious injuries attributed to hook and line fisheries, or an annual average of 25 animals (Carretta *et al*. 2014b). One sea lion death was reported in a tribal salmon gillnet in 2009 along the U.S. west coast.

Table 1. Summary of available information on the mortality and serious injury of California sea lions in commercial fisheries that might take this species (Carretta *et al*. 2014a. 2009, 2010, 2012a, 2012b; Heery *et al*. 2010; Jannot *et al*. 2011; Appendix 1). Mean annual takes are based on 2008-2012 data unless noted otherwise.

Fishery Name	Year(s)	Data Type	Percent Observer Coverage	Observed Mortality	Estimated Mortality (CV in parentheses)	Mean Annual Takes (CV in parentheses)

Unknown trawl fishery and bait barge net entanglement	2008-2012	stranding	n/a	2		≥ 2 (n/a)
Minimum total annual takes						≥ 331 (0.14)

Other Mortality

Live strandings and dead beach-cast California sea lions are regularly observed with gunshot wounds in California (Lowry and Folk 1987, Goldstein *et al*. 1999, Carretta *et al*. 2013). A summary of stranding records for 2008 to 2012 from California, Oregon, and Washington shows the following non-fishery related human-caused mortality and serious injuries: boat collisions (13), car collisions (3), entrainment in power plants (59), shootings (151), marine debris entanglement or ingestion (37), research-related (18), and other sources, including dog attacks, harassment, seal bombs, stabbings, and, blunt force trauma (10). Stranding records are a gross under-estimate of mortality and serious injury because many animals and carcasses are never recovered. The minimum number of non-fishery related deaths and serious injuries during 2008-2012 was 291 sea lions, or an annual average of 58 animals.

Under authorization of MMPA Section 120, individually identifiable California sea lions have been killed or relocated since 2008 in response to their predation on endangered salmon and steelhead stocks in the Columbia River. Relocated animals were transferred to aquaria and/or zoos. Between 2009 and 2013, a total of 47 California sea lions were removed from this stock (40 lethal removals and 7 relocations to aquaria and/or zoos). The average annual mortality due to direct removals for the 2009-2013 period is 9.4 animals per year (relocations to aquaria/zoos are treated the same as mortality because animals are effectively removed from the stock).

Between 2008 and 2012, 18 California sea lions were incidentally killed, 2 seriously injured, and 8 non-serious injuries along the U.S. west coast during scientific trawl and longline operations conducted by NMFS (Carretta *et al*., 2014b). The average annual research-related mortality and serious injury of California sea lions from 2008 to 2012 is 4.0 animals.

Habitat Concerns

Sea lion mortality linked to the algal-produced neurotoxin domoic acid has been documented sporadically since 1998 (Scholin *et al*. 2000, Brodie *et al*. 2006, Ramsdell and Zabka 2008). Future mortality may be expected to occur, due to the repeated occurrence of such harmful algal blooms.

Exposure to anthropogenic sound may impact individual sea lions. Experimental exposure of captive California sea lions to simulated mid-frequency sonar (Houser *et al*. 2013) and acoustic pingers (Bowles and Anderson 2012) resulted in a wide variety of behavioral responses, including increases in respiration, refusal to participate in tasks involving food rewards, evasive hauling out, and prolonged submergence. Despite exposure to sources of anthropogenic sound in the wild, the California sea lion population continues to grow.

Expanding pinniped populations in general have resulted in increased human-caused serious injury and mortality, due to shootings, entrainment in power plants, interactions with recreational hook and line fisheries, separation of mothers and pups due to human disturbance, dog bites, and vessel and vehicle strikes (Carretta et al. 2014b).

STATUS OF STOCK

California sea lions in the U.S. are not listed as "endangered" or "threatened" under the Endangered Species Act or as "depleted" under the MMPA. The optimum sustainable population (OSP) status of this population has not been formally determined. The average annual commercial fishery mortality is 331 animals per year (Table 1). Other sources of human-caused mortality (shootings, direct removals, recreational hook and line fisheries, tribal takes, entrainment in power plant intakes, etc.) average 58 animals per year. Total human-caused mortality of this stock is at least 389 animals per year. California sea lions are not considered "strategic" under the MMPA because total human-caused mortality is less than the PBR (9,200). The total fishery mortality and serious injury rate (389 animals/year) for this stock is less than 10% of the calculated PBR and, therefore, is considered to be insignificant and approaching a zero mortality and serious injury rate.

HARBOR SEAL (*Phoca vitulina richardii*): California Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Harbor seals (*Phoca vitulina*) are widely distributed in the North Atlantic and North Pacific. Two subspecies exist in the Pacific: *P. v. stejnegeri* in the western North Pacific, near Japan, and *P. v. richardii* in the eastern North Pacific. The latter subspecies inhabits coastal and estuarine areas from Mexico to Alaska. These seals do not make extensive pelagic migrations, but do travel 300-500 km to find food or suitable breeding areas (Herder 1986; Harvey and Goley 2011). In California, approximately 400-600 harbor seal haulout sites are widely distributed along the mainland and on offshore islands, including intertidal sandbars, rocky shores and beaches (Hanan 1996; Lowry *et al.* 2008).

Within the subspecies *P. v. richardii*, abundant evidence of geographic structure comes from differences in mitochondrial DNA (Huber *et al.* 1994, 2010, 2012; Burg 1996; Lamont *et al.* 1996; Westlake and O'Corry-Crowe 2002; O'Corry-Crowe *et al.* 2003), mean pupping dates (Temte 1986), pollutant loads (Calambokidis *et al.* 1985), pelage coloration (Kelly 1981) and movement patterns (Jeffries 1985; Brown 1988). LaMont *et al.* (1996) identified four discrete subpopulation differences in mtDNA between harbor seals from Washington (two locations), Oregon, and California. Another mtDNA study (Burg 1996) supported the existence of three separate groups of harbor seals between Vancouver Island and southeastern Alaska. Three genetically distinct populations of harbor seals within Washington inland waters are also evident, based on work by Huber *et al.* (2010, 2012). Although geographic structure exists along an almost continuous distribution of harbor seals from California to Alaska, stock boundaries are difficult to draw because any rigid line is arbitrary from a biological perspective. Nonetheless, failure to recognize geographic structure in defining management stocks can lead to depletion of local populations. Previous assessments of the status of harbor seals have recognized three stocks along the west coast of the continental U.S.: 1) California, 2) Oregon and Washington outer coast waters, and 3) inland waters of Washington. Although the need for stock boundaries for management is real and is supported by biological information, the exact placement of a boundary between California and Oregon was largely a political/jurisdictional convenience. An unknown number of harbor seals also occur along the west coast of Baja California, at least as far south as Isla Asuncion, which is about 100 miles south of Punta Eugenia. Animals along Baja California are not considered to be a part of the California stock because it is not known if there is any demographically significant movement of harbor seals between California and Mexico and there is no international agreement for joint management of harbor seals. Lacking any new information on which to base a revised boundary, the harbor seals of California are treated as a separate stock in this report (Fig. 1). Other Marine Mammal Protection Act (MMPA) stock assessment reports cover the other stocks that are recognized along the U.S. west coast: 1) Southern Puget Sound (south of the Tacoma Narrows Bridge); 2) Washington Northern Inland Waters (including Puget Sound north of the Tacoma Narrows Bridge, the San Juan Islands, and the Strait of Juan de Fuca); 3) Hood Canal; and 4) Oregon/Washington Coast.

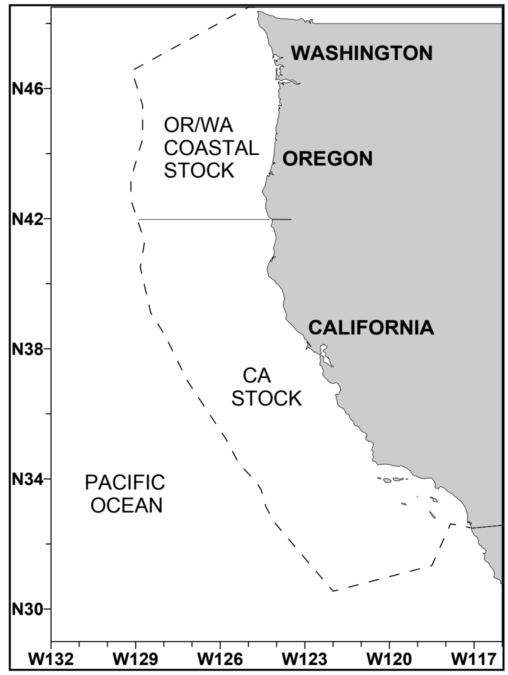

Figure 1. Stock boundaries for the California and Oregon/Washington coastal stocks of harbor seals. Dashed line represents the U.S. EEZ.

POPULATION SIZE

A complete count of all harbor seals in California is impossible because not all animals are hauled out simultaneously. A complete pup count (as is done for other pinnipeds in California) is also not possible because harbor seal pups enter the water almost immediately after birth. Population size is estimated by counting the number of seals ashore during the peak haul-out period (May to July) and by multiplying this count by a correction factor equal to the inverse of the estimated fraction of seals on land. Harvey and Goley (2011) calculated a correction factor of 1.54 (CV=0.157), based on 180 radio-tagged seals in California. This correction factor is based on the mean of four date-specific correction factors (1.31, 1.38, 1.62, 1.84) calculated for central and northern California. Based on the most recent harbor seal counts during May-July of 2012 (20,109 animals) (NMFS unpublished data) and the Harvey and Goley (2011) correction factor, the harbor seal population in California in 2012 is estimated to number 30,968 seals (CV=0.157).

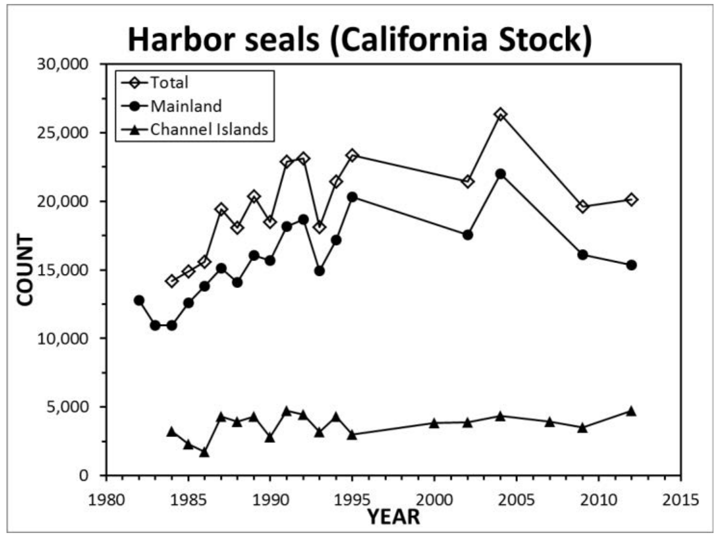

Figure 2. Harbor seal haulout counts in California during May to July (Hanan 1996; R. Read, CDFG unpubl. data; Lowry *et al*. 2008, NMFS unpubl. data from 2009-2012 surveys).

Minimum Population Estimate

The minimum population size is estimated from the number of hauled out seals counted in 2012 (20,109), multiplied by the lower 20th percentile of the correction factor (1.36), or 27,348 seals.

Current Population Trend

Counts of harbor seals in California increased from 1981 to 2004 when the statewide maximum count was recorded. Subsequent surveys conducted in 2009 and 2012 have been lower than the 2004 maximum count (Fig. 2).

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Historically, the largest known source of human-caused mortality of California harbor seals was the California halibut set gillnet fishery (Julian and Beeson 1998), where estimates of bycatch mortality were approximately 1-2% of the estimated population size between 1990 and 1995. Since 1996, that fishery been observed infrequently and at low observer coverage levels, though fishing effort levels have declined. Any estimate of current net productivity level should account for human-caused mortality, otherwise estimated net productivity will be negatively-biased. At this time, there are insufficient data on bycatch (only 3 of the last 5 years have observations from the fishery, with low observer coverage) and uncertainty regarding the degree of negative biases for other sources of human-caused mortality to reliably estimate the current net productivity level. An assessment of *maximum net productivity levels* is not possible, because abundance estimates were not available when the population was very small and presumably recovering from past exploitation (Bonnot 1928).

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (27,348) times one half the default maximum net productivity rate for pinnipeds (½ of 12%) times a recovery factor of 1.0 (for a stock of unknown status that is growing or for a stock at OSP, Wade and Angliss 1997), resulting in a PBR of 1,641 animals per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Serious Injury Guidelines

NMFS uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to distinguish serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an "*injury that is more likely than not to result in mortality*".

Historical Takes

Prior to state and federal protection and especially during the nineteenth century, harbor seals along the west coast of North America were greatly reduced by commercial hunting (Bonnot 1928, 1951; Bartholomew and Boolootian 1960). Only a few hundred individuals survived in a few isolated areas along the California coast (Bonnot 1928). In the last half of the last century, the population increased dramatically.

Fishery Information

A summary of known commercial fishery mortality and serious injury for this stock of harbor seals for the period 2008-2012 is given in Table 1. Historically, the set gillnet fishery for halibut and white seabass was the largest source of fishery mortality and remains the most likely fishery in California to interact with harbor seals. Julian and Beeson (1998) reported a range of annual mortality estimates from 227 to 1,204 seals (mean = 584) from 1990 to 1994, based on 5% to 15% fishery observer coverage and representing between 1-2% of the estimated population size. This fishery has been observed infreqently since 1995 and fishing effort has declined from approximately 5,000 trips in the early 1990s to 1,300 trips in 2012 (Carretta *et al*. 2014a.).

Table 1. Summary of available information on the mortality and serious injury of harbor seals (California stock) in commercial fisheries that might take this species (Carretta and Enriquez 2006, 2009, Carretta *et al*. 2014a; Heery *et al*. 2010); n/a indicates that data are not available. Mean annual takes are based on 2008-2012 data unless noted otherwise.

Fishery Name	Year(s)	Data Type	Percent Observer Coverage	Observed Mortality	Estimated Mortality (CV in parentheses)	Mean Annual Takes (CV in parentheses)

Unknown net fisheries	2008-2012	stranding	n/a	5	n/a	≥ 1.0
Total annual takes						30 (0.59)

Other Mortality

NMFS stranding records for California for the period 2008-2012 include the following human-caused mortality and serious injury not included in Table 1: shootings (1), ship/vessel strikes (3), entrainment in power plants (40), hook and line fisheries (6), human-induced abandonment of pups or harassment (9), marine debris entanglement (2), stabbing/gaff wounds (2), and research-related deaths (1) (Carretta *et al*. 2014b.). The total non-fishery related mortality and serious injury for the period totals 64 harbor seals, or an annual average of 12.8 seals.

STATUS OF STOCK

A review of harbor seal dynamics through 1991 concluded that their status relative to OSP could not be determined with certainty (Hanan 1996). California harbor seals are not listed as "endangered" or "threatened" under the Endangered Species Act nor designated as "depleted" under the MMPA. Annual human-caused mortality from commercial fisheries (30/yr) and other human-caused sources (12.8/yr) is 42.8 animals, which is less than the calculated PBR for this stock (1,641), and thus they are <u>not</u> considered a "strategic" stock under the MMPA. The average annual rate of incidental commercial fishery mortality (30 animals) is less than 10% of the calculated PBR (1,641 animals); therefore, fishery mortality is considered insignificant and approaching zero mortality and serious injury rate. The population size has increased since the 1980s when statewide censuses were first conducted. The highest population counts occurred in 2004 and subsequent counts in 2009 and 2012 have been lower. Expanding pinniped populations in general have resulted in increased human-caused serious injury and mortality, due to shootings, entrainment in power plants, interactions with recreational hook and line fisheries, separation of mothers and pups due to human disturbance, dog bites, and vessel and vehicle strikes (Carretta et al. 2014b). All west-coast harbor seals that have been tested for morbilliviruses were found to be seronegative, indicating that this disease is not endemic in the population and that this population is extremely susceptible to an epidemic of this disease (Ham-Lammé *et al*. 1999).

Revised 7/15/2014

HARBOR SEAL (*Phoca vitulina richardii*): Oregon/Washington Coast Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Harbor seals inhabit coastal and estuarine waters off Baja California, north along the western coasts of the continental U.S., British Columbia, and Southeast Alaska, west through the Gulf of Alaska and Aleutian Islands, and in the Bering Sea north to Cape Newenham and the Pribilof Islands. They haul out on rocks, reefs, beaches, and drifting glacial ice and feed in marine, estuarine, and occasionally fresh waters. Harbor seals generally are non-migratory, with local movements associated with tides, weather, season, food availability, and reproduction (Scheffer and Slipp 1944; Fisher 1952; Bigg 1969, 1981). Harbor seals do not make extensive pelagic migrations, though some long distance movement of tagged animals in Alaska (900 km) and along the U.S. west coast (up to 550 km) have been recorded (Brown and Mate 1983, Herder 1986, Womble 2012). Harbor seals have also displayed strong fidelity to haulout sites (Pitcher and Calkins 1979, Pitcher and McAllister 1981).

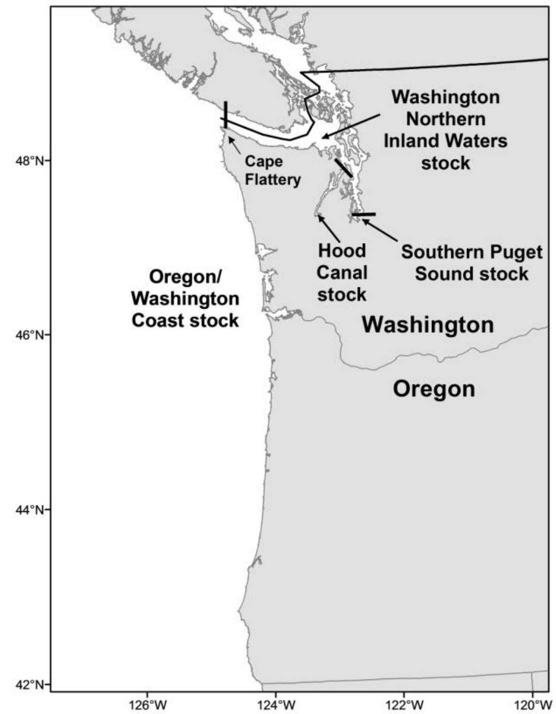

Figure 1. Harbor seal stocks in the U.S. Pacific Northwest

Until recently, differences in mean pupping date (Temte 1986), movement patterns (Jeffries 1985, Brown 1988), pollutant loads (Calambokidis et al. 1985), and fishery interactions led to the recognition of three separate harbor seal stocks along the west coast of the continental U.S. (Boveng 1988): 1) inland waters of Washington State (including Hood Canal, Puget Sound, and the Strait of Juan de Fuca out to Cape Flattery), 2) outer coast of Oregon and Washington, and 3) California Recent genetic evidence suggests that the population of harbor seals in Washington inland waters has more structure than was previously recognized. Studies of pupping phenology, mitochondrial DNA, and microsatellite variation of harbor seals in Washington and Canada-U.S. transboundary waters confirm the currently recognized stock boundary between the Washington Coast and Washington Inland Waters harbor seal stocks, but three genetically distinct populations of harbor seals within Washington inland waters are also evident (Huber et al. 2010, 2012). Within U.S. west coast waters, five stocks of harbor seals are recognized: 1) Southern Puget Sound (south of the Tacoma Narrows Bridge); 2) Washington Northern Inland Waters (including Puget Sound north of the Tacoma Narrows Bridge, the San Juan Islands, and the Strait of Juan de Fuca); 3) Hood Canal; 4) Oregon/Washington Coast; and 5) California. This report considers only the Oregon/Washington Coast stock. Stock assessment reports for California harbor seals and harbor seals in Washington inland waters (including the Southern Puget Sound, Washington Northern Inland Waters, and Hood Canal stocks) also appear in this volume. Harbor seal stocks that occur in the inland and coastal waters of Alaska are discussed separately in the Alaska Stock Assessment Reports. Harbor seals occurring in British Columbia are not included in any of the U.S. Marine Mammal Protection Act (MMPA) stock assessment reports.

POPULATION SIZE

Aerial surveys of harbor seals in Oregon and Washington were conducted by personnel from the National Marine Mammal Laboratory (NMML) and the Oregon and Washington Departments of Fish and Wildlife (ODFW and WDFW) during the 1999 pupping season. Total numbers of hauled-out seals (including pups) were counted during these surveys. In 1999, the mean count of harbor seals occurring along the Washington coast was 10,430 (CV=0.14) animals (Jeffries et al. 2003). In 1999, the mean count of harbor seals occurring along the Oregon coast and in the Columbia River was 5,735 (CV=0.14) animals (Brown 1997; ODFW, unpublished data). Combining these counts results in 16,165 (CV=0.10) harbor seals in the Oregon/Washington Coast stock.

Radio-tagging studies conducted at six locations (three Washington inland waters sites and three Oregon and Washington coastal sites) collected information on haulout patterns from 63 harbor seals in 1991 and 61 harbor seals in 1992. Haulout data from coastal and inland sites were not significantly different and were thus pooled, resulting in a correction factor of 1.53 (CV=0.065) to account for animals in the water which are missed during the aerial surveys (Huber et al. 2001). Using this correction factor results in a population estimate of 24,732 (16,165 x 1.53; CV=0.12) for the Oregon/Washington Coast stock of harbor seals in 1999 (Jeffries et al. 2003; ODFW, unpublished data). However, because the most recent abundance estimate is >8 years old, there is no current estimate of abundance available for this stock.

Minimum Population Estimate

No current information on abundance is available to obtain a minimum population estimate for the Oregon/Washington Coast stock of harbor seals.

Current Population Trend

Historical levels of harbor seal abundance in Oregon and Washington are unknown. The population apparently decreased during the 1940s and 1950s due to state-financed bounty programs. Approximately 17,133 harbor seals were killed in Washington by bounty hunters between 1943 and 1960 (Newby 1973). More than 3,800 harbor seals were killed in Oregon between 1925 and 1972 by bounty hunters and a state-hired seal hunter (Pearson 1968). The population remained relatively low during the 1960s but, since the termination of the harbor seal bounty program and with the protection provided by the passage of the MMPA in 1972, harbor seal counts for this stock have increased from 6,389 in 1977 to 16,165 in 1999 (Jeffries et al. 2003; ODFW, unpublished data). Based on the analyses of Jeffries et al. (2003) and Brown et al. (2005), both the Washington and Oregon portions of this stock were reported as reaching carrying capacity (Fig. 2). In the absence of recent abundance estimates, the current population trend is unknown.

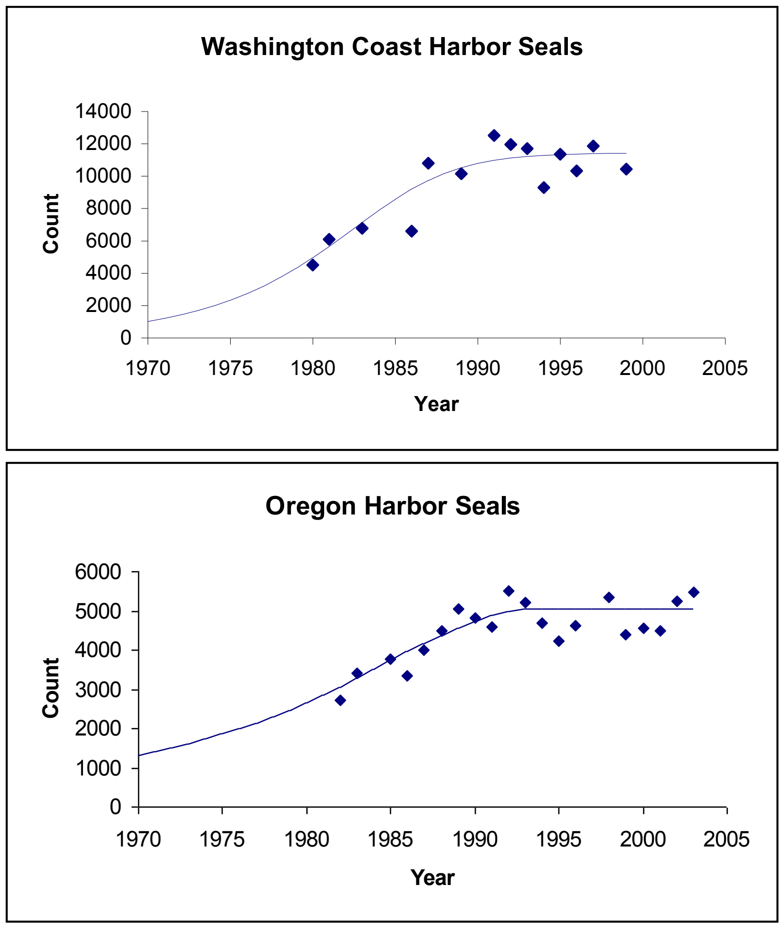

Figure 2. Generalized logistic growth curves of Washington Coast (Jeffries et al. 2003) and Oregon (Brown et al. 2005) harbor seals.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

The Oregon/Washington Coast harbor seal stock increased at an annual rate of 7% from 1983 to 1992 and at 4% from 1983 to 1996 (Jeffries et al. 1997). Because the population was not at a very low level by 1983, the observed rates of increase may underestimate the maximum net productivity rate (R_{MAX}). When a logistic model was fit to the Washington portion of the 1975-1999 abundance data, the resulting estimate of R_{MAX} was 18.5% (95% CI = 12.9-26.8%) (Jeffries et al. 2003). When a logistic model was fit to the Oregon portion of the 1977-2003 abundance data, estimates of R_{MAX} ranged from 6.4% (95% CI = 4.6-27%) for the south coast of Oregon to 10.1% (95% CI = 8.6-20%) for the north coast (Brown et al. 2005). Until a combined analysis for the entire stock is completed, the pinniped default maximum theoretical net productivity rate (R_{MAX}) of 12% will be used for this harbor seal stock (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Because there is no current estimate of minimum abundance, a potential biological removal (PBR) cannot be calculated for this stock.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

New Serious Injury Guidelines

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen *et al*. 2008, NOAA 2012). NMFS defines serious injury as an "*injury that is more likely than not to result in mortality*". Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

Fisheries Information

Fishing effort in the northern Washington marine gillnet tribal fishery is conducted within the range of the Oregon/Washington Coast and Washington Northern Inland Waters stocks of harbor seals. Movement of animals between Washington's coastal and inland waters is likely, although tagging data do not show movement of harbor seals between the two locations (Huber et al. 2001). For the purposes of this report, animals taken in waters south and west of Cape Flattery, WA, are assumed to belong to the Oregon/Washington Coast stock and Table 1 includes data only from that portion of the fishery. Fishing effort in the coastal marine set gillnet tribal fishery has declined since 2004. A test set gillnet fishery, with 100% observer coverage, was conducted in coastal waters in 2008 and 2010. This test fishery required the use of nets equipped with acoustic alarms, and observers reported one harbor seal death in 2008 and three in 2010 (Makah Fisheries Management, unpublished data). The mean annual mortality for the marine set gillnet tribal fishery in 2007-2011 is 0.8 (CV=0) harbor seals from observer data.

The U.S. West Coast groundfish fishery was monitored for incidental takes in 2005-2009 (Jannot et al. 2011). Harbor seal deaths were observed in the groundfish trawl fishery (Pacific hake at-sea processing component) in 2005, 2006, and 2008; the nearshore fixed gear fishery in 2006 and 2008; and the non-nearshore fixed gear (limited entry non-primary sablefish) fishery in 2009. The mean annual mortality for each of these fisheries in 2005-2009 is 1.0 (CV=0.24) harbor seals for the groundfish trawl fishery, 5.6 (CV=0.68) for the nearshore fixed gear fishery, and 0.2 for the non-nearshore fixed gear fishery.

Table 1. Summary of available information on the incidental mortality and serious injury of harbor seals (Oregon/Washington Coast stock) in commercial and tribal fisheries that might take this species and calculation of the mean annual mortality rate; n/a indicates that data are not available. Mean annual takes are based on 2007-2011 data unless otherwise noted.

Fishery name	Years	Data type	Percent observer coverage	Observed mortality	Estimated mortality	Mean annual takes (CV in parentheses)

[1]Percent hauls observed for marine mammals.
[2]Percent observed landings of target species.
[3]Bycatch estimate not provided due to high CV (>80%) for estimate; minimum bycatch of one observed harbor seal is included in the calculation of mean annual take.
[4]This fishery has not been observed since 1993 (see text); these data are not included in the calculation of recent minimum total annual takes.

Commercial salmon drift gillnet fisheries in Washington outer coast waters (Grays Harbor, Willapa Bay) were last observed in 1993 and 1994, with observer coverage levels typically less than 10% (Erstad et al. 1996, Pierce et al. 1994, Pierce et al. 1996, NWIFC 1995). Drift gillnet fishing effort in the outer coast waters has declined considerably since 1994 because fewer vessels participate today (NMFS NW Region, unpublished data), but entanglements of harbor seals likely continue to occur. The most recent data on harbor seal mortality from commercial and tribal gillnet fisheries is included in Table 1.

Combining recent estimates from commercial fisheries observer data for the West Coast groundfish trawl (1.0), West Coast groundfish nearshore fixed gear (5.6), and West Coast groundfish non-nearshore fixed gear (0.2) fisheries results in a mean annual mortality rate of 6.8 harbor seals from these fisheries. An additional 0.8 harbor seals per year were taken in the northern Washington marine set gillnet tribal fishery.

Strandings of harbor seals entangled in fishing gear or with serious injuries caused by interactions with gear are another source of fishery-related mortality. Based on stranding network data, there were three commercial fishery-related deaths of harbor seals from this stock reported in 2011 (listed as unknown West Coast fisheries in Table 1), resulting in a mean annual mortality of 0.6 harbor seals in 2007-2011. Fishery entanglements included two gillnet and one trawl net interaction. Hook and line gear is used by both commercial (salmon troll) and recreational fisheries in coastal waters. Two harbor seal deaths due to ingested hooks were reported in 2007-2011, resulting in an additional mean annual mortality of 0.4 seals from unknown hook and line fisheries. Estimates from stranding data are considered minimum estimates because not all stranded animals are found, reported, or examined for cause of death (via necropsy by trained personnel). An additional harbor seal that stranded with a serious hook injury in 2011 was treated and released with non-serious injuries (Carretta et al. 2013); therefore, it was not included in the mean annual mortality in this report.

Data on fisheries mortality reported in Table 1 likely represent minimum estimates, particularly for fisheries where observer coverage is low and bycatch events are too infrequent to be documented by fishery observers. The magnitude of negative bias in mortality estimates is unknown and methods to correct for such negative biases in these fisheries have not been developed.

Other Mortality

During 2007-2011, one harbor seal from this stock was incidentally killed during scientific halibut longline operations in 2011, resulting in a mean annual research-related mortality of 0.2 animals.

According to Northwest Marine Mammal Stranding Network records, maintained by the NMFS Northwest Region (NMFS, Northwest Regional Office, unpublished data), a total of nine human-caused harbor seal deaths were reported from non-fisheries sources in 2007-2011. Six animals were shot, two animals were struck by boats, and one animal was killed by a dog, resulting in a mean annual mortality of 1.8 harbor seals from this stock. This estimate is considered a minimum because not all stranded animals are found, reported, or examined for cause of death (via necropsy by trained personnel).

Subsistence Harvests by Northwest Treaty Indian Tribes

Tribal subsistence takes of this stock may occur, but no data on recent takes are available.

STATUS OF STOCK

Harbor seals are not considered to be "depleted" under the MMPA or listed as "threatened" or "endangered" under the ESA. Based on currently available data, the minimum level of human-caused mortality and serious injury is 10.6 harbor seals per year: (8.2 from fishery sources in Table 1, plus 0.4 from unknown hook and line fisheries, plus 0.2 scientific takes annually, plus 1.8 non-fishery causes annually). A PBR cannot be calculated for this stock because there is no current abundance estimate. Human-caused mortality relative to PBR is unknown, but it is considered to be small relative to the stock size. Therefore, the Oregon/Washington Coast stock of harbor seals is not classified as a "strategic" stock. The minimum annual commercial fishery mortality and serious injury for this stock, based on recent observer data (6.8) and stranding data (0.6) is 7.4. Since a PBR cannot be calculated for this stock, fishery mortality relative to PBR is unknown. The stock was previously reported to be within its Optimum Sustainable Population (OSP) range (Jeffries et al. 2003, Brown et al. 2005), but in the absence of recent abundance estimates, this stock's status relative to OSP is unknown.

HARBOR SEAL (*Phoca vitulina richardii*): Washington Inland Waters Stocks: (Hood Canal, Southern Puget Sound, Washington Northern Inland Waters)

STOCK DEFINITION AND GEOGRAPHIC RANGE

Harbor seals inhabit coastal and estuarine waters off Baja California, north along the western coasts of the continental U.S., British Columbia, and Southeast Alaska, west through the Gulf of Alaska and Aleutian Islands, and in the Bering Sea north to Cape Newenham and the Pribilof Islands. They haul out on rocks, reefs, beaches, and drifting glacial ice and feed in marine, estuarine, and occasionally fresh waters. Harbor seals generally are non-migratory, with local movements associated with such factors as tides, weather, season, food availability, and reproduction (Scheffer and Slipp 1944; Fisher 1952; Bigg 1969, 1981). Harbor seals do not make extensive pelagic migrations, though some long distance movement of tagged animals in Alaska (900 km) and along the U.S. west coast (up to 550 km) have been recorded (Brown and Mate 1983, Herder 1986, Womble 2012). Harbor seals have also displayed strong fidelity for haulout sites (Pitcher and Calkins 1979, Pitcher and McAllister 1981).

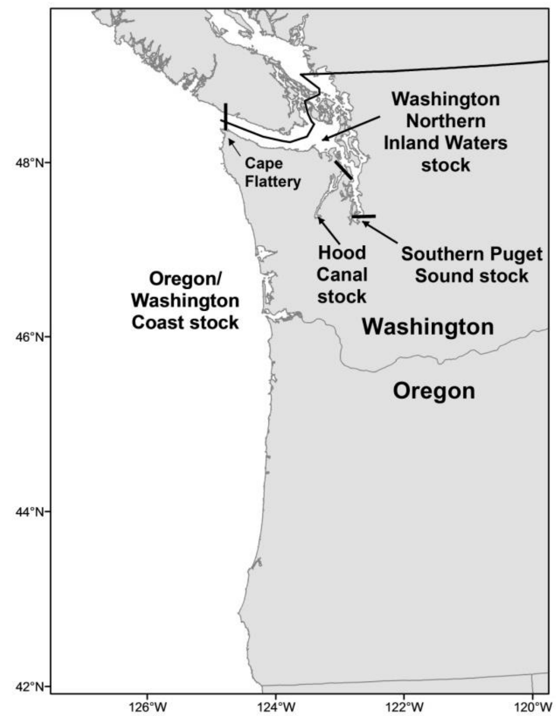

Figure 1. Approximate distribution of harbor seal stocks in the U.S. Pacific Northwest (shaded area). Stock boundaries separating the three stocks are shown.

Until recently, differences in mean pupping date (Temte 1986), movement patterns (Jeffries 1985, Brown 1988), pollutant loads (Calambokidis et al. 1985), and fishery interactions have led to the recognition of three separate harbor seal stocks along the west coast of the continental U.S. (Boveng 1988): 1) inland waters of Washington State (including Hood Canal, Puget Sound, and the Strait of Juan de Fuca out to Cape Flattery), 2) outer coast of Oregon and Washington, and 3) California Recent genetic evidence suggests that the population of harbor seals in Washington inland waters has more structure than is currently was previously recognized . Studies of pupping phenology, mitochondrial DNA, and microsatellite variation of harbor seals in Washington and Canada-U.S. transboundary waters confirm the currently recognized stock boundary between the Washington Coast and Washington Inland Waters harbor seal stocks, but three genetically distinct populations of harbor seals within Washington inland waters are also evident (Huber et al. 2010, 2012). Within U.S. west coast waters, five stocks of harbor seals are recognized: 1) Southern Puget Sound (south of the Tacoma Narrows Bridge); 2) Washington Northern Inland Waters (including Puget Sound north of the Tacoma Narrows Bridge, the San Juan Islands, and the Strait of Juan de Fuca); 3) Hood Canal; 4) Oregon/Washington Coast; and 5) California. This report includes only the stocks in Washington's inland waters. Stock assessment reports for Oregon/Washington Coast and California harbor seals also appear in this volume. Harbor seal stocks that occur in the inland and coastal waters of Alaska are discussed separately in the Alaska Stock Assessment Reports. Harbor seals occurring in British Columbia are not included in any of the U.S. Marine Mammal Protection Act (MMPA) stock assessment reports.

POPULATION SIZE

Aerial surveys of harbor seals in Washington were conducted during the pupping season in 1999, during which time the total numbers of hauled-out seals (including pups) were counted. In 1999, the mean count of harbor seals occurring in Washington's inland waters was 7,213 (CV=0.14) in Washington Northern Inland Waters, 711 (CV=0.14) in Hood Canal, and 1,025 (CV=0.14) in Southern Puget Sound (Jeffries et al. 2003).

Radio-tagging studies conducted at six locations (three Washington inland waters sites and three Oregon and Washington coastal sites) collected information on haulout patterns from 63 harbor seals in 1991 and 61 harbor seals in 1992. Data from coastal and inland sites were not significantly different and were thus pooled, resulting in a correction factor of 1.53 (CV=0.065) to account for animals in the water which are missed during the aerial surveys (Huber et al. 2001). Using this correction factor results in a population estimates of 11,036 (7,213 x 1.53; CV=0.15) for the Washington Northern Inland Waters stock; 1,088 (711 x 1.53; CV=0.15) for the Hood Canal stock; and 1,568 (1,025 x 1.53; CV=0.15) for the Southern Puget Sound stock of harbor seals (Jeffries et al. 2003). However, because the most recent abundance estimates are >8 years old, there are no current estimates of abundance for these stocks. Surveys of harbor seals in Washington inland waters are planned for 2013.

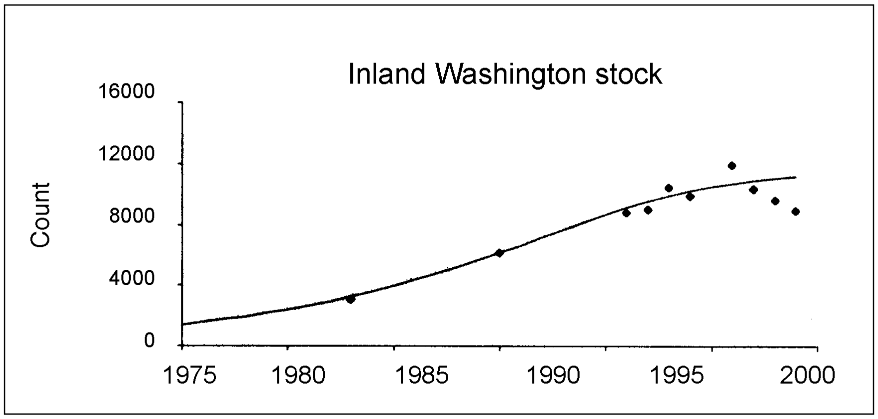

Figure 2. Generalized logistic population growth curve for the Washington Inland Waters stock of harbor seals, 1978-1999 (Jeffries et al. 2003).

Minimum Population Estimate

No current information on abundance is available to obtain a minimum population estimate for the Washington Inland Waters stock of harbor seals.

Current Population Trend

Historical levels of harbor seal abundance in Washington are unknown. The population apparently decreased during the 1940s and 1950s due to a state-financed bounty program. Approximately 17,133 harbor seals were killed in Washington by bounty hunters between 1943 and 1960 (Newby 1973). The population remained relatively low during the 1970s but, since the termination of the harbor seal bounty program in 1960 and with the passage of the Marine Mammal Protection Act (MMPA) in 1972, harbor seal numbers in Washington have increased (Jeffries 1985).

Between 1983 and 1996, the annual rate of increase for this stock was 6% (Jeffries et al. 1997). The peak count occurred in 1996 and, based on a fitted generalized logistic model (Fig. 2), the population is thought to be stable (Jeffries et al. 2003). In the absence of recent abundance estimates, the current population trend is unknown.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

From 1991 to 1996, counts of harbor seals in Washington State have increased at an annual rate of 10% (Jeffries et al. 1997). Because the population was not at a very low level by 1991, the observed rate of increase may underestimate the maximum net productivity rate (R_{MAX}). When a logistic model was fit to the 1978-1999 abundance data, the resulting estimate of R_{MAX} was 12.6% (95% CI = 9.4-18.7%) (Jeffries et al. 2003). This value of R_{MAX} is very close to the default pinniped maximum theoretical net productivity rate of 12% (R_{MAX}), therefore, 12% will be employed for this harbor seal stock (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

Because there is no current estimate of minimum abundance, a potential biological removal (PBR) cannot be calculated for this stock.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

New Serious Injury Guidelines

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen *et al*. 2008, NOAA 2012). NMFS defines serious injury as an "*injury that is more likely than not to result in mortality*". Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

Fisheries Information

Fishing effort in the northern Washington marine gillnet tribal fishery is conducted within the range of the Oregon/Washington Coast and Washington Northern Inland Waters stocks of harbor seals. Some movement of animals between Washington's coastal and inland waters is likely, although data from tagging studies have not shown movement of harbor seals between the two locations (Huber et al. 2001). For the purposes of this stock assessment report, the animals taken in waters east of Cape Flattery, WA, are assumed to have belonged to the Washington Northern Inland Waters stock, and Table 1 includes data only from that portion of the fishery. There was no observer coverage in the northern Washington marine set gillnet tribal fishery in inland waters in 2007-2011; however, there were two fishermen self-reports of harbor seal deaths in this fishery in 2008 and five in 2009 (Makah Fisheries Management, unpublished data). The mean annual mortality for this fishery in 2007-2011 is 1.4 harbor seals from self-reports. Fishing effort in the northern Washington marine drift gillnet tribal fishery in inland waters is also conducted within the range of the Washington Northern Inland Waters stock of harbor seals. This fishery is not observed; however, there was one self-report of a harbor seal death in 2008 (Makah Fisheries Management, unpublished data). The mean annual mortality for this fishery in 2007-2011 is 0.2 harbor seals from self-reports.

Commercial salmon drift gillnet fisheries in Washington inland waters were last observed in 1993 and 1994, with observer coverage levels typically less than 10% (Erstad et al. 1996, Pierce et al. 1994, Pierce et al. 1996, NWIFC 1995). Drift gillnet fishing effort in the inland waters has declined considerably since 1994 because far fewer vessels participate today (NMFS NW Region, unpublished data), but entanglements of harbor seals likely continue to occur. The most recent data on harbor seal mortality from commercial gillnet fisheries is included in Table 1.

Table 1. Summary of available information on the incidental mortality and serious injury of harbor seals (Washington Northern Inland Waters, Hood Canal, and Southern Puget Sound stocks) in commercial and tribal fisheries that might take this species and calculation of the mean annual mortality rate; n/a indicates that data are not available. Mean annual takes are based on 2007-2011 data unless noted otherwise.

Fishery name	Years	Data type	Percent observer coverage	Observed mortality	Estimated mortality	Mean annual takes (CV in parentheses)
Northern WA marine set gillnet (tribal fishery in inland waters)	2008 2009	fisherman self-reports	-	2 5	n/a n/a	1.4 (n/a)
Northern WA marine drift gillnet (tribal fishery in inland waters)	2008	fisherman self-reports	-	1	n/a	>0.2 (n/a)
WA Puget Sound Region salmon set/drift gillnet (observer programs listed below covered segments of this fishery):	-	-	-	-	-	-
Puget Sound non-treaty salmon gillnet (all areas and species)	1993	observer data	1.3%	2	n/a	see text
Puget Sound non-treaty chum salmon gillnet (areas 10/11 and 12/12B)[1]	1994	observer data	11%	1	10	see text[1]
Puget Sound treaty chum salmon gillnet (areas 12, 12B, and 12C)[1]	1994	observer data	2.2%	0	0	see text[1]
Puget Sound treaty chum and sockeye salmon gillnet (areas 4B, 5, and 6C)[1]	1994	observer data	7.5%	0	0	see text[1]
Puget Sound treaty and non-treaty sockeye salmon gillnet (areas 7 and 7A)[1]	1994	observer data	7%	1	15	see text[1]

Fishery name	Years	Data type	Percent observer coverage	Observed mortality	Estimated mortality	Mean annual takes (CV in parentheses)
Unknown Washington Northern Inland Waters fisheries	2007-2011	stranding data	n/a	1, 1, 1, 1, 2	n/a	≥1.2 (n/a)
Unknown Hood Canal fisheries	2007-2011	stranding data	n/a	0, 0, 0, 0, 1	n/a	> 0.2 (n/a)
Unknown Southern Puget Sound fisheries	2007-2011	stranding data	n/a	0, 5, 0, 0, 0	n/a	>1.0 (n/a)
Minimum total annual takes Washington Northern Inland Waters						> 2.8 (n/a)
Minimum total annual takes Hood Canal						> 0.2 (n/a)
Minimum total annual takes Southern Puget Sound						>1.0 (n/a)

[1]This fishery has not been observed since 1994 (see text); these data are not included in the calculation of recent minimum total annual takes.

Strandings of harbor seals entangled in fishing gear or with serious injuries caused by interactions with gear are a final source of fishery-related mortality information. As these strandings could not be attributed to a particular fishery, they have been included in Table 1 as occurring in unknown Washington inland waters fisheries. According to Northwest Marine Mammal Stranding Network records, maintained by the NMFS Northwest Region (NMFS, Northwest Regional Office, unpublished data), 12 fishery-related harbor seal deaths and serious injuries were reported in Washington inland waters in 2007-2011: six from the Washington Northern Inland Waters stock, one from the Hood Canal stock, and five from the Southern Puget Sound stock, resulting in mean annual takes of 1.2 harbor seals in Washington Northern Inland Waters, 0.2 in Hood Canal, and 1.0 in Southern Puget Sound. Fishery interactions included two gaff injuries, two gillnet entanglements, in one fishing net entanglement, and one entanglement in fishing gear in Washington Northern Inland Waters; one gillnet entanglement in Hood Canal; and five gillnet entanglements in Southern Puget Sound. Harbor seal deaths caused by interactions with recreational hook and line fishing gear were also reported in 2007-2011: two seals had hook injuries and one ingested a hook in Washington Northern Inland Waters and two seals ingested hooks in Southern Puget Sound, resulting in mean annual mortalities of 0.6 and 0.4, respectively, from these two stocks. Estimates from stranding data are considered minimum estimates because not all stranded animals are found, reported, or examined for cause of death (via necropsy by trained personnel). Two additional harbor seals that stranded with serious hook injuries from recreational hook and line gear in Washington Northern Inland Waters in 2007-2011 were treated and released with non-serious injuries (Carretta et al. 2013); therefore, they were not included in the mean annual mortality in this report.

Other Mortality

According to Northwest Marine Mammal Stranding Network records, maintained by the NMFS Northwest Region (NMFS, Northwest Regional Office, unpublished data), a total of 32 human-caused harbor seal deaths or serious injuries were reported from non-fisheries sources in 2007-2011 for the Washington Northern Inland Waters stock. Eight animals were shot, 13 nine were struck by boats, two died in oil spills, three two were killed by dogs, and 13 were entangled in marine debris, resulting in a mean annual mortality of 6.4 harbor seals from this stock. During the same time period, 10 human-caused deaths or serious injuries were reported for the Southern Puget Sound stock: one animal entangled in marine debris, six were shot, one was killed by a dog, one entangled in a buoy line, and one entangled in a scientific research net, resulting in a mean annual mortality of 2.0 harbor seals. These are considered minimum estimates because not all stranded animals are found, reported, or examined for cause of death (via necropsy by trained personnel). An additional seriously injured harbor seal was disentangled from marine debris and released with non-serious injuries in Washington Northern Inland Waters in 2007 (Carretta et al. 2013); therefore, it was not included in the mean annual mortality in this report.

Subsistence Harvests by Northwest Treaty Indian Tribes

Tribal subsistence takes of this stock may occur, but no data on recent takes are available.

STATUS OF STOCK

Harbor seals are not considered to be "depleted" under the MMPA or listed as "threatened" or "endangered" under the Endangered Species Act. Based on currently available data, the minimum level of human-caused mortality and serious injury is 9.8 harbor seals per year for the Washington Northern Inland Waters stock (2.8 from fishery sources in Table 1 + 0.6 from recreational hook and line fisheries + 6.4 from non-fishery sources). Annual human-caused serious injury and mortality for the Hood Canal stock is 0.2 from unknown fishery sources. Annual human-caused serious injury and mortality for the Southern Puget Sound stock is 3.4, including 1.0 from fishery sources listed in Table 1, 0.4 from recreational hook and line fisheries, and 2.0 from non-fishery sources. PBRs cannot be calculated for these stocks because there are no current abundance estimates. Human-caused mortality relative to PBR is unknown for these stocks, but is considered to be small relative to stock size. Therefore, the Washington Northern Inland Waters, Hood Canal, and Southern Puget Sound stocks of harbor seals are not classified as "strategic" stocks. At present, the minimum annual fishery mortality and serious injury for these stocks (based on stranding data) are 1.2 for the Washington Northern Inland Waters stock, 0.2 for the Hood Canal stock, and 1.0 for the Southern Puget Sound stock. Since a PBR cannot be calculated for these stocks, fishery mortality relative to PBR is unknown. The stock was previously reported to be within its Optimum Sustainable Population (OSP) range (Jeffries et al. 2003), but in the absence of recent abundance estimates, this stock's status relative to OSP is unknown.

NORTHERN ELEPHANT SEAL (*Mirounga angustirostris*): California Breeding Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Northern elephant seals breed and give birth in California (U.S.) and Baja California (Mexico), primarily on offshore islands (Stewart et al. 1994), from December to March (Stewart and Huber 1993). Spatial segregation in foraging areas between males and females is evident from satellite tag data (Le Beouf et al. 2000). Males migrate to the Gulf of Alaska and western Aleutian Islands along the continental shelf to feed on benthic prey, while females migrate to pelagic areas in the Gulf of Alaska and the central North Pacific to feed on pelagic prey (Le Beouf et al. 2000). Adults return to land between March and August to molt, with males returning later than females. Adults return to their feeding areas again between their spring/summer molting and their winter breeding seasons.

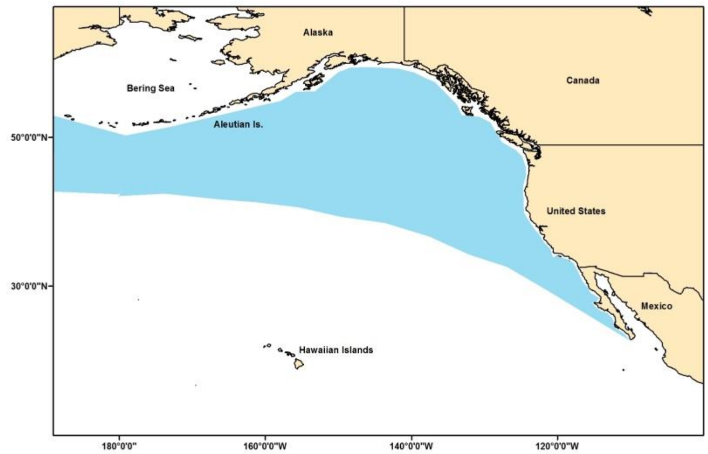

Figure 1. Pelagic range of northern elephant seals in the eastern North Pacific. Major breeding rookeries occur along the west coast of Baja California and the California coast, as described in Lowry et al. (2014).

Populations of northern elephant seals in the U.S. and Mexico have recovered after being nearly hunted to extinction (Stewart et al. 1994). Northern elephant seals underwent a severe population bottleneck and loss of genetic diversity when the population was reduced to an estimated 10-30 individuals (Hoelzel *et al*. 2002). Although movement and genetic exchange continues between rookeries, most elephant seals return to natal rookeries when they start breeding (Huber et al. 1991). The California breeding population is now demographically isolated from the Baja California population. No international agreements exist for the joint management of this species by the U.S. and Mexico. The California breeding population is considered here to be a separate stock.

POPULATION SIZE

A complete population count of elephant seals is not possible because all age classes are not ashore simultaneously. Elephant seal population size is estimated by counting the number of pups produced and multiplying by the inverse of the expected ratio of pups to total animals (McCann 1985). Based on counts of elephant seals at U.S. rookeries in 2010, Lowry *et al*. (2014) reported that 40,684 pups were born. Lowry *et al*. (2014) applied a multiplier of 4.4 to extrapolate from total pup counts to a population estimate of approximately 179,000 elephant seals. This multiplier is derived from life tables based on published elephant seal fecundity and survival rates, and reflects a population with approximately 23% pups (Cooper & Stewart, 1983; Le Boeuf & Reiter, 1988; Hindell, 1991; Huber et al., 1991; Reiter & Le Boeuf, 1991; Clinton & Le Boeuf, 1993; Le Boeuf et al., 1994; Pistorius & Bester, 2002; McMahon et al., 2003; Pistorius et al., 2004; Condit et al., 2014).

Minimum Population Estimate

The minimum population size for northern elephant seals in 2010 can be estimated very conservatively as 81,368 seals, which is equal to twice the observed pup count (to account for the pups and their mothers) .

Current Population Trend

The population is reported to have grown at 3.8% annually since 1988 (Lowry *et al*. 2014).

CURRENT AND MAXIMUM NET PRODUCTIVITY RATE

An annual growth rate of 17% for elephant seals in the U.S. from 1958 to 1987 is reported by Lowry *et al.* (2014), but some of this growth is likely due to immigration of animals from Mexico and the consequences of a small population recovering from past exploitation. From 1988 to 2010, the population is estimated to have grown 3.8% annually (Lowry et al. 2014). For this stock assessment report, we use the default maximum theoretical net productivity rate for pinnipeds, or 12% (Wade and Angliss 1997).

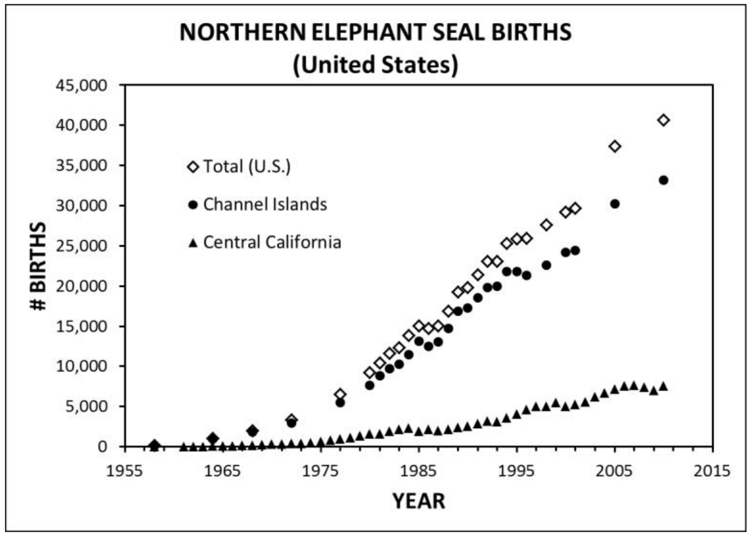

Figure 2. Estimated number of northern elephant seal births in California 1958-2010. Multiple independent estimates are presented for the Channel Islands 1988-91. Estimates are from Stewart et al. (1994), Lowry et al. (1996), Lowry (2002), Lowry et al. (2014), and unpublished data from Sarah Allen, Dan Crocker, Brian Hatfield, Ron Jameson, Bernie Le Boeuf, Mark Lowry, Pat Morris, Guy Oliver, Derek Lee, and William Sydeman.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (81,368) times one half the observed maximum net growth rate for this stock (½ of 12%) times a recovery factor of 1.0 (for a stock of unknown status that is increasing, Wade and Angliss 1997) resulting in a PBR of 4,882 animals per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Serious Injury Guidelines

NMFS uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to distinguish serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an "*injury that is more likely than not to result in mortality*".

Fisheries Information

A summary of known commercial fishery mortality and serious injury for this stock of northern elephant seals is given in Table 1. More detailed information on these fisheries is provided in Appendix 1.

Table 1. Summary of available information on the mortality and serious injury of northern elephant seals (California breeding stock) in commercial fisheries that might take this species (Carretta and Enriquez 2009, 2010, 2012a, 2012b, Carretta *et al*. 2014a). n/a indicates information is not available. Mean annual takes are based on 2008-2012 data unless noted otherwise.

Fishery Name	Year(s)	Data Type	Percent Observer Coverage	Observed Mortality	Estimated Mortality (CV in parentheses)	Mean Annual Takes (CV in parentheses)
CA thresher shark/swordfish drift gillnet fishery	2008 2009 2010 2011 2012	observer data	13.5% 13.3% 11.9% 19.5% 18.6%	0 0 0 0 0	0 0 0 0 0	0 (n/a)

Fishery Name	Year(s)	Data Type	Percent Observer Coverage	Observed Mortality	Estimated Mortality (CV in parentheses)	Mean Annual Takes (CV in parentheses)
CA halibut and white seabass set gillnet fishery	2008 2009 2010 2011 2012	observer data	0% 0% 12.5% 8.0% 5.5%	n/a n/a 0 0 0	n/a n/a 0 0 0	0 (n/a)
CA small-mesh drift gillnet fishery for white seabass, yellowtail, barracuda, and tuna	2010 2011 2012	observer data	0.7% 3.3% 4.6%	0 0 0	0 0 0	0 (n/a)
WA, OR, CA domestic groundfish trawl fishery (includes at-sea hake and other limited-entry groundfish sectors)	2005 2006 2007 2008 2009	observer data	98% to 100% of tows in at-sea hake fishery Generally less than 30% of landings observed in other groundfish sectors	0 1 3 7 2	0 (n/a) 1 (n/a) 3 (n/a) 9 (n/a) 2 (n/a)	3 (n/a)
Unknown gillnet fishery	2008-2012	stranding	n/a	1	1 (n/a)	≥1
Total annual takes						≥4.0 (n/a)

Although all of the mortality in Table 1 occurred in U.S. waters, some may be of seals from Mexico's breeding population that are migrating through U.S. waters.

Other Mortality

For the period 2008-2012, mortality and serious injuries from the following non-commercial fishery sources were documented: shootings (9); marine debris entanglement (7); hook and line fisheries (3); power plant entrainment (2); research-related (1); tar/oil (1); and vessel strike (1) (Carretta *et al.* 2014b). These non-commerical fishery sources of mortality and serious injury total 24 animals, or an average of 4.8 elephant seals annually (Carretta *et al.* 2014b).

STATUS OF STOCK

Northern elephant seals are not listed as "endangered" or "threatened" under the Endangered Species Act nor designated as "depleted" under the MMPA. Because their annual human-caused mortality (≥8.8) is much less than the calculated PBR for this stock (4,882), northern elephant seals are not considered a "strategic" stock under the MMPA. The average rate of incidental fishery mortality for this stock over the last five years ≥4.0) also appears to be less than 10% of the calculated PBR; therefore, the total fishery mortality appears to be insignificant and approaching a zero mortality and serious injury rate. The population growth rate between 1958 and 1987 was 17% annually (Lowry *et al.* 2014). From 1988 to 2010, the population grew at an annual rate of 3.8% (Lowry *et al.* 2014). The population continues to grow, with most births occurring at southern California rookeries (Lowry et al. 2014). No estimate of carrying capacity is available for this population and the population status relative to OSP is unknown. There are no known habitat issues that are of concern for this stock. However, expanding pinniped populations in general have resulted in increased human-caused serious injury and mortality, due to shootings, entrainment in power plants, interactions with recreational hook and line fisheries, separation of mothers and pups due to human disturbance, dog bites, and vessel and vehicle strikes (Carretta et al. 2014b).

GUADALUPE FUR SEAL (*Arctocephalus townsendi*)

STOCK DEFINITION AND GEOGRAPHIC RANGE

Commercial sealing during the 19th century reduced the once abundant Guadalupe fur seal to near extinction in 1894 (Townsend 1931). Prior to the harvest it ranged from Monterey Bay, California, to the Revillagigedo Islands, Mexico (Hanni *et al.* 1997, Repenning *et al.* 1971; Figure 1). The prehistoric distribution of Guadalupe fur seals during the Holocene was apparently quite different from today, as the archeological record indicates Guadalupe fur seal remains accounted for 40%-80% of all pinniped bones at the California Channel Islands (Rick *et al.* 2009). The live capture of two adult males (and killing of ~ 60 more animals) at Guadalupe Island in 1928 established the continued existence of the species (Townsend 1931). Guadalupe fur seals pup and breed mainly at Isla Guadalupe, Mexico. In 1997, a second rookery was discovered at Isla Benito del Este, Baja California (Maravilla-Chavez and Lowry 1999) and a pup was born at San Miguel Island, California (Melin and DeLong 1999). Since 2008, individual adult females, subadult males, and between one and three pups have been observed annually on San Miguel Island (NMFS, unpublished data). The population at Isla Benito del Este is now well-established, though very few pups are observed there. Population increases at Isla San Benito are attributed to immigration of animals from Isla Guadalupe (Aurioles-Gamboa *et al.* 2010, García-Capitanachi 2011). Along the U.S. west coast, strandings occur almost annually in California waters and animals are increasingly observed in Oregon and Washington waters. In 2015-2016, Guadalupe fur seal strandings totaled approximately 175 animals along the coast of California (compared with approximately 10 animals annually in prior years), and NMFS declared an unusual mortality event[1]. Most strandings involved animals less than 2 years old with evidence of malnutrition. Individuals have stranded or been sightedinside the Gulf of California and as far south as Zihuatanejo, Mexico (Hanni et al. 1997 and Aurioles-Gamboa and Hernadez-Camacho 1999) and another in 2012, at Cerro Hermoso, Oaxaca, Mexico (Esperon-Rodriguez and Gallo-Reynoso 2012). Recent video records of pinnipeds hooked in the mouth from international waters west of the California Current involving the shallow set Hawaii longline fishery were independently reviewed by pinniped experts and at least one animal in early 2016 was identified as a Guadalupe fur seal. Guadalupe fur seals that stranded in central California and treated at rehabilitation centers were fitted with satellite tags and documented to travel as far north as Graham Island and Vancouver Island, British Columbia, Canada (Norris *et al.* 2015). Some satellite-tagged animals traveled far offshore outside the U.S. EEZ to areas 700 nmi west of the California / Oregon border. The population is considered to be a single stock because all are recent descendants from one breeding colony at Isla Guadalupe, Mexico.

POPULATION SIZE

[1] http://www.nmfs.noaa.gov/pr/health/mmume/guadalupefurseals2015.html

The size of the population prior to the commercial harvests of the 19th century is not known, but estimates range from 20,000 to 100,000 animals (Fleischer 1987). Surveys conducted between 2008 and 2010 resulted in a total estimated population size of approximately 20,000 animals, with ~17,500 at Isla Guadalupe and ~2,500 at Isla San Benito (García-Capitanachi 2011, Aurioles-Gamboa 2015). These estimates are corrected for animals not seen during the surveys.

Minimum Population Estimate

All the individuals of the population cannot be counted because all age and sex classes are never ashore at the same time and some individuals that are on land are not visible during the census. Direct counts of animals at Isla Guadalupe and Isla San Benito during 2010 resulted in a minimum of 13,327 animals and 2,503 animals respectively, for a minimum population size of 15,830 animals (García-Capitanachi 2011).

Current Population Trend

Counts of Guadalupe fur seals have been made sporadically since 1954. Records of Guadalupe fur seal counts through 1984 were compiled by Seagars (1984), Fleischer (1987), and Gallo (1994). The count for 1988 was taken from Torres et al. (1990). More recent counts from 1977-2010 are summarized in García-Capitanachi (2011). Also, the counts that are documented in the literature generally provide only the total of all Guadalupe fur seals counted (i.e., the counts are not separated by age/sex class). The counts that were made during the breeding season, when the maximum number of animals are present at the rookery, were used to examine population growth (Gallo 1994, García-Capitanachi 2011). The natural logarithm of the counts was regressed against year to calculate the growth rate of the population. These data indicate that Guadalupe fur seals are increasing at an average annual growth rate of 10.3% (Figure 2).

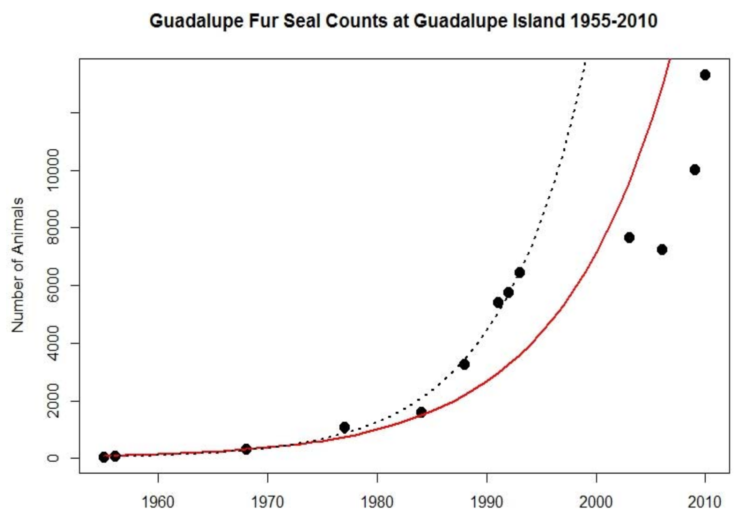

Figure 2. Counts of Guadalupe fur seals at Guadalupe Island, Mexico, and the estimated population growth curves derived from counts made during the breeding season. Direct counts of animals are shown as black dots. An estimated annual growth rate of 13% is based on counts made between 1955 and 1993 (black dashed line). The estimated growth rate over the period 1955-2010 is approximately 10% annually (solid red line).

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Reported annual growth rates of 21% at Isla San Benito over an 11-year period are too high and likely result from immigration from Isla Guadalupe (Esperón-Rodríguez and Gallo-Reynoso 2012). The maximum net productivity rate can be assumed to be equal to the maximum annual growth rate observed between 1955 and 1993 (13.7%) because the population was at a very low level and should have been growing at nearly its maximum rate (Gallo 1994). Based on direct counts of animals at Guadalupe Island between 1955 and 2010, the estimated annual population growth rate is 10.3%.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) for this stock is calculated as the minimum population size (15,830) <u>times</u> one half the maximum net growth rate observed for this species (½ of 13.7%) <u>times</u> a recovery factor of 0.5 (for a threatened species, Wade and Angliss 1997), resulting in a PBR of 542 Guadalupe fur seals per year. The vast majority of this PBR would apply towards incidental mortality in Mexico as most of the population occurs outside of U.S. waters.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY
Fisheries Information

Table 1. Summary of available information on the incidental mortality and injury of Guadalupe fur seals in commercial fisheries and other unidentified fisheries that might take this species.

Fishery Name	Year(s)	Data Type	Percent Observer Coverage	Observed Mortality and Serious Injury	Estimated Mortality and Serious Injury (CV)	Mean Annual Takes (CV)
CA driftnet fishery for sharks and swordfish	2010-2014	observer	12%-37%	0	0	0
CA set gillnet fishery for halibut/white seabass and other species	2010-2014	observer	9%	0	0	0
Unidentified fishery interactions	2010-2014	strandings	n/a	16	≥ 16	≥ 3.2
Minimum total annual takes						≥3.2

No Guadalupe fur seals have been observed entangled in California gillnet fisheries between 1990 and 2014 (Julian and Beeson 1998, Carretta *et al*. 2004, Carretta *et al*. 2016b), although stranded animals have been found entangled in gillnet of unknown origin (see 'Other mortality' below). Gillnets have been documented to entangle marine mammals off Baja California (Sosa-Nishizaki *et al*. 1993), but no recent bycatch data from Mexico are available.

One confirmed interaction of a mouth-hooked Guadalupe fur seal in the Hawaii shallow set longline fishery has been reviewed by U.S. west coast pinniped experts from video taken at sea in early 2016. Two additional videos of unidentified pinnipeds that were hooked in the mouth in 2015 in the same fishery were also reviewed. These interactions occurred outside of the U.S. EEZ, west of the California Current.

Other mortality and serious injury

There were 16 records of human-related deaths and/or serious injuries to Guadalupe fur seals from stranding data for the most recent 5-year period of 2010-2014 (Carretta *et al.* 2016a). These strandings included entanglement in marine debris and gillnet of unknown origin, and shootings. The average annual observed human-caused mortality and serious injury of Guadalupe fur seals for 2010-2014 is 3.2 animals annually (16 animals / 5 years). Observed human-caused mortality and serious injury for this stock very likely represents a fraction of the true impacts because not all cases are documented. No correction factors to account for undetected mortality and injury are currently available for pinnipeds along the U.S. west coast.

STATUS OF STOCK

The Endangered Species Act lists the Guadalupe fur seal as a threatened species, which automatically qualifies this stock as "depleted" and "strategic" stock under the Marine Mammal Protection Act. There is insufficient information to determine whether fishery mortality in Mexico exceeds the PBR for this stock, but given the observed growth of the population over time, this is unlikely. The total U.S. fishery mortality and serious injury for this stock (≥ 3.2 animals per year) is less than 10% of the calculated PBR for the entire stock, but it is not currently possible to calculate a prorated PBR for U.S. waters with which to compare serious injury and mortality from U.S. fisheries. Therefore, it is unknown whether total U.S. fishery mortality is insignificant and approaching zero mortality and serious injury rate. The population is growing at approximately 10% per year.

NORTHERN FUR SEAL (*Callorhinus ursinus*): California Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

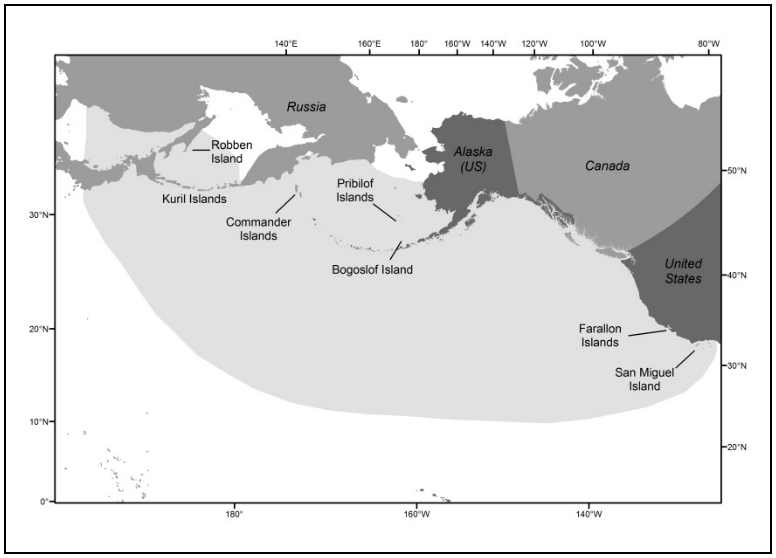

Figure 1. Approximate distribution of northern fur seals in the North Pacific (shaded area).

Northern fur seals occur from southern California north to the Bering Sea and west to the Okhotsk Sea and Honshu Island, Japan (Fig. 1). As of 2014, the worldwide population size is approximately 1.1 million animals (Gelatt *et al*. 2015). During the breeding season, approximately 45% of the worldwide population is found on the Pribilof Islands in the southern Bering Sea, with the remaining animals spread throughout the North Pacific Ocean (Gelatt *et al*. 2015). Of the seals in U.S. waters outside of the Pribilofs, approximately 9% of the population is found on Bogoslof Island in the southern Bering Sea, 1% on San Miguel Island off southern California, and 0.3% on the Farallon Islands off central California (Gelatt *et al*. 2015). Northern fur seals may temporarily haul out on land at other sites in Alaska, British Columbia, and on islets along the coast of the continental United States, but generally this occurs outside of the breeding season (Fiscus 1983).

Due to differing requirements during the annual reproductive season, adult males and females typically occur ashore at different, though overlapping, times. Adult males occur ashore and defend reproductive territories during a 3-month period from June through August, though some may be present until November (well after giving up their territories). Adult females are found ashore for as long as 6 months (June-November). After their respective times ashore, fur seals of both sexes spend the next 7 to 8 months at sea (Roppel 1984). Adult females and pups from the Pribilof Islands migrate through the Aleutian Islands into the North Pacific Ocean, often to waters off Washington, Oregon, and California. Many pups may remain at sea for 22 months before returning to their natal rookery. Adult females and pups from San Miguel Island and the Farallon Islands migrate northward to these same areas (Lea *et al*. 2009). Adult males from the Pribilof Islands generally migrate only as far south as the Gulf of Alaska (Kajimura 1984). Little is known about where adult males from San Miguel Island and the Farallon Islands migrate.

The following information was considered in classifying stock structure based on the Dizon *et al*. (1992) phylogeographic approach: 1) Distributional data: continuous geographic distribution during feeding, geographic separation during the breeding season, and high natal site fidelity (DeLong 1982); 2) Population response data: substantial differences in population dynamics between the Pribilofs and San Miguel Island (DeLong 1982, DeLong and Antonelis 1991, NMFS 2007); 3) Phenotypic data: unknown; and 4) Genotypic data: little evidence of genetic differentiation among breeding islands (Ream 2002, Dickerson *et al*. 2010). Based on this information, two separate stocks of northern fur seals are recognized within U.S. waters: an Eastern Pacific stock and a California stock (including San Miguel Island and the Farallon Islands). The Eastern Pacific stock is reported separately in the Stock Assessment Reports for the Alaska Region.

POPULATION SIZE

The population estimate for northern fur seals on San Miguel Island is calculated as the estimated number of pups at rookeries multiplied by an expansion factor. Based on research conducted on the Eastern Pacific stock of northern fur seals, Lander's (1981) life table analysis was used to estimate the number of yearlings, two-year-olds, three-year-olds, and animals at least four years old. The resulting population estimate was equal to the pup count multiplied by 4.475. The expansion factors are based on a sex and age distribution estimated after the commercial harvest of juvenile males was terminated in 1984. A more appropriate expansion factor for San Miguel Island is 4.0, because immigration of recruitment-aged females is occurring in the population (DeLong 1982), as well as mortality and possible emigration of adults associated with the El Niño events in 1982-1983 and 1997-1998 (Melin *et al*. 2008). A 1998 pup count resulted in an 80% decrease from the 1997 count (Melin *et al*. 2005). In 1999, the population began to recover, and in 2010 the highest total pup count of 3,408 was recorded (Orr *et al*. in review). A possible cause for the decline in total pup counts from 2010 to 2011 was a combination of oceanographic events that occurred in the California Current in 2009, a coastal upwelling relaxation event in May and June and an El Niño event from Fall 2009 to Spring 2010. The oceanographic events caused fewer reproductive males and females to return to San Miguel Island to breed in 2010. During 2012, the population increased 9.4% from 2011 and this level was maintained during 2013. No counts were conducted at Castle Rock in 2014; however, a record number of pups (2,289) were counted at Adam's Cove that year. Additionally, the second highest number of territorial bulls (224) was observed in 2014 (Orr *et al*. in review). Based on these factors, and assuming the trends were similar at Castle Rock, the population size during 2014 would have been the highest recorded. However, based on the 2013 count (the most recent complete data set) and the expansion factor, the most recent population estimate of northern fur seals at San Miguel Island is 13,384 (3,346 x 4.0) northern fur seals (Orr *et al*. in review). Currently, a coefficient of variation (CV) for the expansion factor is unavailable; however, studies are underway to determine the accuracy and precision of the expansion factor.

The population estimate for northern fur seals on the Farallon Islands is calculated as the highest number of pups, juveniles, and adults counted at the rookery. The long-term population estimate at the Farallon Islands should be regarded as an index of abundance rather than a precise indicator of population size for several reasons: 1) population censuses are incomplete because researchers do not enter rookery areas until the end of the breeding/pupping season in order to reduce human disturbance to other breeding pinnipeds and nesting seabirds; 2) mortality occurring early in the season is not accounted for; and 3) estimates of the number of pups are compromised because by the time counts are conducted, many pups have learned to swim and may not be present at the rookery. Additionally, yearlings may be present at rookeries and misidentified as pups. Keeping these factors in mind, the peak counts of northern fur seals increased steadily from 1995 to 2006 and have increased exponentially from 2008 to 2013 (Tietz 2012, Berger *et al*. 2013). Based solely on the count, the population estimate of northern fur seals at the Farallon Islands was 666 in 2013 and increased to 1,019 in 2014 (Orr *et al*. in review).

The most recent population estimate for the entire stock of California northern fur seals, which incorporates estimates from San Miguel Island and the Farallon Islands in 2013, is 14,050 (13,384 + 666).

Minimum Population Estimate

Minimum population size is calculated as the sum of the minimum number of animals at San Miguel Island and the Farallon Islands in 2013 (Tietz 2012, Berger *et al*. 2013, Orr *et al*. in review). The minimum number of animals at San Miguel Island is twice the pup count (3,346 x 2 = 6,692), to account for pups and mothers, plus the number of territorial males (166) counted the same year (i.e., 2013), or 6,858 fur seals. The minimum number at the Farallon Islands is the total number of individuals (666) counted during the survey in 2013. It should be noted that 1,019 individuals were counted in 2014, but this number is not used here to be consistent with data collected at San Miguel Island. The total minimum population size is the sum of the minimum population sizes at San Miguel Island (6,858) and the Farallon Islands (666) in 2013, or 7,524 northern fur seals.

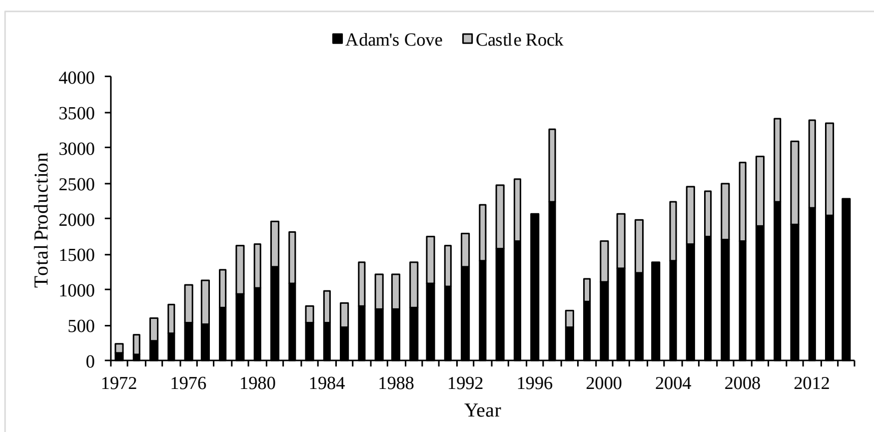

Figure 2. Total production of northern fur seal pups counted on San Miguel Island, including the mainland (Adam's Cove) and the offshore islet (Castle Rock), 1972-2014.

Current Population Trend

Northern fur seals were extirpated on San Miguel Island and the Farallon Islands during the late 1700s and early 1800s. Immigrants from the Pribilof Islands and Russian populations recolonized San Miguel Island during the late 1950s or early 1960s (DeLong 1982). The colony has increased steadily, since its discovery in 1968, except for severe declines in 1983 and 1998 associated with El Niño events in 1982-1983 and 1997-1998 (DeLong and Antonelis 1991, Melin *et al*. 2005). El Niño events impact population growth of northern fur seals at San Miguel Island and are an important regulatory mechanism for this population (DeLong and Antonelis 1991; Melin and DeLong 1994, 2000; Melin *et al*. 1996, 2005, 2008; Orr *et al.* 2012, in review).

Live pup counts increased about 24% annually from 1972 through 1982 (Fig. 2), partly due to immigration of females from the Bering Sea and the western North Pacific Ocean (DeLong 1982). The 1982-1983 El Niño event resulted in a 60% decline in the northern fur seal population at San Miguel Island (DeLong and Antonelis 1991). It took the population 7 years to recover from this decline, because adult female mortality or emigration occurred in addition to pup mortality (Melin and DeLong 1994). The 1992-1993 El Niño resulted in reduced pup production in 1992, but the population recovered in 1993 and increased during 1994 (Melin *et al*. 1996).

The northern fur seal population appears to be greatly affected by El Niño events. These events cause changes in marine communities by altering sea-level height, sea-surface temperature, thermocline and nutricline depths, current-flow patterns, and upwelling strength. Fur seal prey generally move to more productive areas farther north and deeper in the water column and, thereby, become less accessible for fur seals. Consequently, fur seals at San Miguel Island are in poor physical condition during El Niño events and the population experiences reduced reproductive success and high mortality of pups and, occasionally, adults. From July 1997 through May 1998, the most severe El Niño event in recorded history affected California coastal waters (Lynn *et al*. 1998). In 1997, total fur seal pup production was the highest recorded since the colony has been monitored. However, it appears that up to 87% of the pups born in 1997 died before weaning, and total production in 1998 declined 80% from 1997 (Melin *et al*. 2005). Total production increased to a record high of 3,408 in 2010 and, except for a slight decrease during 2011, levels have remained around 3,350 individuals in subsequent years (Orr *et al*. in review). The total production of northern fur seals has exceeded the 1997 levels during three of the last four years with complete counts; therefore, the San Miguel Island population has recovered from the 1997-1998 El Niño event.

Compared to San Miguel Island, less information is known about the population of northern fur seals on the Farallon Islands. Based on tag-resight data, it appears that the population originated from emigrants from San Miguel Island. The first pup was observed on the Farallon Islands in 1996 (Pyle *et al*. 2001). After this discovery, annual ground surveys were conducted in early fall to document population trends of the colony (Tietz 2012). The colony increased steadily from 1996 to the early 2000s. However, the population has grown exponentially during the past several years, with an occasional decline (Tietz 2012). Because counts are conducted during the fall after the breeding season, population trends and demographic information are less clear than for San Miguel Island.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Currently, productivity rates for northern fur seals on the Farallon Islands are unknown. A growth rate of 20% was calculated for northern fur seals on San Miguel Island in 1972-1982 by linear regression of the natural logarithm of pup count against year. However, it is clear that this rate of increase was due in part to immigration of females from Russian and Pribilof Islands populations (DeLong 1982). Immigration was also occurring from the early 1980s to 1997. In the absence of a reliable estimate of the maximum net productivity rate for the California stock of northern fur seals, the pinniped default maximum theoretical net productivity rate (R_{MAX}) of 12% (Wade and Angliss 1997) is used as an estimate of R_{MAX}.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population estimate (7,524) times one-half the default maximum net growth rate (½ of 12%) times a recovery factor of 1.0 (for stocks of unknown status that are increasing in size: Wade and Angliss 1997), resulting in a PBR of 451 northern fur seals from the California stock per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Northern fur seals taken by commercial fisheries during the winter/spring along the west coast of the continental U.S. could be from either the Eastern Pacific or California stock; therefore, any mortality or serious injury of northern fur seals reported off the coasts of California, Oregon, or Washington during December through May will be assigned to both the Eastern Pacific and California stocks of northern fur seals. There were no observer reports of northern fur seal deaths or serious injuries in any observed fishery along the west coast of the continental U.S. in 2009-2013 (Carretta and Enriquez 2010, 2012a, 2012b; Jannot *et al*. 2011; Carretta *et al*. 2014a, 2015).

Table 1. Summary of available information on the incidental mortality and serious injury of the California stock of northern fur seals in commercial fisheries that might take this species and calculation of the mean annual mortality and serious injury rate; n/a indicates that data are not available. Mean annual takes are based on 2009-2013 data unless noted otherwise.

Fishery name	Years	Data type	Percent observer coverage	Observed mortality	Estimated mortality	Mean annual takes (CV in parentheses)
Unknown West Coast fisheries	2009-2013	stranding data	n/a	1, 0, 2, 1, 0	n/a	$\geq$0.8 (n/a)
Minimum total annual takes						$\geq$0.8 (n/a)

Strandings of northern fur seals entangled in fishing gear or with serious injuries caused by interactions with gear are another source of fishery-related mortality information. According to stranding records for California, Oregon, and Washington (Carretta *et al*. 2014b, 2015), four fishery-related deaths (in unidentified net and unknown trawl fisheries) were reported between 2009 and 2013 (Table 1), resulting in a mean annual mortality and serious injury rate of 0.8 California northern fur seals. This estimate is considered a minimum because not all stranded animals are found, reported, or examined for cause of death (via necropsy by trained personnel). Two of the fishery-related deaths (one in an unidentified fishing net in February 2009 and one in trawl gear in April 2011) were also assigned to the Eastern Pacific stock of northern fur seals. Two additional northern fur seal strandings in 2012 (one in May and one in July) with serious injuries due to fishery interactions were treated and released with non-serious injuries (Carretta *et al*. 2014b). Both of these animals were assigned to the California stock of northern fur seals and the animal that stranded in May 2012 was also assigned to the Eastern Pacific stock.

Other Mortality

Since the Eastern Pacific and California stocks of northern fur seals overlap off the west coast of the continental U.S. during December through May, non-fishery mortality and serious injury reported off the coasts of California, Oregon, or Washington during that time will be assigned to both stocks. Mortality and serious injury of northern fur seals may occur incidental to research fishery activities. In 2007 and 2008, four northern fur seals were incidentally killed in California waters during scientific sardine trawling operations conducted by NMFS (Carretta *et al*. 2013): one death in 2007 and one in 2008 occurred before NMFS scientists implemented a mitigation plan to avoid future mortality. The initial mitigation plan included use of 162 dB acoustic pingers, a marine mammal watch, and scheduling trawls to occur when the ship first arrived on station to avoid attracting animals to a stationary vessel. Two additional northern fur seals were killed in subsequent 2008 trawls, so a marine mammal excluder device was added to the trawls in 2009 and no northern fur seal deaths or serious injuries were observed in this research fishery in 2009-2013. However, one northern fur seal was killed in a scientific rockfish trawling operation conducted by NMFS (Carretta *et al*. 2014b) in California waters in May 2009. This death was assigned to both the California and Eastern Pacific stocks of northern fur seals. The mean annual research-related mortality and serious injury rate of California northern fur seals from 2009 to 2013 is 0.2 northern fur seals.

According to stranding records for California, Oregon, and Washington (Carretta *et al*. 2014b, 2015), four human-caused northern fur seal deaths were reported from non-fisheries sources in 2009-2013. Three northern fur seals were entangled in marine debris in Oregon waters in April 2009 and one was entrained in the cooling water system of a California power plant in May 2012. All four of these deaths were assigned to both the California and Eastern Pacific stocks of northern fur seals. The mean annual mortality and serious injury rate from non-fishery sources in 2009-2013 is 0.8 California northern fur seals. This estimate is considered a minimum because not all stranded animals are found, reported, or examined for cause of death (via necropsy by trained personnel).

STATUS OF STOCK

The California northern fur seal stock is not considered to be "depleted" under the Marine Mammal Protection Act (MMPA) or listed as "threatened" or "endangered" under the Endangered Species Act. Based on currently available data, the minimum annual level of total human-caused mortality and serious injury (1.8) does not exceed the PBR (451). Therefore, the California stock of northern fur seals is not classified as a "strategic" stock. The minimum annual commercial fishery mortality and serious injury rate for this stock (0.8) is not known to exceed 10% of the calculated PBR (45) and, therefore, appears to be insignificant and approaching zero mortality and serious injury rate. The stock (based on San Miguel Island data) decreased 80% from 1997 to 1998, began to recover in 1999, and currently has surpassed the 1997 level by 2%. The status of this stock relative to its Optimum Sustainable Population (OSP) is unknown, unlike the Eastern Pacific northern fur seal stock which is formally listed as "depleted" under the MMPA.

HAWAIIAN MONK SEAL (*Neomonachus schauinslandi*)

STOCK DEFINITION AND GEOGRAPHIC RANGE

Hawaiian monk seals are distributed throughout the Northwestern Hawaiian Islands (NWHI), with subpopulations at French Frigate Shoals, Laysan Island, Lisianski Island, Pearl and Hermes Reef, Midway Atoll, Kure Atoll, and Necker and Nihoa Islands. They also occur throughout the main Hawaiian Islands (MHI). Genetic variation among monk seals is extremely low and may reflect a long-term history at low population levels and more recent human influences (Kretzmann *et al*. 1997, 2001, Schultz *et al*. 2009). Though monk seal subpopulations often exhibit asynchronous variation in demographic parameters (such as abundance trends and survival rates), they are connected by animal movement throughout the species' range (Johanos *et al*. 2013). Genetic analysis (Schultz *et al*. 2011) indicates the species is a single panmictic population. The Hawaiian monk seal is therefore considered a single stock. Scheel et al. (2014) established a new genus, *Neomonachus*, comprising the Caribbean and Hawaiian monk seals, based upon molecular and skull morphology evidence.

POPULATION SIZE

The best estimate of the total population size is 1,272, which is the sum of abundance estimates throughout the species' range (Table 1). In 2014, for the third consecutive year, NWHI field camps were shorter in duration relative to historic field effort levels. The low effort at some sites certainly resulted in negatively-biased abundance estimates and a degradation of the long-term monk seal demographic database. The number of individual seals identified is used as the population estimate at NWHI sites where total enumeration is achieved, according to the criteria established by Baker *et al*. (2006). Where total enumeration is not achieved, capture-recapture estimates from Program CAPTURE are used (Baker 2004; Otis *et al*. 1978, Rexstad & Burnham 1991, White *et al*. 1982). When no reliable estimator is obtainable in Program CAPTURE (i.e., the model selection criterion is < 0.75, following Otis *et al*. 1978), the total number of seals identified is the best available estimate. Sometimes capture-recapture estimates are less than the known minimum abundance (Baker 2004), and in these cases, the total number of seals actually identified is used. In 2014, total enumeration was achieved only at Kure Atoll, and capture-recapture estimates were obtained for Laysan Island and Midway Atoll. At French Frigate Shoals, Lisianski Island and Pearl and Hermes Reef, capture-recapture estimates were either not obtainable or were lower than known minimum abundance. Consequently, only minimum abundance was available for those sites. Counts at Necker and Nihoa Islands are conducted from zero to a few times per year. A new method for estimating non-pup abundance uses the empirical distribution of the ratio of beach counts to total population size at other NWHI subpopulations to correct beach counts at Necker and Nihoa Islands. This method is described in a manuscript currently in preparation (Harting *et al*. in prep.) and the resulting estimates are presented in Table 1. Pups are born over the course of many months and have very different haulout patterns compared to older animals. Therefore, pup production at Necker and Nihoa Islands is estimated as the mean of the total pups observed in the past 5 years, excluding counts occurring early in the pupping season when most have yet to be born. There were no counts conducted at Necker Island in 2014, so two beach counts conducted in 2013 were used to estimate abundance (no change in abundance since 2013 assumed). Three counts were conducted at Nihoa Island in 2014.

In the MHI, NMFS collects information on seal sightings reported throughout the year by a variety of sources, including a volunteer network, the public, and directed NMFS observation effort. In recent years, a small number of surveys of Ni'ihau and nearby Lehua Islands have been conducted through a collaboration between NMFS, Ni'ihau residents and the U.S. Navy. Total MHI monk seal abundance is estimated by adding the number of individually identifiable seals documented in 2014 on all MHI other than Ni'ihau and Lehua to an estimate for these latter two islands based on counts expanded by a haulout correction factor. A recent telemetry study (Wilson *et al*., in prep.) found that MHI monk seals (N=23) spent a greater proportion of time ashore than Harting *et al*. (in prep) estimated for NWHI seals. Therefore, the total non-pup estimate for Ni'ihau and Lehua Islands was the total beach count at those sites (less three individual seals already counted at other MHI) divided by the mean proportion of time hauled out in the MHI (Wilson *et al*., in prep). The total pups observed at Ni'ihau and Lehua Islands were added to obtain the total (Table 1).

Table 1. Total and minimum estimated abundance of Hawaiian monk seals by location in 2014. The estimation method is indicated for each site.

	Total			Minimum			
Location	**Non-pups**	**Pups**	**Total**	**Non-pups**	**Pups**	**Total**	**Method**
French Frigate Shoals	136	38	174	136	38	174	Minimum count
Laysan	188	35	223	181	35	216	Capture-recapture
Lisianski	129	11	140	129	11	140	Minimum count
Pearl and Hermes Reef	119	16	135	119	16	135	Minimum count
Midway	55	8	63	53	8	61	Capture-recapture
Kure	62	13	75	62	13	75	Total enumeration
Necker	63	5	68	50	5	55	Haulout correction
Nihoa	110	9	119	87	9	96	Haulout correction
MHI_(without Ni'ihau/ Lehua)	132	15	147	132	15	147	Minimum count
Ni'ihau/Lehua	108	20	128	86	20	106	Haulout correction
Total	*1102*	*170*	***1272***	*1035*	*170*	***1205***	

Minimum Population Estimate

The total numbers of seals identified at the NWHI subpopulations other than Necker and Nihoa, and in the MHI other than Ni'ihau and Lehua, are the best estimates of minimum population size at those sites. Minimum population sizes for Necker and Nihoa Islands are estimated as the lower 20^{th} percentiles of the non-pup abundance distributions generated using the Harting *et al*. (in prep.) haulout correction, plus the pup estimate. The mean proportion of time non-pups spent hauled out in the MHI was 0.370 (sd = 0.089, CV = 0.241) (Wilson *et al*. in prep.). Minimum abundance at Ni'ihau and Lehua Islands were calculated by applying the formula in Wade and Angliss (1997) to the Ni'ihau and Lehua non-pup estimate with a CV of 0.241, plus the observed pup tally. The minimum abundance estimates for each site and for all sites combined (1,205) are presented in Table 1.

Current Population Trend

In past years, the total stock abundance was not adequately assessed. However, in 2014, a range-wide total abundance estimate was generated using new methods for correcting beach counts at rarely visited sites (Necker, Nihoa and Ni'ihau/Lehua). Maintaining the commitment to conduct future counts at these latter sites will allow for the eventual estimation of total population trend. The following describes trends within different portions of the monk seal's range. The trend in abundance at the six most-studied NWHI subpopulations estimated with a log-linear regression of estimated abundance on year for the past 10 years (2005- 2014) yields a decline of -2.8% yr^{-1} (95% CI = -3.7% to -1.9% yr^{-1}). This rate of decline has been moderating in recent years. Sporadic beach counts at Necker and Nihoa Islands suggest either stability or some positive growth over the past decade. The MHI monk seal population appears to be increasing. Using life table analysis, Baker *et al*. (2011) estimated an intrinsic population growth rate (λ) of 6.5% per year based on data available through 2008. An updated analysis using MHI monk seal data through 2014 yields an estimated growth rate of 5.2% per year. However, the realized growth rate may differ considerably from λ, depending upon the unknown current age and sex structure. Given the uncertainties in these regional trends, it is not known whether the total stock abundance is decreasing, stable or possibly increasing. A reliable conclusion regarding population trend will only be apparent after more annual range-wide abundance estimates have accrued.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Trends in abundance vary considerably among subpopulations. Mean non-pup beach counts are used as a long-term index of abundance for years when data are insufficient to estimate total abundance as described above. Prior to 1999, beach count increases of up to 7% annually were observed at Pearl and Hermes Reef, and this is the highest estimate of the maximum net productivity rate (R_{max}) observed for this species.

POTENTIAL BIOLOGICAL REMOVAL

Using current minimum population size (1,205), R_{max} (0.07) and a recovery factor (F_r) for ESA endangered stocks (0.1), would yield a Potential Biological Removal (PBR) of 4.2. However, PBR is designed to allow stocks to recover to, or remain above, the maximum net productivity level (MNPL) (Wade 1998). An underlying assumption in the application of the PBR equation is that marine mammal stocks exhibit certain dynamics. Specifically, it is assumed that a depleted stock will naturally grow toward OSP (Optimum Sustainable Population), and that some surplus growth could be removed while still allowing recovery. The Hawaiian monk seal population is far below historical levels and has undergone a prolonged decline in abundance. Thus, past reports have concluded that the stock's dynamics do not conform to the underlying model for calculating PBR such that PBR for the Hawaiian monk seal has been undetermined. Given what appears to be an easing of the decline in the NWHI and continued growth in the MHI, this situation may have changed. If future monitoring reveals that the population is exhibiting positive growth, a valid PBR could be determined.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Human-related mortality has caused two major declines of the Hawaiian monk seal (Ragen 1999). In the 1800s, this species was decimated by sealers, crews of wrecked vessels, and guano and feather hunters (Dill and Bryan 1912; Wetmore 1925; Bailey 1952; Clapp and Woodward 1972). Following a period of at least partial recovery in the first half of the 20th century (Rice 1960), most subpopulations again declined. This second decline has not been fully explained, but long-term trends at several sites appear to have been driven both by variable oceanic productivity (represented by the Pacific Decadal Oscillation) and by human disturbance (Baker *et al*. 2012, Ragen 1999, Kenyon 1972, Gerrodette and Gilmartin 1990). Currently, human activities in the NWHI are limited and human disturbance is relatively rare, but human-seal interactions, have become an important issue in the MHI. Intentional killing of seals in the MHI is a relatively new and alarming issue (Table 2).

Table 2. Intentional and potentially intentional killings of MHI monk seals, and anthropogenic mortalities not associated with fishing gear since 2010.

Year	Age/sex	Island	Cause of Death	Comments
2010	Juvenile female	Kauai	Multiple skull fractures, blunt force trauma	Intent unconfirmed
2011	Adult male	Molokai	Skull fracture, blunt force trauma	Intent unconfirmed
	Juvenile female	Molokai	Skull fracture, blunt force trauma	Intent unconfirmed
2012	Juvenile male	Kauai	Gunshot wound	
	Subadult male	Kauai	Skull fracture	Intent unconfirmed
2014	Adult male	Oahu	Suspected trauma	Intent unconfirmed
	Pup female	Kauai	Skull fracture, blunt force trauma	Likely intentional
	Pup male	Kauai	Dog attack/bite wounds	4 other seals injured during this event

In July 2014, single or multiple dogs on Kauai attacked and injured at least five monk seals, one of which, a nursing pup, died from its wounds. The other four injured seals all recovered, one of which was a female nursing pup that required subsequent treatment for a bite-caused abscess. Four months later this same pup was killed on Kauai when its skull was crushed, likely by a human using a rock that was found nearby. An adult male on Oahu also died from what appeared to be trauma in 2014, but the carcass was too decomposed to draw conclusions about the cause of death. It is extremely unlikely that all carcasses of intentionally killed monk seals are discovered and reported. Studies of the recovery rates of carcasses for other marine mammal species have shown that the probability of detecting and documenting most deaths (whether from human or natural causes) is quite low (Peltier *et al*. 2012; Williams *et al*. 2011; Perrin *et al*. 2011; Punt and Wade 2010).

Fishery Information

Fishery interactions with monk seals can include direct interaction with gear (hooking or entanglement), seal consumption of discarded catch, and competition for prey. Entanglement of monk seals in derelict fishing gear, which is believed to originate outside the Hawaiian archipelago, is described in a separate section. Fishery interactions are a serious concern in the MHI, especially involving nearshore fisheries managed by the State of Hawaii. In 2014, 14 seal hookings were documented, 13 of which either were captured and had the hooks removed, or the hooks detached without intervention. A yearling male seal was found dead as result of hooking and the necropsy revealed that a 'J' hook had perforated the esophagus and part of one lung, causing pneumothorax and acute death. The remaining 13 hookings were all classified as non-serious injuries, although 9 of these would have been deemed serious had they not been mitigated. Several incidents involved hooks used to catch ulua (jacks, *Caranx* spp.). Nearshore gillnets became a more common source of mortality in the 2000s, with three seals confirmed dead in these gillnets (2006, 2007, and 2010), and one additional seal in 2010 may have also died in similar circumstances but the carcass was not recovered. No gillnet-related mortality or injuries have been documented since 2010. Most reported hookings and gillnet entanglements have occurred since 2000 (NMFS unpubl. data). The MHI monk seal population appears to have been increasing in abundance during this period (Baker *et al*. 2011). No mortality or serious injuries have been attributed to the MHI bottomfish handline fishery (Table 3). Published studies on monk seal prey selection based upon scat/spew analysis and video from seal-mounted cameras revealed evidence that monk seals fed on families of bottomfish which contain commercial species (many prey items recovered from scats and spews were identified only to the level of family; Goodman-Lowe 1998, Longenecker *et al*. 2006, Parrish *et al*. 2000). Quantitative fatty acid signature analysis (QFASA) results support previous studies illustrating that monk seals consume a wide range of species (Iverson *et al*. 2011). However, deepwater-slope species, including two commercially targeted bottomfishes and other species not caught in the fishery, were estimated to comprise a large portion of the diet for some individuals. Similar species were estimated to be consumed by seals regardless of location, age or gender, but the relative importance of each species varied. Diets differed considerably between individual seals. These results highlight the need to better understand potential ecological interactions with the MHI bottomfish handline fishery.

Table 3. Summary of mortality, serious and non-serious injury of Hawaiian monk seals due to fisheries and calculation of annual mortality rate. n/a indicates that sufficient data are not available. Percent observer coverage for the deep and shallow-set components, respectively, of the pelagic longline fishery, are shown. Total non-serious injuries are presented as well as, in parentheses, the number of those injuries that would have been deemed serious had they not been mitigated (*e.g.,* by de-hooking or disentangling). Data for MHI bottomfish and nearshore fisheries are based upon incidental observations (i.e., hooked seals and those entangled in active gear). All hookings not clearly attributable to either fishery with certainty were attributed to the bottomfish fishery, and hookings which resulted in injury of unknown severity were classified as serious. Nearshore fisheries injuries and mortalities include seals entangled/drowned in nearshore gillnets and hooked/entangled in hook-and-line gear, recognizing that it is not possible to determine whether the nets or hook-and-line gear involved were being used for commercial purposes.

Fishery Name	Year	Data Type	% Obs. coverage	Observed/Reported Mortality/Serious Injury	Estimated Mortality/ Serious Injury	Non-serious (Mitigated serious)	Mean Takes (CV)

There are no fisheries operating in or near the NWHI. In the past, interactions between the Hawaii-based domestic pelagic longline fishery and monk seals were documented (Nitta and Henderson 1993). This fishery targets swordfish and tunas and does not compete with Hawaiian monk seals for prey. In October 1991, in response to 13 unusual seal wounds thought to have resulted from interactions with this fishery, NMFS established a Protected Species Zone extending 50 nautical miles around the NWHI and the corridors between the islands. Subsequently, no additional monk seal interactions with the swordfish or tuna components of the longline fishery have been observed.

Fishery Mortality Rate

Total fishery mortality and serious injury is not insignificant and approaching a rate of zero. Monk seals are being hooked and entangled in the MHI at a rate that has not been reliably assessed but is certainly greater than zero. The information above represents only reported direct interactions, and without directed observation effort, the true interaction rate cannot be estimated. Monk seals also die from entanglement in fishing gear and other debris throughout their range (likely originating from various sources outside of Hawaii), and NMFS along with partner agencies are pursuing a program to mitigate entanglement (see below). Indirect interactions (i.e., involving competition for prey or consumption of discards) remain a topic of ongoing investigation.

Entanglement in Marine Debris

Hawaiian monk seals become entangled in fishing and other marine debris at rates higher than reported for other pinnipeds (Henderson 2001). A total of 347 cases of monk seals entangled in fishing gear or other debris have been observed from 1982 to 2014 (Henderson 2001; NMFS, unpubl. data). Nine documented deaths resulted from entanglement in marine debris (Henderson 1990, 2001; NMFS, unpubl. data). The fishing gear fouling the reefs and beaches of the NWHI and entangling monk seals only rarely includes types used in Hawaii fisheries. For example, trawl net and monofilament gillnet accounted for approximately 35% and 34%, respectively, of the debris removed from reefs in the NWHI by weight, and trawl net alone accounted for 88% of the debris by frequency (Donohue *et al*. 2001), despite the fact that trawl fisheries have been prohibited in Hawaii since the 1980s.

The NMFS and partner agencies continue to mitigate impacts of marine debris on monk seals as well as turtles, coral reefs and other wildlife. Marine debris is removed from beaches and seals are disentangled during annual population assessment activities at the main reproductive sites. Since 1996, annual debris survey and removal efforts in the NWHI coral reef habitat have been ongoing (Donohue *et al*. 2000, Donohue *et al*. 2001, Dameron *et al*. 2007).

Other Mortality

In the past 10 years (2004-2013) two monk seals died during enhancement activities (in 2005 and 2006) and one died during research in 2007 (NMFS unpubl. data).

Sources of mortality that impede recovery include food limitation (see Habitat Issues), single and multiple-male intra-species aggression (mobbing), shark predation, and disease/parasitism. Male seal aggression has caused episodes of mortality and injury. Past interventions to remove aggressive males greatly mitigated, but have not eliminated, this source of mortality (Johanos *et al*. 2010). Galapagos shark predation on monk seal pups has been a chronic and significant source of mortality at French Frigate Shoals since the late 1990s, despite mitigation efforts by NMFS (Gobush 2010). Infectious disease effects on monk seal demographic trends are low relative to other stressors. However, land-to-sea transfer of pathogens has been increasingly evident; since the early 2000's through 2014, six monk seal mortalities have been directly caused by protozoal infections, most often by *Toxoplasma gondii*, a protozoal parasite that is shed in the feces of cats. Furthermore, the consequences of a disease outbreak introduced from livestock, feral animals, pets or other carrier wildlife may be catastrophic to the immunologically naïve monk seal population. Key disease threats include West Nile virus, morbillivirus and influenza.

Habitat Issues

Poor juvenile survival rates and variability in the relationship between weaning size and survival suggest that prey availability is limiting recovery of NWHI monk seals (Baker and Thompson 2007, Baker *et al*. 2007, Baker 2008). Multiple strategies for improving juvenile survival, including translocation and captive care are being implemented (Baker and Littnan 2008, Baker *et al*. 2013, Norris 2013). A testament to the effectiveness of past actions to improve survival, Harting *et al.* (2014) demonstrated that approximately one-third of the monk seal population alive in 2012 was made up of seals that either had been intervened with to mitigate life-threatening situations, or were descendants of such seals. In 2014, NMFS produced a final Programmatic Environmental Impact Statement (PEIS) on current and future anticipated research and enhancement activities, and issued a permit covering the activities described in the PEIS preferred alternative (http://www.nmfs.noaa.gov/pr/permits/eis/hawaiianmonksealeis.htm). A major habitat issue involves loss of terrestrial habitat at French Frigate Shoals, where some pupping and resting islets have shrunk or virtually disappeared (Antonelis *et al*. 2006). Projected increases in global average sea level may further significantly reduce terrestrial habitat for monk seals in the NWHI (Baker *et al*. 2006, Reynolds *et al*. 2012).

Goodman-Lowe (1998) provided information on prey selection using hard parts in scats and spewings. Information on at-sea movement and diving is available for seals at all six main subpopulations in the NWHI using satellite telemetry (Stewart *et al*. 2006). Cahoon (2011) and Cahoon *et al*. (2013) described diet and foraging behavior of MHI monk seals, and found no striking difference in prey selection between the NWHI and MHI.

Remains of the seawall at Tern Island, French Frigate Shoals, is an entrapment hazard for seals. Vessel groundings pose a continuing threat to monk seals and their habitat, through potential physical damage to reefs, oil spills, and release of debris into habitats.

Monk seal abundance is increasing in the main Hawaiian Islands (Baker *et al*. 2011). Further, the excellent condition of pups weaned on these islands suggests ample prey resource availability, perhaps in part due to fishing pressure that has reduced monk seal competition with large fish predators (sharks and jacks) (Baker and Johanos 2004). If the monk seal population continues to expand in the MHI, it may bode well for the species' recovery and long-term persistence. In contrast, there are many challenges that may limit the potential for growth in this region. The human population in the MHI is approximately 1.4 million compared to fewer than 100 in the NWHI, so that the potential impact of disturbance in the MHI is great. Intentional killing of seals (noted above) is a very serious concern. Also, the same fishing pressure that may have reduced the monk seal's competitors is a source of injury and mortality. Finally, vessel traffic in the populated islands carries the potential for collision with seals and impacts from oil spills. The causes of two recent non-serious injuries (in 2010 and 2011) to seals were attributed to boat propellers. Thus, issues surrounding monk seals in the main Hawaiian Islands will likely become an increasing focus for management and recovery of this species.

STATUS OF STOCK

In 1976, the Hawaiian monk seal was designated depleted under the Marine Mammal Protection Act and as endangered under the Endangered Species Act. The species is well below its optimum sustainable population and has not recovered from past declines. Therefore, the Hawaiian monk seal is a strategic stock. Annual human-caused mortality for the most recent 5-year period (2010-2014) was at least ≥2.8 animals, including fishery-related mortality in nearshore gillnets and hook-and-line gear (≥1.2/yr, Table 3), and intentional killings and other human-caused mortalities (≥1.6/yr, Table 2).

HARBOR PORPOISE (*Phocoena phocoena*): Morro Bay Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

In the Pacific, harbor porpoise are found in coastal and inland waters from Point Conception, California to Alaska and across to Kamchatka and Japan (Gaskin 1984). Harbor porpoise appear to have more restricted movements along the western coast of the continental U.S. than along the eastern coast. Regional differences in pollutant residues in harbor porpoise indicate that they do not move extensively between California, Oregon, and Washington (Calambokidis and Barlow 1991). That study also showed some regional differences within California (although the sample size was small). This pattern stands as a sharp contrast to the eastern coast of the U.S. and Canada where harbor porpoise are believed to migrate seasonally from as far south as the Carolinas to the Gulf of Maine and Bay of Fundy (Polacheck et al. 1995). A phylogeographic analysis of genetic data from northeast Pacific harbor porpoise did not show complete concordance between DNA sequence types and geographic location (Rosel 1992). However, an analysis of molecular variance (AMOVA) of the same data with additional samples found significant genetic differences for four of the six pair-wise comparisons between the four areas investigated: California, Washington, British Columbia, and Alaska (Rosel et al. 1995). These results demonstrate that harbor porpoise along the west coast of North America are not panmictic or migratory, and movement is sufficiently restricted that genetic differences have evolved. Subsequent genetic analyses of samples ranging from Monterey Bay, California to Vancouver Island, British Columbia indicate that there is small-scale subdivision within the U.S. portion of this range (Chivers *et al.*, 2002, 2007).

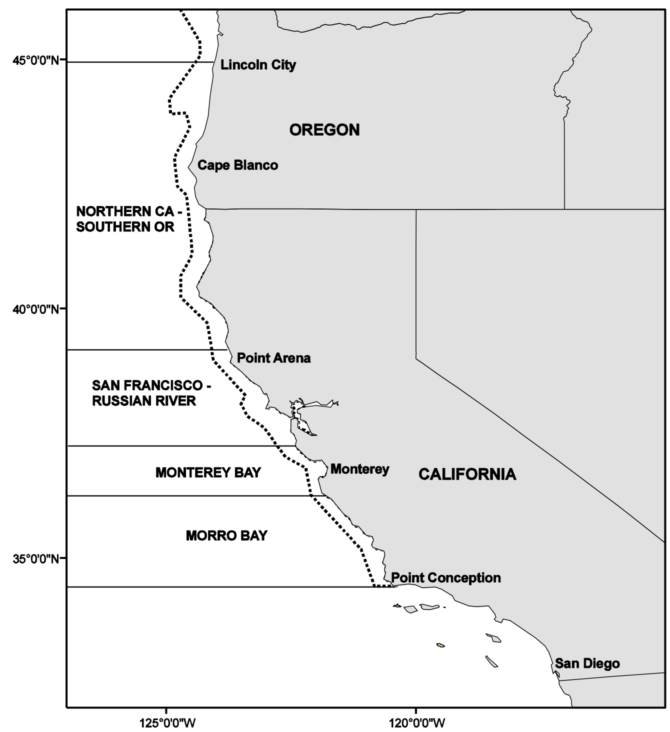

Figure 1. Stock boundaries and distributional range of harbor porpoise along the California and southern Oregon coasts. Dashed line represents harbor porpoise habitat (0-200 m) in this region.

In their assessment of harbor porpoise, Barlow and Hanan (1995) recommended that the animals inhabiting central California (defined to be from Point Conception to the Russian River) be treated as a separate stock. Their justifications for this were: 1) fishery mortality of harbor porpoise was limited to central California, 2) movement of individual animals appears to be restricted within California, and consequently 3) fishery mortality could cause the local depletion of harbor porpoise if central California is not managed separately. Although geographic structure exists along an almost continuous distribution of harbor porpoise from California to Alaska, stock boundaries are difficult to draw because any rigid line is (to a greater or lesser extent) arbitrary from a biological perspective. Nonetheless, failure to recognize geographic structure by defining management stocks can lead to depletion of local populations. Based on more recent genetic findings (Chivers *et al.*, 2002, 2007), California coast stocks were re-evaluated, and significant genetic differences were found among 4 identified sampling sites. Revised stock boundaries are presented here based on these genetic data and density discontinuities identified from aerial surveys, resulting in six California/Oregon/Washington stocks where previously there had been four (Carretta *et al.*

2001a). The stock boundaries for animals that occur in California/southern Oregon waters are shown in Figure 1. For the 2009 Marine Mammal Protection Act (MMPA) Stock Assessment Reports, other Pacific coast harbor porpoise stocks include: 1) a Monterey Bay stock, 2) a San Francisco-Russian River stock, 3) a northern California/southern Oregon stock, 4) a northern Oregon/Washington coast stock, 5) an Inland Washington stock, 6) a Southeast Alaska stock, 7) a Gulf of Alaska stock, and 8) a Bering Sea stock. Stock assessment reports for harbor porpoise stocks within waters of California, Oregon, and Washington appear in this volume. The three Alaska harbor porpoise stocks are reported separately in the Stock Assessment Reports for the Alaska Region.

POPULATION SIZE

Previous estimates of abundance for California harbor porpoise were based on aerial surveys conducted between the coast and the 50-fm isobath during 1988-95 (Barlow and Forney 1994, Forney 1999). These estimates did not include an unknown number of animals found in deeper waters. Barlow (1988) found that the vast majority of harbor porpoise in California were within the 0-50-fm depth range; however, Green et al. (1992) found that 24% of harbor porpoise seen during aerial surveys of Oregon and Washington were between the 100m and 200m isobaths (55 to 109 fathoms). A systematic ship survey of depth strata out to 90 m in northern California showed that porpoise abundance declined significantly in waters deeper than 60 m (Carretta *et al.* 2001b). Since 1999, aerial surveys have extended farther offshore (to the 200m depth contour or a minimum of 10 nmi from shore in the region of the Morro Bay stock) to provide a more complete abundance estimate. The most recent estimate of abundance for the Morro Bay stock, based on 2012 aerial surveys is 2,917 (CV=0.41) harbor porpoises (Forney et al. 2013). This estimate includes a correction factor of 3.42 (1/g(0); g(0)=0.292, CV=0.366) (Laake *et al.* 1997), to adjust for groups missed by aerial observers.

Minimum Population Estimate

The minimum population estimate for the Morro Bay harbor porpoise stock is taken as the lower 20th percentile of the log-normal distribution of the abundance estimated from the 2012 aerial surveys, or 2,102 animals.

Current Population Trend

The latest abundance estimate is greater than previous estimates dating back to 1988, which were < 2,100 harbor porpoises (see previous stock assessment reports). However, confidence limits are wide and estimates are not independent, so it is not statistically valid to infer a population trend directly from these points. Further analyses will be required to estimate population trends from the available abundance estimates, taking into account the fact that individual estimates were derived using common parameters and some shared survey data.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Based on what are argued to be biological limits of the species (i.e. females give birth first at age 4 and produce one calf per year until death), the theoretical, maximum-conceivable growth rate of a closed harbor porpoise population was estimated as 9.4% per year based on a human survivorship curve (Barlow and Boveng 1991). This maximum theoretical rate represents maximum survival in a protected environment and may not be achievable for any wild population (Barlow and Boveng 1991). Woodley and Read (1991) calculate a maximum growth rate of approximately 5% per year, but their argument for this being a maximum (i.e. that porpoise survival rates cannot exceed those of Himalayan thar) is not well justified. Population growth rates have not actually been measured for any harbor porpoise population. Because a reliable estimate of the maximum net productivity rate is not available for harbor porpoise, we use the default maximum net productivity rate (R_{MAX}) of 4% for cetaceans (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (2,102) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.5 (for a stock of unknown status; Wade and Angliss 1997), resulting in a PBR of 21.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fishery Information

Gillnet fisheries for halibut and white seabass that historically operated in the vicinity of Morro Bay were eliminated in this stock's range in 2002 by a ban on gillnets inshore of 60 fathoms (~110 m) from Point Arguello to Point Reyes, California. The large-mesh drift gillnet fishery for swordfish and thresher shark operates too far offshore to interact with harbor porpoise in this region. In the most recent five-year period for which data are available (2007-2011), one fishery-related stranding of harbor porpoise was documented within this stock's range (in 2008, Table 1). The responsible fishery has not been identified.

Table 1. Summary of available on incidental mortality and serious injury of Morro Bay Stock harbor porpoise in commercial fisheries that might take this species. Mean annual takes are based on 2007-2011 data. n/a indicates that data are not available.

Fishery Name	Year(s)	Data Type	Percent Observer Coverage	Observed Mortality	Kill/Day	Estimated Mortality (CV in parentheses)	Mean Annual Takes (CV in parentheses)
Unidentified gillnet fishery	2007-2011	Stranding	n/a	1	n/a	≥1	≥ 0.2 (n/a)
Minimum total annual takes							≥ 0.2 (n/a)

STATUS OF STOCK

Harbor porpoise in California are not listed as threatened or endangered under the Endangered Species Act nor as depleted under the Marine Mammal Protection Act. Barlow and Hanan (1995) calculate the status of harbor porpoise relative to historic carrying capacity (K) using a technique called back-projection. They calculate that the central California population (including Morro Bay, Monterey Bay, and San Francisco-Russian River stocks) could have been reduced to between 30% and 97% of K by incidental fishing mortality, depending on the choice of input parameters. They conclude that there is no practical way to reduce the range of this estimate. New information does not change this conclusion, and the status of central California harbor porpoise populations relative to their Optimum Sustainable Population (OSP) levels must be treated as unknown.

Fishery-related mortality of harbor porpoises is occasionally documented through strandings within this stock's range, although the total bycatch levels and responsible fisheries are unknown. Because the overall level of fishery mortality is unknown relative to the PBR it cannot be considered to be insignificant and approaching zero mortality and injury rate. Although there is uncertainty regarding the observed levels of fishery-related mortality for this stock, documented mortality is much less than the PBR, and thus this stock is not considered "strategic" under the MMPA. There are no known habitat issues that are presently of concern for this stock, although harbor porpoise are sensitive to disturbance by anthropogenic sound sources, such as those generated during the installation and operation of marine renewable energy facilities (Teilmann and Carstensen 2012).

Revised 6/4/2014

HARBOR PORPOISE (*Phocoena phocoena*): Monterey Bay Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

In the Pacific, harbor porpoise are found in coastal and inland waters from Point Conception, California to Alaska and across to Kamchatka and Japan (Gaskin 1984). Harbor porpoise appear to have more restricted movements along the western coast of the continental U.S. than along the eastern coast. Regional differences in pollutant residues in harbor porpoise indicate that they do not move extensively between California, Oregon, and Washington (Calambokidis and Barlow 1991). That study also showed some regional differences within California (although the sample size was small). This pattern stands as a sharp contrast to the eastern coast of the U.S. and Canada where harbor porpoise are believed to migrate seasonally from as far south as the Carolinas to the Gulf of Maine and Bay of Fundy (Polacheck et al. 1995). A phylogeographic analysis of genetic data from northeast Pacific harbor porpoise did not show complete concordance between DNA sequence types and geographic location (Rosel 1992). However, an analysis of molecular variance (AMOVA) of the same data with additional samples found significant genetic differences for four of the six pair-wise comparisons between the four areas investigated: California, Washington, British Columbia, and Alaska (Rosel et al. 1995). These results demonstrate that harbor porpoise along the west coast of North America are not panmictic or migratory, and movement is sufficiently restricted that genetic differences have evolved. Subsequent genetic analyses of samples ranging from Monterey Bay, California to Vancouver Island, British Columbia indicate that there is small-scale subdivision within the U.S. portion of this range (Chivers *et al*., 2002, 2007).

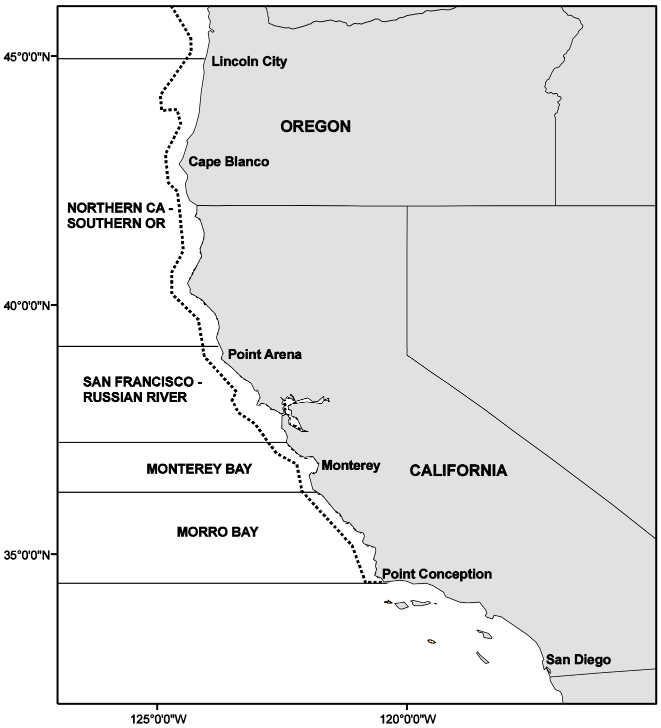

Figure 1. Stock boundaries and distributional range of harbor porpoise along the California/southern Oregon coast. Dashed line represents harbor porpoise habitat (0-200 m) along the U.S. west coast.

In their assessment of harbor porpoise, Barlow and Hanan (1995) recommended that the animals inhabiting central California (defined to be from Point Conception to the Russian River) be treated as a separate stock. Their justifications for this were: 1) fishery mortality of harbor porpoise was limited to central California, 2) movement of individual animals appears to be restricted within California, and consequently 3) fishery mortality could cause the local depletion of harbor porpoise if central California is not managed separately. Although geographic structure exists along an almost continuous distribution of harbor porpoise from California to Alaska, stock boundaries are difficult to draw because any rigid line is (to a greater or lesser extent) arbitrary from a biological perspective. Nonetheless, failure to recognize geographic structure by defining management stocks can lead to depletion of local populations. Based on more recent genetic findings (Chivers *et al*., 2002, 2007), California coast stocks were re-evaluated, and significant genetic differences were found among 4 identified sampling sites. Revised stock boundaries are presented here based on these genetic data and density discontinuities identified from aerial surveys, resulting in six California/Oregon/Washington stocks where previously there had been four (Carretta *et al.* 2001a). The stock boundaries for animals that occur in California/southern Oregon waters are shown in Figure 1. For the 2009 Marine Mammal Protection Act (MMPA) Stock Assessment Reports, other Pacific coast harbor porpoise stocks include: 1) a Monterey Bay stock, 2) a San Francisco-Russian River stock, 3) a northern California/southern Oregon stock, 4) a northern Oregon/Washington coast stock, 5) an Inland Washington stock, 6) a Southeast Alaska stock, 7) a Gulf of Alaska stock, and 8) a Bering Sea stock. Stock assessment reports for harbor porpoise stocks within waters of California, Oregon, and Washington appear in this volume. The three Alaska harbor porpoise stocks are reported separately in the Stock Assessment Reports for the Alaska Region.

POPULATION SIZE

Previous estimates of abundance for California harbor porpoise were based on aerial surveys conducted between the coast and the 50-fm isobath during 1988-95 (Barlow and Forney 1994, Forney 1999). These estimates did not include an unknown number of animals found in deeper waters. Barlow (1988) found that the vast majority of harbor porpoise in California were within the 0-50-fm depth range; however, Green et al. (1992) found that 24% of harbor porpoise seen during aerial surveys of Oregon and Washington were between the 100m and 200m isobaths (55 to 109 fathoms). A systematic ship survey of depth strata out to 90 m in northern California showed that porpoise abundance declined significantly in waters deeper than 60 m (Carretta et al. 2001b). Starting in 1999, aerial surveys extended farther offshore (to the 200m depth contour or a minimum of 15 nmi from shore in the region of the Monterey Bay stock) to provide a more complete abundance estimate. The most recent estimate of abundance for the Monterey Bay stock, based on 2011 aerial surveys is 3,715 (CV=0.51) harbor porpoises (Forney et al. 2013). This estimate includes a correction factor of 3.42 (1/g(0); g(0)=0.292, CV=0.366) (Laake *et al.* 1997), to adjust for groups missed by aerial observers.

Minimum Population Estimate

The minimum population estimate for the Monterey Bay harbor porpoise stock is taken as the lower 20th percentile of the log-normal distribution of the abundance estimated from the 2011 aerial surveys, or 2,480 animals.

Current Population Trend

The latest abundance estimate is markedly greater than previous estimates dating back to 1988, which were < 1,500-2,000 harbor porpoises (see previous stock assessment reports), but confidence limits are wide. Further analyses will be required to estimate population trends from the available abundance estimates, particularly because the abundance estimates are derived using common parameters and some shared survey data.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Based on what are argued to be biological limits of the species (i.e. females give birth first at age 4 and produce one calf per year until death), the theoretical, maximum-conceivable growth rate of a closed harbor porpoise population was estimated as 9.4% per year based on a human survivorship curve (Barlow and Boveng 1991). This maximum theoretical rate represents maximum survival in a protected environment and may not be achievable for any wild population (Barlow and Boveng 1991). Woodley and Read (1991) calculate a maximum growth rate of approximately 5% per year, but their argument for this being a maximum (i.e. that porpoise survival rates cannot exceed those of Himalayan thar) is not well justified.. Population growth rates have not actually been measured for any harbor porpoise population. Because a reliable estimate of the maximum net productivity rate is not available for harbor porpoise, we use the default maximum net productivity rate (R_{MAX}) of 4% for cetaceans (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (2,480) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.50(for a stock of unknown status ; Wade and Angliss 1997), resulting in a PBR of 25.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fishery Information

Gillnet fisheries for halibut and white seabass that historically operated in the vicinity of Monterey Bay were eliminated in this stock's range in 2002 by a ban on gillnets inshore of 60 fathoms (~110 m) from Point Arguello to Point Reyes, California. The large-mesh drift gillnet fishery for swordfish and thresher shark operates too far offshore to interact with harbor porpoise in this region. In the most recent five-year period for which data are available (2007-2011), no fishery-related mortality or injury of harbor porpoise within the range of the Monterey Bay stock has been documented.

Table 1. Summary of available on incidental mortality and injury of harbor porpoise in commercial fisheries that might take this species. Mean annual takes are based on 2007-2011 data. n/a indicates that data are not available.

Fishery Name	Year(s)	Data Type	Percent Observer Coverage	Observed Mortality	Kill/Day	Estimated Mortality (CV in parentheses)	Mean Annual Takes (CV in parentheses)
Unidentified fisheries	2007-2011	Stranding	n/a	none	n/a	n/a	0 (n/a)
Minimum total annual takes							0 (n/a)

STATUS OF STOCK

Harbor porpoise in California are not listed as threatened or endangered under the Endangered Species Act nor as depleted under the Marine Mammal Protection Act. Barlow and Hanan (1995) calculate the status of harbor porpoise relative to historic carrying capacity (K) using a technique called back-projection. They calculate that the central California population could have been reduced to between 30% and 97% of K by incidental fishing mortality, depending on the choice of input parameters. They conclude that there is no practical way to reduce the range of this estimate. New information does not change this conclusion, and the status of harbor porpoise relative to their Optimum Sustainable Population (OSP) levels in central California must be treated as unknown.

No fishery-related mortality of harbor porpoise has been documented within this stock's range during 2007-2011, and fishery mortality can be considered insignificant and approaching zero mortality rate. The Monterey Bay harbor porpoise stock is not considered "strategic" under the MMPA. There are no known habitat issues that are of particular concern for this stock, although harbor porpoise are sensitive to disturbance by anthropogenic sound sources, such as those generated during the installation and operation of marine renewable energy facilities (Teilmann and Carstensen 2012).

Revised 6/4/2014

HARBOR PORPOISE (*Phocoena phocoena*): San Francisco-Russian River Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

In the Pacific, harbor porpoise are found in coastal and inland waters from Point Conception, California to Alaska and across to Kamchatka and Japan (Gaskin 1984). Harbor porpoise appear to have more restricted movements along the western coast of the continental U.S. than along the eastern coast. Regional differences in pollutant residues in harbor porpoise indicate that they do not move extensively between California, Oregon, and Washington (Calambokidis and Barlow 1991). That study also showed some regional differences within California (although the sample size was small). This pattern stands as a sharp contrast to the eastern coast of the U.S. and Canada where harbor porpoise are believed to migrate seasonally from as far south as the Carolinas to the Gulf of Maine and Bay of Fundy (Polacheck et al. 1995). A phylogeographic analysis of genetic data from northeast Pacific harbor porpoise did not show complete concordance between DNA sequence types and geographic location (Rosel 1992). However, an analysis of molecular variance (AMOVA) of the same data with additional samples found significant genetic differences for four of the six pair-wise comparisons between the four areas investigated: California, Washington, British Columbia, and Alaska (Rosel et al. 1995). These results demonstrate that harbor porpoise along the west coast of North America are not panmictic or migratory, and movement is sufficiently restricted that genetic differences have evolved. Subsequent genetic analyses of samples ranging from Monterey Bay, California to Vancouver Island, British Columbia indicate that there is small-scale subdivision within the U.S. portion of this range (Chivers *et al.*, 2002, 2007).

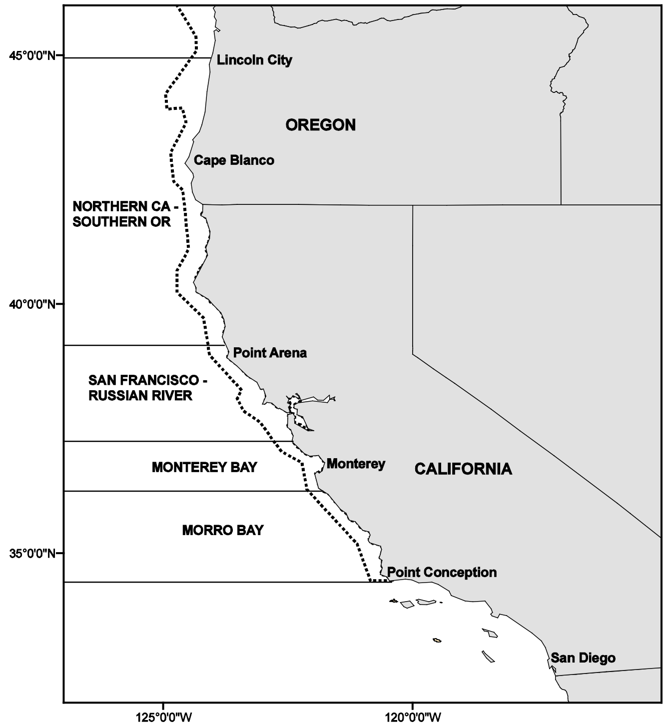

Figure 1. Stock boundaries and distributional range of harbor porpoise along the California and southern Oregon coasts. Dashed line represents harbor porpoise habitat (0-200 m) along the U.S. west coast.

In their assessment of harbor porpoise, Barlow and Hanan (1995) recommended that the animals inhabiting central California (defined to be from Point Conception to the Russian River) be treated as a separate stock. Their justifications for this were: 1) fishery mortality of harbor porpoise was limited to central California, 2) movement of individual animals appears to be restricted within California, and consequently 3) fishery mortality could cause the local depletion of harbor porpoise if central California is not managed separately. Although geographic structure exists along an almost continuous distribution of harbor porpoise from California to Alaska, stock boundaries are difficult to draw because any rigid line is (to a greater or lesser extent) arbitrary from a biological perspective. Nonetheless, failure to recognize geographic structure by defining management stocks can lead to depletion of local populations. Based on more recent genetic findings (Chivers *et al.*, 2002, 2007), California coast stocks were re-evaluated, and significant genetic differences were found among 4 identified sampling sites. Revised stock boundaries are presented here based on these genetic data and density discontinuities identified from aerial surveys, resulting in six California/Oregon/Washington stocks where previously there had been four (Carretta *et al.*

2001a). The stock boundaries for animals that occur in California/southern Oregon waters are shown in Figure 1. For the 2002 Marine Mammal Protection Act (MMPA) Stock Assessment Reports, other Pacific coast harbor porpoise stocks include: 1) a Morro Bay stock, 2) a Monterey Bay stock, 3) a northern California/southern Oregon stock, 4) a northern Oregon/Washington coast stock, 5) an Inland Washington stock, 6) a Southeast Alaska stock, 7) a Gulf of Alaska stock, and 8) a Bering Sea stock. Stock assessment reports for harbor porpoise stocks within waters of California, Oregon, and Washington appear in this volume. The three Alaska harbor porpoise stocks are reported separately in the Stock Assessment Reports for the Alaska Region.

POPULATION SIZE

Previous estimates of abundance for California harbor porpoise were based on aerial surveys conducted between the coast and the 50-fm isobath during 1988-95 (Barlow and Forney 1994, Forney 1999). These estimates did not include an unknown number of animals found in deeper waters. Barlow (1988) found that the vast majority of harbor porpoise in California were within the 0-50-fm depth range; however, Green et al. (1992) found that 24% of harbor porpoise seen during aerial surveys of Oregon and Washington were between the 100m and 200m isobaths (55 to 109 fathoms). A systematic ship survey of depth strata out to 90 m in northern California showed that porpoise abundance declined significantly in waters deeper than 60 m (Carretta *et al.* 2001b). Since 1999, aerial surveys extended farther offshore (to the 200m depth contour or a minimum of 15 nmi from shore in the region of the San Francisco-Russian River stock) to provide a more complete abundance estimate. The most recent estimate of abundance for the San Francisco-Russian River stock, based on 2007-2011 aerial surveys is 9,886 (CV=0.51) harbor porpoises (Forney et al. 2013). This estimate includes a correction factor of 3.42 (1/g(0); g(0)=0.292, CV=0.366) (Laake *et al*. 1997), to adjust for groups missed by aerial observers.

Minimum Population Estimate

The minimum population estimate for the San Francisco-Russian River harbor porpoise stock is taken as the lower 20th percentile of the log-normal distribution of the abundance estimated from 2007-2011 aerial surveys, or 6,625 animals.

Current Population Trend

The latest abundance estimate is very similar to the previous 2002-2007 estimate of 9,189 harbor porpoises (see previous stock assessment reports), and no recent trend is apparent. Further analyses will be required to estimate long-term population trends from the available abundance estimates, particularly because the abundance estimates are derived using common parameters and some shared survey data.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Based on what are argued to be biological limits of the species (i.e. females give birth first at age 4 and produce one calf per year until death), the theoretical, maximum-conceivable growth rate of a closed harbor porpoise population was estimated as 9.4% per year based on a human survivorship curve (Barlow and Boveng 1991). This maximum theoretical rate represents maximum survival in a protected environment and may not be achievable for any wild population (Barlow and Boveng 1991). Woodley and Read (1991) calculate a maximum growth rate of approximately 5% per year, but their argument for this being a maximum (i.e. that porpoise survival rates cannot exceed those of Himalayan thar) is not well justified. Population growth rates have not actually been measured for any harbor porpoise population. Because a reliable estimate of the maximum net productivity rate is not available for harbor porpoise, we use the default maximum net productivity rate (R_{MAX}) of 4% for cetaceans (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (6,625) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.5 (for a stock of unknown status; Wade and Angliss 1997), resulting in a PBR of 66.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fishery Information

Although coastal gillnets are prohibited throughout this stock's range, there have been fishery-related strandings in past years. In the most recent five-year period for which data are available (2007-2011), no fishery-related mortality or injury of harbor porpoise within the range of the San Francisco-Russian River stock has been documented.

Table 1. Summary of available information on incidental mortality and injury of harbor porpoise (San Francisco-Russian River stock) in commercial fisheries that might take this species. No fishery takes or fishery-related strandings were reported in this region between 2007 and 2011. n/a indicates that data are not available.

Fishery Name	Year(s)	Data Type	Percent Observer Coverage	Observed Mortality	Kill/Day	Estimated Mortality (CV in parentheses)	Mean Annual Takes (CV in parentheses)
Unknown fishery	2007-2011	stranding	n/a	none	n/a	n/a	0 (n/a)
Minimum total annual takes							0 (n/a)

STATUS OF STOCK

Harbor porpoise in California are not listed as threatened or endangered under the Endangered Species Act nor as depleted under the Marine Mammal Protection Act. Barlow and Hanan (1995) calculate the status of harbor porpoise relative to historic carrying capacity (K) using a technique called back-projection. They calculate that the central California population (including Morro Bay, Monterey Bay, and San Francisco-Russian River stocks) could have been reduced to between 30% and 97% of K by incidental fishing mortality, depending on the choice of input parameters. They conclude that there is no practical way to reduce the range of this estimate. New information does not change this conclusion, and the status of central California harbor porpoise populations relative to their Optimum Sustainable Population (OSP) levels must be treated as unknown. Because the known human-caused mortality or serious injury (zero harbor porpoise per year) is less than the PBR (66), this stock is not considered a "strategic" stock under the MMPA, and fishery mortality can be considered insignificant and approaching zero mortality and serious injury rate. There are no known habitat issues that are presently of concern for this stock, although harbor porpoise are sensitive to disturbance by anthropogenic sound sources, such as those generated during the installation and operation of marine renewable energy facilities (Teilmann and Carstensen 2012).

HARBOR PORPOISE (*Phocoena phocoena*): Northern California/Southern Oregon Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

In the Pacific, harbor porpoise are found in coastal and inland waters from Point Conception, California to Alaska and across to Kamchatka and Japan (Gaskin 1984). Harbor porpoise appear to have more restricted movements along the western coast of the continental U.S. than along the eastern coast. Regional differences in pollutant residues in harbor porpoise indicate that they do not move extensively between California, Oregon, and Washington (Calambokidis and Barlow 1991). That study also showed some regional differences within California (although the sample size was small). This pattern stands as a sharp contrast to the eastern coast of the U.S. and Canada where harbor porpoise are believed to migrate seasonally from as far south as the Carolinas to the Gulf of Maine and Bay of Fundy (Polacheck et al. 1995). A phylogeographic analysis of genetic data from northeast Pacific harbor porpoise did not show complete concordance between DNA sequence types and geographic location (Rosel 1992). However, an analysis of molecular variance (AMOVA) of the same data with additional samples found significant genetic differences for four of the six pair-wise comparisons between the four areas investigated: California, Washington, British Columbia, and Alaska (Rosel et al. 1995). These results demonstrate that harbor porpoise along the west coast of North America are not panmictic or migratory, and movement is sufficiently restricted that genetic differences have evolved. Subsequent genetic analyses of samples ranging from Monterey Bay, California to Vancouver Island, British Columbia indicate that there is small-scale subdivision within the U.S. portion of this range Chivers *et al.*, 2002, 2007).

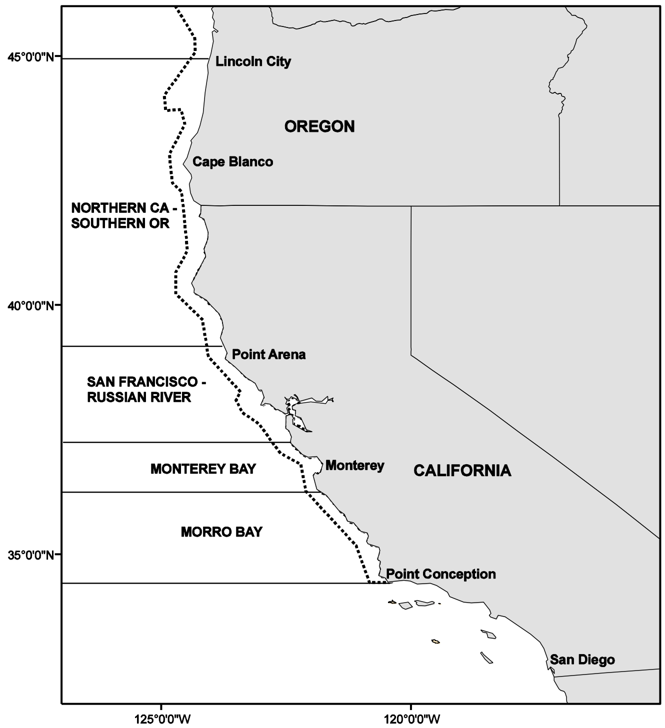

Figure 1. Stock boundaries and distributional range of harbor porpoise along the California/southern Oregon coasts. Dashed line represents harbor porpoise habitat (0-200 m) along the U.S. west coast.

In their assessment of harbor porpoise, Barlow and Hanan (1995) recommended that the animals inhabiting central California (defined to be from Point Conception to the Russian River) be treated as a separate stock. Their justifications for this were: 1) fishery mortality of harbor porpoise was limited to central California, 2) movement of individual animals appears to be restricted within California, and consequently 3) fishery mortality could cause the local depletion of harbor porpoise if central California is not managed separately. Although geographic structure exists along an almost continuous distribution of harbor porpoise from California to Alaska, stock boundaries are difficult to draw because any rigid line is (to a greater or lesser extent) arbitrary from a biological perspective. Nonetheless, failure to recognize geographic structure by defining management stocks can lead to depletion of local populations. Based on more recent genetic findings (Chivers *et al.*, 2002, 2007), California coast stocks were re-evaluated and significant genetic differences were found among four identified sampling sites. Revised stock boundaries were identified based on these genetic data and density discontinuities identified from aerial surveys (Figure 1). For the 2002 Marine Mammal Protection Act (MMPA) Stock Assessment Reports, other

Pacific coast harbor porpoise stocks include: 1) a Morro Bay stock, 2) a Monterey Bay stock, 3) a San Francisco-Russian River stock, 4) a northern Oregon/Washington coast stock, 5) an Inland Washington stock, 6) a Southeast Alaska stock, 7) a Gulf of Alaska stock, and 8) a Bering Sea stock. The stock assessment reports for harbor porpoise stocks within waters of California, Oregon, and Washington appear in this volume. The three Alaska harbor porpoise stocks are reported separately in the Stock Assessment Reports for the Alaska Region.

POPULATION SIZE

Previous estimates of abundance for California harbor porpoise were based on aerial surveys conducted between the coast and the 50-fm isobath during 1988-95 (Barlow and Forney 1994, Forney 1999). These estimates did not include an unknown number of animals found in deeper waters. Barlow (1988) found that the vast majority of harbor porpoise in California were within the 0-50-fm depth range; however, Green et al. (1992) found that 24% of harbor porpoise seen during aerial surveys of Oregon and Washington were between the 100m and 200m isobaths (55 to 109 fathoms). A systematic ship survey of depth strata out to 90 m in northern California showed that porpoise abundance declined significantly in waters deeper than 60 m (Carretta et al. 2001b). Since 1999, aerial surveys extended farther offshore (to the 200m depth contour or 15 nmi distance, whichever is farther) to provide a more complete abundance estimate. The most recent estimate of abundance for the northern California/southern Oregon stock, based on 2007-2011 aerial surveys is 35,769 (CV=0.52) harbor porpoises (Forney et al. 2013). This estimate includes a correction factor of 3.42 (1/g(0); g(0)=0.292, CV=0.366) (Laake *et al*. 1997), to adjust for groups missed by aerial observers.

Minimum Population Estimate

The minimum population estimate for harbor porpoise in northern California/southern Oregon is taken as the lower 20th percentile of the log-normal distribution of the abundance estimate obtained from 2007-2011 aerial surveys, or 23,749 animals.

Current Population Trend

The latest abundance estimate is similar to the previous 2002-2007 estimate of 39,581 harbor porpoises (see previous stock assessment reports), and no recent trend is apparent. Further analyses will be required to estimate long-term population trends from the available abundance estimates, particularly because the abundance estimates are derived using common parameters and some shared survey data.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Based on what are argued to be biological limits of the species (i.e. females give birth first at age 4 and produce one calf per year until death), the theoretical, maximum-conceivable growth rate of a closed harbor porpoise population was estimated as 9.4% per year based on a human survivorship curve (Barlow and Boveng 1991). This maximum theoretical rate represents maximum survival in a protected environment and may not be achievable for any wild population (Barlow and Boveng 1991). Woodley and Read (1991) calculate a maximum growth rate of approximately 5% per year, but their argument for this being a maximum (i.e. that porpoise survival rates cannot exceed those of Himalayan thar) is not well justified. Population growth rates have not actually been measured for any harbor porpoise population. Because a reliable estimate of the maximum net productivity rate is not available for harbor porpoise, we use the default maximum net productivity rate (R_{MAX}) of 4% for cetaceans (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (23,749) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 1.0 (for a species within its Optimal Sustainable Population; Wade and Angliss 1997), resulting in a PBR of 475.

HUMAN-CAUSED MORTALITY

Fishery Information

There were three harbor porpoise strandings in this stock's range that showed evidence of interactions with entangling net fisheries during 2007. Two of these were reported to be entangled in lost river salmon gillnet gear, while the third was an unidentified fishery interaction.

Table 1. Summary of available information on incidental mortality and injury of harbor porpoise (northern California/southern Oregon stock) in commercial fisheries that might take this species during 2007-2011. n/a indicates that data are not available.

Fishery Name	Year(s)	Data Type	Percent Observer Coverage	Observed Mortality	Estimated Mortality (CV in parentheses)	Mean Annual Takes (CV in parentheses)
Unknown fishery	2007-2011	Stranding	n/a	3	n/a	≥0.6 (n/a)
Minimum total annual takes						≥0.6 (n/a)

STATUS OF STOCK

Harbor porpoise in northern California/southern Oregon are not listed as threatened or endangered under the Endangered Species Act nor as depleted under the Marine Mammal Protection Act. The northern California portion of this harbor porpoise stock was determined to be within their Optimum Sustainable Population (OSP) level in the mid-1990s (Barlow and Forney 1994), based on a lack of significant anthropogenic mortality. The amount of anthropogenic mortality as documented through fishery-related strandings appears to be negligible compared with the population size and the stock is still considered to be within the range of OSP. Because the known human-caused mortality or serious injury (≥0.6 harbor porpoise per year) is less than the PBR (475), this stock is not considered a "strategic" stock under the MMPA. Because average annual fishery mortality is less than 10% of the PBR, the fishery mortality can be considered insignificant and approaching zero mortality and serious injury rate. There are no known habitat issues that are presently of concern for this stock, although harbor porpoise are sensitive to disturbance by anthropogenic sound sources, such as those generated during the installation and operation of marine renewable energy facilities (Teilmann and Carstensen 2012).

Revised 6/4/2014

HARBOR PORPOISE (*Phocoena phocoena*): Northern Oregon/Washington Coast Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

In the eastern North Pacific Ocean, harbor porpoise are found in coastal and inland waters from Point Barrow, along the Alaskan coast, and down the west coast of North America to Point Conception, California (Gaskin 1984). Harbor porpoise are known to occur year-round in the inland trans-boundary waters of Washington and British Columbia, Canada (Osborne *et al*. 1988) and along the Oregon/Washington coast (Barlow 1988, Barlow *et al*. 1988, Green *et al*. 1992). Aerial survey data from coastal Oregon and Washington, collected during all seasons, suggest that harbor porpoise distribution varies by depth (Green *et al*. 1992). Although distinct seasonal changes in abundance along the west coast have been noted, and attributed to possible shifts in distribution to deeper offshore waters during late winter (Dohl *et al*. 1983, Barlow 1988), seasonal movement patterns are not fully understood.

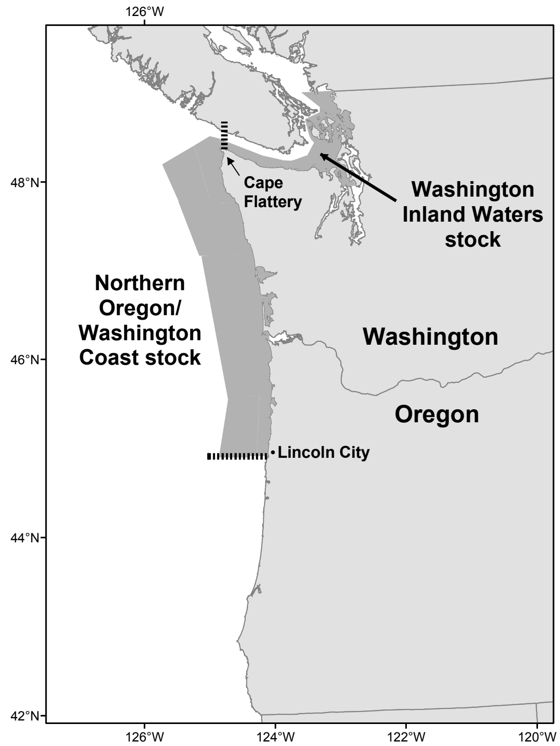

Figure 1. Stock boundaries (dashed lines) and approximate distribution (shaded areas) of harbor porpoise along the coasts of Washington and northern Oregon.

Investigation of pollutant loads in harbor porpoise ranging from California to the Canadian border suggests restricted harbor porpoise movements (Calambokidis and Barlow 1991). Stock discreteness in the eastern North Pacific was analyzed using mitochondrial DNA from samples collected along the west coast (Rosel 1992) and is summarized in Osmek *et al*. (1994). Two distinct mtDNA groupings or clades exist. One clade is present in California, Washington, British Columbia, and Alaska (no samples were available from Oregon), while the other is found only in California and Washington. Although these two clades are not geographically distinct by latitude, the results may indicate a low mixing rate for harbor porpoise along the west coast of North America. Further genetic testing of the same data, along with additional samples, found significant genetic differences for four of the six pair-wise comparisons between the four areas investigated: California, Washington, British Columbia, and Alaska (Rosel *et al*. 1995). These results demonstrate that harbor porpoise along the west coast of North America are not panmictic or migratory and that movement is sufficiently restricted that genetic differences have evolved. Recent preliminary genetic analyses of samples ranging from Monterey Bay, California, to Vancouver Island, British Columbia, indicate that there is small-scale subdivision within the U.S. portion of this range (Chivers *et al*. 2002, 2007). This is consistent with low movement suggested by genetic analysis of harbor porpoise specimens from the North Atlantic, where numerous stocks have been delineated with clinal differences over areas as small as the waters surrounding the British Isles.

Using the 1990-1991 aerial survey data of Calambokidis *et al*. (1993) for water depths <50 fathoms, Osmek *et al*. (1996) found significant differences in harbor porpoise mean densities ($Z=6.9$, $P<0.001$) between the waters of coastal Oregon/Washington and inland Washington/southern British Columbia, Canada (i.e., Strait of Juan de Fuca/San Juan Islands). Following a risk-averse management strategy, two stocks were recognized in the waters of Oregon and Washington, with a boundary at Cape Flattery, Washington. Based on recent genetic evidence, which suggests that the population of eastern

North Pacific harbor porpoise is more finely structured (Chivers *et al*. 2002, 2007), stock boundaries on the Oregon/Washington coast have been revised, resulting in three stocks in Oregon/Washington waters: a Northern California/Southern Oregon stock (Point Arena, CA, to Lincoln City, OR), a Northern Oregon/Washington Coast stock (Lincoln City, OR, to Cape Flattery, WA), and the Washington Inland Waters stock (in waters east of Cape Flattery). Additional analyses are needed to determine whether to adjust the stock boundaries for harbor porpoise in Washington inland waters (Chivers *et al*. 2007).

In their assessment of California harbor porpoise, Barlow and Hanan (1995) recommended two stocks be recognized in California, with the stock boundary at the Russian River. Based on recent genetic findings (Chivers *et al*. 2002, 2007), California coast stocks were re-evaluated and significant genetic differences were found among four identified sampling sites. Revised stock boundaries, based on these genetic data and density discontinuities identified from aerial surveys, resulted in six California/Oregon/Washington stocks where previously there had been four (e.g., Carretta *et al*. 2001): 1) the Washington Inland Waters stock, 2) the Northern Oregon/Washington Coast stock, 3) the Northern California/Southern Oregon stock, 4) the San Francisco-Russian River stock, 5) the Monterey Bay stock, and 6) the Morro Bay stock. The stock boundaries for animals that occur in northern Oregon/Washington waters are shown in Figure 1. This report considers only the Northern Oregon/Washington Coast stock. Stock assessment reports for Washington Inland Waters, Northern California/Southern Oregon, San Francisco-Russian River, Monterey Bay, and Morro Bay harbor porpoise also appear in this volume. Stock assessment reports for the three harbor porpoise stocks in the inland and coastal waters of Alaska, including 1) the Southeast Alaska stock, 2) the Gulf of Alaska stock, and 3) the Bering Sea stock, are reported separately in the Stock Assessment Reports for the Alaska Region. The harbor porpoise occurring in British Columbia have not been included in any of the U.S. stock assessment reports.

POPULATION SIZE

Two separate aerial surveys for leatherback turtles were conducted during 2010 and 2011 from the coast approximately to the 2,000 m isobath between Cape Blanco, Oregon, and Cape Flattery, Washington. Some additional adaptive surveys were conducted in areas of special interest for leatherback turtles; although these transects were not included in the analysis, the corresponding harbor porpoise sightings were included for estimation of the detection function in this study. Using a correction factor of 3.42 (1/g(0); g(0)=0.292, CV=0.366) (Laake *et al*. 1997a), to adjust for groups missed by aerial observers, the corrected estimate of abundance for harbor porpoise in the coastal waters of northern Oregon (north of Lincoln City) and Washington in 2010-2011 is 21,487 (CV = 0.44) (Forney et al. 2013).

Minimum Population Estimate

The minimum population estimate for this stock is calculated as the lower 20th percentile of the log-normal distribution (Wade and Angliss 1997) of the 2010-2011 population estimate of 21,487, which is 15,123 harbor porpoise.

Current Population Trend

There are no reliable data on population trends of harbor porpoise for coastal Oregon, Washington, or British Columbia waters; however, the uncorrected estimates of abundance for the Northern Oregon/Washington Coast stock in 1997 (6,406; SE=826.5) and 2002 (4,583) were not significantly different (Z=-1.73, P=0.08), although the survey area in 1997 (Regions I-S through III) was slightly larger than in 2002 (Strata D-G) (Laake *et al*. 1998a; J. Laake, unpublished data). The 2010-2011 Northern Oregon/Washington Coast stock estimate (21,487, CV = 0.44) is greater than the previous 2002 estimate of 15,674 (CV = 0.39), but the previous estimate is within the confidence limit of the current abundance estimate (Forney et al. 2013).

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Based on what are argued to be biological limits of the species (i.e. females give birth first at age 4 and produce one calf per year until death), the theoretical, maximum-conceivable growth rate of a closed harbor porpoise population was estimated as 9.4% per year based on a human survivorship curve (Barlow and Boveng 1991). This maximum theoretical rate represents maximum survival in a protected environment and may not be achievable for any wild population (Barlow and Boveng 1991). Woodley and Read (1991) calculate a maximum growth rate of approximately 5% per year, but their argument for this being a maximum (i.e. that porpoise survival rates cannot exceed those of Himalayan thar) is not well justified. Population growth rates have not actually been measured for any harbor porpoise population. Because a reliable estimate of the maximum net productivity rate is not available for harbor porpoise, we use the default maximum net productivity rate (R_{MAX}) of 4% for cetaceans (Wade and Angliss 1997).

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (15,123) times one-half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.5 (for a stock of unknown status, Wade and Angliss 1997), resulting in a PBR of 151 harbor porpoise per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Within the EEZ boundaries of the coastal waters of northern Oregon and Washington, harbor porpoise deaths are known to occur in the northern Washington marine set gillnet tribal fishery. Total fishing effort in this fishery is conducted within the range of both harbor porpoise stocks (Northern Oregon/Washington Coast and Washington Inland Waters) occurring in Washington State waters (Gearin *et al.* 1994). Some movement of harbor porpoise between Washington's coastal and inland waters is likely, but it is currently not possible to quantify the extent of such movements. For the purposes of this stock assessment report, the animals taken in waters south and west of Cape Flattery, WA, are assumed to have belonged to the Northern Oregon/Washington Coast stock, and Table 1 includes data only from that portion of the fishery. Fishing effort in the coastal marine set gillnet tribal fishery has declined since 2004. A test set gillnet fishery, with 100% observer coverage, was conducted in coastal waters in 2008 and 2011. This test fishery required the use of nets equipped with acoustic alarms, and no harbor porpoise deaths were reported (Makah Fisheries Management, unpublished data). The mean estimated mortality for this fishery in 2007-2011 is 0 (CV=0) harbor porpoise per year from observer data.

Table 1. Summary of incidental mortality and serious injury of harbor porpoise (Northern Oregon/Washington Coast stock) in commercial and tribal fisheries that might take this species and calculation of the mean annual mortality rate; n/a indicates that data are not available. Mean annual takes are based on 2007-2011 data unless noted otherwise.

Fishery name	Years	Data type	Percent observer coverage	Observed mortality	Estimated mortality	Mean annual takes (CV in parentheses)
Northern WA marine set gillnet (tribal test fishery in coastal waters)[1]	2007 2008 2009 2010 2011	observer	no fishery 100% no fishery 100% no fishery	0 0 0 0 0	0 (0) 0 (0) 0 (0) 0 (0) 0 (0)	0 (0)
Unknown West Coast fisheries	2007-2011	stranding		2, 1, 3, 3, 6	n/a	>3.0 (n/a)
Minimum total annual takes						>3.0 (n/a)

[1]This is a tribal fishery; therefore, it is not listed in the NMFS list of commercial fisheries.

In 1995-1997, data were collected for the coastal portions (areas 4 and 4A) of the northern Washington marine set gillnet fishery as part of an experiment, conducted in cooperation with the Makah Tribe, designed to explore the merits of using acoustic alarms to reduce bycatch of harbor porpoise in salmon gillnets. Results in 1995-1996 indicated that the nets equipped with acoustic alarms had significantly lower entanglement rates, as only 2 of the 49 deaths occurred in alarmed nets (Gearin *et al.* 1996, 2000; Laake *et al.* 1997b). In 1997, 96% of the sets were equipped with acoustic alarms and 13 deaths were observed (Gearin *et al.* 2000; P. Gearin, unpublished data). Harbor porpoise were displaced by an acoustic buffer around the alarmed nets, but it is unclear whether the porpoise or their prey were repelled by the alarms (Kraus *et al.* 1997, Laake *et al.* 1998b). However, the acoustic alarms did not appear to affect the target catch (chinook salmon and sturgeon) in the fishery (Gearin *et al.* 2000). For the past decade, Makah tribal regulations have required nets set in coastal waters (areas 4 and 4A) to be equipped with acoustic alarms.

According to Northwest Marine Mammal Stranding Network records, maintained by the NMFS Northwest Region (NMFS, Northwest Regional Office, unpublished data), there were 15 fishery-related strandings of harbor porpoise from this stock reported on the northern Oregon/Washington coast in 2007-2011 (2 in 2007, 1 in 2008, 3 in 2009, 3 in 2010, and 6 in 2011), resulting in a mean annual mortality of 3.0 harbor porpoise in 2007-2011. Evidence of fishery interactions included net marks, rope marks, and knife cuts (Carretta et al. 2013). Since these deaths could not be attributed to a particular fishery, and were the only confirmed fishery-related deaths in this area in 2007-2011, they are listed in Table 1 as occurring in unknown West Coast fisheries. Seven additional strandings reported in 2007-2011 (2 in 2007, 1 in 2008, 1 in 2009 , and 3 in 2011) were considered possible fishery-related strandings but were not included in the estimate of mean annual mortality. This estimate is considered a minimum because not all stranded animals are found, reported, or examined for cause of death (via necropsy by trained personnel).

Other Mortality

A significant increase in the number of harbor porpoise strandings reported throughout Oregon and Washington in 2006 prompted the Working Group on Marine Mammal Unusual Mortality Events to declare an Unusual Mortality Event (UME) on 3 November 2006 (Huggins 2008). A total of 114 harbor porpoise strandings were reported and confirmed throughout Oregon/Washington coast and Washington inland waters in 2006 and 2007 (Huggins 2008). The cause of the UME has not been determined, and several factors, including contaminants, genetics, and environmental conditions, are still being investigated. Cause of death, determined for 48 of 81 porpoise that were examined in detail, was attributed mainly to trauma and infectious disease. Suspected or confirmed fishery interactions were the primary cause of adult/subadult traumatic injuries, while birth-related trauma was responsible for the neonate deaths. Although six of the Northern Oregon/Washington Coast harbor porpoise deaths examined as part of the UME were suspected to have been caused by fishery interactions, only two could be confirmed as fishery-related deaths; these two deaths are listed in Table 1 as occurring in unknown West Coast fisheries in 2007.

STATUS OF STOCK

Harbor porpoise are not listed as "depleted" under the MMPA or listed as "threatened" or "endangered" under the Endangered Species Act. Based on currently available data, the minimum annual level of total human-caused mortality and serious injury (3.0 per year) does not exceed the PBR (151). Therefore, the Northern Oregon/Washington Coast stock of harbor porpoise is not classified as "strategic." The minimum annual fishery mortality and serious injury for this stock (3.0) is not known to exceed 10% of the calculated PBR (15.1) and, therefore, can be considered to be insignificant and approaching zero mortality and serious injury rate The status of this stock relative to its Optimum Sustainable Population (OSP) level and population trends is unknown.

Revised 2/6/2017

HARBOR PORPOISE (*Phocoena phocoena vomerina*): Washington Inland Waters Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

In the eastern North Pacific Ocean, harbor porpoise are found in coastal and inland waters from Point Barrow, along the Alaskan coast, and down the west coast of North America to Point Conception, California (Gaskin 1984). Harbor porpoise are known to occur year-round in the inland trans-boundary waters of Washington and British Columbia, Canada (Osborne et al. 1988), and along the Oregon/Washington coast (Barlow 1988, Barlow et al. 1988, Green et al. 1992). Aerial survey data from coastal Oregon and Washington, collected during all seasons, suggest that harbor porpoise distribution varies by depth (Green et al. 1992). Although distinct seasonal changes in abundance along the west coast have been noted, and attributed to possible shifts in distribution to deeper offshore waters during late winter (Dohl et al. 1983, Barlow 1988), seasonal movement patterns are not fully understood.

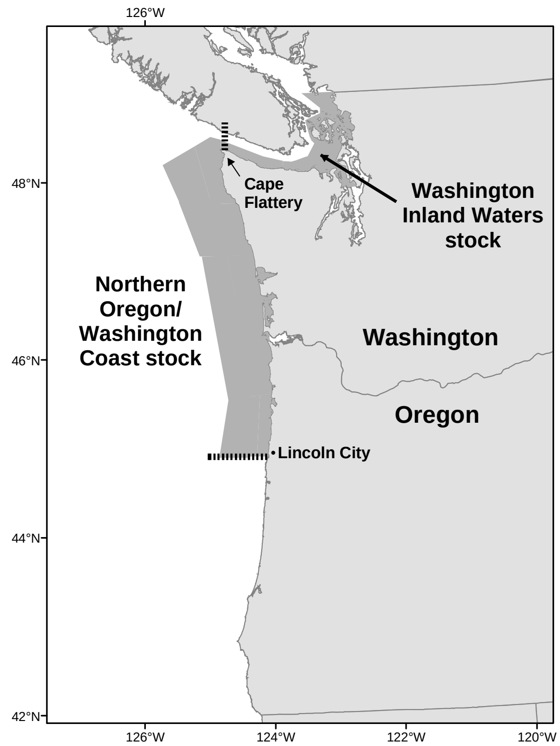

Figure 1. Stock boundaries (dashed lines) and approximate distribution (dark shaded areas) of harbor porpoise along the coasts of Washington and northern Oregon. The range of the Northern California/Southern Oregon stock of harbor porpoise (not shown), extends from Lincoln City. OR, south to Pt. Arena, CA.

Investigation of pollutant loads in harbor porpoise ranging from California to the Canadian border suggests restricted harbor porpoise movements (Calambokidis and Barlow 1991). Stock discreteness in the eastern North Pacific was analyzed using mitochondrial DNA from samples collected along the west coast (Rosel 1992) and is summarized in Osmek et al. (1994). Two distinct mtDNA groupings or clades exist. One clade is present in California, Washington, British Columbia, and Alaska (no samples were available from Oregon), while the other is found only in California and Washington. Although these two clades are not geographically distinct by latitude, the results may indicate a low mixing rate for harbor porpoise along the west coast of North America. Further genetic testing of the same data, along with additional samples, found significant genetic differences for four of the six pair-wise comparisons between the four areas investigated: California, Washington, British Columbia, and Alaska (Rosel et al. 1995). These results demonstrate that harbor porpoise along the west coast of North America are not panmictic or migratory and that movement is sufficiently restricted that genetic differences have evolved. Subsequent genetic analyses of samples ranging from Monterey Bay, California, to Vancouver Island, British Columbia, indicate that there is small-scale subdivision within the U.S. portion of this range (Chivers et al. 2002, 2007). This is consistent with low movement suggested by genetic analysis of harbor porpoise specimens from the North Atlantic, where numerous stocks have been delineated with clinal differences over areas as small as the waters surrounding the British Isles.

Using the 1990-1991 aerial survey data of Calambokidis et al. (1993) for water depths <50 fathoms, Osmek et al. (1996) found significant differences in harbor porpoise mean densities ($Z=6.9$, $P<0.001$) between the waters of coastal Oregon/Washington and inland Washington/southern British Columbia, Canada (i.e., Strait of Juan de Fuca/San Juan Islands). Following a risk averse management strategy, two stocks were recognized in the waters of Oregon and Washington, with a boundary at Cape Flattery, Washington. Based on more recent genetic evidence, which suggests that the population of eastern North Pacific harbor porpoise is more finely structured (Chivers et al. 2002, 2007), stock boundaries on the Oregon/Washington coast have been revised, resulting in three stocks in Oregon/Washington waters: a Northern California/Southern Oregon stock (Point Arena, CA, to Lincoln City, OR), a

Northern Oregon/Washington Coast stock (Lincoln City, OR, to Cape Flattery, WA), and the Washington Inland Waters stock (in waters east of Cape Flattery). Additional analyses are needed to determine whether to adjust the stock boundaries for harbor porpoise in Washington inland waters (Chivers et al. 2007).

Barlow and Hanan (1995) recommended two stocks of harbor porpoise be recognized in California, with the stock boundary at the Russian River. Based on more recent genetic findings (Chivers et al. 2002, 2007), California coast stocks were re-evaluated and significant genetic differences were found among four identified sampling sites. Revised stock boundaries, based on these genetic data and density discontinuities identified from aerial surveys, resulted in six California/Oregon/Washington stocks where previously there had been four (e.g., Carretta et al. 2001): 1) the Washington Inland Waters stock, 2) the Northern Oregon/Washington Coast stock, 3) the Northern California/Southern Oregon stock, 4) the San Francisco-Russian River stock, 5) the Monterey Bay stock, and 6) the Morro Bay stock. The stock boundaries for animals that occur in northern Oregon/Washington waters are shown in Figure 1. This report considers only the Washington Inland Waters stock. Stock assessment reports for Northern Oregon/Washington Coast, Northern California/Southern Oregon, San Francisco-Russian River, Monterey Bay, and Morro Bay harbor porpoise also appear in this volume. Stock assessment reports for the three harbor porpoise stocks in the inland and coastal waters of Alaska, including 1) the Southeast Alaska stock, 2) the Gulf of Alaska stock, and 3) the Bering Sea stock, are reported separately in the Stock Assessment Reports for the Alaska Region. The harbor porpoise occurring in British Columbia have not been included in any of the U.S. stock assessment reports.

POPULATION SIZE

Aerial surveys of the inside waters of Washington and southern British Columbia were conducted from 2013 to 2015 (Smultea *et al.* 2015a, 2015b). These aerial surveys included the Strait of Juan de Fuca, San Juan Islands, Gulf Islands, Strait of Georgia, Puget Sound, and Hood Canal. These are the waters inhabited by the Washington Inland Waters stock of harbor porpoise as well as harbor porpoise from British Columbia. Harbor porpoise abundance estimates were corrected for trackline animals missed by aerial observers using $g(0)$ from prior studies in the same area and using similar methods (Laake *et al*. 1997). For U.S. waters, the current estimate of abundance is 11,233 porpoise (CV=0.37) (Smultea *et al*. 2015a).

Minimum Population Estimate

The minimum population estimate for the Washington Inland Waters stock of harbor porpoise is calculated as the lower 20th percentile of the log-normal distribution (Wade and Angliss 1997) of the 2015 population estimate of 11,233 harbor porpoise, or 8,308 animals.

Current Population Trend

Estimates of population size for Washington Inland waters from 1990-1991 aerial surveys were 3,298 (CV=0.26) animals, corrected for diving animals not seen by observers (Calambokidis *et al.* 1993). Estimates of harbor porpoise abundance for the same region from 2013-2015 surveys (11,233; CV=0.37, Smultea *et al.* 2015a), are considerably higher, however a formal trend analysis has not been performed for this stock.

In southern Puget Sound, harbor porpoise were common in the 1940s (Scheffer and Slipp 1948), but marine mammal surveys (Everitt et al. 1980), stranding records since the early 1970s (Osmek et al. 1995), and harbor porpoise surveys in 1991 (Calambokidis et al. 1992) and 1994 (Osmek et al. 1995) indicated that harbor porpoise abundance had declined in southern Puget Sound. In 1994, a total of 769 km of vessel survey effort and 492 km of aerial survey effort conducted during favorable sighting conditions produced no sightings of harbor porpoise in southern Puget Sound. Reasons for the apparent decline are unknown, but it may have been related to fishery interactions, pollutants, vessel traffic, or other factors (Osmek et al. 1995). Annual winter aerial surveys conducted by the Washington Department of Fish and Wildlife from 1995 to 2015 revealed an increasing trend in harbor porpoise in Washington inland waters, including the return of harbor porpoise to Puget Sound. The data suggest that harbor porpoise were already present in Juan de Fuca, Georgia Straits, and the San Juan Islands from the mid-1990s to mid-2000s, and then expanded into Puget Sound and Hood Canal from the mid-2000s to 2015, areas they had used historically but abandoned. Changes in fishery-related entanglement was suspected as the cause of their previous decline and more recent recovery, including a return to Puget Sound (Evenson *et al*. 2016). Seasonal surveys conducted in spring, summer, and fall 2013-2015 in Puget Sound and Hood Canal documented substantial numbers of harbor porpoise in Puget Sound. Observed porpoise numbers were twice as high in spring as in fall or summer, indicating a seasonal shift in distribution of harbor porpoise (Smultea 2015b). The reasons for the seasonal shift and for the increase in sightings is unknown.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

A reliable estimate of the maximum net productivity rate is not available for harbor porpoise. Therefore, until additional data become available, it is recommended that the cetacean maximum theoretical net productivity rate (R_{MAX}) of 4% (Wade and Angliss 1997) be employed for the Washington Inland Waters harbor porpoise stock.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) for this stock is calculated as the minimum population size (8,308) times one-half the default maximum net growth rate for cetaceans (1/2 of 4%) times a recovery factor of 0.4 (for a stock of unknown status and high uncertainty in the mortality and injury estimate), resulting in a PBR of 66 harbor porpoise per year. Although no CV is available for the mortality and serious injury estimate, there is large uncertainty because the available data are limited to stranding information, which is known to have a substantial downward bias (Carretta *et al*. 2016a, Williams *et al.* 2014). For this reason, the recovery factor was set equal to the value for a stock of unknown status with mortality and serious injury CV > 0.80 (Wade and Angliss 1997).

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Fishing effort in the northern Washington marine gillnet tribal fishery is conducted within the range of both harbor porpoise stocks (Northern Oregon/Washington Coast and Washington Inland Waters) occurring in Washington State waters (Gearin et al. 1994). Some movement of harbor porpoise between Washington's coastal and inland waters is likely, but it is currently not possible to quantify the extent of such movements. For the purposes of this stock assessment report, animals taken in waters east of Cape Flattery, WA, are assumed to have belonged to the Washington Inland Waters stock. Between 2010 and 2014, no harbor porpoise deaths or serious injuries were reported in this fishery (Makah Fisheries Management, unpublished data).

Table 1. Summary of incidental mortality and serious injury of harbor porpoise (Washington Inland Waters stock) in commercial and tribal fisheries that might take this species and calculation of the mean annual mortality rate; n/a indicates that data are not available. Mean annual takes are based on 2010-2014 data unless noted otherwise.

Fishery name	Years	Data type	Percent observer coverage	Observed mortality	Estimated mortality	Mean annual takes (CV in parentheses)
WA Puget Sound Region salmon set/drift gillnet (observer programs listed below covered segments of this fishery):						
Puget Sound non-treaty salmon gillnet (all areas and species)	1993	observer data	1.3%	0	0	see text[1]
Puget Sound non-treaty chum salmon gillnet (areas 10/11 and 12/12B)	1994	observer data	11%	0	0	see text[1]
Puget Sound treaty chum salmon gillnet (areas 12, 12B, and 12C)	1994	observer data	2.2%	0	0	see text[1]
Puget Sound treaty chum and sockeye salmon gillnet (areas 4B, 5, and 6C)	1994	observer data	7.5%	0	0	see text[1]
Puget Sound treaty and non-treaty sockeye salmon gillnet (areas 7 and 7A)	1994	observer data	7%	1	15	see text[1]
Unknown Puget Sound Region fishery	2010-2014	stranding data		2, 0, 7, 1, 2	n/a	$\geq$ 2.4 (n/a)
Minimum total annual takes						$\geq$2.4 (n/a)

[1]This fishery has not been observed since 1994 (see text); these data are not included in the calculation of recent minimum total annual takes.

Commercial salmon drift gillnet fisheries in Washington inland waters were last observed in 1993 and 1994, with observer coverage levels typically <10% (Pierce et al. 1994, 1996; NWIFC 1995; Erstad et al. 1996). Drift gillnet fishing effort in the inland waters has declined considerably since 1994 because far fewer vessels participate today (NMFS WC Region, unpublished data), but entanglements of harbor porpoise likely continue to occur. The most recent data on harbor porpoise mortality from commercial gillnet fisheries is included in Table 1.

Strandings of dead or seriously injured harbor porpoise entangled in fishing gear are another source of fishery-related mortality. There were 12 fishery-related strandings of harbor porpoise from this stock in 2010-2014 (2 in 2010, 7 in 2012, 1 in 2013, and 2 in 2014), resulting in an average annual mortality and serious injury rate of 2.4 harbor porpoise per year (Carretta *et al.* 2016b). Evidence of fishery interactions included observed entanglements, net marks, and line marks. Since these deaths could not be attributed to a particular fishery, and were the only confirmed fishery-related deaths in this area in 2010-2014, they are listed in Table 1 as occurring in an unknown Puget Sound Region fishery. There are no observed fisheries in Washington inland waters, and the estimate of human-caused mortality of harbor porpoise (2.4/yr) is based solely on stranding data, which are uncorrected for negative biases in cetacean carcass recovery (Williams *et al.* 2014). The only published carcass recovery rate for harbor porpoise (<0.01) is from an oceanic-coast habitat in the NE United States (Moore and Read 2008), but due to the confined nature of inland waterways, recovery rates in Washington State inland waters are likely higher than that estimated by Moore and Read (2008). Wells *et al*. (2015) reported a carcass recovery rate (0.33) for bottlenose dolphins that inhabit the densely populated Sarasota Bay area. If this recovery rate of 0.33 is applied to Washington Inland Waters harbor porpoise fishery-related strandings for the period 2010-2014, annual mortality would be estimated at 7.2 (12 documented fishery-related strandings, times a correction factor of 3, divided by 5 years), which is less than the PBR of 66. In the absence of a carcass recovery correction factor for Washington inland waters harbor porpoise, a minimum correction factor of 3 from the Wells *et al*. (2015) coastal bottlenose dolphin study is applied to fishery-related strandings here, resulting in an estimate of 7.2 porpoise annually. Additional data are required to estimate a carcass recovery rate for harbor porpoise in Washington inland waters.

Although commercial gillnet fisheries in Canadian waters are known to have taken harbor porpoise in the past (Barlow et al. 1994, Stacey et al. 1997), few data are available because the fisheries were not monitored. In 2001, the Department of Fisheries and Oceans, Canada, conducted a federal fisheries observer program and a survey of license holders to estimate the incidental mortality of harbor porpoise in selected salmon fisheries in southern British Columbia (Hall et al. 2002). Based on the observed bycatch of porpoise (2 harbor porpoise deaths) in the 2001 fishing season, the estimated mortality for southern British Columbia in 2001 was 20 porpoise per 810 boat days fished or a total of 80 harbor porpoise. However, it is not known how many harbor porpoise from the Washington Inland Waters stock are currently taken in the waters of southern British Columbia.

Other Mortality

A significant increase in harbor porpoise strandings reported throughout Oregon and Washington in 2006 prompted the Working Group on Marine Mammal Unusual Mortality Events to declare an Unusual Mortality Event (UME) on 3 November 2006 (Huggins 2008). A total of 114 harbor porpoise strandings were reported and confirmed along the Oregon and Washington outer coasts and Washington inland waters in 2006 and 2007 (Huggins 2008). A more recent analysis of strandings before and after the suspected UME indicates that no UME occurred (Huggins *et al*. 2015). The perceived increase in mortality was the result of multiple factors: an increase in the population of harbor porpoise, a shift of the population into Washington inland waters, and a well-established stranding network with improved response and reporting (Huggins *et al*. 2015).

STATUS OF STOCK

Harbor porpoise are not listed as "depleted" under the MMPA or listed as "threatened" or "endangered" under the Endangered Species Act. Based on currently available data, the minimum annual level of total human-caused mortality and serious injury (7.2) harbor porpoise per year (corrected for undetected strandings) does not exceed the PBR of 66 animals. Therefore, the Washington Inland Waters harbor porpoise stock is not classified as "strategic." The minimum annual fishery mortality and serious injury for this stock (7.2 harbor porpoise per year) exceeds 10% of PBR (6.6) and, therefore, cannot be considered to be insignificant and approaching zero mortality and serious injury rate. The status of this stock relative to its Optimum Sustainable Population (OSP) and population trends is unknown. Although harbor porpoise sightings in southern Puget Sound declined from the 1940s through the 1990s, harbor porpoise sightings have increased seasonally in this area in the last 10 years.

This stock is not recognized as "strategic," however, the current mortality rate is based on stranding data, since the Washington Puget Sound Region salmon set/drift gillnet fishery has not been observed since 1994.

Evaluation of the estimated take level is complicated by a lack of knowledge about the extent to which harbor porpoise from U.S. waters frequent the waters of British Columbia and are, therefore, subject to fishery-related mortality. It is appropriate to consider whether the current take level is different from the take level in 1994, when the fishery was last observed. No new information is available about mortality per set, but 1) fishing effort has decreased since 1994. Based on surveys conducted in between 1991/1992 and 2015 (Calambokidis *et al.* 1993, Smultea *et al.* 2015a, 2015b), the population appears to have increased, but a statistical trend analysis has not been performed with existing data. However, an increase in harbor porpoise use of southern Puget Sound in recent years is apparent (Evenson *et al*. 2016).

DALL'S PORPOISE (*Phocoenoides dalli dalli*): California/Oregon/Washington Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Dall's porpoises are endemic to temperate waters of the North Pacific Ocean. Off the U.S. west coast, they are commonly seen in shelf, slope and offshore waters (Figure 1; Morejohn 1979). Sighting patterns from aerial and shipboard surveys conducted in California, Oregon and Washington (Green et al. 1992, 1993; Forney and Barlow 1998; Barlow 2016) suggest that north-south movement between these states occurs as oceanographic conditions change, both on seasonal and inter-annual time scales. The southern end of this population's range is not well-documented, but they are commonly seen off Southern California in winter, and during cold-water periods they probably range into Mexican waters off northern Baja California. The stock structure of eastern North Pacific Dall's porpoises is not known, but based on patterns of stock differentiation in the western North Pacific, where they have been more intensively studied, it is expected that separate stocks will emerge when data become available (Perrin and Brownell 1994). Although Dall's porpoises are not restricted to U.S. territorial waters, there are no cooperative management agreements with Mexico or Canada for fisheries which may take this species (e.g. gillnet fisheries). For the Marine Mammal Protection Act (MMPA) stock assessment reports, Dall's porpoises within the Pacific U.S. Exclusive Economic Zone are divided into two discrete, non-contiguous areas: 1) waters off California, Oregon and Washington (this report), and 2) Alaskan waters.

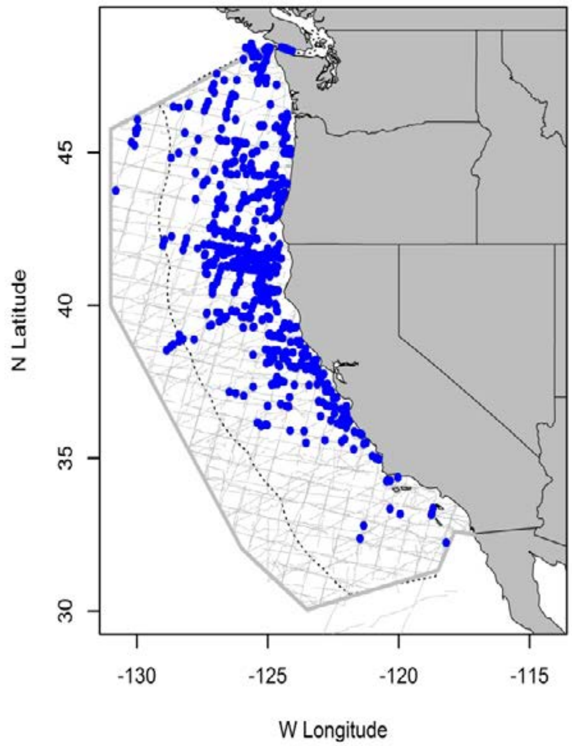

Figure 1. Dall's porpoise sightings based on shipboard surveys off California, Oregon, and Washington, 1991-2014 (Barlow 2016). Dashed line represents the U.S. EEZ, thin gray lines represent the completed transect effort of all surveys combined.

POPULATION SIZE

Dall's porpoise distribution in this region is highly variable between years and appears to be affected by oceanographic conditions (Forney 1997; Forney and Barlow 1998, Barlow 2016). Because animals may spend time outside the U.S. Exclusive Economic Zone as oceanographic conditions change, a multi-year average abundance estimate is the most appropriate for management within U.S. waters. The most recent estimate of Dall's porpoise abundance is the geometric mean of estimates from 2008 and 2014 summer/autumn vessel-based line-transect surveys of California, Oregon, and Washington waters, or 25,750 (CV=0.45) animals (Barlow 2016). This estimate includes new correction factors for animals missed during the surveys. Additional numbers of Dall's porpoises occur in the inland waters of Washington state, but the most recent abundance estimate obtained in 1996 (900 animals, CV=0.40) is over 8 years old (Calambokidis et al. 1997) and is not included in the overall estimate of abundance for this stock.

Minimum Population Estimate

The log-normal 20th percentile of the 2008-2014 average abundance estimate for the outer coast of California, Oregon and Washington waters is 17,954 Dall's porpoises.

Current Population Trend

The distribution and abundance of Dall's porpoise off California, Oregon and Washington varies considerably at both seasonal and interannual time scales (Forney and Barlow 1998, Becker *et al*. 2012, Barlow 2016), but no longterm trends have been identified.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

No information on current or maximum net productivity rates is available for Dall's porpoise off the U.S. west coast.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (17,954) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.48 (for a species of unknown status and mortality rate CV between 0.3 and 0.6; Wade and Angliss 1997), resulting in a PBR of 172 Dall's porpoises per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fishery Information

A summary of recent fishery mortality and injury information for this stock of Dall's porpoises is given in Table 1. More detailed information on these fisheries is provided in Appendix 1. The estimate of mortality and serious injury for Dall's porpoise in the California drift gillnet fishery for the five most recent years of monitoring, 2010-2014, averages 0.3 animals per year (Carretta *et al*. 2017). Although Dall's porpoises have been incidentally killed in West Coast groundfish fisheries in the past, no takes of this species were observed during the five most recent years for which data are available, 2009-2013 (Jannot et al. 2011; NWFSC unpublished data). Gillnets have been documented to entangle marine mammals off Baja California (Sosa-Nishizaki et al. 1993), where Dall's porpoise may occasionally be found, but no recent bycatch data from Mexico are available.

Table 1. Summary of available information on the incidental mortality and serious injury of Dall's porpoises (California/ Oregon/Washington Stock) in commercial fisheries that might take this species (Carretta *et al*. 2017; Jannot *et al*. 2011). All observed entanglements of Dall's porpoises resulted in the death of the animal. Coefficients of variation for mortality estimates are provided in parentheses; n/a = not available. Mean annual takes are based on 2010-2014 data for the CA/OR swordfish drift gillnet fishery and 2005-2009 for groundfish fisheries.

Fishery Name	Data Type	Year(s)	Percent Observer Coverage	Observed Mortality	Estimated Annual Mortality (CV)	Mean Annual Takes (CV)
CA/OR thresher shark/swordfish drift gillnet fishery	observer	2010 2011 2012 2013 2014	12% 20% 19% 37% 24%	0 0 0 0 1	0 0 0 0.2 (2.3) 1.1 (0.29)	0.3 (0.53)
WA/OR/CA groundfish (bottom trawl)[a]	observer	2009-2013	23% (2009) 18% (2010) 100% (2011-2013)	0	0	0

WA/OR/CA groundfish (midwater trawl - at-sea hake sector)	observer	2009-2013	100%	0	0	0
WA/OR/CA groundfish (midwater trawl - shoreside hake sector)[b]	observer	2011-2013	100%	0	0	0
Minimum total annual takes						0.3 (0.53)

[a]The bottom trawl fishery was a limited entry fishery in 2010 and a catch shares fishery in 2011-2013.
[b]Fishery observers began monitoring the shoreside hake sector of the fishery in 2011.

STATUS OF STOCK

The status of Dall's porpoises in California, Oregon and Washington relative to OSP is not known, and there are insufficient data to evaluate potential trends in abundance. No habitat issues are known to be of concern for this species. It is not listed as "threatened" or "endangered" under the Endangered Species Act nor as "depleted" under the MMPA. The average annual human-caused mortality of Dall's porpoise (0.3 animals) is estimated to be less than the PBR (172), and they are not classified as a "strategic" stock under the MMPA. The total fishery mortality and serious injury for this stock is less than 10% of the calculated PBR and, therefore, can be considered to be insignificant and approaching zero mortality and serious injury rate.

PACIFIC WHITE-SIDED DOLPHIN (*Lagenorhynchus obliquidens*): California/Oregon/Washington, Northern and Southern Stocks

STOCK DEFINITION AND GEOGRAPHIC RANGE

Pacific white-sided dolphins are endemic to temperate waters of the North Pacific Ocean, and common both on the high seas and along the continental margins (Brownell et al. 1999). Off the U.S. west coast, Pacific white-sided dolphins occur primarily in shelf and slope waters (Figure 1). Sighting patterns from aerial and shipboard surveys conducted in California, Oregon and Washington (Green et al. 1992; 1993; Forney and Barlow 1998; Barlow 2016) suggest seasonal north-south movements, with animals found primarily off California during the colder water months and shifting northward into Oregon and Washington as water temperatures increase in late spring and summer.

Stock structure throughout the North Pacific is poorly understood, but based on morphological evidence, two forms are known off the California coast (Walker et al. 1986). Specimens belonging to the northern form were collected from north of about 33ºN, (Southern California to Alaska), and southern specimens were obtained from about 36ºN southward along the coasts of California and Baja California. Samples of both forms have been collected in the Southern California Bight, but it is unclear whether this indicates sympatry in this region or whether they may occur there at different times (seasonally or interannually). Genetic analyses have confirmed the distinctness of animals found off Baja California from animals occurring in U.S. waters north of Point Conception, California and the high seas of the North Pacific (Lux et al. 1997). Based on these genetic data, an area of mixing between the two forms appears to be located off Southern California (Lux et al. 1997). Two types of echolocation have been documented for Pacific white-sided dolphins off Southern California and these have been hypothesized to reflect acoustic differences between the two forms (Soldevilla et al. 2008, 2011; Henderson et al. 2011).

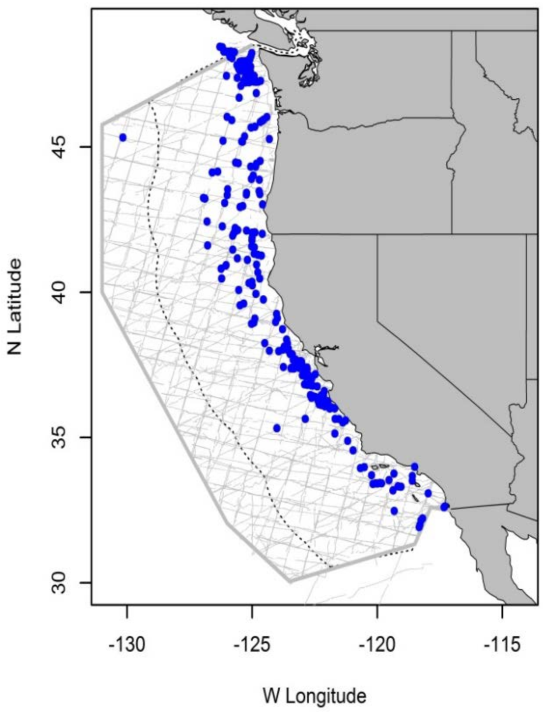

Figure 1. Pacific white-sided dolphin sightings based on shipboard surveys off California, Oregon, and Washington, 1991-2014 (Barlow 2016). Dashed line represents the U.S. EEZ, thin gray lines indicate completed transect effort of all surveys combined.

Although there is clear evidence that two forms of Pacific white-sided dolphins occur along the U.S. west coast, there are no known differences in color pattern, and it is not currently possible to distinguish the two stocks reliably during surveys. Geographic stock boundaries appear dynamic and are poorly understood, and therefore cannot be used to differentiate the two forms. Until means of differentiating the two forms for abundance and mortality estimation are developed, these two stocks are managed as a single unit. Pacific white-sided dolphins are not restricted to U.S. territorial waters, but there are no cooperative management agreements with Mexico or Canada for fisheries which may take this species (e.g. gillnet fisheries). For the Marine Mammal Protection Act (MMPA) stock assessment reports, Pacific white-sided dolphins within the Pacific U.S. Exclusive Economic Zone are divided into two discrete, non-contiguous areas: 1) waters off California, Oregon and Washington (this report), and 2) Alaskan waters.

POPULATION SIZE

The distribution of Pacific white-sided dolphins throughout this region is highly variable, apparently in response to oceanographic changes on both seasonal and interannual time scales (Forney and Barlow 1998, Barlow 2016). As oceanographic conditions vary, Pacific white-sided dolphins may spend time outside the U.S. Exclusive Economic Zone, and therefore a multi-year average abundance estimate including California, Oregon and Washington is the most appropriate for management within U.S. waters. The most recent estimate of Pacific white-sided dolphin abundance is the geometric mean of estimates from 2008 and 2014 summer/autumn vessel-based line-transect surveys of California, Oregon, and Washington waters, 26,814 (CV=0.28) animals (Barlow 2016). This estimate includes new correction factors for animals missed during the surveys.

Minimum Population Estimate

The log-normal 20th percentile of the 2008-2014 average abundance estimate is 21,195 Pacific white-sided dolphins.

Current Population Trend

The distribution and abundance of Pacific white-sided dolphins off California, Oregon and Washington varies considerably at both seasonal and interannual time scales (Forney and Barlow 1998, Becker et al. 2012, Barlow 2016), but no long-term trends have been identified.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

No information on current or maximum net productivity rates is available for Pacific white-sided dolphins off the U.S. west coast.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (21,195) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.45 (for a species of unknown status with a mortality rate CV between 0.6 and 0.8; Wade and Angliss 1997), resulting in a PBR of 191 Pacific white-sided dolphins per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fishery Information

A summary of recent fishery mortality and injury information for this stock of Pacific white-sided dolphin is shown in Table 1. More detailed information on these fisheries is provided in Appendix 1. The estimate of mortality and serious injury for Pacific white-sided dolphin in the California drift gillnet fishery for the five most recent years of monitoring, 2010-2014, is 1.1 animals (CV=0.97) per year (Carretta *et al*. 2017). Although some Pacific-white sided dolphins have been incidentally killed in West Coast groundfish fisheries in the past, no takes of this species were observed during 2009-2013 (Jannot et al. 2011, NWFSC unpublished data). Gillnets have been documented to entangle marine mammals off Baja California (Sosa-Nishizaki et al. 1993), but no recent bycatch data from Mexico are available.

Table 1. Summary of available information on the incidental mortality and injury of Pacific white-sided dolphins (California/ Oregon/Washington Stock) in commercial fisheries that might take this species (Carretta *et al*. 2017; Jannot *et al*. 2011). All observed entanglements of Pacific white-sided dolphins resulted in the death of the animal. Coefficients of variation for mortality estimates are provided in parentheses; n/a = not available. Mean annual takes are based on 2010-2014 data unless noted otherwise.

Fishery Name	Data Type	Year(s)	Percent Observer Coverage	Observed Mortality	Estimated Annual Mortality	Mean Annual Takes (CV in parentheses)
CA/OR thresher shark/swordfish drift gillnet fishery	observer	2010	12%	0	1.3 (2.5)	1.1 (0.97)
		2011	20%	0	1.4 (2)	
		2012	19%	0	0.8 (2.2)	
		2013	37%	0	0.9 (1.5)	
		2014	24%	0	0.9 (2)	

Fishery Name	Data Type	Year(s)	Percent Observer Coverage	Observed Mortality	Estimated Annual Mortality	Mean Annual Takes (CV in parentheses)
WA/OR/CA groundfish (bottom trawl)	observer	2009-2013	23% (2009) 18% (2010) 100% (2011-2013)	0	0	0
WA/OR/CA groundfish (midwater trawl - at-sea hake sector)	observer	2009-2013	100%	0	0	0
WA/OR/CA groundfish (midwater trawl - shoreside hake sector)	observer	2011-2013	100%	0	0	0
Minimum total annual takes						1.1 (0.97)

Other removals

Pacific white-sided dolphins have been seriously injured and killed in scientific research trawls for sardines and rockfish. From 2010 through 2014, there were 26 deaths and 2 serious injuries of Pacific white-sided dolphins in scientific research trawls, or an average of 5.6 annually (Carretta *et al*. 2016a). One Pacific white-sided dolphin stranded dead in Washington Inland waters during 2014, and the cause of death was determined to be a vessel strike (Carretta *et al*. 2016a). Human-caused mortality and injury documentation is often based on stranding data, where raw counts are negatively-biased because only a fraction of carcasses are detected. Carretta et al. (2016b) estimated the mean recovery rate of California coastal bottlenose dolphin carcasses to be 25% (95% CI 20% - 33%) and stated that given the extremely coastal habits of coastal bottlenose dolphins, carcass recovery rates for this stock represented a maximum, compared with more pelagic dolphin species in the region. Therefore, in this stock assessment report and others involving dolphins along the U.S. West Coast, human-related deaths and injuries counted from beach strandings along the outer U.S. West Coast are multiplied by a factor of 4 to account for the non-detection of most carcasses (Carretta et al. 2016b). Applying this correction factor to the one stranded Pacific white-sided dolphin yields a minimum estimate of 4 vessel strike-related deaths during 2010-2014, or 0.8 animals annually. The average annual mortality and serious injury of Pacific white-sided dolphin from other anthropogenic activities during 2010-2014 is 5.6 (research takes), plus 0.8 animals (vessel strikes, corrected for undetected carcasses), or 6.4 animals per year.

STATUS OF STOCK

The status of Pacific white-sided dolphins in California, Oregon and Washington relative to OSP is not known, and there is no indication of a trend in abundance for this stock. No habitat issues are known to be of concern for this species. They are not listed as "threatened" or "endangered" under the Endangered Species Act nor as "depleted" under the MMPA. The average annual human-caused mortality and serious injury from fisheries (1.1 animals), plus other anthropogenic sources (6.4) during 2010-2014 7.5 is estimated to be less than the PBR (191), and therefore this stock of Pacific white-sided dolphins is not classified as a "strategic" stock under the MMPA. The total commercial fishery mortality and serious injury for this stock (1.1/yr) is less than 10% of the calculated PBR and, therefore, is considered to be insignificant and approaching zero.

RISSO'S DOLPHIN (*Grampus griseus*): California/Oregon/Washington Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Risso's dolphins are distributed world-wide in tropical and warm-temperate waters. Off the U.S. West coast, Risso's dolphins are commonly seen on the shelf in the Southern California Bight and in slope and offshore waters of California, Oregon and Washington. Based on sighting patterns from recent aerial and shipboard surveys conducted in these three states during different seasons (Figure 1), animals found off California during the colder water months are thought to shift northward into Oregon and Washington as water temperatures increase in late spring and summer (Green et al. 1992, 1993). The southern end of this population's range is not well-documented, but previous surveys have shown a conspicuous 500 nmi distributional gap between these animals and Risso's dolphins sighted south of Baja California and in the Gulf of California (Mangels and Gerrodette 1994). Thus this population appears distinct from animals found in the eastern tropical Pacific and the Gulf of California. Although Risso's dolphins are not restricted to U.S. waters, cooperative management agreements with Mexico exist only for the tuna purse seine fishery and not for other fisheries which may take this species (e.g. gillnet fisheries). For the Marine Mammal Protection Act (MMPA) stock assessment reports, Risso's dolphins within the Pacific U.S. Exclusive Economic Zone are divided into two discrete, non-contiguous areas: 1) waters off California, Oregon and Washington (this report), and 2) Hawaiian waters.

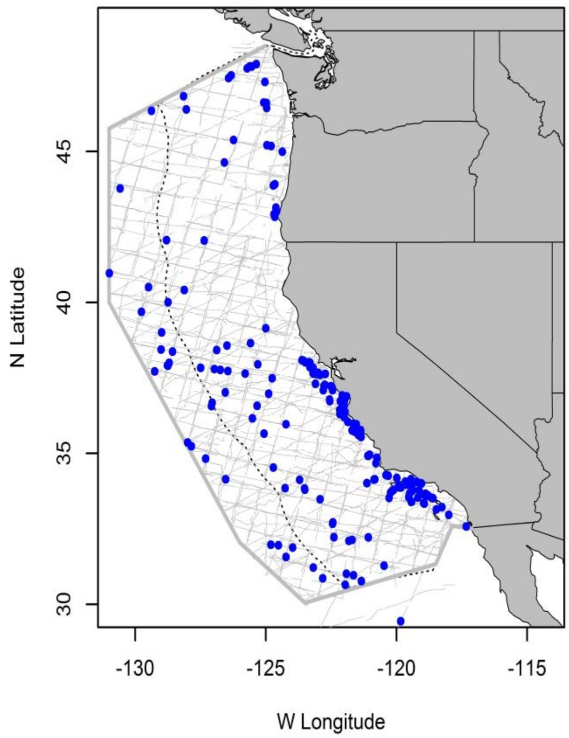

Figure 1. Risso’s dolphin sightings based on shipboard surveys off California, Oregon, and Washington, 1991-2014 (Barlow 2016). Dashed line represents the U.S. EEZ, thin gray lines indicate completed transect effort of all surveys combined.

POPULATION SIZE

The distribution of Risso’s dolphins throughout this region is highly variable, apparently in response to oceanographic changes on both seasonal and interannual time scales (Forney and Barlow 1998). As oceanographic conditions vary, Risso’s dolphins may spend time outside the U.S. Exclusive Economic Zone, and therefore a multi-year average abundance estimate is the most appropriate for management within U.S. waters. The most recent estimate of Risso’s dolphin abundance is the geometric mean of estimates from 2008 and 2014 summer/autumn vessel-based line-transect surveys of California, Oregon, and Washington waters, 6,336 (CV=0.32) animals (Barlow 2016). This estimate includes new correction factors for animals missed during the surveys.

Minimum Population Estimate

The log-normal 20th percentile of the 2008-2014 geometric mean abundance estimate is 4,817 Risso's dolphins.

Current Population Trend

The distribution and abundance of Risso's dolphins off California, Oregon and Washington varies considerably at both seasonal and interannual time scales (Forney and Barlow 1998, Becker *et al*. 2012, Barlow 2016), but no long-term trends have been identified.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

No information on current or maximum net productivity rates is available for this stock.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (4,817) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.48 (for a species of unknown status with a mortality rate CV between 0.3 and 0.6; Wade and Angliss 1997), resulting in a PBR of 46 Risso's dolphins per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fishery Information

A summary of recent fishery mortality and injury information for this stock of Risso's dolphin is shown in Table 1. More detailed information on these fisheries is provided in Appendix 1. The estimate of mortality and serious injury for Risso's dolphin in the California drift gillnet fishery for the five most recent years of monitoring, 2010-2014, is an average of 1.3 per year (Carretta *et al*. 2017, Table 1). Although some Risso's dolphins have been incidentally killed in West Coast groundfish fisheries in the past, no takes of this species were observed during 2009-2013 (Jannot *et al*. 2011, NWFSC unpublished data). Gillnets have been documented to entangle marine mammals off Baja California (Sosa-Nishizaki *et al*. 1993), but no recent bycatch data from Mexico are available.

Historically, Risso's dolphin mortality has been documented in the squid purse seine fishery off Southern California (Heyning et al. 1994). This mortality probably represented animals killed intentionally to protect catch or gear, rather than incidental mortality, and such intentional takes are now illegal under the 1994 Amendment to the MMPA. This fishery has expanded markedly since 1992 (California Department of Fish and Game, unpubl. data). An observer program in the squid purse seine fishery from 2004-2008 observed 377 sets (<10%) without an observed Risso's dolphin interaction.

Human-caused mortality and injury documentation is often based on stranding data, where raw counts are negatively-biased because only a fraction of carcasses are detected (Carretta *et al*. 2016a). Carretta *et al.* (2016b) estimated the mean recovery rate of California coastal bottlenose dolphin carcasses to be 25% (95% CI 20% - 33%) and stated that given the extremely coastal habits of coastal bottlenose dolphins, carcass recovery rates for this stock represented a maximum, compared with more pelagic dolphin species in the region. Therefore, in this stock assessment report and others involving dolphins along the U.S. West Coast, human-related deaths and injuries counted from beach strandings along the outer U.S. West Coast are multiplied by a factor of 4 to account for the non-detection of most carcasses (Carretta *et al*. 2016b). Three Risso's dolphins stranded during 2010-2014 with evidence of fishery interaction (Carretta *et al*. 2016a), yielding a minimum estimate of 12 fishery-related dolphin deaths.

Table 1. Summary of available information on the incidental mortality and serious injury of Risso's dolphin (California/ Oregon/Washington Stock) in commercial fisheries that might take this species (Carretta *et al*. 2016b, 2017; Jannot *et al*. 2011; NWFSC, unpublished data). All observed entanglements of Risso's dolphins resulted in the death of the animal. Human-caused mortality values based on strandings recovered along the outer U.S. West Coast are multiplied by a correction factor of 4 to account for undetected mortality (Carretta *et al*. 2016a). Coefficients of variation for mortality estimates are provided in parentheses; n/a = not available.

Fishery Name	Data Type	Year(s)	Percent Observer Coverage	Observed Mortality	Estimated AnnualMortality (CV)	Mean Annual Takes (CV)
CA/OR thresher shark/swordfish drift gillnet fishery	observer	2010	12%	0	1.5 (2.5)	1.3 (0.93)
		2011	20%	1	2.8 (1.3)	
		2012	19%	0	0.8 (2.8)	
		2013	37%	0	0.9 (1.9)	
		2014	24%	0	0.7 (2.8)	

Fishery Name	Data Type	Year(s)	Percent Observer Coverage	Observed Mortality	Estimated AnnualMortality (CV)	Mean Annual Takes (CV)
CA deep set longline fishery	observer	2005-2008	100%	0	0	0
Market squid purse seine	observer	2004-2008	<10%	0	0	0
Unknown fishery	Stranding	2007-2013	n/a	3	≥ 12	≥2.4 (0.46)[1]
WA/OR/CA groundfish (bottom trawl)[a]	observer	2009-2013	23% (2009) 18% (2010) 100% (2011-2013)	0	0	0
Minimum total annual takes (includes correction for unobserved beach strandings)						≥ 3.7 (0.44)

STATUS OF STOCK

The status of Risso's dolphins off California, Oregon and Washington relative to OSP is not known, and there are insufficient data to evaluate potential trends in abundance. No habitat issues are known to be of concern for this species. They are not listed as "threatened" or "endangered" under the Endangered Species Act nor as "depleted" under the MMPA. Over the last 5-year period (2010-2014), the average annual human-caused mortality (3.7 animals) is estimated to be less than the PBR (46), and therefore they are not classified as a "strategic" stock under the MMPA. The total fishery mortality and serious injury for this stock (3.7) is less than 10% of the calculated PBR and, therefore, can be considered to be insignificant and approaching zero mortality and serious injury rate.

Revised 2/9/2017

COMMON BOTTLENOSE DOLPHIN (*Tursiops truncatus*): California Coastal Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Bottlenose dolphins are distributed world-wide in tropical and warm-temperate waters. In many regions, including California, separate coastal and offshore populations are known (Walker 1981; Ross and Cockcroft 1990; Van Waerebeek et al. 1990). The California coastal stock of bottlenose dolphins is distinct from the offshore stock, based on significant differences in genetics and cranial morphology (Perrin et al. 2011, Lowther-Thielking *et al*. 2015). Of 56 haplotypes found among coastal and offshore bottlenose dolphins in the region, only one is shared by both populations (Perrin et al. 2011). California coastal bottlenose dolphins are found within about one kilometer of shore (Hansen, 1990; Carretta et al. 1998; Defran and Weller 1999) from central California south into Mexican waters, at least as far south as San Quintin, Mexico (Figure 1). In southern California, animals are found within 500 m of the shoreline 99% of the time and within 250 m 90% of the time (Hanson and Defran 1993). Oceanographic events appear to influence the distribution of animals along the coasts of California and Baja California, Mexico, as indicated by a change in residency patterns along Southern California and a northward range extension into central California after the 1982-83 El Niño (Hansen and Defran 1990; Wells et al. 1990). Since the 1982-83 El Niño, which increased water temperatures off California, they have been consistently sighted in central California as far north as San Francisco. Photo-identification studies have documented north-south movements of coastal bottlenose dolphins (Hansen 1990; Defran et al. 1999), and monthly counts based on surveys between the U.S./Mexican border and Point Conception are variable (Carretta et al. 1998), indicating that animals are moving into and out of this area. There is little site fidelity of coastal bottlenose dolphins along the California coast; over 80% of the dolphins identified in Santa Barbara, Monterey, and Ensenada have also been identified off San Diego (Defran et al. 1999, Feinholz 1996, Defran *et al.* 2015). The area between Ensenada and San Quintin, Mexico may represent a southern boundary for the California coastal population, as very low rates of photo-ID overlap of individuals (3%) have been found between the two areas, compared to higher overlap rates to the north (Defran *et al.* 2015, Figure 1). Although coastal bottlenose dolphins are not restricted to U.S. waters, cooperative management agreements with Mexico exist only for the tuna purse seine fishery and not for other fisheries which may take this species. Therefore, the management stock includes only animals found within U.S. waters. For the Marine Mammal Protection Act (MMPA) stock assessment reports, bottlenose dolphins within the Pacific U.S. Exclusive Economic Zone are divided into seven stocks: 1) California coastal stock (this report), 2) California, Oregon and Washington offshore stock, and five stocks in Hawaiian waters: 3) Kauai/Niihau, 4) Oahu, 5) 4-Islands (Molokai, Lanai, Maui, Kahoolawe), 6) Hawaii Island and 7) the Hawaiian Pelagic Stock.

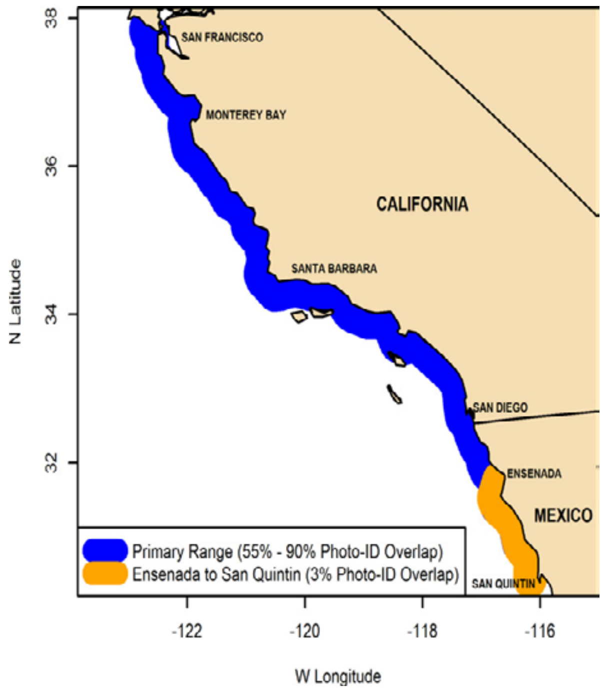

Figure 1. Approximate range of California coastal bottlenose dolphins, based on aerial and boat-based sighting surveys. This population of bottlenose dolphins is found within about 1 km of shore.

POPULATION SIZE

Based on photographic mark-recapture surveys conducted along the San Diego coast from 2009 to 2011 (Weller *et al*. 2016), two separate population size estimates were generated from open and closed mark-recapture models. The best open model generated an estimate of 515 (95% CI = 470–564, CV= 0.05) animals, while the best closed model produced an estimate of 453 (95% CI = 411–524, CV=0.06) animals. These estimates are for *marked animals only* and do not include an estimated ~ 40% of animals that are not individually recognizable (Weller *et al.* 2016). The estimated fraction of unmarked animals is highly uncertain because it is unknown how often unmarked animals are resighted. The new estimates are the largest obtained for this stock, dating back to the 1980s (Defran and Weller 1999, Dudzik 1999, Dudzik *et al.* 2006). For comparison with previous estimates of this stock, the closed population estimate of 453 (CV=0.06) animals is used as the best estimate of abundance.

Minimum Population Estimate

The minimum population size is based on the minimum number of individually identifiable animals documented during surveys in 2009-2011, or 346 animals (Weller *et al.* 2016). This number of individually recognizable dolphins exceeds the number recorded in previous survey periods: 1984-1986 (160 dolphins); 1987-1989 (284); 1996-1998 (260); and 2004-2005 (164) (Weller *et al.* 2016).

Current Population Trend

Based on a comparison of mark-recapture abundance estimates for the periods 1987-89 ($\hat{N}$= 354), 1996-98 ($\hat{N}$= 356), and 2004-05 ($\hat{N}$= 323), Dudzik et al. (2006) stated that the population size had remained stable over this period. New estimates of 450 – 515 animals based on 2009-2011 surveys are the highest to date and include a high proportion (~75%) of previously uncatalogued dolphins (Weller *et al.* 2016). The number of individually-identifiable animals from 2009-2011 surveys (346) is equal to or exceeds previous mark-recapture *abundance estimates* for this stock. This suggests that the population may be growing, although the movement of dolphins north from Mexican waters may also contribute to the observed increase in unique individuals.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

No information on current or maximum net productivity rates is available for California coastal bottlenose dolphins.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (346) <u>times</u> one half the default maximum net growth rate for cetaceans (½ of 4%) <u>times</u> a recovery factor of 0.48 (for a species of unknown status with mortality rate CV ≥ 0.3 and ≤ 0.6; Wade and Angliss 1997), resulting in a PBR of 3.3 coastal bottlenose dolphins per year. Not all California coastal bottlenose dolphins are present in U.S. waters at any given moment and approximately 18% of the stock's range occurs in Mexican waters. Thus, the PBR is prorated by a minimum factor of 0.82 to account for time that animals spend outside of U.S. waters. Without additional data on the residence times of dolphins in Mexican waters, this factor cannot be improved upon. Because this stock spends some of its time outside the U.S. EEZ, the PBR allocation for U.S. waters is 3.3 x 0.82 = 2.7 dolphins per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fishery Information

Due to its exclusive use of coastal habitats, this bottlenose dolphin population is susceptible to fishery-related mortality in coastal gillnet fisheries, such as the halibut and yellowtail set gillnet fishery, which was responsible for one documented coastal bottlenose dolphin death in 2003. Observer coverage in this fishery from 2010-2014 has been 9% (806 observed sets from an estimated 8,654 sets fished), with no observations of coastal bottlenose dolphin entanglements. Between 2010 and 2014, there were two fishery-related deaths of coastal bottlenose dolphins (stock ID confirmed via genetics, Lowther-Thielking *et al.* 2015). Both animals had evidence of entanglement with rope of unknown origin. A summary of information on fishery mortality and injury for this stock of bottlenose dolphin is shown in Table 1. Coastal gillnet fisheries exist in Mexico and may take animals from this population, but no details are available.

Human-caused mortality and injury documentation is often based on stranding data, where raw counts are negatively-biased because only a fraction of carcasses are detected (Williams *et al.* 2011), even for extremely coastal species (Wells *et al.* 2015). Carretta *et al.* (2016b) estimated the mean recovery rate of carcasses of California coastal bottlenose dolphins to be 25% (95% CI 20% - 33%). Given the extremely coastal habits of California coastal bottlenose dolphins, Carretta *et al.* (2016b) argue that carcass recovery rates for this population represent a maximum rate, compared to more pelagic dolphin species in the region. Therefore, in this stock assessment report and others involving dolphins along the U.S. west coast, human-related deaths and injuries counted from beach strandings are multiplied by a factor of 4 to account for the non-detection of most carcasses (Carretta *et al*. 2016b).

Other removals

Seven coastal bottlenose dolphins were collected during the late 1950s in the vicinity of San Diego (Norris and Prescott 1961). Twenty-seven additional bottlenose dolphins were captured off California between 1966 and 1982 (Walker 1975; Reeves and Leatherwood 1984), but based on the locations of capture activities, these animals probably were offshore bottlenose dolphins (Walker 1975). No additional captures of coastal bottlenose dolphins have been documented since 1982, and no live-capture permits are currently active for this species.

In 2012, a coastal bottlenose dolphin (stock ID confirmed via genetics) was found floating under a U.S. Navy marine mammal program dolphin pen enclosure dock and was assumed to have become entangled in the net curtain (Carretta *et al.* 2016a). Another, presumed coastal bottlenose dolphin (based on proximity to shore) became entrapped and drowned in a sea otter research net in 2012. The average annual non-fishery related mortality and serious injury of coastal bottlenose dolphins from 2010-2014 is 0.4 animals (2 animals / 5 years).

Table 1. Summary of available information on the incidental mortality and serious injury of bottlenose dolphins (California Coastal Stock) in commercial fisheries that might take this species. Human-caused mortality values based on strandings recovered on the outer U.S. West Coast are multiplied by a correction factor of 4 to account for undetected mortality (Carretta *et al*. 2016b).

Fishery Name	Data Type	Year(s)	Percent Observer Coverage	Observed Mortality	Estimated Annual Mortality	Mean Annual Takes (CV in parentheses)
CA angel shark/ halibut and other species large mesh (>3.5in) set gillnet fishery	observer	2010-2014	9%	0	0	0
Unknown fishery	stranding	2010-2014	Two strandings with evidence of entanglement in rope or braided material.			≥ 0.4 x 4 (correction factor) = 1.6 (0.46)[1]
Minimum total annual takes (includes correction for unobserved beach strandings)						≥ 1.6 (0.46)

STATUS OF STOCK

The status of coastal bottlenose dolphins in California relative to OSP is not known, and there is no evidence of a trend in abundance. They are not listed as "threatened" or "endangered" under the Endangered Species Act nor as "depleted" under the MMPA. Coastal bottlenose dolphins are not classified as a "strategic" stock under the MMPA because total annual fishery (1.6) and other anthropogenic mortality (0.4) and serious injury for this stock (≥ 2.0 per year) is less than the PBR (2.7). The total human-caused mortality and serious injury for this stock is not less than 10% of the calculated PBR and, therefore, cannot be considered to be insignificant and approaching zero. Recent population size estimates of 450 to 515 marked individuals are the highest recorded to date (Weller *et al.* 2016), but it is unknown how much of this increase is due to population growth versus immigration.

Habitat Issues

Pollutant levels, especially DDT residues, found in Southern California coastal bottlenose dolphins have been found to be among the highest of any cetacean examined (O'Shea et al. 1980; Schafer et al. 1984). Although the effects of pollutants on cetaceans are not well understood, they may affect reproduction or make the animals more prone to other mortality factors (Britt and Howard 1983; O'Shea et al. 1999). This population of bottlenose dolphins may also be vulnerable to the effects of morbillivirus

[1] The coefficient of variation (CV) for corrected carcass counts was derived from the results of Carretta *et al*. (2016b), who estimated that 25% (95% CI = 20% - 33%) of all available carcasses were recovered / documented.

outbreaks, which were implicated in the 1987-88 mass mortality of bottlenose dolphins on the U.S. Atlantic coast (Lipscomb et al. 1994).

Revised 2/7/2017

COMMON BOTTLENOSE DOLPHIN (*Tursiops truncatus truncatus*): California/Oregon/Washington Offshore Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Bottlenose dolphins are distributed world-wide in tropical and warm-temperate waters. In many regions, including California, separate coastal and offshore populations are known (Walker 1981; Ross and Cockcroft 1990; Van Waerebeek et al. 1990; Lowther 2006). On surveys conducted off California, offshore bottlenose dolphins have been found at distances greater than a few kilometers from the mainland and throughout the Southern California Bight. They have also been documented in offshore waters as far north as about 41ºN (Figure 1), and they may range into Oregon and Washington waters during warm-water periods. Sighting records off California and Baja California (Lee 1993; Mangels and Gerrodette 1994) suggest that offshore bottlenose dolphins have a continuous distribution in these two regions. There is no apparent seasonality in distribution (Forney and Barlow 1998). Offshore bottlenose dolphins are not restricted to U.S. waters, but cooperative management agreements with Mexico exist only for the tuna purse seine fishery and not for other fisheries which may take this species (e.g. gillnet fisheries). Therefore, the management stock includes only animals found within U.S. waters. For the Marine Mammal Protection Act (MMPA) stock assessment reports, bottlenose dolphins within the Pacific U.S. Exclusive Economic Zone are divided into seven stocks: 1) California coastal stock, 2) California, Oregon and Washington offshore stock (this report), and five stocks in Hawaiian waters: 3) Kauai/Niihau, 4) Oahu, 5) 4-Islands (Molokai, Lanai, Maui, Kahoolawe), 6) Hawaii Island and 7) the Hawaiian Pelagic Stock.

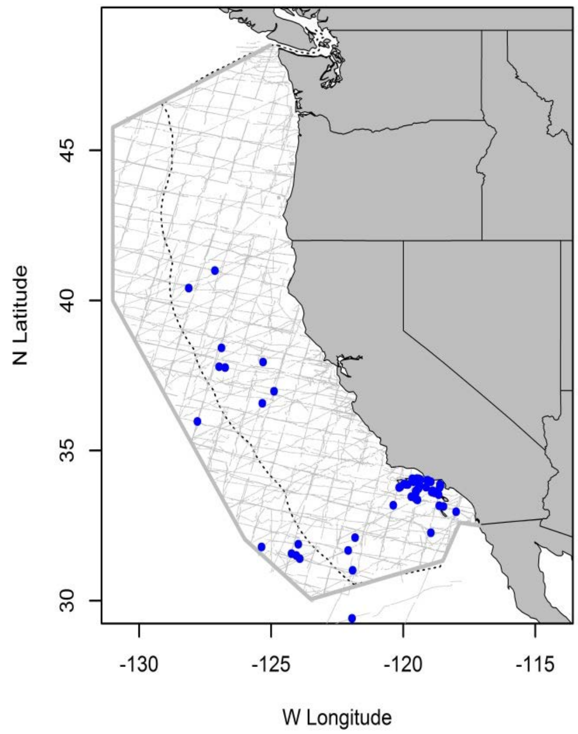

Figure 1. Offshore bottlenose dolphin sightings based on shipboard surveys off California, Oregon, and Washington, 1991-2014 (Barlow 2016). Dashed line represents the U.S. EEZ, thin gray lines indicate completed transect effort of all surveys combined.

POPULATION SIZE

The most recent estimate of bottlenose dolphin abundance is the geometric mean of estimates from 2008 and 2014 summer/autumn vessel-based line-transect surveys of California, Oregon, and Washington waters, 1,924 (CV=0.54) animals (Barlow 2016). This estimate includes new correction factors for animals missed during the surveys.

Minimum Population Estimate

The log-normal 20th percentile of the 2008-2014 geometric mean abundance estimate is 1,255 offshore bottlenose dolphins.

Current Population Trend

Trend analyses for this stock have not been performed to date, while other stocks with more urgent conservation concerns are analyzed (e.g., Moore and Barlow 2011, 2013).

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

No information on current or maximum net productivity rates is available for this population of offshore bottlenose dolphins.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (1,255) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.45 (for a species of unknown status with fishery mortality CV between 0.6 and 0.8; Wade and Angliss 1997), resulting in a PBR of 11 offshore bottlenose dolphins per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fishery Information

A summary of known fishery mortality and serious injury for this stock of bottlenose dolphin is shown in Table 1. The estimate of mortality and serious injury for bottlenose dolphin in the California drift gillnet fishery for the five most recent years of monitoring, 2010-2014, is 6.9 (CV=0.74) individuals, or an average of 1.4 per year (CV=0.74) (Carretta *et al*. 2017). One bottlenose dolphin was seriously injured in the limited entry fixed gear sablefish fishery during 2009, but no other deaths or injuries were reported in West Coast groundfish fisheries for the period 2009-2013 (Jannot *et al*. 2011). Gillnets have been documented to entangle marine mammals off Baja California (Sosa-Nishizaki *et al*. 1993), but no recent bycatch data from Mexico are available. Gillnets have been documented to entangle marine mammals off Baja California (Sosa-Nishizaki et al. 1993), but no recent bycatch data from Mexico are available.

Table 1. Summary of available information on the incidental mortality and serious injury of bottlenose dolphins (California/ Oregon/Washington Offshore Stock) in commercial fisheries that might take this species (Carretta *et al*. 2016, 2017; Jannot *et al*. 2011). Coefficients of variation for mortality estimates are provided in parentheses; n/a = not available.

Fishery Name	Data Type	Year(s)	Percent Observer Coverage	Observed Mortality (and Serious Injury)	Estimated Mortality and Serious Injury (CV)	Mean Annual Takes (CV in parentheses)
CA/OR thresher shark/swordfish drift gillnet fishery	observer	2010 2011 2012 2013 2014	12% 20% 19% 37% 24%	1 0 0 0 0	6.8 (0.75) 0.1 (7.6) 0 (n/a) 0 (n/a) 0 (n/a)	1.4 (0.74)
CA halibut / white seabass and other species set gillnet fishery	observer	2010-2014	9%	0 0 0 0	0	0
California yellowtail, barracuda, and white seabass drift gillnet fishery	observer	2010-2012	~4%	0	0	0
CA lobster trap/pot	At-sea disentanglement	2008	n/a	0 (1)	1 (n/a)	0.2 (n/a)
Limited entry fixed gear (longline) sablefish fishery	At-sea disentanglement	2005 2006 2007 2008 2009	0.5% 1.5% 3.4% 1.5% 2.4%	0 (1)	1 (n/a)*	0.2 (n/a)
Minimum total annual takes						≥1.6 (0.74)

*No estimate of bycatch was derived from the one observation of a bottlenose dolphin released injured from sablefish gear (Jannot *et al*. 2011).

STATUS OF STOCK

The status of offshore bottlenose dolphins in California relative to OSP is not known, and there are insufficient data to evaluate trends in abundance. No habitat issues are known to be of concern for this species. They are not listed as "threatened" or "endangered" under the Endangered Species Act nor as "depleted" under the MMPA. Because average annual fishery takes (1.6 /yr) are less than the calculated PBR (11), offshore bottlenose dolphins are not classified as a "strategic" stock under the MMPA. The total fishery mortality and serious injury for this stock is less than 10% of the PBR and, therefore, can be considered to be insignificant and approaching zero.

Revised 02/09/2017

STRIPED DOLPHIN (*Stenella coeruleoalba*): California/Oregon/Washington Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Striped dolphins are distributed world-wide in tropical and warm-temperate pelagic waters. Striped dolphins are commonly encountered in warm offshore waters of California, and a few sightings have been made off Oregon (Figure 1, Barlow 2016). Striped dolphins are also commonly found in the central North Pacific, but sampling between this region and California has been insufficient to determine whether the distribution is continuous. Based on sighting records off California and Mexico, striped dolphins appear to have a continuous distribution in offshore waters of these two regions (Perrin et al. 1985; Mangels and Gerrodette 1994). No information on possible seasonality in distribution is available, because the California surveys which extended 300 nmi offshore were conducted only during the summer/fall period. Although striped dolphins are not restricted to U.S. waters, cooperative management agreements with Mexico exist only for the tuna purse seine fishery and not for other fisheries which may take this species (e.g. gillnet fisheries). Therefore, the management stock includes only animals found within U.S. waters. For the Marine Mammal Protection Act (MMPA) stock assessment reports, striped dolphins within the Pacific U.S. Exclusive Economic Zone are divided into two discrete, non-contiguous areas: 1) waters off California, Oregon and Washington (this report), and 2) waters around Hawaii.

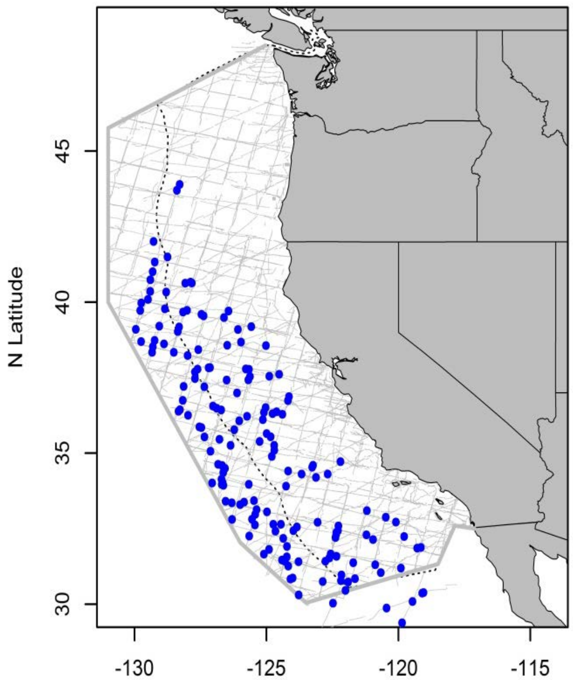

Figure 1. Striped dolphin sightings based on shipboard surveys off California, Oregon, and Washington, 1991-2014 (Barlow 2016). Dashed line represents the U.S. EEZ, thin gray lines indicate the completed transect effort of all surveys combined.

POPULATION SIZE

The abundance of striped dolphins in this region appears to be variable between years and may be affected by oceanographic conditions, as with other odontocete species (Forney 1997, Becker et al. 2012, Barlow 2016). Because animals may spend time outside the U.S. Exclusive Economic Zone as oceanographic conditions change, a multi-year average abundance estimate is the most appropriate for management within U.S. waters. The most recent estimate of striped dolphin abundance is the geometric mean of estimates from 2008 and 2014 summer/autumn vessel-based line-transect surveys of California, Oregon, and Washington waters, 29,211 (CV=0.20) animals (Barlow 2016). This estimate includes new correction factors for animals missed during the surveys.

Minimum Population Estimate

The log-normal 20th percentile of the 2008-2014 average abundance estimate is 24,782 striped dolphins.

Current Population Trend

The distribution and abundance of striped dolphins off California, Oregon and Washington varies interannually (Becker et al. 2012, Barlow 2016), but no long-term trends have been identified.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

No information on current or maximum net productivity rates is available for striped dolphins off California.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (24,782) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.48 (for a species of unknown status with fishery mortality CV > 0.3 and < 0.6; Wade and Angliss 1997), resulting in a PBR of 238 striped dolphins per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fishery Information

A summary of recent fishery mortality and injury for this stock of striped dolphin is shown in Table 1. More detailed information on these fisheries is provided in Appendix 1. The estimate of mortality and serious injury for striped dolphin in the California drift gillnet fishery for the five most recent years of monitoring, 2010-2014, is zero animals per year (Carretta et al. 2017). Human-caused mortality and injury documentation is often based on stranding data, where raw counts are negatively-biased because only a fraction of carcasses are detected. Carretta *et al*. (2016a) estimated the mean recovery rate of California coastal bottlenose dolphin carcasses to be 25% (95% CI 20% - 33%) and stated that given the extremely coastal habits of coastal bottlenose dolphins, carcass recovery rates for this stock represented a maximum, compared with more pelagic dolphin species in the region. Therefore, in this stock assessment report and others involving dolphins along the U.S. West Coast, human-related deaths and injuries counted from beach strandings along the outer U.S. West Coast are multiplied by a factor of 4 to account for the non-detection of most carcasses (Carretta *et al*. 2016a). One striped dolphin stranded during 2010-2014 with evidence of fishery interaction (Carretta *et al*. 2016b), yielding a minimum estimate of four fishery-related dolphin deaths. Gillnets have been documented to entangle marine mammals off Baja California (Sosa-Nishizaki et al. 1993), but no recent bycatch data from Mexico are available.

Table 1. Summary of available information on the incidental mortality and serious injury of striped dolphins (California/ Oregon/Washington Stock) in commercial fisheries that might take this species (Carretta *et al*. 2016a, 2016b, 2017.). Human-caused mortality values based on strandings recovered along the outer U.S. West Coast are multiplied by a correction factor of 4 to account for undetected mortality (Carretta *et al*. 2016a). Coefficients of variation for mortality estimates are provided in parentheses.

Fishery Name	Data Type	Year(s)	Percent Observer Coverage	Observed Mortality	Estimated Mortality	Mean Annual Takes (CV in parentheses)
CA/OR thresher shark/swordfish drift gillnet fishery	observer	2010 2011 2012 2013 2014	12% 20% 19% 37% 24%	0 0 0 0 0	0 (n/a)	0 (n/a)
Unidentified fishery	Stranding	2010-2014	-	1	≥ 4	≥ 0.8 (0.46)[1]
Minimum total annual takes (includes correction for unobserved beach strandings)						≥ 0.8 (0.46)

STATUS OF STOCK

The status of striped dolphins in California relative to OSP is not known, and there are insufficient data to evaluate potential trends in abundance. No habitat issues are known to be of concern for this species. They are not listed as "threatened" or "endangered" under the Endangered Species Act nor as "depleted" under the MMPA. Because recent fishery and human-caused mortality (≥0.80) is less than 10% of the PBR (238), striped dolphins are not classified as a "strategic" stock under the MMPA, and the total fishery mortality and serious injury for this stock can be considered to be insignificant and approaching zero.

[1] The coefficient of variation (CV) for corrected carcass counts was derived from the results of Carretta *et al*. (2016a), who estimated that 25% (95% CI = 20% - 33%) of all available carcasses were recovered / documented.

SHORT-BEAKED COMMON DOLPHIN (*Delphinus delphis*): California/Oregon/Washington Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Short-beaked common dolphins are the most abundant cetacean off California, and are widely distributed between the coast and at least 300 nmi distance from shore (Figure 1). The abundance of this species off California has been shown to change on both seasonal and inter-annual time scales (Dohl *et al.* 1986; Forney and Barlow 1998; Barlow 2016). Significant seasonal shifts in the abundance and distribution of common dolphins have been identified based on winter/spring 1991-92 and summer/fall 1991 surveys (Forney and Barlow 1998). The distribution of short-beaked common dolphins is continuous southward into Mexican waters to about 13ºN (Perrin *et al.* 1985; Wade and Gerrodette 1993; Mangels and Gerrodette 1994), and short-beaked common dolphins off California may be an extension of the "northern common dolphin" stock defined for management of eastern tropical Pacific tuna fisheries (Perrin *et al.* 1985). However, preliminary data on variation in dorsal fin color patterns suggest there may be multiple stocks in this region, including at least two possible stocks in California (Farley 1995). Although short-beaked common dolphins are not restricted to U.S. waters, cooperative management agreements with Mexico exist only for the tuna purse seine fishery and not for other fisheries which may take this species. Under the Marine Mammal Protection Act (MMPA), short-beaked common dolphins involved in tuna purse seine fisheries in international waters of the eastern tropical Pacific are managed separately, and they are not included in the assessment reports. For the MMPA stock assessment reports, there is a single Pacific management stock including only animals found within the U.S. Exclusive Economic Zone of California, Oregon and Washington.

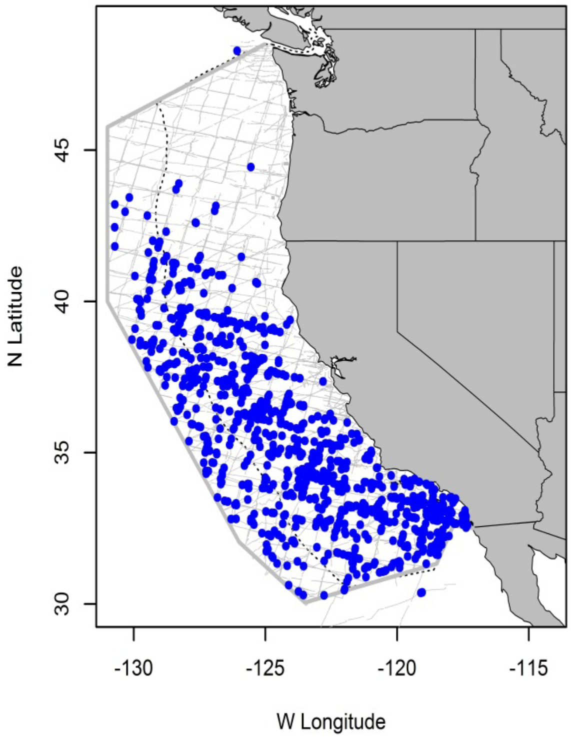

Figure 1. Short-beaked common dolphin sightings based on shipboard surveys off California, Oregon, and Washington, 1991-2014 (Barlow 2016). Dashed line represents the U.S. EEZ, thin gray lines indicate completed transect effort of all surveys combined.

POPULATION SIZE

The distribution of short-beaked common dolphins throughout this region is highly variable, apparently in response to oceanographic changes on both seasonal and interannual time scales (Heyning and Perrin 1994; Forney 1997; Forney and Barlow 1998). As oceanographic conditions vary, short-beaked common dolphins may spend time outside the U.S. Exclusive Economic Zone, and therefore a multi-year average abundance estimate is the most appropriate for management within U.S. waters. The most recent estimate of short-beaked common dolphin abundance is the geometric mean of estimates from 2008 and 2014 summer/autumn vessel-based line-transect surveys of California, Oregon, and Washington waters, 969,861 (CV = 0.17) animals (Barlow 2016). This estimate includes new correction factors for animals missed during the surveys.

Minimum Population Estimate

The log-normal 20th percentile of the 2008-2014 average abundance estimate is 839,325 short-beaked common dolphins.

Current Population Trend

Short-beaked common dolphin abundance off the U.S. West Coast is known to increase during warm-water periods (Dohl *et al.* 1986, Forney and Barlow 1998, Barlow 2016). The most recent 2014 survey was conducted during extremely warm ocean conditions (Bond *et al*. 2015) and resulted in the largest abundance estimate since large-scale surveys began in 1991. The increase in short-beaked common dolphin abundance is likely a result of northward movement of this transboundary stock from waters off Mexico (Barlow 2016).

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

There are no estimates of current or maximum net productivity rates for short-beaked common dolphins.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (839,325) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.50 (for a species of unknown status with a mortality rate CV< 0.30; Wade and Angliss 1997), resulting in a PBR of 8,393 short-beaked common dolphins per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fishery Information

A summary of recent fishery mortality and injury for short-beaked common dolphins is shown in Table 1. The summed estimate of mortality and serious injury for short-beaked common dolphin in the California drift gillnet fishery for the five most recent years of monitoring, 2010-2014, is approximately 100 individuals, or an average of 20 (CV=0.18) per year (Carretta *et al*. 2017) (Table 1). No takes were documented by observers during the most recent five years of monitoring for other gillnet and purse seine fisheries that have interacted with short-beaked common dolphins in the past. However, two short-beaked common dolphins stranded with evidence of fishery interaction with an unidentified gillnet fishery. Human-caused mortality and injury documentation is often based on stranding data, where raw counts are negatively-biased because only a fraction of carcasses are detected. Carretta *et al*. (2016a) estimated the mean recovery rate of California coastal bottlenose dolphin carcasses to be 25% (95% CI 20% - 33%) and stated that given the extremely coastal habits of coastal bottlenose dolphins, carcass recovery rates for this stock represented a maximum, compared with more pelagic dolphin species in the region. Therefore, in this stock assessment report and others involving dolphins along the U.S. West Coast, human-related deaths and injuries counted from beach strandings along the outer U.S. West Coast are multiplied by a factor of 4 to account for the non-detection of most carcasses (Carretta *et al*. 2016a). Applying this correction factor to the two stranded short-beaked common dolphins yields a minimum estimate of 8 fishery-related dolphin deaths.

Table 1. Summary of available information on the incidental mortality and injury of short-beaked common dolphins (California/Oregon/Washington Stock) in commercial fisheries that might take this species (Carretta *et al*. 2016b, 2017). All entanglements resulted in the death of the animal. Coefficients of variation for mortality estimates are provided in parentheses; n/a = not available. Human-caused mortality values based on strandings recovered along the outer U.S. West Coast are multiplied by a correction factor of 4 to account for undetected mortality (Carretta *et al.* 2016a).

Fishery Name	Data Type	Year	Percent Observer Coverage	Observed Mortality (and Serious Injury)	Estimated Mortality and Serious Injury	Mean Annual Takes (CV in parentheses)
CA/OR thresher shark/swordfish drift gillnet fishery	observer	2010 2011 2012 2013 2014	12% 20% 19% 37% 24%	3 2 5 6 6	21.2 (0.53) 15.2 (0.46) 21.3 (0.41) 16.5 (0.25) 23.5 (0.31)	20 (0.18)

Fishery Name	Data Type	Year	Percent Observer Coverage	Observed Mortality (and Serious Injury)	Estimated Mortality and Serious Injury	Mean Annual Takes (CV in parentheses)
CA squid purse seine	observer	2004 2005 2006 2007 2008	unknown 1.1% unknown <5% <5%	0 1 0 (1) 0 0	0 87 (0.98) ≥ 1 (n/a)0 0	18 (0.98)
CA halibut / white seabass and other species set gillnet fishery	observer	2010-2014	9%	0	0	0 (n/a)
Hawaii Shallow Set Longline fishery	observer	2010-2014	100%	0 0 (1) 0 0 0 (1)	0 (2)	0.4 (n/a)
Unidentified gillnet fishery	Stranding	2010-2014	-	2	≥8	≥1.6 (0.46)[1]
Minimum total annual takes (includes correction for unobserved beach strandings)						≥ 40 (0.45)

The California squid purse seine fishery has not been observed since 2008. Between 2004 and 2008, there were 377 sets observed in the squid purse seine fishery and one short-beaked common dolphin mortality was observed in 2005, with a resulting mortality estimate of 87 (CV=0.98) animals (Carretta and Enriquez 2006). It is likely, due to the low observer coverage that year (~1%), combined with a relatively rare entanglement event, that this estimate is positively-biased (Carretta and Moore 2014). In addition, there was one squid purse seine set in 2006 where 8 unidentified dolphins were encircled. Seven were released alive and the eighth was seriously injured. For purposes of this stock assessment report, it is assumed that the unidentified seriously injured dolphin was a short-beaked common dolphin, due to its high abundance within the fishing area and a previous record of this species having been killed in the fishery.

Two short-beaked common dolphins were reported released injured from the Hawaii shallow set longline fishery (one each in 2011 and 2014 with 100% observer coverage, Table 1). These interactions occurred outside of the U.S. EEZ just west of the California Current and likely involved dolphins from the CA/OR/WA stock of short-beaked common dolphins (NOAA Pacific Islands Regional Office 2017).

Other Mortality

In the eastern tropical Pacific, 'northern common dolphins' have been incidentally killed in international tuna purse-seine fisheries since the late 1950's and are managed separately under a section of the MMPA written specifically for the management of dolphins involved in eastern tropical Pacific tuna fisheries. Cooperative international management programs have dramatically reduced overall dolphin mortality in these fisheries in recent decades (IATTC 2015). Between 2007 and 2014, annual fishing mortality of northern common dolphins (potentially including both short-beaked and long-beaked common dolphins) ranged between 35 and 124 animals, with an average of 75 (IATTC, 2015). Although it is unclear whether these animals are part of the same population as short-beaked common dolphins found off California, the distributions of both of the species that comprise the 'northern common dolphins' appear to shift into U.S. waters during certain oceanographic conditions (IATTC 2006).

STATUS OF STOCK

The status of short-beaked common dolphins in Californian waters relative to OSP is not known. The observed increase in abundance of this species off California probably reflects a distributional shift

[1] The coefficient of variation (CV) for corrected carcass counts was derived from the results of Carretta *et al*. (2016a), who estimated that 25% (95% CI = 20% - 33%) of all available carcasses were recovered / documented.

(Anganuzzi *et al.* 1993; Forney and Barlow 1998, Barlow 2016), rather than an overall population increase due to growth. No habitat issues are known to be of concern for this species. They are not listed as "threatened" or "endangered" under the Endangered Species Act nor as "depleted" under the MMPA. The average annual human-caused mortality in 2010-2014 (40 animals) is estimated to be less than the PBR (8,393), and therefore they are not classified as a "strategic" stock under the MMPA. The total estimated fishery mortality and injury for short-beaked common dolphins is less than 10% of the calculated PBR and, therefore, can be considered to be insignificant and approaching zero mortality and serious injury rate.

LONG-BEAKED COMMON DOLPHIN (*Delphinus capensis*): California Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Long-beaked common dolphins were recognized as a distinct species in the 1990s (Heyning and Perrin 1994; Rosel *et al.* 1994). Along the U.S. west coast, their distribution overlaps with that of the short-beaked common dolphin. Long-beaked common dolphins are commonly found within about 50 nmi of the coast, from Baja California (including the Gulf of California) northward to about central California (Figure 1). Along the west coast of Baja California, long-beaked common dolphins primarily occur inshore of the 250 m isobath, with very few sightings (<15%) in waters deeper than 500 meters (Gerrodette and Eguchi 2011). Stranding and sighting records indicate that the abundance of this species off California changes both seasonally and inter-annually (Heyning and Perrin 1994, Forney and Barlow 1998, Barlow 2016). Although long-beaked common dolphins are not restricted to U.S. waters, cooperative management agreements with Mexico exist only for the tuna purse seine fishery and not for other fisheries which may take this species (e.g. gillnet fisheries). For the MMPA stock assessment reports, there is a single Pacific management stock including only animals found within the U.S. Exclusive Economic Zone off California.

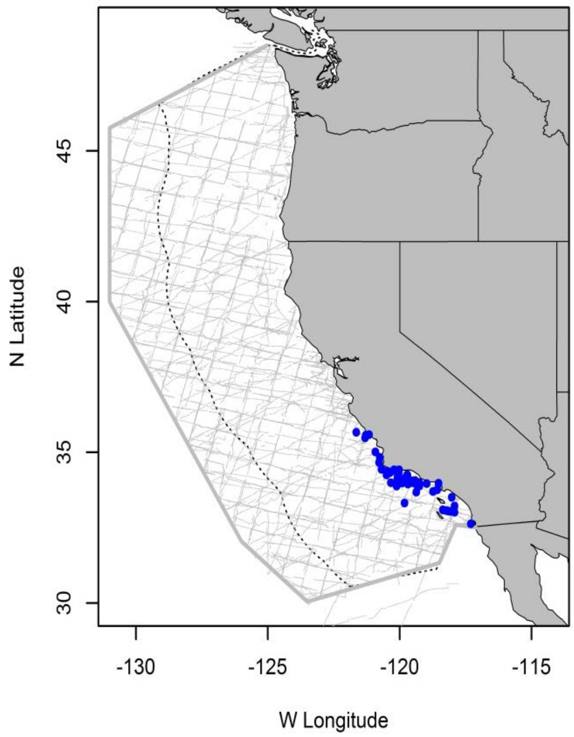

Figure 1. Long-beaked common dolphin sightings based on shipboard surveys off California, Oregon, and Washington, 1991- 2014 (Barlow 2016). Dashed line represents the U.S. EEZ, thin gray lines indicate completed transect effort of all surveys combined.

POPULATION SIZE

The distribution and abundance of long-beaked common dolphins off California varies inter-annually and seasonally (Heyning and Perrin 1994). As oceanographic conditions change, long-beaked common dolphins may move between Mexican and U.S. waters, and therefore a multi-year average abundance estimate is the most appropriate for management within the U.S. waters. The geometric mean abundance estimate for California, Oregon and Washington waters based on two ship surveys conducted in 2008 and 2014 (Barlow 2016) is 101,305 (0.49) long-beaked common dolphins. This estimate includes new correction factors for animals missed during the surveys. Although Carretta *et al.* (2011) also estimated abundance of this stock from a 2009 survey, that estimate did not include the correction factors and had high imprecision for one of the geographic strata, so it is not included in the multi-year average.

Minimum Population Estimate

The log-normal 20th percentile of the weighted 2008-2014 abundance estimate is 68,432 long-beaked common dolphins.

Current Population Trend

California waters represent the northern limit for this stock and animals likely move between U.S. and Mexican waters. While no formal statistical trend analysis exists for this stock of long-beaked common dolphin, abundance estimates for California waters from vessel-based line-transect surveys have been greater in recent years as water conditions have been warmer (Barlow 2016). The ratio of strandings of long-beaked to short-beaked common dolphin in southern California has varied, suggesting that the proportions of each species present change as ocean conditions vary (Heyning and Perrin 1994, Danil *et al*. 2010). During a 2009 ship-based survey of California and Baja California waters, the ratio of long-beaked to short-beaked common dolphin sightings was nearly 1:1, whereas during previous surveys conducted from 1986 to 2008 in the same geographic strata, the ratio was approximately 1:3.5 (Carretta *et al*. 2011). There appears to be an increasing trend of long-beaked common dolphins in California waters over the last 30 years, but a trend analysis for this stock has not been performed to date, while other stocks with more urgent conservation concerns are analyzed (e.g., Moore and Barlow 2011, 2013).

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

There are no estimates of current or maximum net productivity rates for long-beaked common dolphins.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (68,432) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.48 (for a species of unknown status with a mortality rate CV of 0.3 to 0.6 ; Wade and Angliss 1997), resulting in a PBR of 657 long-beaked common dolphins per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fishery Information

A summary of recent fishery mortality and injury for long-beaked common dolphins is shown in Table 1. More detailed information on these fisheries is provided in Appendix 1. The estimate of mortality and serious injury for long-beaked common dolphin in the California drift gillnet fishery for the five most recent years of monitoring, 2010-2014, averages 2.0 (CV=0.99) per year (Carretta *et al*. 2017). One interaction with the halibut set gillnet fishery was observed during 2010-2014, resulting in an estimate of 7 (CV=1.17) dolphins (Carretta and Enriquez 2012). No mortality or serious injury has been documented by observers during the most recent five years of monitoring for the small mesh gillnet fishery, which has interacted with long-beaked common dolphins in the past. However, 36 long-beaked common dolphins stranded with evidence of interaction with unidentified fisheries. Human-caused mortality and injury documentation is often based on stranding data, where raw counts are negatively-biased because only a fraction of carcasses are detected. Carretta *et al*. (2016a) estimated the mean recovery rate of California coastal bottlenose dolphin carcasses to be 25% (95% CI 20% - 33%) and stated that given the extremely coastal habits of coastal bottlenose dolphins, carcass recovery rates for this stock represented a maximum, compared with more pelagic dolphin species in the region. Therefore, in this stock assessment report and others involving dolphins along the U.S. West Coast, human-related deaths and injuries counted from beach strandings along the outer U.S. West Coast are multiplied by a factor of 4 to account for the non-detection of most carcasses (Carretta *et al*. 2016a). Applying this correction factor to the 36 stranded long-beaked common dolphins yields a minimum estimate of 144 fishery-related dolphin deaths, or an average of 29 per year. Gillnets have been documented to entangle marine mammals off Baja California (Sosa-Nishizaki *et al*. 1993), but no recent bycatch data from Mexico are available.

Table 1. Summary of available information on the incidental mortality and serious injury of long-beaked common dolphins (California Stock) in commercial fisheries that might take this species (Carretta *et al*. 2016b, 2017). All observed entanglements resulted in the death of the animal. Coefficients of variation for mortality estimates are provided in parentheses, when available. n/a = information not available. Human-caused mortality values based on strandings recovered along the outer U.S. West Coast are multiplied by a correction factor of 4 to account for undetected mortality (Carretta *et al*. 2016a).

Fishery Name	Data Type	Year(s)	Percent Observer Coverage	Observed (or self-reported)	Estimated Annual Mortality (CV)	Mean Annual Takes (CV

Fishery Name	Data Type	Year(s)	Percent Observer Coverage	Observed (or self-reported)	Estimated Annual Mortality (CV)	Mean Annual Takes (CV
CA thresher shark/swordfish drift gillnet fishery	observer	2010 2011 2012 2013 2014	12% 20% 19% 37% 24%	1 1 0 0 0	1.9 (1.1) 5.1 (1.3) 0 (n/a) 0.2 (2.2) 2.8 (1.4)	2.0 (0.99)
CA small mesh drift gillnet fishery for white seabass, yellowtail, barracuda, and tuna	observer	2010-2012	~4%	0	0	0 (n/a)
CA halibut/white seabass and other species set gillnet fishery	observer	2010-2014	9%	1	7 (1.17)	1.4 (1.17)
Unidentified fishery interaction	Strandings	2010-2014	-	36	≥144	≥29 (0.46)[1]
Minimum total annual takes (includes correction for unobserved beach strandings)						≥32 (0.42)

Other Mortality

Three long-beaked common dolphins died near San Diego in 2011 as the result of blast trauma associated with underwater detonations conducted by the U.S. Navy. Three days later, a fourth animal stranded approximately 70 km north of that location with similar injuries (Danil and St. Leger 2011). One long-beaked common dolphin was incidentally killed during fishery research during 2013 (Carretta *et al*. 2016b). Stranding records from 2010-2014 include three additional human-related long-beaked common dolphin deaths, including one animal that was struck by a vessel, one animal that had ingested marine debris, and one animal that had been cut in half (Carretta *et al*. 2016b). Applying the minimum correction factor to account for undetected mortality (Carretta *et al*. 2016a), this yields an estimated 12 human-caused long-beaked common dolphin deaths. From all sources combined, this results in a total of 17 non-fishery human-caused deaths between 2010 and 2014, or an average of 3.4 dolphins per year.

'Unusual mortality events' of long-beaked common dolphins off California due to domoic acid toxicity have been documented by NMFS as recently as 2007. One study suggests that increasing anthropogenic CO_2 levels and ocean acidification may increase the toxicity of the diatom responsible for these mortality events (Tatters *et al*. 2012).

In the eastern tropical Pacific, 'northern common dolphins' have been incidentally killed in international tuna purse-seine fisheries since the late 1950's and are managed separately under a section of the MMPA written specifically for the management of dolphins involved in eastern tropical Pacific tuna fisheries. Cooperative international management programs have dramatically reduced overall dolphin mortality in these fisheries (Joseph 1994). Between 2007 and 2014, annual fishing mortality of northern common dolphins (potentially including both short-beaked and long-beaked common dolphins) ranged between 35 and 124 animals, with an average of 75 (IATTC 2015). The distributions of both of the species that comprise the 'northern common dolphins' appear to shift into U.S. waters during certain oceanographic conditions (IATTC 2006).

STATUS OF STOCK

The status of long-beaked common dolphins in California waters relative to OSP is not known, and there are insufficient data to evaluate potential trends in abundance. Exposure to blast trauma resulting from underwater detonations is a local concern for this stock, but population level impacts from such activities are unclear. In response to the 2011 event, the U.S. Navy has implemented new training protocols to reduce the probability of blast trauma events occurring (Danil and St. Leger 2011). Long-

[1] The coefficient of variation (CV) for corrected carcass counts was derived from the results of Carretta *et al*. (2016a), who estimated that 25% (95% CI = 20% - 33%) of all available carcasses were recovered / documented.

beaked common dolphins are not listed as "threatened" or "endangered" under the Endangered Species Act nor as "depleted" under the MMPA. The average annual human-caused mortality from commercial fisheries (≥32 dolphins /year) and other sources (3.4 dolphins/year) is 35.4 long-beaked common dolphins. This does not exceed the PBR (657), and therefore they are not classified as a "strategic" stock under the MMPA. The average total fishery mortality and injury for long-beaked common dolphins (32/yr) is less than 10% of the PBR and therefore, is considered to be insignificant and approaching zero mortality and serious injury rate.

NORTHERN RIGHT-WHALE DOLPHIN (*Lissodelphis borealis*): California/Oregon/Washington Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Northern right-whale dolphins are endemic to temperate waters of the North Pacific Ocean. Off the U.S. west coast, they have been seen primarily in shelf and slope waters (Figure 1), with seasonal movements into the Southern California Bight (Leatherwood and Walker 1979; Dohl et al. 1980; 1983). Sighting patterns from recent aerial and shipboard surveys conducted in California, Oregon and Washington during different seasons (Green et al. 1992; 1993; Forney and Barlow 1998; Barlow 2016) suggest seasonal north-south movements, with animals found primarily off California during the colder water months and shifting northward into Oregon and Washington as water temperatures increase in late spring and summer. The southern end of this population's range is not well-documented, but during cold-water periods, they probably range into Mexican waters off northern Baja California. Genetic analyses have not found statistically significant differences between northern right-whale dolphins from the U.S. West coast and other areas of the North Pacific (Dizon et al. 1994); however, power analyses indicate that the ability to detect stock differences for this species is poor, given traditional statistical error levels (Dizon et al. 1995). Although northern right-whale dolphins are not restricted to U.S. territorial waters, there are currently no international agreements for cooperative management. For the Marine Mammal Protection Act (MMPA) stock assessment reports, there is a single management stock including only animals found within the U.S. Exclusive Economic Zone of California, Oregon and Washington.

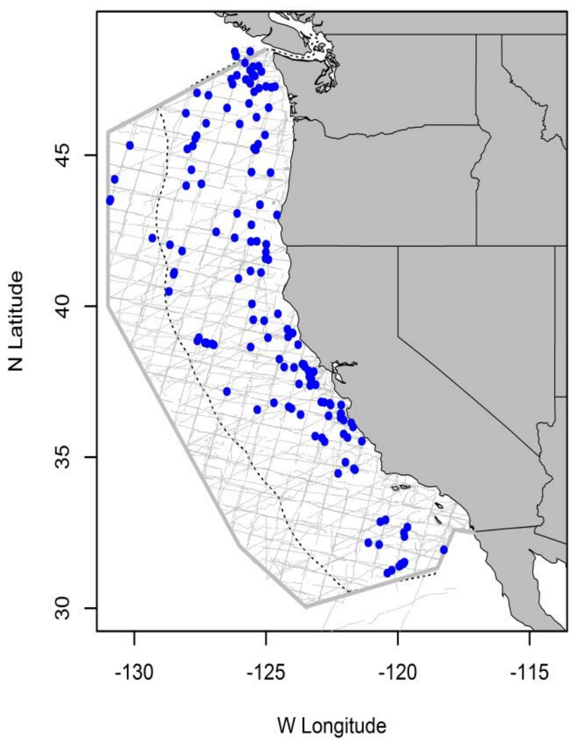

Figure 1. Northern right whale dolphin sightings based on shipboard surveys off California, Oregon, and Washington, 1991-2014 (Barlow 2016). Dashed line represents the U.S. EEZ, thin gray lines indicate completed transect effort of all surveys combined.

POPULATION SIZE

The distribution of northern right-whale dolphins throughout this region is highly variable, apparently in response to oceanographic changes on both seasonal and interannual time scales (Forney and Barlow 1998, Barlow 2016). As oceanographic conditions vary, northern right-whale dolphins may spend time outside the U.S. Exclusive Economic Zone, and therefore a multi-year average abundance estimate is the most appropriate for management within U.S. waters. The most recent estimate of northern right whale dolphin abundance is the geometric mean of estimates from 2008 and 2014 summer/autumn vessel-based line-transect surveys of California, Oregon, and Washington waters, 26,556 (CV=0.44) animals (Barlow 2016). This estimate includes new correction factors for animals missed during the surveys.

Minimum Population Estimate

The log-normal 20th percentile of the 2008-2014 average abundance estimate is 18,608 northern right-whale dolphins.

Current Population Trend

The distribution and abundance of northern right whale dolphins off California, Oregon and Washington varies considerably at both seasonal and interannual time scales (Forney and Barlow 1998, Becker *et al*. 2012, Barlow 2016), but no long term trends have been identified.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

No information on current or maximum net productivity rates is available for northern right-whale dolphins off the U.S. west coast.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (18,608) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.48 (for a species of unknown status with a mortality rate CV between 0.3 and 0.6; Wade and Angliss 1997), resulting in a PBR of 179 northern right-whale dolphins per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fishery Information

A summary of recent fishery mortality and injury information for this stock of northern right-whale dolphin is shown in Table 1. More detailed information on these fisheries is provided in Appendix 1. The estimate of mortality and serious injury for northern right whale dolphin in the California drift gillnet fishery for the five most recent years of monitoring, 2010-2014, is 17.6 (CV=0.36) individuals, or an average of 3.5 per year (Carretta *et al*. 2016). Gillnets have been documented to entangle marine mammals off Baja California (Sosa-Nishizaki *et al*. 1993), but no recent bycatch data from Mexico are available.

Table 1. Summary of available information on the incidental mortality and serious injury of northern right-whale dolphins (California/Oregon/Washington Stock) in commercial fisheries that might take this species (Carretta *et al*. 2017). All observed entanglements of northern right-whale dolphins resulted in the death of the animal. Coefficients of variation for mortality estimates are provided in parentheses.

Fishery Name	Data Type	Year(s)	Percent Observer Coverage	Observed Mortality	Estimated Annual Mortality (CV)	Mean Annual Takes (CV)
CA/OR thresher shark/swordfish drift gillnet fishery	observer data	2010 2011 2012 2013 2014	12% 20% 19% 37% 24%	1 1 1 2 1	3.9 (1) 5.5 (0.85) 3.7 (0.95) 3.3 (0.45) 2.5 (0.83)	3.8 (0.40)
Minimum total annual takes						3.8 (0.40)

STATUS OF STOCK

The status of northern right-whale dolphins in California, Oregon and Washington relative to OSP is not known, and there are insufficient data to evaluate trends in abundance. No habitat issues are known to be of concern for this species. They are not listed as "threatened" or "endangered" under the Endangered Species Act nor as "depleted" under the MMPA. The average annual human-caused mortality in 2010-2014 (3.8 animals) is estimated to be less than the PBR (179), and therefore they are not classified as a "strategic" stock under the MMPA. The total fishery mortality and serious injury for northern right-whale dolphins does not exceed 10% of the calculated PBR and, therefore, can be considered to be insignificant and approaching zero mortality and serious injury rate.

Revised 01/15/2011

KILLER WHALE (*Orcinus orca*): Eastern North Pacific Offshore Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Killer whales have been observed in all oceans and seas of the world (Leatherwood and Dahlheim 1978). Although reported from tropical and offshore waters, killer whales prefer the colder waters of both hemispheres, with greatest abundances found within 800 km of major continents (Mitchell 1975). Along the west coast of North America, killer whales occur along the entire Alaskan coast (Braham and Dahlheim 1982), in British Columbia and Washington inland waterways (Bigg et al. 1990), and along the outer coasts of Washington, Oregon and California (Green et al. 1992; Barlow 1995, 1997; Forney et al. 1995; Barlow and Forney 2007). Seasonal and year-round occurrence have been noted for killer whales throughout Alaska (Braham and Dahlheim 1982) and in the intracoastal waterways of British Columbia and Washington, where pods have been labeled as 'resident', 'transient' and 'offshore' (Bigg et al. 1990, Ford et al. 1994) based on aspects of morphology, ecology, genetics and behavior (Ford and Fisher 1982; Baird and Stacey 1988; Baird et al. 1992, Hoelzel et al. 1998). Through examination of photographs of recognizable individuals and pods, movements of whales between geographical areas have been documented. For example, whales identified in Prince William Sound have been observed near Kodiak Island (Heise et al. 1991) and whales identified in Southeast Alaska have been observed in Prince William Sound, British Columbia, and Puget Sound (Leatherwood et al. 1990, Dahlheim et al. 1997). Movements of killer whales between the waters of Southeast Alaska and central California have also been documented (Goley and Straley 1994).

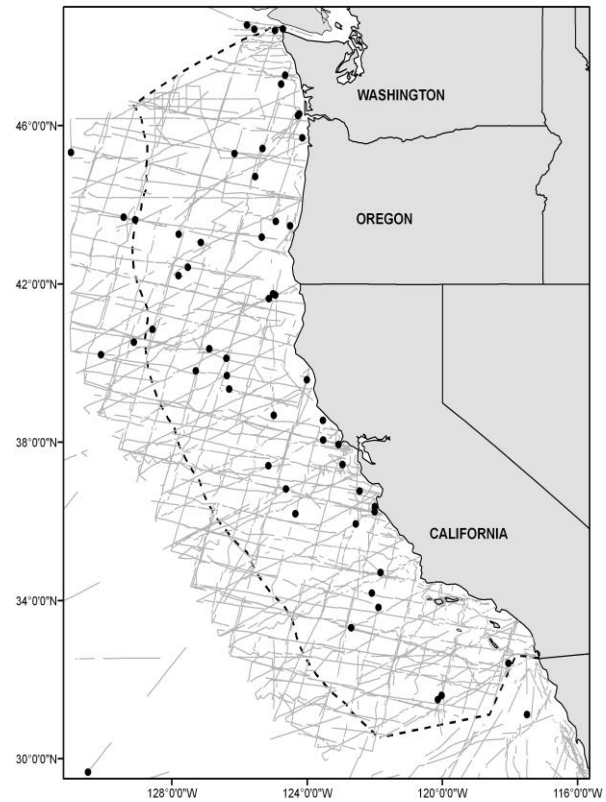

Figure 1. Killer whale sightings based on shipboard surveys off California, Oregon and Washington, 1991-2008 (see Appendix 2 for data sources and information on timing and location of survey effort). Sightings include killer whales from all stocks found in this region. Dashed line represents the U.S. EEZ, thin lines indicate completed transect effort of all surveys combined.

Offshore killer whales have more recently also been identified off the coasts of California, Oregon, and rarely, in Southeast Alaska (Ford et al. 1994, Black et al. 1997, Dahlheim et al. 1997). They apparently do not mix with the transient and resident killer whale stocks found in these regions (Ford et al. 1994, Black et al. 1997). Studies indicate the 'offshore' type, although distinct from the other types ('resident' and 'transient'), appears to be more closely related genetically, morphologically, behaviorally, and vocally to the 'resident' type killer whales (Black et al. 1997, Hoelzel et al. 1998; J. Ford, pers. comm.; L. Barrett-Lennard, pers. comm.). Based on data regarding association patterns, acoustics, movements, genetic differences and potential fishery interactions, eight killer whale stocks are recognized within the Pacific U.S. EEZ: 1) the Eastern North Pacific Alaska Resident stock - occurring from Southeast Alaska to the Bering Sea, 2) the Eastern North Pacific Northern Resident stock - occurring from British Columbia through Alaska, 3) the Eastern North Pacific Southern Resident stock - occurring mainly within the inland waters of Washington State and southern British Columbia but extending from central California into southern Southeast Alaska, 4) the West Coast Transient stock - occurring from Alaska through California, 5) the Gulf of Alaska, Aleutian Islands, and Bering Sea Transient stock - occurring from southeast Alaska to the Bering Sea, 6) the AT1 Stock – found only in Prince William Sound, 7) the Eastern North Pacific Offshore stock - occurring from Southeast Alaska through California, 8) the Hawaiian stock. The Stock Assessment Reports for the Alaska Region contain information concerning the Eastern North Pacific Alaska Resident, Eastern North Pacific Northern Resident and the Gulf of Alaska, Aleutian Islands, and Bering Sea, AT1, and West Coast Transient stocks.

POPULATION SIZE

Off British Columbia, approximately 200 offshore killer whales were identified between 1989 and 1993 (Ford et al. 1994), and 20 of these individuals have also been seen off California (Black et al. 1997). Using only good quality photographs that clearly show characteristics of the dorsal fin and saddle patch region, an additional 11 offshore killer whales that were not previously known have been identified off the California coast, bringing the total number of known individuals in this population to 211. This is certainly an underestimate of the total population size, because not all animals in this population have been photographed. In the future, it may be possible estimate the total abundance of this transboundary stock using mark-recapture analyses based on individual photographs. Based on summer/fall shipboard line-transect surveys in 2005 (Forney 2007) and 2008 (Barlow 2010), the total number of killer whales within 300 nmi of the coasts of California, Oregon and Washington is estimated to be 691 animals (CV=0.49). There is currently no way to reliably distinguish the different stocks of killer whales from sightings at sea, but photographs of individual animals can provide a rough estimate of the proportion of whales in each stock. A total of 161 individual killer whales photographed off California and Oregon have been determined to belong to the transient (105 whales) and offshore (56 whales) stocks (Black et al. 1997). Using these proportions to prorate the line transect abundance estimate yields an estimate of 56/161 * 691 = 240 offshore killer whales along the U.S. west coast. This is expected to be a conservative estimate of the number of offshore killer whales, because offshore whales apparently are less frequently seen near the coast (Black et al. 1997), and therefore photographic sampling may be biased towards transient whales. For stock assessment purposes, this combined value is currently the best available estimate of abundance for offshore killer whales off the coasts of California, Oregon and Washington.

Minimum Population Estimate

The total number of known offshore killer whales along the U.S. West coast, Canada and Alaska is 211 animals, but it is not known what proportion of time this transboundary stock spends in U.S. waters, and therefore this number is difficult to work with for PBR calculations. A minimum abundance estimate for all killer whales along the coasts of California, Oregon and Washington can be estimated from the 2005-2008 line-transect surveys as the 20th percentile of the geometric mean 2005-2008 abundance estimate, or 466 killer whales. Using the same prorating as above, a minimum of 56/161 * 466 = 162 offshore killer whales are estimated to be in U.S. waters off California, Oregon and Washington.

Current Population Trend

No information is available regarding trends in abundance of Eastern North Pacific offshore killer whales.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

No information on current or maximum net productivity rates is available for killer whales in this region.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (162) <u>times</u> one half the default maximum net growth rate for cetaceans (½ of 4%) <u>times</u> a recovery factor of 0.50 (for a species of unknown status with no known fishery mortality; Wade and Angliss 1997), resulting in a PBR of 1.6 offshore killer whales per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fishery Information

A summary of information on fisheries that may take animals from this killer whale stock is shown in Table 1 (Carretta et al. 2005, Carretta and Enriquez 2006, 2007, 2009a, 2009b). More detailed information on these fisheries is provided in Appendix 1. In the California drift gillnet fishery, no offshore killer whales have been observed entangled (Julian 1997; Julian and Beeson 1998; Cameron and Forney 1999, 2000; Carretta and Chivers 2004, Carretta et al. 2005a, 2005b, Carretta and Enriquez 2006, 2007, 2009a, 2009b), but one killer whale from the Eastern North Pacific Transient Stock was observed taken in 1995, and offshore killer whales may also occasionally be entangled. Additional potential sources of killer whale mortality are set gillnets and longlines. In California, an observer program between July 1990 and December 1994 and additional observations between 2000 and 2008 monitored 5-15% of all sets in the large mesh (>3.5") set gillnet fishery for halibut , and no killer whales were observed taken. Based on observations for longline fisheries in other regions (i.e. Alaska; Yano and Dahlheim 1995), fishery interactions may also occur with U.S. West coast pelagic longline fisheries, but no such interactions have been documented to date.

Table 1. Summary of available information on the incidental mortality and injury of killer whales (Eastern North Pacific Offshore Stock) in commercial fisheries that might take this species. Mean annual takes are based on 2004-2008 data unless noted otherwise.

Fishery Name	Data Type	Year(s)	Percent Observer Coverage	Observed Mortality	Estimated Annual Mortality	Mean Annual Takes (CV in parentheses)
CA/OR thresher shark/swordfish drift gillnet fishery	observer data	2004 2005 2006 2007 2008	20.6% 20.9% 18.5% 16.4% 13.5%	0 0 0 0 0	0 0 0 0 0	0
Minimum total annual takes						0

Drift gillnet fisheries for swordfish and sharks exist along the entire Pacific coast of Baja California, Mexico and may take animals from this population. Quantitative data are available only for the Mexican swordfish drift gillnet fishery, which uses vessels, gear, and operational procedures similar to those in the U.S. drift gillnet fishery, although nets may be up to 4.5 km long (Holts and Sosa-Nishizaki 1998). The fleet increased from two vessels in 1986 to 31 vessels in 1993 (Holts and Sosa-Nishizaki 1998). The total number of sets in this fishery in 1992 can be estimated from data provided by these authors to be approximately 2700, with an observed rate of marine mammal bycatch of 0.13 animals per set (10 marine mammals in 77 observed sets; Sosa-Nishizaki et al. 1993). This overall mortality rate is similar to that observed in California driftnet fisheries during 1990-95 (0.14 marine mammals per set; Julian and Beeson, 1998), but species-specific information is not available for the Mexican fisheries. Previous efforts to convert the Mexican swordfish driftnet fishery to a longline fishery have resulted in a mixed-fishery, with 20 vessels alternately using longlines or driftnets, 23 using driftnets only, 22 using longlines only, and seven with unknown gear type (Berdegué 2002).

STATUS OF STOCK

The status of killer whales in California in relation to OSP is unknown, and there are insufficient data to evaluate trends in abundance. No habitat issues are known to be of concern for this stock. They are not listed as "threatened" or "endangered" under the Endangered Species Act nor as "depleted" under the MMPA. There has been no documented human-caused mortality of this stock, and therefore they are not classified as a "strategic" stock under the MMPA. The total fishery mortality and serious injury for offshore killer whales is zero and can be considered to be insignificant and approaching zero mortality and serious injury rate.

KILLER WHALE (*Orcinus orca*): Eastern North Pacific Southern Resident Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Killer whales have a cosmopolitan distribution, ranging from equatorial to polar waters, with highest densities found in coastal temperate waters (Forney and Wade 2006). Along the west coast of North America, killer whales occur along the entire Alaskan coast as far north as Barrow (George *et al.* 1994, Lowry *et al.* 1987, Clarke *et al.* 2013), in British Columbia and Washington inland waterways (Bigg *et al.* 1990), and along the outer coasts of Washington, Oregon, and California (Barlow and Forney 2007). Seasonal and year-round occurrence has been noted for killer whales throughout Alaska (Braham and Dahlheim 1982) and in the intra-coastal waterways of British Columbia and Washington State, where pods have been labeled as 'resident,' 'transient,' and 'offshore' (Bigg *et al.* 1990, Ford *et al.* 1994) based on aspects of morphology, ecology, genetics, and behavior (Ford and Fisher 1982, Baird and Stacey 1988, Baird *et al.* 1992, Hoelzel *et al.* 1998). Through examination of photographs of recognizable individuals and pods, movements of whales between Prince William Sound and Kodiak Island have been observed (Matkin *et al.* 1999) and whales identified in Southeast Alaska have been observed in Prince William Sound, British Columbia, and Puget Sound (Leatherwood *et al.* 1990, Dahlheim *et al.* 1997).

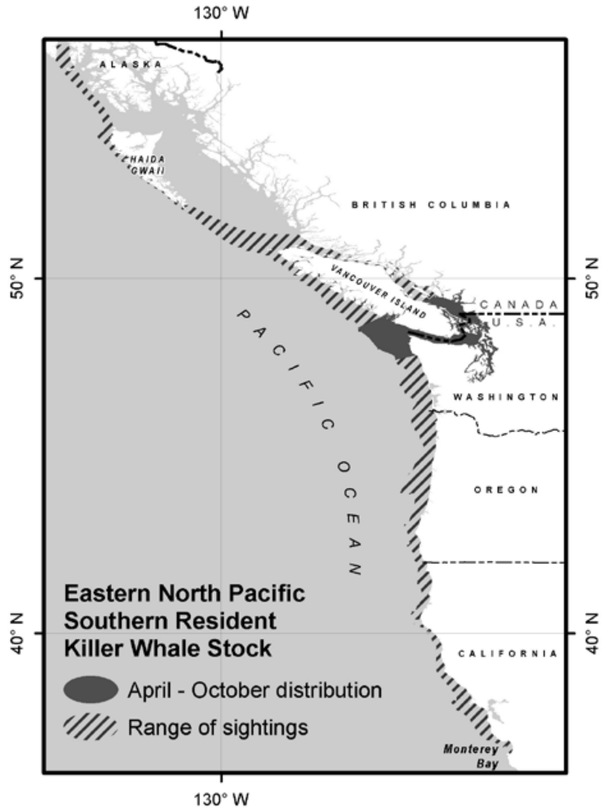

Figure 1. Approximate April - October distribution of the Eastern North Pacific Southern Resident killer whale stock (shaded area) and range of sightings (diagonal lines).

Genetic studies provide evidence that the 'resident' and 'transient' types are distinct (Stevens *et al.* 1989, Hoelzel 1991, Hoelzel and Dover 1991, Hoelzel *et al.* 1998, Morin *et al.* 2010). Analyses of complete mitochondrial genomes indicates that transient killer whales should be recognized as a separate species, and that, pending additional data, resident killer whales should be recognized as a separate subspecies (Morin *et al.* 2010). The genetic data results support previous lines of evidence for separation of the transient and resident ecotypes, including differences in 1) acoustic dialects; 2) skull features; 3) morphology; 4) feeding specializations; and 5) a lack of interbreeding between the two sympatric ecotypes (Krahn *et al.* 2004).

Most sightings of the Eastern North Pacific Southern Resident stock of killer whales have occurred in the summer in inland waters of Washington and southern British Columbia. However, pods belonging to this stock have also been sighted in coastal waters off southern Vancouver Island and Washington (Bigg *et al.* 1990, Ford *et al.* 2000, NWFSC unpubl. data). The complete winter range of this stock is uncertain. Of the three pods comprising this stock, one (J1) is commonly sighted in inshore waters in winter, while the other two (K1 and L1) apparently spend more time offshore (Ford *et al.* 2000). These latter two pods have been sighted as far south as Monterey Bay and central California in recent years. They sometimes have also been seen entering the inland waters of Vancouver Island through Johnstone Strait in the spring (Ford *et al.* 2000), suggesting that they may spend time along the outer coast of Vancouver Island during the winter. In June 2007, whales from L-pod were sighted off Chatham Strait, Alaska, the farthest north they have ever been documented (J. Ford, pers. comm.). Passive autonomous acoustic recorders have recently provided more information on the seasonal occurrence of these pods along the west coast of the U.S. (Hanson *et al.* 2013). In addition, satellite-linked tags were recently deployed in winter months on members of J, K, and L pods. Results were consistent with previous data, but provided much greater detail, showing wide-ranging use of inland waters by J Pod whales and extensive movements in U.S. coastal waters by K and L Pods.

Based on data regarding association patterns, acoustics, movements, genetic differences and potential fishery interactions, eight killer whale stocks are recognized within the Pacific U.S. EEZ: 1) the Eastern North Pacific Alaska Resident stock - occurring from Southeast Alaska to the Bering Sea, 2) the Eastern North Pacific Northern Resident stock - occurring from British Columbia through Alaska, 3) the Eastern North Pacific Southern Resident stock - occurring mainly within the inland waters of Washington State and southern British Columbia but extending from central California into southern Southeast Alaska (see Fig. 1), 4) the West Coast Transient stock - occurring from Alaska through California, 5) the Gulf of Alaska, Aleutian Islands, and Bering Sea Transient stock - occurring from southeast Alaska to the Bering Sea, 6) the AT1 Stock – found only in Prince William Sound, 7) the Eastern North Pacific Offshore stock - occurring from Southeast Alaska through California, 8) the Hawaiian stock. The Stock Assessment Reports for the Alaska Region contain information concerning the Eastern North Pacific Alaska Resident, Eastern North Pacific Northern Resident and the Gulf of Alaska, Aleutian Islands, and Bering Sea, AT1, and Eastern North Pacific Transient stocks.

POPULATION SIZE

The Eastern North Pacific Southern Resident stock is a trans-boundary stock including killer whales in inland Washington and southern British Columbia waters. Photo-identification of individual whales through the years has advanced knowledge of this stock's structure, behaviors, and movements. In 1993, the three pods comprising this stock totaled 96 killer whales (Ford *et al.* 1994). The population increased to 99 whales in 1995, then declined to 79 whales in 2001, and most recently numbered 81 whales in 2015 (Fig. 2; Ford *et al.* 2000; Center for Whale Research 2016). The 2001-2005 counts included a whale born in 1999 (L-98) that was listed as missing during the annual census in May and June 2001 but was subsequently discovered alone in an inlet off the west coast of Vancouver Island. L-98 remained separate from L pod until 10 March 2006 when he died due to injuries associated with a vessel interaction in Nootka Sound. L-98 has been subtracted from the official 2006 and subsequent population censuses. The most recent census spanning 1 July 2014 through 1 July 2015 includes 5 new calves (3 presumed male, one female) and the deaths of one reproductive age adult female (that was pregnant with a female neonate), and a calf of unknown sex. This does not include 5 additional calves born between September 2015 and January 2016. In addition, a young adult female was observed pushing a dead neonate (not one of the recently born calves) in January 2016.

Minimum Population Estimate

The abundance estimate for this stock of killer whales is a direct count of individually identifiable animals. It is thought that the entire population is censused every year. This estimate therefore serves as both a best estimate of abundance and a minimum estimate of abundance. Thus, the minimum population estimate (N_{min}) for the Eastern North Pacific Southern Resident stock of killer whales is 81 animals.

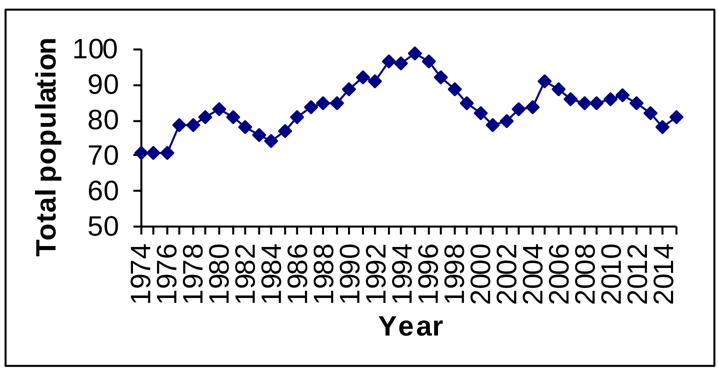

Figure 2. Population of Eastern North Pacific Southern Resident stock of killer whales, 1974-2015. Each year's count includes animals first seen and first missed; a whale is considered first missed the year after it was last seen alive (Ford *et al.* 2000; Center for Whale Research 2015).

Current Population Trend

During the live-capture fishery that existed from 1967 to 1973, it is estimated that 47 killer whales, mostly immature, were taken out of this stock (Ford *et al.* 1994). Since the first complete census of this stock in 1974 when 71 animals were identified, the number of southern resident killer whales has fluctuated annually. Between 1974 and the mid-1990s, the Southern Resident stock increased approximately 35% (Ford *et al.* 1994), representing a net annual growth rate of 1.8% during those years. Following the peak census count of 99 animals in 1995, the population size has declined and currently stands at 81 animals as of the 2015 census (Ford *et al.* 2000; Center for Whale Research 2015).

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

A reliable estimate of the maximum net productivity rate is currently unavailable for this stock of killer whales. Matkin *et al.* (2014) estimated a maximum population annual growth rate of 1.035 for southern Alaska resident killer whales. The authors noted that the 3.5% annual rate estimated for southern Alaska residents is higher than previously measured rates for British Columbia northern residents (2.9%, Olesiuk *et al.* 1990) and "probably represents a population at r-max (maximum rate of growth)." In the absence of published estimates of R_{max} for southern resident killer whales, the maximum annual rate of 3.5% found for southern Alaska residents is used for this stock of southern resident killer whales. This reflects more information about the known life history of resident killer whales than the default R_{max} of 4% and results in a more conservative estimate of potential biological removal (PBR).

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (81) <u>times</u> one-half the maximum net growth rate for *Alaska* resident killer whales (½ of 3.5%) <u>times</u> a recovery factor of 0.1 (for an endangered stock, Wade and Angliss 1997), resulting in a PBR of 0.14 whales per year, or approximately 1 animal every 7 years.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Salmon drift gillnet fisheries in Washington inland waters were last observed in 1993 and 1994 and no killer whale entanglements were documented, though observer coverage levels were less than 10% (Erstad *et al.* 1996, Pierce *et al.* 1994, Pierce *et al.* 1996, NWIFC 1995). Fishing effort in the inland waters drift gillnet fishery has declined considerably since 1994 because far fewer vessels participate today (NOAA West Coast Region). Past marine mammal entanglements in this fishery included harbor porpoise, Dall's porpoise, and harbor seals. Coastal marine tribal set gillnets also occur along the outer Washington coast and no killer whale interactions have been reported in this fishery since the inception of the observer program in 1988, though the fishery is not active every year (Gearin *et al.* 1994, Gearin *et al.* 2000, Makah Fisheries Management,).

An additional source of information on killer whale mortality and injury incidental to commercial fishery operations is the self-reported fisheries information required of vessel operators by the MMPA. No self-report records of killer whale mortality have been reported.

Due to a lack of observer programs, there are few data concerning the mortality of marine mammals incidental to Canadian commercial fisheries. Since 1990, there have been no reported fishery-related strandings of killer whales in Canadian waters. However, in 1994 one killer whale was reported to have contacted a salmon gillnet but did not entangle (Guenther *et al.* 1995). Data regarding the level of killer whale mortality related to commercial fisheries in Canadian waters are not available.

The known total fishery mortality and serious injury for this stock is zero.

Other Mortality

No human-caused killer whale mortality or serious injuries were reported from non-fisheries sources in 2010-2014 (Carretta *et al.* 2016). In 2012, a moderately decomposed juvenile female southern resident killer whale (L-112) was found dead near Long Beach, WA. A full necropsy was performed and the cause of death was determined to be blunt force trauma to the head, however the source of the trauma (vessel strike, intraspecific aggression, or other unknown source) could not be established (NOAA 2014). There was documentation of a whale-boat collision in Haro Strait in 2005 which resulted in a minor injury to a whale. In 2006, whale L98 was killed during a vessel interaction. It is important to note that L98 had become habituated to regularly interacting with vessels during its isolation in Nootka Sound. The annual known level of non-fishery human-caused mortality for this stock over the past five years (2010-2014) is zero animals per year.

STATUS OF STOCK

Total annual fishery mortality and serious injury for this stock (0) is not known to exceed 10% of the calculated PBR (0.14) and, therefore, appears to be insignificant and approaching zero mortality and serious injury rate. The estimated annual level of human-caused mortality and serious injury of zero animals per year does not exceed the PBR (0.14). Southern Resident killer whales were formally listed as "endangered" under the ESA in 2005 and consequently the stock is automatically considered as a "strategic" stock under the MMPA. This stock was considered "depleted" prior to its 2005 listing under the ESA.

Habitat Issues

Several potential risk factors identified for this population have habitat implications. The summer range of this population, the inland waters of Washington and British Columbia, are home to a large commercial whale watch industry, and high levels of recreational boating and commercial shipping. Potential for acoustic masking effects on the whales' communication and foraging due to vessel traffic remains a concern (Erbe 2002, Clark *et al.* 2009). In 2011 vessel approach regulations were implemented to restrict vessels from approaching closer than 200m. Oil tankers also regularly transit these inland waters and as such the risk of oil spills to this population is of concern. This population appears to be Chinook salmon specialists (Ford and Ellis 2006, Hanson *et al.* 2010), although other species, such as chum, pink, and coho salmon also appear to be important elements of the diet (Ford *et al.* 1998). There is evidence that changes in Chinook abundance have affected this population (Ford *et al.* 2009, Ward *et al.* 2009). In addition, the high trophic level and longevity of the animals has predisposed them to accumulate levels of contaminants that are high enough to cause potential health impacts. In particular, there is recent evidence of extremely high levels of flame retardants in young animals (Krahn *et al.* 2007, 2009). The recovery plan for southern resident killer whales highlights risk factors related to high PCB levels found in southern resident killer whales, including possible immune suppression and reproductive impairment (NOAA 2008).

Revised 02/06/2017

SHORT-FINNED PILOT WHALE (*Globicephala macrorhynchus*): California/Oregon/Washington Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Two genetically and morphologically distinct short-finned pilot whale types are described in the Pacific ('Shiho' and 'Naisa') by Van Cise *et al*. (2016), which correspond to the northern and southern types (respectively) described off Japan (Kasuya *et al.* 1988; Wada 1988; Miyazaki and Amano 1994). Shiho type animals are largely confined to the California Current and eastern tropical Pacific, while Naisa type pilot whales occur in the central Pacific and Japan. Differences in body size, head shape, coloration, and number of teeth characterize Shiho and Naisa morphotypes, with the larger eastern Pacific Shiho type characterized by a rounder melon and distinct light saddle patch. Short-finned pilot whales were once common off Southern California, with an apparently resident population around Santa Catalina Island, as well as seasonal migrants (Dohl et al. 1980). After a strong El Niño event in 1982-83, short-finned pilot whales virtually disappeared from this region, and despite increased survey effort along the entire U.S. west coast, sightings and fishery takes are rare and have primarily occurred during warm-water years (Julian and Beeson 1998, Carretta *et al*. 2004, Barlow 2016). Figure 1 summarizes the sightings of short-finned pilot whales off the U.S. west coast from 1991-2014. Pilot whales in the California Current and eastern tropical Pacific likely represent a single population, based on a lack of differentiation in mtDNA (Van Cise *et al.* 2016), while animals in Hawaiian waters are characterized by unique haplotypes that are absent from eastern and southern Pacific samples, despite relatively large sample sizes from Hawaiian waters. For the Marine Mammal Protection Act (MMPA) stock assessment reports, short-finned pilot whales within the Pacific U.S. Exclusive Economic Zone are divided into two discrete, non-contiguous areas: 1) waters off California, Oregon and Washington (this report), and 2) Hawaiian waters. Shiho-type short-finned pilot whales comprise the California, Oregon and Washington stock, and are covered in this report. Naisa-type short-finned pilot whales comprise the Hawaiian stock.

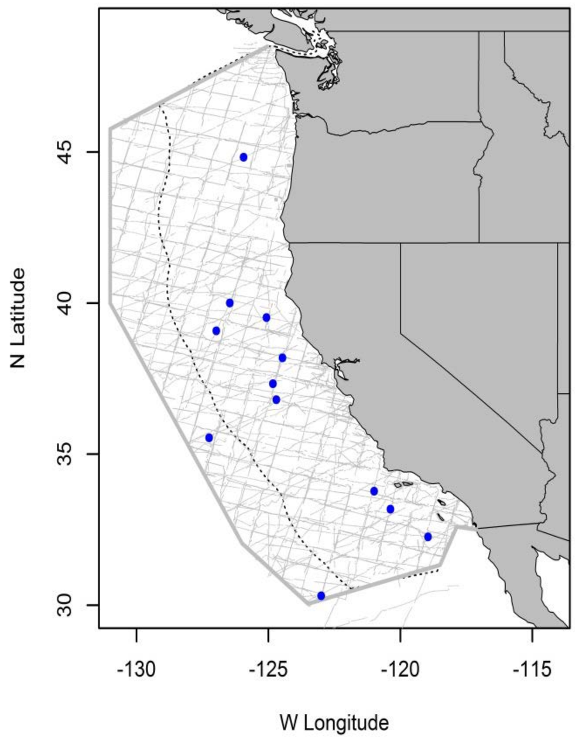

Figure 1. Short-finned pilot whale sightings made during shipboard surveys conducted off California, Oregon, and Washington, 1991-2014 (Barlow 2016). Dashed line represents the U.S. EEZ, thin gray lines indicate completed transect effort of all surveys combined.

POPULATION SIZE

The abundance of short-finned pilot whales in this region is variable and may be influenced by prevailing oceanographic conditions (Forney 1997, Forney and Barlow 1998, Barlow 2016). Because animals may spend time outside the U.S. Exclusive Economic Zone as oceanographic conditions change, a multi-year average abundance estimate is the most appropriate for management within U.S. waters. The most recent estimate of short-finned pilot whale abundance is the geometric mean of estimates from 2008 and 2014 summer/autumn vessel-based line-transect surveys of California, Oregon, and Washington waters, or 836 (CV=0.79) animals (Barlow 2016). This estimate includes new correction factors for animals missed during the surveys.

Minimum Population Estimate

The log-normal 20th percentile of the 2008-2014 geometric mean abundance estimate is 466 short-finned pilot whales.

Current Population Trend

Following the virtual disappearance of short-finned pilot whales from California after the 1982-83 El Niño, they have been encountered infrequently and primarily during warm-water years, such as 1991, 1993, 1997, 2014, and 2015 (e.g., Carretta et al. 1995, Julian and Beeson 1998, Carretta et al. 2004, Barlow 2016). These patterns likely reflect large-scale, long-term movements of this species in response to changing oceanographic conditions. It is not known whether the animals sighted more recently are part of the same population that was documented off Southern California before the mid-1980s or a different wide-ranging pelagic population. Therefore, no inferences can be drawn regarding trends in abundance of short-finned pilot whales off California, Oregon and Washington.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

No information on current or maximum net productivity rates is available for short-finned pilot whales off California, Oregon and Washington.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (466) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.48 (for a species of unknown status with bycatch mortality rate CV between 0.3 and 0.6; Wade and Angliss 1997), resulting in a PBR of 4.5 short-finned pilot whales per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fishery Information

A summary of known fishery mortality and injury for this stock of short-finned pilot whale is shown in Table 1. More detailed information on these fisheries is provided in Appendix 1. The estimate of mortality and serious injury for short-finned pilot whale in the California drift gillnet fishery for the five most recent years of monitoring, 2010-2014, is 6 (CV= 0.39) individuals, or an average of 1.2 per year (Carretta *et al*. 2017). Bycatch of short-finned pilot whales in the drift gillnet fishery is rarely-observed (14 animals in 8,711 observed sets), but high multivariate El Niño index values associated with warm-water years (Wolter and Timlin 2011) were identified as a significant predictor of bycatch in a recent analysis (Carretta et al. 2017).

Historically, short-finned pilot whales were also killed in squid purse seine operations off Southern California (Miller et al. 1983; Heyning et al. 1994), but these deaths occurred when pilot whales were still common in the region. An observer program in the squid purse seine fishery was initiated in 2004 and a total of 377 sets (<10% of effort) were observed through 2008 without a pilot whale interaction. Gillnets have been documented to entangle marine mammals off Baja California (Sosa-Nishizaki et al. 1993), but no recent bycatch data from Mexico are available.

Table 1. Summary of available information on the incidental mortality and serious injury of short-finned pilot whales (California/Oregon/Washington Stock) in commercial fisheries that might take this species (Carretta *et al*. 2017). Coefficients of variation for mortality estimates are provided in parentheses; n/a = not available.

Fishery Name	Data Type	Year(s)	Percent Observer Coverage	Observed Mortality	Estimated Mortality	Mean Annual Takes (CV in parentheses)

Fishery Name	Data Type	Year(s)	Percent Observer Coverage	Observed Mortality	Estimated Mortality	Mean Annual Takes (CV in parentheses)
CA/OR thresher shark/swordfish drift gillnet fishery	observer	2010 2011 2012 2013 2014	12% 20% 19% 37% 24%	0 0 0 0 2	0 0 0 0 6 (0.39)	1.2 (0.39)
Market squid purse seine	observer	2004-2008	<10%	0	0	0
Minimum total annual takes						1.2 (0.39)

STATUS OF STOCK

The status of short-finned pilot whales off California, Oregon and Washington in relation to OSP is unknown. They have declined in abundance in the Southern California Bight, since the 1982-83 El Niño, but the nature of these changes and potential habitat issues are not adequately understood. Short-finned pilot whales are not listed as "threatened" or "endangered" under the Endangered Species Act nor as "depleted" under the MMPA. The average annual human-caused mortality, 1.2 animals, is less than the PBR of 4.5, and therefore they are not classified as a "strategic" stock under the MMPA. Total annual human-caused mortality and serious injury for this stock is greater than 10 % of PBR; therefore, mortality and serious injury cannot be considered to be approaching a zero mortality and serious injury rate.

BAIRD'S BEAKED WHALE (*Berardius bairdii*): California/Oregon/Washington Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Baird's beaked whales are distributed throughout deep waters and along the continental slopes of the North Pacific Ocean (Balcomb 1989, Macleod et al. 2006). They have been harvested and studied in Japanese waters, but little is known about this species elsewhere (Balcomb 1989). Along the U.S. west coast, Baird's beaked whales have been seen primarily along the continental slope (Figure 1) from late spring to early fall. They have been seen less frequently and are presumed to be farther offshore during the colder water months of November through April. For the Marine Mammal Protection Act (MMPA) stock assessment reports, Baird's beaked whales within the Pacific U.S. Exclusive Economic Zone are divided into two discrete, non-contiguous areas: 1) waters off California, Oregon and Washington (this report), and 2) Alaskan waters.

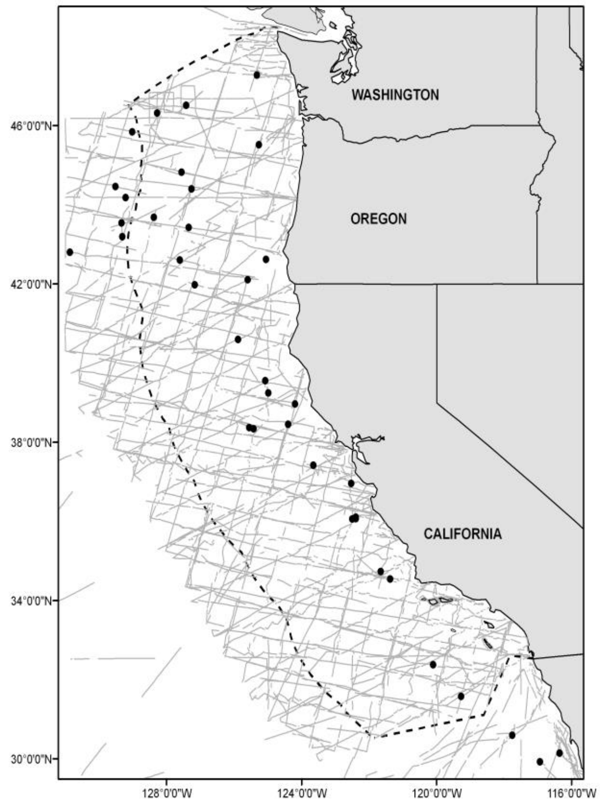

Figure 1. Baird's beaked whale sightings based on shipboard surveys off California, Oregon and Washington, 1991-2008 (see Appendix 2 for data sources and information on timing and location of survey effort). Dashed line represents the U.S. EEZ, thin lines indicate completed transect effort of all surveys combined.

POPULATION SIZE

Two summer/fall shipboard surveys were conducted within 300 nmi of the coasts of California, Oregon and Washington 2005 (Forney 2007) and 2008 (Barlow 2010). Because the distribution of Baird's beaked whale varies and animals probably spend time outside the U.S. Exclusive Economic Zone, a multi-year average abundance estimate is the most appropriate for management within U.S. waters. A geometric mean abundance estimate for California, Oregon and Washington waters based on ship surveys from 2005 and 2008 was 907 (CV=0.49) Baird's beaked whales (Forney 2007, Barlow 2010). This abundance estimate included correction factors for the proportion of animals missed, based on a model of their diving behavior, detection distances, and the searching behavior of observers (Barlow 1999). About 96% of all trackline groups are estimated to be seen. A trend-based analysis of line-transect data from surveys conducted between 1991 and 2008 yielded new estimates of abundance (Moore and Barlow 2013). Based on this analysis and a lack of a detected trend in abundance, a multi-year average of the 2005 and 2008 trend estimates is the most appropriate estimate for this stock. The geometric mean of the best (50th percentile) estimates of abundance for Baird's beaked whales in 2005 (767, CV=1.29) and 2008 (937, CV=1.34) in waters off California, Oregon and Washington is 847 (CV=0.81).

Minimum Population Estimate

The log-normal 20th percentile of the 2005-2008 geometric mean abundance estimate is 466 Baird's beaked whales.

Current Population Trend

The analysis by Moore and Barlow (2013) did not suggest evidence of an abundance trend during 1991–2008 for Baird's beaked whale in waters off the U.S. west coast (Figure 2).

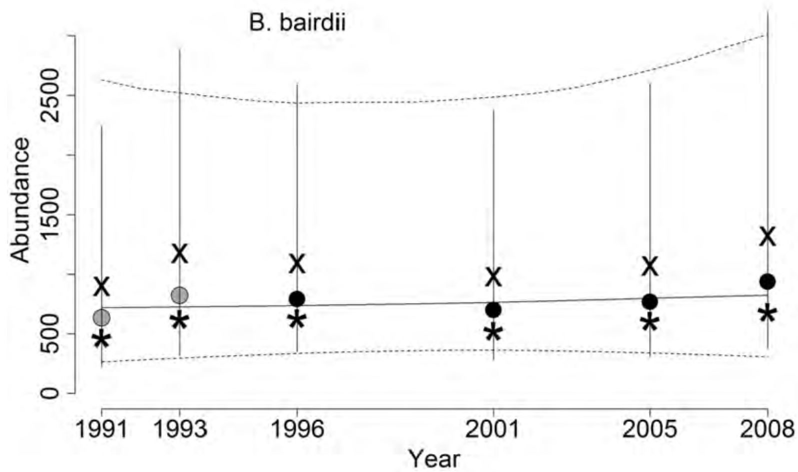

Figure 2. Abundance and trend estimates for Baird's beaked whales in the California Current, 1991-2008 (Moore and Barlow 2013). For each year, the Bayesian posterior median (●), mean (x) and mode (*) abundance estimates are shown, along with 90% CRIs.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

No information on current or maximum net productivity rates is available for this species.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (466) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.50 (for a species of unknown status with no fishery mortality; Wade and Angliss 1997), resulting in a PBR of 4.7 Baird's beaked whales per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fishery Information

The California large mesh drift gillnet fishery has been the only fishery known to interact with this stock. One Baird's beaked whale was incidentally killed in this fishery in 1994 (Julian and Beeson 1998), before acoustic pingers were first used in the fishery in 1996 (Barlow and Cameron 2003). Since 1996, no beaked whale of *any* species have been observed entangled or killed in this fishery (Carretta et al. 2008, Carretta and Enriquez 2009a, 2009b, Carretta and Barlow 2011, Carretta and Enriquez 2012a, 2012b). Mean annual takes in Table 1 are based on 2007-2011 data. This results in an average estimated annual mortality of zero Baird's beaked whales. Gillnets have been documented to entangle marine mammals off Baja California (Sosa-Nishizaki et al. 1993), but no recent bycatch data from Mexico are available.

Table 1. Summary of available information on the incidental mortality and injury of Baird's beaked whales (California/Oregon/Washington Stock) in commercial fisheries that might take this species. The single observed entanglement resulted in the death of the animal. Coefficients of variation for mortality estimates are provided in parentheses. Mean annual takes are based on 2007-2011 data unless noted otherwise.

Fishery Name	Data Type	Year(s)	Percent Observer Coverage	Observed Mortality	Estimated Annual Mortality	Mean Annual Takes (CV in parentheses)
CA/OR thresher shark/swordfish drift gillnet fishery	observer data	2007 2008 2009 2010 2011	16.4% 13.5% 13.3% 11.9% 19.5%	0 0 0 0 0	0 0 0 0 0	0

Fishery Name	Data Type	Year(s)	Percent Observer Coverage	Observed Mortality	Estimated Annual Mortality	Mean Annual Takes (CV in parentheses)
Minimum total annual takes						0

Other mortality

California coastal whaling operations killed 15 Baird's beaked whales between 1956 and 1970, and 29 additional Baird's beaked whales were taken by whalers in British Columbian waters (Rice 1974). One Baird's beaked whale stranded in Washington state in 2003 and the cause of death was attributed to a ship strike. No other human-caused mortality has been reported for this stock for the period 2007-2011.

Anthropogenic sound sources, such as military sonar and seismic testing have been implicated in the mass strandings of beaked whales, including atypical events involving multiple beaked whale species (Simmonds and Lopez-Jurado 1991, Frantiz 1998, Anon. 2001, Jepson et al. 2003, Cox et al. 2006). While D'Amico et al. (2009) note that most mass strandings of beaked whales are unassociated with documented sonar activities, lethal or sub-lethal effects of such activities would rarely be documented, due to the remote nature of such activities and the low probability that an injured or dead beaked whale would strand. Filadelpho et al. (2009) reported statistically significant correlations between military sonar use and mass strandings of beaked whales in the Mediterranean and Caribbean Seas, but not in Japanese and Southern California waters, and hypothesized that regions with steep bathymetry adjacent to coastlines are more conducive to stranding events in the presence of sonar use. In Hawaiian waters, Faerber & Baird (2010) suggest that the probability of stranding is lower than in some other regions due to nearshore currents carrying animals away from beaches, and that stranded animals are less likely to be detected due to low human population density near many of Hawaii's beaches. Actual and simulated sonar are known to interrupt the foraging dives and echolocation activities of tagged beaked whales (Tyack et al. 2011). Blainville's beaked whale presence was monitored on hydrophone arrays before, during, and after sonar activities on a Caribbean military range, with evidence of avoidance behavior: whales were detected throughout the range prior to sonar exposure, not detected in the center of the range coincident with highest sonar use, and gradually returned to the range center after the cessation of sonar activity (Tyack et al. 2011). Fernández et al. (2013) report that there have been no mass strandings of beaked whales in the Canary Islands following a 2004 ban on sonar activities in that region. The absence of beaked whale bycatch in California drift gillnets following the introduction of acoustic pingers into the fishery implies additional sensitivity of beaked whales to anthropogenic sound (Carretta et al. 2008, Carretta and Barlow 2011).

STATUS OF STOCK

The status of Baird's beaked whales in California, Oregon and Washington waters relative to OSP is not known, and no abundance trend is evident. They are not listed as "threatened" or "endangered" under the Endangered Species Act nor as "depleted" under the MMPA. The average annual human-caused mortality during 2007-2011 is zero animals/year. Because recent fishery and human-caused mortality is less than the PBR (4.7), Baird's beaked whales are not classified as a "strategic" stock under the MMPA. The total fishery mortality and serious injury for this stock is zero and can be considered to be insignificant and approaching zero. The impacts of anthropogenic sound on beaked whales remains a concern (Barlow and Gisiner 2006, Cox et al. 2006, Hildebrand et al. 2005, Weilgart 2007).

MESOPLODONT BEAKED WHALES (*Mesoplodon* spp.): California/Oregon/Washington Stocks

STOCK DEFINITION AND GEOGRAPHIC RANGE

Mesoplodont beaked whales are distributed throughout deep waters and along the continental slopes of the North Pacific Ocean. The six species known to occur in this region are: Blainville's beaked whale (*M. densirostris*), Perrin's beaked whale (*M. perrini*), Lesser beaked whale (*M. peruvianus*), Stejneger's beaked whale (*M. stejnegeri*), Gingko-toothed beaked whale (*M. gingkodens*), and Hubbs' beaked whale (*M. carlhubbsi*) (Mead 1989, Henshaw *et al.* 1997, Dalebout *et al.* 2002, MacLeod et al. 2006). Based on bycatch and stranding records in this region, it appears that Hubb's beaked whale is most commonly encountered (Carretta et al. 2008, Moore and Barlow 2013). Insufficient sighting records exist off the U.S. west coast (Figure 1) to determine any possible spatial or seasonal patterns in the distribution of mesoplodont beaked whales.

Until methods of distinguishing these six species at-sea are developed, the management unit must be defined to include all *Mesoplodon* stocks in this region. However, in the future, species-level management is desirable, and a high priority should be placed on finding means to obtain species-specific abundance information. For the Marine Mammal Protection Act (MMPA) stock assessment reports, three *Mesoplodon* stocks are defined: 1) all *Mesoplodon* species off California, Oregon and Washington (this report), 2) *M. stejnegeri* in Alaskan waters, and 3) *M. densirostris* in Hawaiian waters.

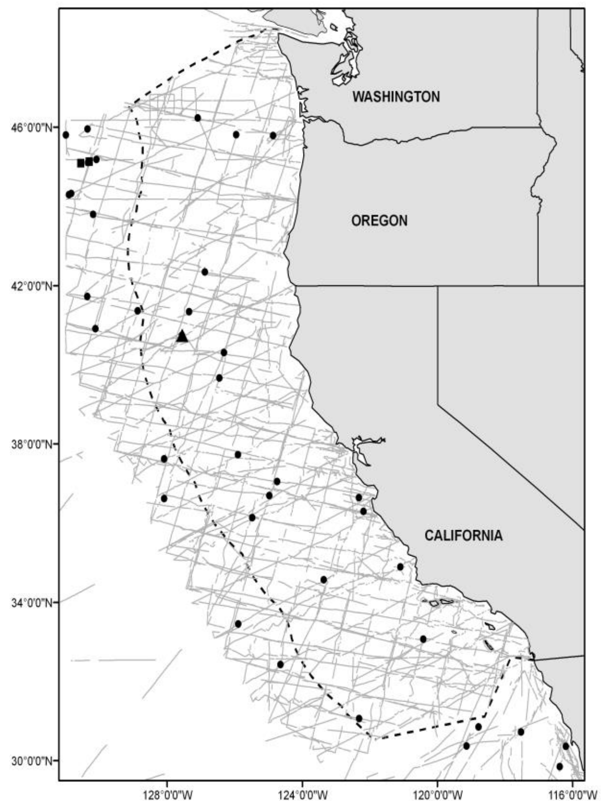

Figure 1. *Mesoplodon* beaked whale sightings based on shipboard surveys off California, Oregon and Washington, 1991-2008 (see Appendix 2 for data sources and information on timing and location of survey effort). Key: • = *Mesoplodon* spp.; ▲= identified *Mesoplodon densirostris*; ■ = identified *Mesoplodon carlhubbsi*. Dashed line represents the U.S. EEZ, thin lines indicate completed transect effort of all surveys combined.

POPULATION SIZE

Although mesoplodont beaked whales have been sighted along the U.S. west coast on several line transect surveys utilizing both aerial and shipboard platforms, the rarity of sightings has historically precluded reliable population estimates. Early abundance estimates are imprecise and biased low by an unknown amount because of the large proportion of time this species spends submerged, and because the ship surveys before 1996 covered only California waters, and thus did not include animals off Oregon/Washington. Furthermore, survey data include a large number of unidentified beaked whale sightings that are probably either *Mesoplodon* sp. or Cuvier's beaked whales (*Ziphius cavirostris*). An abundance estimate of 1,024 (CV = 0.77) for all species of *Mesoplodon* beaked whales in the California Current was obtained based on combining data from the two most recent surveys (2005, 2008) conducted within 300 nmi of the coasts of California, Oregon and Washington (Forney 2007, Barlow and Forney 2007, Barlow 2010). This estimate was based in part on a correction factor to account for the proportion of animals on the survey trackline that were likely to missed by observers (0.55), calculated from a model of beaked whale diving behavior, detection distances and searching behavior by the observers (Barlow 1999). Of the 5 sightings of *Mesoplodon* made during 2005-2008 surveys [all 5 sightings were made during the 2005 survey] two were identified to the 'probable' species level (one *Mesoplodon densirostris* and one *Mesoplodon carlhubbsi*). An estimate of Blainville's beaked whale abundance (603, CV = 1.16) was based on this one probable sighting, while the Hubb's beaked whale sighting was not recorded during standard survey effort, and thus there is no estimate of abundance. The abundance estimate for mesoplodont beaked whales of unknown species, based on the same 2005-2008 surveys was 421 (CV=0.88). A trend-based analysis of line-transect data from surveys conducted between 1991 and 2008 yielded new estimates of *Mesoplodon* species abundance (Moore and Barlow 2013). The new estimate accounts for the proportion of unidentified beaked whale sightings likely to be *Mesoplodon* beaked whales and uses a correction factor for missed animals adjusted to account for the fact that the proportion of animals on the trackline missed by observers increases in rough observing conditions. The trend-model analysis incorporates information from the entire 1991-2008 time series for each annual estimate of abundance, and given the strong evidence of a decreasing abundance trend over that time (Moore and Barlow 2013), the best estimate of abundance is represented by the model-averaged estimate for 2008. Based on this analysis, the best (50th percentile) estimate of abundance for all species of *Mesoplodon* species combined in 2008 in waters off California, Oregon and Washington is 694 (CV=0.65).

Minimum Population Estimate

The minimum population estimate (defined as the log-normal 20th percentile of the abundance estimate) for mesoplodont beaked whales in California, Oregon, and Washington is 389 animals.

Current Population Trend

There is strong evidence, based on line-transect survey data and the historical stranding record off the U.S. west coast, that the abundance of *Mesoplodon* beaked whales has recently declined in waters off California, Oregon and Washington (Moore and Barlow 2013, Figure 2). Statistical analysis of line-transect survey data from 1991 - 2008 indicates a 0.96 probability of decline during this period, with the mean annual rate of population change estimated to have been −7.0% per year (95% CRI: −16.7% to +1.0%). Patterns in the historical stranding record alone provide limited information about beaked whale abundance trends, but the stranding record appears generally consistent rather than at-odds with results of the line-transect survey analysis. Regional stranding networks along the Pacific coast of the U.S. and Canada originated during the 1980s, and beach coverage and reporting rates are thought to have increased throughout the 1990s and in to the early 2000s. Therefore, for a stable or increasing population, an overall increasing trend in stranding reports between the 1980s and 2000s would be expected. In contrast, reported strandings for *M. carlhubbsi* and *M. stejnegeri* in the California Current region have declined monotonically since the 1980s.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

No information on current or maximum net productivity rates is available for mesoplodont beaked whales.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (389) <u>times</u> one half the default maximum net growth rate

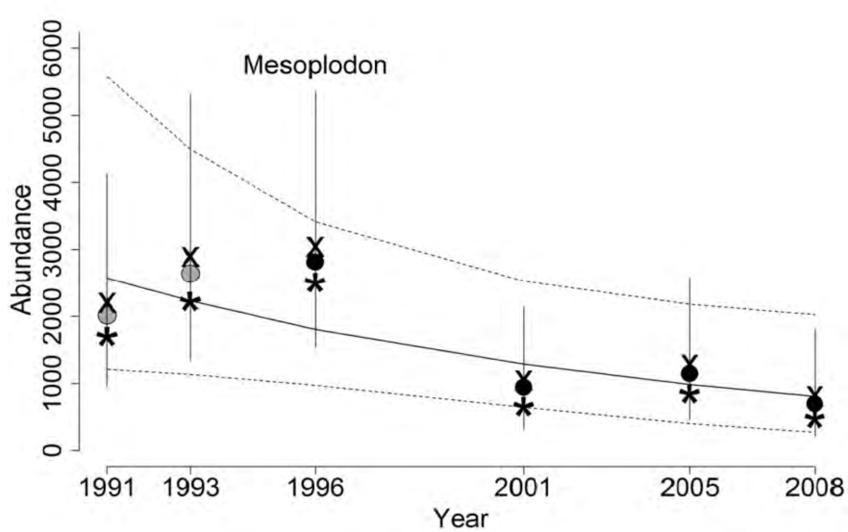

Figure 2. Abundance and trend estimates for mesoplodont beaked whales in the California Current, 1991-2008 (Moore and Barlow 2013). For each year, the Bayesian posterior median (●), mean (x) and mode (*) abundance estimates are shown, along with 90% CRIs.

for cetaceans (½ of 4%) times a recovery factor of 0.50 (for a species of unknown status with no known recent fishery mortality; Wade and Angliss 1997), resulting in a PBR of 3.9 mesoplodont beaked whales per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fishery Information

The California large mesh drift gillnet fishery has been the only fishery historically known to interact with *Mesoplodon* beaked whales in this region. Between 1990 and 1995, a total of eight *Mesoplodon* beaked whales (5 Hubb's beaked whales (*Mesoplodon carlhubbsi*), one Stejneger's beaked whale (*Mesoplodon stejnegeri*), and two unidentified whales of the genus *Mesoplodon* were observed entangled in approximately 3,300 sets (Julian and Beeson 1998, Carretta *et al*. 2008). Following the introduction of acoustic pingers into this fishery (Barlow and Cameron 2003), no beaked whales of any species have been observed entangled in over 4,000 observed sets (Carretta *et al*. 2008, Carretta and Enriquez 2009a, 2009b, 2010, 2012a, 2012b, Carretta and Barlow 2011). Mean annual takes in Table 1 are based on 2007-2011 data. This results in an average estimated annual mortality of zero mesoplodont beaked whales.

Gillnets have been documented to entangle marine mammals off Baja California (Sosa-Nishizaki et al. 1993), but no recent bycatch data from Mexico are available.

Table 1. Summary of available information on the incidental mortality and injury of *Mesoplodon* beaked whales (California/Oregon/Washington Stocks) in commercial fisheries that might take these species. Mean annual takes are based on 2007-2011 data unless noted otherwise.

Fishery Name	Data Type	Year	Percent Observer Coverage	Observed Mortality	Estimated Annual Mortality	Mean Annual Takes (CV in parentheses)
CA/OR thresher shark/swordfish drift gillnet fishery	observer	2007 2008 2009 2010 2011	16.4% 13.5% 13.3% 11.9% 19.5%	0 0 0 0 0	0 0 0 0 0	0
Minimum total annual takes of *Mesoplodon* beaked whales						0

Other mortality

Anthropogenic sound sources, such as military sonar and seismic testing have been implicated in the mass strandings of beaked whales, including atypical events involving multiple beaked whale species (Simmonds and Lopez-Jurado 1991, Frantiz 1998, Anon. 2001, Jepson et al. 2003, Cox et al. 2006). While D'Amico et al. (2009) note that most mass strandings of beaked whales are unassociated with documented sonar activities, lethal or sub-lethal effects of such activities would rarely be documented, due to the remote nature of such activities and the low probability that an injured or dead beaked whale would strand. Filadelpho et al. (2009) reported statistically significant correlations between military sonar use and mass strandings of beaked whales in the Mediterranean and Caribbean Seas, but not in Japanese and Southern California waters, and hypothesized that regions with steep bathymetry adjacent to coastlines are more conducive to stranding events in the presence of sonar use. In Hawaiian waters, Faerber & Baird (2010) suggest that the probability of stranding is lower than in some other regions due to nearshore currents carrying animals away from beaches, and that stranded animals are less likely to be detected due to low human population density near many of Hawaii's beaches. Actual and simulated sonar are known to interrupt the foraging dives and echolocation activities of tagged beaked whales (Tyack et al. 2011, DeRuiter et al. 2013). Cuvier's beaked whales tagged and tracked during simulated mid-frequency sonar exposure showed avoidance reactions, including prolonged diving, cessation of echolocation click production associated with foraging, and directional travel away from the simulated sonar source (DeRuiter et al. 2013). Blainville's beaked whale presence was monitored on hydrophone arrays before, during, and after sonar activities on a Caribbean military range, with evidence of avoidance behavior: whales were detected throughout the range prior to sonar exposure, not detected in the center of the range coincident with highest sonar use, and gradually returned to the range center after the cessation of sonar activity (Tyack et al. 2011). Fernández et al. (2013) report that there have been no mass strandings of beaked whales in the Canary Islands following a 2004 ban on sonar activities in that region. The absence of beaked whale bycatch in California drift gillnets following the introduction of acoustic pingers into the fishery implies additional sensitivity of beaked whales to anthropogenic sound (Carretta et al. 2008, Carretta and Barlow 2011).

STATUS OF STOCKS

The status of mesoplodont beaked whales in California, Oregon and Washington waters relative to OSP is not known, but evidence suggests a high likelihood of population decline in the California Current since the early 1990s, at a mean rate of −7.0% per year, which corresponds to trend-fitted abundance levels in 2008 (most recent survey) being at approximately 30% of 1991 levels. Moore and Barlow (2013) ruled out bycatch as a cause of the decline in mesoplodont beaked whale abundance and suggest that impacts from anthropogenic sound such as naval sonar and deepwater ecosystem changes within the California Current are plausible hypotheses warranting further investigation. None of the six species is listed as "threatened" or "endangered" under the Endangered Species Act, but given the long-term decline in mesoplodont beaked whale abundance in the California Current reported by Moore and Barlow (2013), these stocks are considered strategic. The degree of decline (trend-fitted 2008 abundance at approximately 30% of 1991 levels) also suggests that these stocks are likely well below their carrying capacity and may be depleted. The average annual known human-caused fishery mortality between 2007 and 2011 is zero. It is likely that the difficulty in identifying these animals in the field will remain a critical obstacle to obtaining species-specific abundance estimates and stock assessments in the future. The impacts of anthropogenic sound on beaked whales remains a concern (Barlow and Gisiner 2006, Cox et al. 2006, Hildebrand et al. 2005, Weilgart 2007).

CUVIER'S BEAKED WHALE (*Ziphius cavirostris*): California/Oregon/Washington Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Cuvier's beaked whales are distributed widely throughout deep waters of all oceans (MacLeod et al. 2006). Off the U.S. west coast, this species is the most commonly encountered beaked whale (Figure 1). No seasonal changes in distribution are apparent from stranding records, and morphological evidence is consistent with the existence of a single eastern North Pacific population from Alaska to Baja California, Mexico (Mitchell 1968). For the Marine Mammal Protection Act (MMPA) stock assessment reports, Cuvier's beaked whales within the Pacific U.S. Exclusive Economic Zone are divided into three discrete, non-contiguous areas: 1) waters off California, Oregon and Washington (this report), 2) Alaskan waters, and 3) Hawaiian waters.

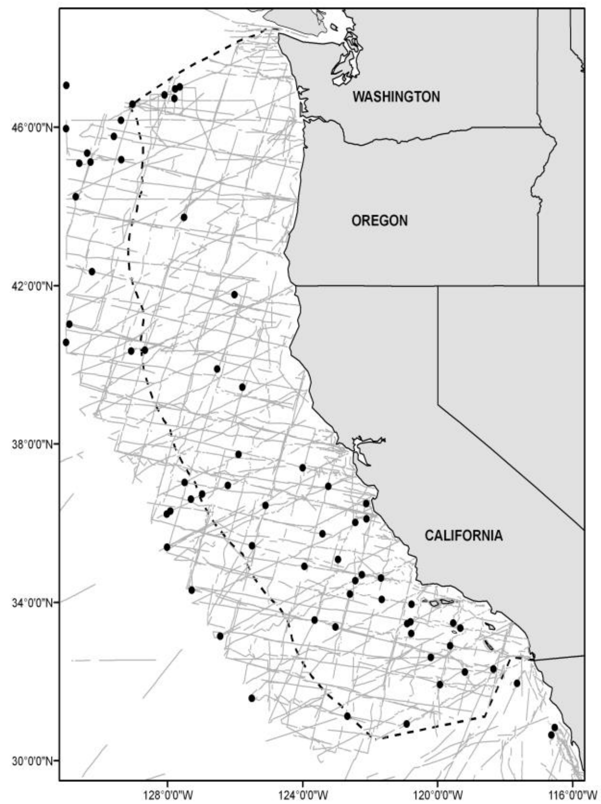

Figure 1. Cuvier's beaked whale sightings based on shipboard surveys off California, Oregon and Washington, 1991-2008 (see Appendix 2, for data sources and information on timing and location of survey effort). Dashed line represents the U.S. EEZ, thin lines indicate completed transect effort of all surveys combined.

POPULATION SIZE

Although Cuvier's beaked whales have been sighted along the U.S. west coast on several line transect surveys utilizing both aerial and shipboard platforms, the rarity of sightings has historically precluded reliable population estimates. Early abundance estimates were imprecise and biased low by an unknown amount because of the large proportion of time this species spends submerged, and because ship surveys before 1996 covered only California waters, and thus did not include animals off Oregon/Washington. Furthermore, survey data include a large number of unidentified beaked whale sightings that are probably either *Mesoplodon* sp. or Cuvier's beaked whales (*Ziphius cavirostris*). An abundance estimate of 2,143 (CV = 0.65) was obtained based on combining data from the two most recent surveys (2005, 2008) conducted within 300 nmi of the coasts of California, Oregon and Washington (Forney 2007, Barlow and Forney 2007, Barlow 2010). This estimate was based in part on a correction factor to account for the proportion of animals on the survey trackline that were likely to missed by observers (0.67), calculated from a model of Cuvier's beaked whale diving behavior, detection distances and searching behavior by the observers (Barlow 1999). A trend-based analysis of line-transect data from surveys conducted between 1991 and 2008 yielded new estimates of Cuvier's beaked whale abundance (Moore and Barlow 2013). The new estimate is substantially higher than previous estimates in part because it accounts for the proportion of unidentified beaked whale sightings likely to be Cuvier's beaked whales and because the correction factor for missed animals was adjusted to account for the fact that the proportion of animals on the trackline missed by observers increases in rough observing conditions. The trend-model analysis incorporates information from the entire

1991-2008 time series for each annual estimate of abundance, and given the strong evidence of a decreasing abundance trend over that time (Moore and Barlow 2013), the best estimate of abundance is represented by the model-averaged estimate for 2008. Based on this analysis, the best (50^{th} percentile) estimate of abundance for Cuvier's beaked whales in 2008 in waters off California, Oregon and Washington was 6,590 (CV=0.55).

Minimum Population Estimate

Based on the analysis by Moore and Barlow (2013), the minimum population estimate (defined as the log-normal 20th percentile of the abundance estimate) for Cuvier's beaked whales in California, Oregon, and Washington is 4,481 animals.

Current Population Trend

There is substantial evidence, based on line-transect survey data and the historical stranding record off the U.S. west coast, that the abundance of Cuvier's beaked whales has recently declined in waters off California, Oregon and Washington (Moore and Barlow 2013, Figure 2). Statistical analysis of line-transect survey data from 1991 - 2008 indicates a 0.84 probability of decline during this period, with the mean annual rate of population change estimated to have been −2.9% per year (95% CRI: −8.8% to +3.3%). Patterns in the historical stranding record alone provide limited information about beaked whale abundance trends, but the stranding record appears generally consistent rather than at-odds with results of the line-transect survey analysis. Regional stranding networks along the Pacific coast of the U.S. and Canada originated during the 1980s, and beach coverage and reporting rates are thought to have increased throughout the 1990s and in to the early 2000s. Therefore, for a stable or increasing population, an overall increasing trend in stranding reports between the 1980s and 2000s would be expected. Patterns of Cuvier's beaked whale strandings data are highly variable across stranding network regions, but an overall increasing trend from the 1980s through 2000s is not evident within the California Current area, contrary to patterns for Baird's beaked whales (Moore and Barlow 2013) and for cetaceans in general (e.g., Norman et al. 2004, Danil et al. 2010).

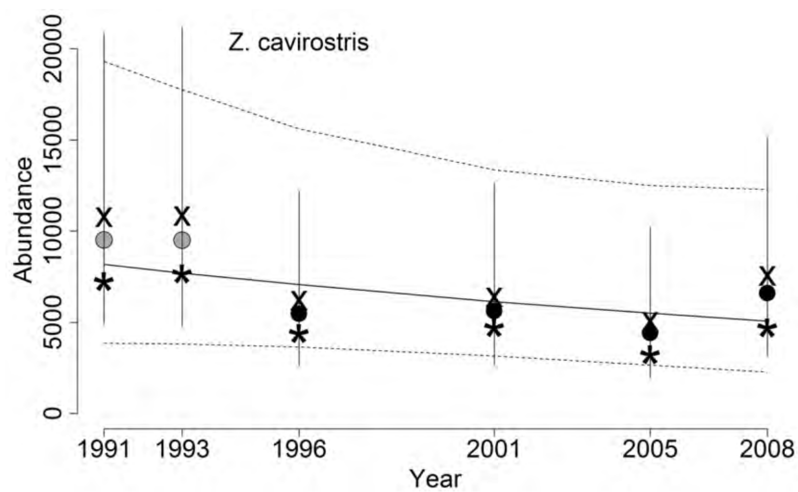

Figure 2. Abundance and trend estimates for Cuvier's beaked whales in the California Current, 1991-2008 (Moore and Barlow 2013). For each year, the Bayesian posterior median (●), mean (x) and mode (*) abundance estimates are shown, along with 90% CRIs.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

No information on current or maximum net productivity rates is available for this species.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (4,481) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.50 (for a species of unknown status with no known fishery mortality; Wade and Angliss 1997), resulting in a PBR of 45 Cuvier's beaked whales per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fishery Information

A summary of recent fishery mortality and injury for Cuvier's beaked whales in this region is shown in Table 1. The California large mesh drift gillnet fishery has been the only fishery historically known to interact with this stock. There have been no Cuvier's beaked whales observed entangled in over 4,000 drift gillnet fishery sets since acoustic pingers were first used in this fishery in 1996 (Barlow and Cameron 2003, Carretta et al. 2008, Carretta and Enriquez 2009a, 2009b, 2010, 2012a, 2012b, Carretta and Barlow 2011). Prior to 1996, there were a total of 21 Cuvier's beaked whales entangled in approximately 3,300 drift gillnet fishery sets: 1992 (six animals), 1993 (three), 1994 (six) and 1995 (six) (Julian and Beeson 1998). Mean annual takes in Table 1 are based only on 2007-2011 data. This results in an average estimated annual mortality of zero Cuvier's beaked whales.

Table 1. Summary of available information on the incidental mortality and injury of Cuvier's beaked whales (California/ Oregon/Washington Stock) in commercial fisheries that might take this species. Mean annual takes are based on 2007-2011 data unless noted otherwise.

Fishery Name	Data Type	Year(s)	Percent Observer Coverage	Observed Mortality + ReleasedAlive	Estimated Annual Mortality / Mortality + Entanglements	Mean Annual Takes (CV in parentheses)
CA/OR thresher shark/swordfish drift gillnet fishery	observer data	2007 2008 2009 2010 2011	16.4% 13.5% 13.3% 11.9% 19.5%	0 0 0 0 0	0 0 0 0 0	0
Minimum total annual takes						0

Gillnets have been documented to entangle marine mammals off Baja California (Sosa-Nishizaki et al. 1993), but no recent bycatch data from Mexico are available.

Other mortality

Anthropogenic sound sources, such as military sonar and seismic testing have been implicated in the mass strandings of beaked whales, including atypical events involving multiple beaked whale species (Simmonds and Lopez-Jurado 1991, Frantiz 1998, Anon. 2001, Jepson et al. 2003, Cox et al. 2006). While D'Amico et al. (2009) note that most mass strandings of beaked whales are unassociated with documented sonar activities, lethal or sub-lethal effects of such activities would rarely be documented, due to the remote nature of such activities and the low probability that an injured or dead beaked whale would strand. Filadelpho et al. (2009) reported statistically significant correlations between military sonar use and mass strandings of beaked whales in the Mediterranean and Caribbean Seas, but not in Japanese and Southern California waters, and hypothesized that regions with steep bathymetry adjacent to coastlines are more conducive to stranding events in the presence of sonar use. In Hawaiian waters, Faerber & Baird (2010) suggest that the probability of stranding is lower than in some other regions due to nearshore currents carrying animals away from beaches, and that stranded animals are less likely to be detected due to low human population density near many of Hawaii's beaches. Actual and simulated sonar are known to interrupt the foraging dives and echolocation activities of tagged beaked whales (Tyack et al. 2011, DeRuiter et al. 2013). Cuvier's beaked whales tagged and tracked during simulated mid-frequency sonar exposure showed avoidance reactions, including prolonged diving, cessation of echolocation click production associated with foraging, and directional travel away from the simulated sonar source (DeRuiter et al. 2013). Blainville's beaked whale presence was monitored on hydrophone arrays before, during, and after sonar activities on a Caribbean military range, with evidence of avoidance behavior: whales were detected throughout the range prior to sonar exposure, not detected in the center of the range coincident with highest sonar use, and gradually returned to the range center after the cessation of sonar activity (Tyack et al. 2011). Fernández et al. (2013) report that there have been no mass strandings of beaked whales in the Canary Islands following a 2004 ban on sonar activities in that region. The absence of beaked whale bycatch in California drift gillnets following the introduction of acoustic pingers into the fishery implies additional sensitivity of beaked whales to anthropogenic sound (Carretta et al. 2008, Carretta and Barlow 2011).

STATUS OF STOCK

The status of Cuvier's beaked whales in California, Oregon and Washington waters relative to OSP is not known, but evidence suggests a substantial likelihood of population decline in the California

Current since the early 1990s, at a mean rate of -2.9% per year, which corresponds to trend-fitted abundance levels in 2008 (most recent survey) being at 61% of 1991 levels. They are not listed as "threatened" or "endangered" under the Endangered Species Act nor as "depleted" under the MMPA, but given the long-term decline in Cuvier's beaked whale abundance in the California Current reported by Moore and Barlow (2013), this stock is considered strategic. The degree of decline (trend-fitted 2008 abundance at approximately 61% of 1991 levels) also suggests that this stock is likely below its carrying capacity and may be depleted. Moore and Barlow (2013) ruled out bycatch as a cause of the decline in Cuvier's beaked whale abundance and suggest that impacts from anthropogenic sounds such as naval sonar and deepwater ecosystem changes within the California Current are plausible hypotheses warranting further investigation. The average annual known human-caused mortality between 2007 and 2011 is zero. The total fishery mortality and serious injury for this stock is less than 10% of the PBR and thus can be considered to be insignificant and approaching zero. The impacts of anthropogenic sound on beaked whales remains a concern (Barlow and Gisiner 2006, Cox et al. 2006, Hildebrand et al. 2005, Weilgart 2007).

PYGMY SPERM WHALE (*Kogia breviceps*): California/Oregon/Washington Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Pygmy sperm whales are distributed throughout deep waters and along the continental slopes of the North Pacific and other ocean basins (Ross 1984; Caldwell and Caldwell 1989). Along the U.S. west coast, sightings of this species and of animals identified only as *Kogia* sp. have been rare (Figure 1). However, this probably reflects their pelagic distribution, small body size and cryptic behavior, rather than a measure of rarity. Strandings of pygmy sperm whales in this region are known from California, Oregon and Washington (Roest 1970; Caldwell and Caldwell 1989; NMFS, Northwest Region, unpublished data; NMFS, Southwest Region, unpublished data), while strandings of dwarf sperm whales (*Kogia sima*) are rare in this region. At-sea sightings in this region have all been either of pygmy sperm whales or unidentified *Kogia* sp. Available data are insufficient to identify any seasonality in the distribution of pygmy sperm whales, or to delineate possible stock boundaries. For the Marine Mammal Protection Act (MMPA) stock assessment reports, pygmy sperm whales within the Pacific U.S. Exclusive Economic Zone are divided into two discrete, non-contiguous areas: 1) waters off California, Oregon and Washington (this report), and 2) Hawaiian waters.

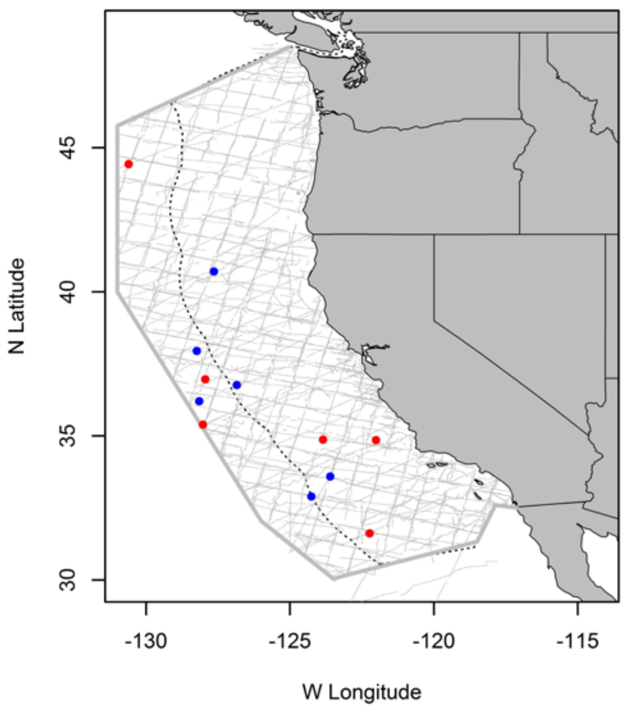

Figure 1. *Kogia* sightings based on shipboard surveys off California, Oregon and Washington, 1991-2014. Key: ● = *Kogia breviceps*, ● = *Kogia* spp. Dashed line represents the U.S. EEZ, thin lines indicate completed transect effort of all surveys combined.

POPULATION SIZE

Most sightings of *Kogia* in the California Current are only identified to genus due to their cryptic nature, but based on positively-identified sightings from previous surveys and historical stranding data, most of these sightings were probably pygmy sperm whales; *K. breviceps*. The rarity of sightings likely reflects the cryptic nature of this species (they are detected almost exclusively in extremely calm sea conditions), rather than an absence of animals in the region. The best estimate of abundance for this stock is the geometric mean of 2008 and 2014 shipboard line-transect surveys, or 4,111 (CV=1.12) animals. This estimate is considerably higher than previous abundance estimates for the genus *Kogia* and results from a new and lower estimate of *g(0)*, the trackline detection probability (Barlow 2015). Only 3% of *Kogia* groups were estimated to have been detected on the trackline during 1991-2014 surveys (Barlow 2016).

Minimum Population Estimate

The minimum population estimate is taken as the log-normal 20th percentile of the 2008 and 2014 average abundance estimate for California, Oregon, and Washington waters, or 1,924 animals.

Current Population Trend

Due to the rarity of sightings of this species on surveys along the U.S. West coast, no information exists regarding trends in abundance of this population.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

No information on current or maximum net productivity rates is available for this species.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (1,924) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.50 (for a species of unknown status with no known fishery mortality during the last five years; Wade and Angliss 1997), resulting in a PBR of 19 pygmy sperm whales per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fishery Information

A summary of recent fishery mortality and injury for pygmy sperm whales and unidentified *Kogia*, which may have been pygmy sperm whales, is shown in Table 1. In the California swordfish drift gillnet fishery (the only U.S. west coast fishery likely to interact with *Kogia*), no mortality of pygmy sperm whales or unidentified *Kogia* was observed during the most recent five years of monitoring (Carretta *et al*. 2017). Over 8,600 fishing sets have been monitored in the California swordfish drift gillnet fishery between 1990 and 2014 and only 2 pygmy sperm whales were observed entangled (Carretta et al. 2017). Both animals were entangled in years that predated the use of acoustic pingers in the fishery to reduce bycatch (Barlow and Cameron 2003), but the small sample size of *Kogia breviceps* bycatch in the fishery precludes any conclusions regarding the effectiveness of acoustic pingers in reducing bycatch of this species (Carretta and Barlow 2011). Mean annual takes in Table 1 are based on 2010-2014 data. This results in an average estimated annual mortality of zero pygmy sperm whales.

One pygmy sperm whale stranded in California in 2002 with evidence that it died as a result of a shooting (positive metal detector scan). Due to the cryptic and pelagic nature of this species, it is likely that the shooting resulted from an interaction with an unknown entangling net fishery. Although there are no records of fishery-related strandings of pygmy sperm whales along the U.S. west coast in recent years (Carretta *et al*. 2013, 2014, 2015, 2016a), compared with other more coastal cetaceans, the probability of a pygmy sperm whale carcass coming ashore and being detected would be quite low (Carretta *et al*. 2016b).

Other mortality

Unknown levels of injuries and mortality of pygmy sperm whales may occur as a result of anthropogenic sound, such as military sonars. Atypical multispecies mass strandings, sometimes involving pygmy and/or dwarf sperm whales have been associated with military sonar use. One 1988 event from the Canary Islands included 2 pygmy sperm whales and the species *Ziphius cavirostris* and *Hyperoodon ampullatus* (reviewed in D'Amico *et al*. 2009). Another mass stranding and unusual mortality event (UME) in North Carolina, USA in 2005 included 2 dwarf sperm whales, in addition to 33 short-finned pilot whales and a minke whale (Hohn *et al*. 2006). This UME coincided in time and space with military activity using mid-frequency active sonar, although the authors note that a definitive association between the UME and sonar use is lacking (Hohn *et al*. 2006). Such injuries or mortality to pygmy sperm whales would rarely be documented, due to the remote nature of many of these activities and the low probability that an injured or dead pygmy sperm whale would strand.

STATUS OF STOCK

The status of pygmy sperm whales in California, Oregon and Washington waters relative to OSP is not known, and there are insufficient data to evaluate potential trends in abundance. Although the impacts of anthropogenic sounds such as sonar are often focused on beaked whales (Barlow and Gisiner 2006), the impacts of such sounds on deep-diving pygmy beaked whales also warrants concern. They are not listed as "threatened" or "endangered" under the Endangered Species Act nor as "depleted" under the MMPA. Given the rarity of sightings and lack of recent documented fishery interactions in U.S. west coast waters, pygmy sperm whales are not classified as a "strategic" stock under the MMPA.

Table 1. Summary of available information on the incidental mortality and injury of pygmy sperm whales and unidentified *Kogia* sp. (California/Oregon/Washington Stock) in commercial fisheries that might take this species. Coefficients of variation for mortality estimates are provided in parentheses. Mean annual takes are based on 2010-2014 data unless noted otherwise (Carretta *et al.* 2017).

DWARF SPERM WHALE (*Kogia sima*): California/Oregon/Washington Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Dwarf sperm whales are distributed throughout deep waters and along the continental slopes of the North Pacific and other ocean basins (Caldwell and Caldwell 1989; Ross 1984). This species was only recognized as being distinct from the pygmy sperm whale in 1966 (Handley, 1966), and early records for the two species are confounded. Along the U.S. west coast, no at-sea sightings of this species have been reported; however, this may be partially a reflection of their pelagic distribution, small body size and cryptic behavior. A few sightings of animals identified only as *Kogia* sp. have been reported (Figure 1), and some of these may have been dwarf sperm whales. At least five dwarf sperm whales stranded in California between 1967 and 2000 (Roest 1970; Jones 1981; J. Heyning, pers. comm.; NMFS, Southwest Region, unpublished data), and one stranding is reported for western Canada (Nagorsen and Stewart 1983). It is unclear whether records of dwarf sperm whales are so rare because they are not regular inhabitants of this region, or merely because of their cryptic habits and offshore distribution. Available data are insufficient to identify any seasonality in the distribution of dwarf sperm whales, or to delineate possible stock boundaries. For the Marine Mammal Protection Act (MMPA) stock assessment reports, dwarf sperm whales within the Pacific U.S. Exclusive Economic Zone are divided into two discrete, non-contiguous areas: 1) waters off California, Oregon and Washington (this report), and 2) Hawaiian waters.

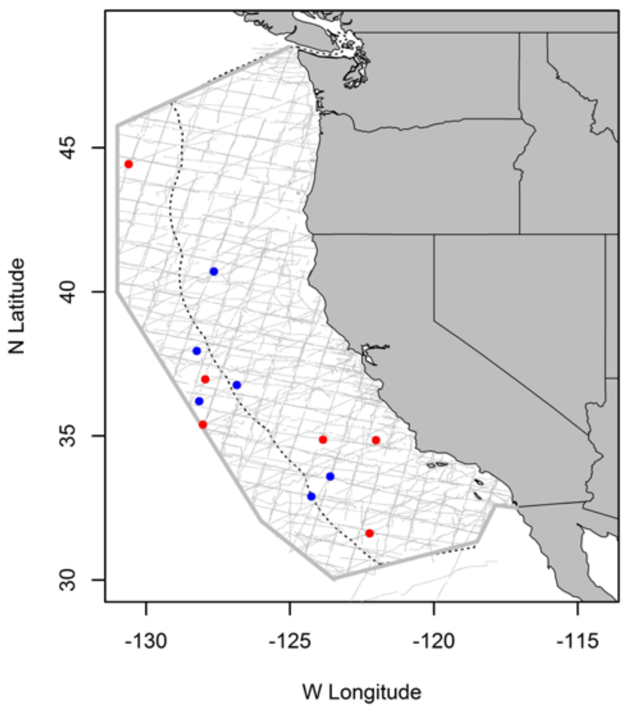

Figure 1. *Kogia* sightings based on shipboard surveys off California, Oregon and Washington, 1991-2014. Key: ● = *Kogia breviceps*; ● = *Kogia* spp. Dashed line represents the U.S. EEZ, thin lines indicate completed transect effort of all surveys combined.

POPULATION SIZE

No information is available to estimate the population size of dwarf sperm whales off the U.S. west coast, as no sightings of this species have been documented despite numerous vessel surveys of this region (Barlow 1995; Barlow and Gerrodette 1996; Barlow and Forney 2007; Forney 2007; Barlow 2010, Barlow 2016). Based on previous sighting surveys and historical stranding data, it is likely that recent ship survey sightings were of pygmy sperm whales; *K. breviceps.*

Minimum Population Estimate

No information is available to obtain a minimum population estimate for dwarf sperm whales.

Current Population Trend

Due to the rarity of records for this species along the U.S. West coast, no information exists regarding trends in abundance of this population.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

No information on current or maximum net productivity rates is available for this species.

POTENTIAL BIOLOGICAL REMOVAL

Based on this stock's unknown status and growth rate, the recovery factor (F_r) is 0.5, and ½R_{max} is the default value of 0.02. However, due to the lack of abundance estimates for this species, no potential biological removal (PBR) can be calculated.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fishery Information

The fishery most likely to interact with dwarf sperm whales in the California Current is the swordfish drift gillnet fishery. There have been no observed dwarf sperm whale entanglements in over 8,600 monitored fishing sets from 1990 to 2014 (Carretta *et al.* 2017). Although there are no records of fishery-related strandings of dwarf sperm whales along the U.S. west coast in recent years (Carretta *et al.* 2013, 2014, 2015, 2016a), compared with other more coastal cetaceans, the probability of a dwarf sperm whale carcass coming ashore and being detected would be quite low (Carretta *et al*. 2016b).

Table 1. Summary of available information on the incidental mortality and injury of dwarf sperm whales and unidentified *Kogia* sp. (California/Oregon/Washington Stock) in commercial fisheries that might take this species. Coefficients of variation for mortality estimates are provided in parentheses. Mean annual takes are based on 2010-2014 data.

Fishery Name	Data Type	Year(s)	Percent Observer Coverage	Observed Mortality *K. breviceps /Kogia* sp.	*Estimated Annual Mortality of K. breviceps/Kogia* sp.	*Mean Annual Takes (CV in parentheses)*
CA/OR thresher shark/swordfish drift gillnet fishery	observer data	2010-2014	12% to 37%	0	0	0
Minimum total annual takes						0

Other Mortality

Unknown levels of injuries and mortality of dwarf sperm whales may occur as a result of anthropogenic sound, such as military sonars. Atypical multispecies mass strandings, sometimes involving dwarf and/or pygmy sperm whales have been associated with military sonar use. One 1988 event from the Canary Islands included 2 pygmy sperm whales and the species *Ziphius cavirostris* and *Hyperoodon ampullatus* (reviewed in D'Amico *et al.* 2009). Another mass stranding and unusual mortality event (UME) in North Carolina, USA in 2005 included 2 dwarf sperm whales, in addition to 33 short-finned pilot whales and a minke whale (Hohn *et al.* 2006). This UME coincided in time and space with military activity using mid-frequency active sonar, although the authors note that a definitive association between the UME and sonar use is lacking (Hohn *et al*. 2006). Such injuries or mortality would rarely be documented, due to the remote nature of many of these activities and the low probability that an injured or dead dwarf sperm whale would strand.

STATUS OF STOCK

The status of dwarf sperm whales in California, Oregon and Washington waters relative to OSP is not known, and there are insufficient data to evaluate potential trends in abundance. Although the impacts of anthropogenic sounds such as sonar are often focused on beaked whales (Barlow and Gisiner 2006), the impacts of such sounds on deep-diving dwarf beaked whales also warrants concern. They are not listed as "threatened" or "endangered" under the Endangered Species Act nor as "depleted" under the MMPA. Given that this species rarely occurs off the U.S. west coast and a lack of recent documented fishery mortality, dwarf sperm whales off California, Oregon and Washington are not classified as a "strategic" stock under the MMPA.

SPERM WHALE (*Physeter macrocephalus*): California/Oregon/Washington Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Sperm whales are distributed across the entire North Pacific and into the southern Bering Sea in summer, but the majority are thought to be south of 40°N in winter (Rice 1974; Rice 1989; Gosho et al. 1984; Miyashita et al. 1995). The International Whaling Commission (IWC) historically divided the North Pacific into two management regions (Donovan 1991) defined by a zig-zag line which starts at 150°W at the equator, is 160°W between 40-50°N, and ends up at 180°W north of 50°N; however, the IWC has not reviewed this stock boundary recently (Donovan 1991). Sperm whales are found year-round in California waters (Dohl et al. 1983; Barlow 1995; Forney et al. 1995), but they reach peak abundance from April through mid-June and from the end of August through mid-November (Rice 1974). Sperm whales are seen off Washington and Oregon in every season except winter (Green et al. 1992). Of 176 sperm whales that were marked with Discovery tags off southern California in winter 1962-70, only three were recovered by whalers: one off northern California in June, one off Washington in June, and another far off British Columbia in April (Rice 1974). Recent summer/fall surveys in the eastern tropical Pacific (Wade and Gerrodette 1993) show that although sperm whales are widely distributed in the tropics, their relative abundance declines westward towards the middle of the tropical Pacific (near the IWC stock boundary at 150°W) and declines northward towards the tip of Baja California. Sperm whale population structure in the eastern tropical Pacific is unknown, but the only photographic matches of known individuals from this area have been between the Galapagos Islands and coastal waters of South America (Dufault and Whitehead 1995) and between the Galapagos Islands and the southern Gulf of California (Jaquet et al. 2003), suggesting that eastern tropical Pacific animals constitute a distinct stock. No apparent distributional hiatus was found between the U.S. EEZ off California and Hawaii during a survey designed specifically to investigate stock structure and abundance of sperm whales in the northeastern temperate Pacific (Barlow and Taylor 2005). Sperm whales in the California Current have been identified as demographically independent from animals in Hawaii and the Eastern Tropical Pacific, based on genetic analyses of single-nucleotide polymorphisms (SNPs), microsatellites, and mtDNA (Mesnick *et al.* 2011). For the Marine Mammal Protection Act (MMPA) stock assessment reports, sperm whales within the Pacific U.S. EEZ are divided into three

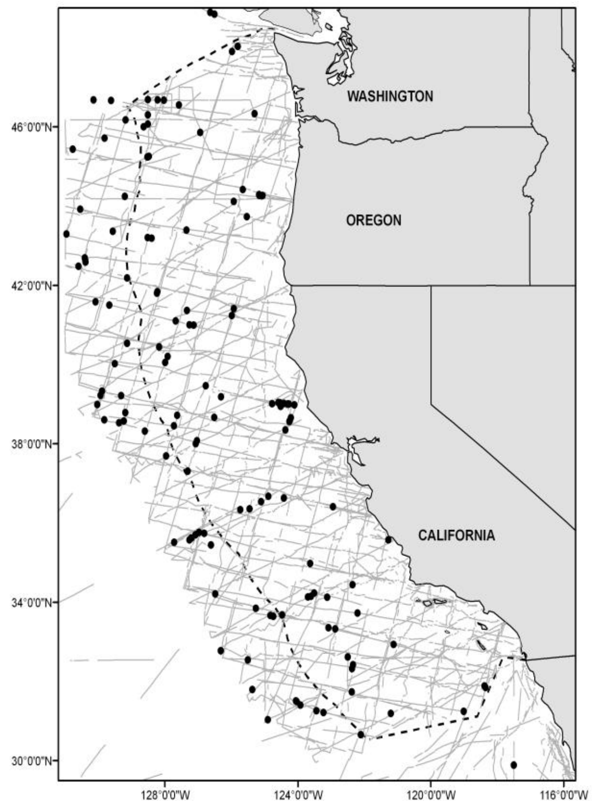

Figure 1. Sperm whale sighting locations from shipboard surveys off California, Oregon, and Washington, 1991-2008. Dashed line represents the U.S. EEZ, thin lines indicate completed transect effort of all surveys combined. See Appendix 2 for data sources and information on timing and location of survey effort.

discrete, non-contiguous areas: 1) California, Oregon and Washington waters (this report), 2) waters around Hawaii, and 3) Alaska waters.

POPULATION SIZE

Previous estimates of sperm whale abundance from 2005 (3,140, CV=0.40, Forney 2007) and 2008 (300, CV=0.51, Barlow 2010) show a ten-fold difference that cannot be attributed to human-caused or natural population declines and likely reflect inter-annual variability in movement of animals into and out of the study area. New estimates of sperm whale abundance in California, Oregon, and Washington waters out to 300 nmi are available from a trend-model analysis of line-transect data collected from six surveys conducted from 1991 to 2008 (Moore and Barlow 2014), using methods similar to previous abundance trend analyses for fin whales (Moore and Barlow 2011) and beaked whales (Moore and Barlow 2013). Abundance trend models incorporate information from the entire 1991-2008 time series to obtain each annual abundance estimate, yielding estimates with less inter-annual variability. The trend model also uses improved estimates of group size and trackline detection probability (Moore and Barlow 2014). Sperm whale abundance estimates based on the trend-model ranged between 2,000 and 3,000 animals for the 1991-2008 time series (Moore and Barlow 2014). The best estimate of sperm whale abundance in the California Current is the trend-based estimate corresponding to the most recent survey (2008), or 2,106 animals (CV=0.58). This estimate is corrected for diving animals not seen during surveys.

Minimum Population Estimate

The minimum population estimate for sperm whales is taken as the lower 20th percentile of the posterior distribution of abundance estimated from 2008 or 1,332 whales (Moore and Barlow 2014).

Current Population Trend

Moore and Barlow (2014) report that sperm whale abundance appeared stable from 1991 to 2008 (Figure 2), but that reliable conclusions on population trends could not be made because the precision of estimated growth rates was poor. However, they also reported that trends in the detection of single animals (presumably large, solitary males) apparently doubled over this time period. The authors could not determine if the apparent increase in sightings of single animals reflected an increase in the number of adult male sperm whales in the population or merely increased use of the U.S. west coast waters by adult males in recent years.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

There are no published estimates of the growth rate for any sperm whale population (Best 1993).

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size (1,332) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.1 (for an endangered stock with N_{min} <1,500; Taylor et al. 2003), resulting in a PBR of 2.7 animals per year.

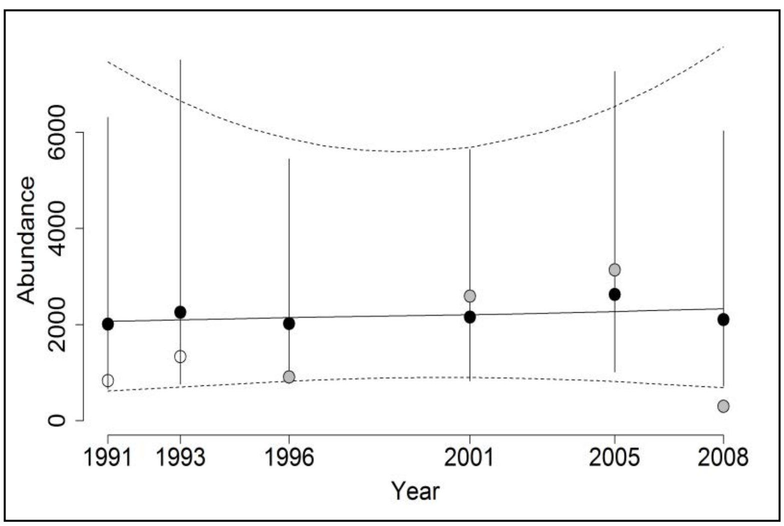

Figure 2. Trend-based estimates of sperm whale abundance in the California Current, 1991-2008 (Moore and Barlow 2014). Abundance estimates (posterior medians [●] and 95% CRIs) from the trend model, with fitted trend line and 95% CRIs for trend. For comparison, open and gray circles depict earlier published estimates from Barlow and Forney (2007) and Barlow (2010), with those for 1991 and 1993 [○] being for a smaller surveyed area.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Serious Injury Guidelines

NMFS uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to distinguis serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an "injury that is more likely than not to result in mortality".

Fishery Information

The fishery most likely to directly take sperm whales from this stock is the California thresher shark/swordfish drift gillnet fishery (Julian and Beeson 1998, Carretta and Enriquez 2012). Observed serious injury and mortality has been rarely documented in the gillnet fishery (10 animals observed during ~8,500 observed sets between 1990 and 2014). Given the historic long-term average observer coverage of ~15% for this fishery (Carretta and Barlow 2011), annual estimates of bycatch will always be either zero (if no sperm bycatch is observed) or at least 7 (if ≥ 1 observed), for estimates made using within-year ratio methods [*e.g.,* estimated bycatch = observed bycatch/percent observer coverage]. If the true average annual mortality and serious injury is > 0, but less than a few animals per year, and if observer coverage generally remains low, then multiple years of data need to be pooled to for unbiased estimation of a mean annual bycatch rates (Carretta and Moore, 2014). Pooling more years reduces bias (estimates of mean annual bycatch approaches the true rate) and provides increased precision of bycatch estimates to better estimate long-term annual mortality and serious injury. Most marine mammal stock assessment reports utilize a 5-year time period for pooling bycatch estimates (NMFS 2005), but in the case of rare events, this 5-year time frame will yield biased estimates (systematic over- or underestimation of true bycatch) with insufficient precision (Carretta and Moore 2014, Moore and Merrick 2011). Since 2001, the drift gillnet fishery has been subject to a time/area closure that restricts most fishing to south of Point Conception, California, in waters generally shallower than 2,000 m, where bycatch risk to sperm whales is lower. The post-2000 time period best represents the current spatial state of the fishery and is used to calculate mean annual bycatch for sperm whales. Between 2001 and 2013, two sperm whales (one death and one serious injury in the same set) were entangled during 2,392 observed sets, resulting in a mean bycatch rate of 0.84 per 1,000 sets. Annual bycatch estimates for the 12-year period of 2001-2012 are presented for the drift gillnet fishery in Table 1 and are based on previously published estimates (Carretta et al. 2004, 2014a, Carretta and Chivers 2004, Carretta et al. 2005, Carretta and Enriquez 2006, 2007, 2009a, 2009b, 2010, 2012).

Although acoustic pingers are known to reduce the entanglement of cetaceans in the California drift gillnet swordfish fishery (Barlow and Cameron 2003, Carretta et al. 2008, Carretta and Barlow 2011), it is unknown whether pingers have any effect on sperm whale entanglement in this fishery due to low sample sizes. Sperm whales have been observed entangled 10 times in approximately 8,500 observed drift gillnet sets since 1990 (Carretta and Enriquez 2012). Six entanglements occurred prior to pinger use in this fishery. Two entanglements (1996 and 1998) occurred in sets that did not use a full complement of pingers, and two animals were entangled in 2010 in a single net where a full complement of 40 pingers was used (Carretta and Enriquez 2012).

Other fisheries may injure or kill sperm whales through entanglement or ingestion of marine debris. Three separate sperm whale strandings in 2008 showed evidence of fishery interactions (Jacobsen et al. 2010; NMFS, unpublished stranding data). Two whales died from gastric impaction as a result of ingesting multiple types of floating polyethylene netting (Jacobsen *et al*. 2010). The variability in size and age of the ingested net material suggests that it was ingested as surface debris and was not the result of fishery depredation (Jacobsen *et al*. 2010). Net types recovered from the whales' stomachs included portions of gillnet, bait nets, and fish/shrimp trawl nets. A third whale in 2008 showed evidence of entanglement scars (NMFS, unpublished stranding data). Two sperm whales also died in 2004 as a result of marine debris ingestion (NMFS, unpublished data): one animal had monofilament gillnet in its stomach and the second animal had nets of differing types in its stomach. Mean annual takes for all fisheries (Table 1) are based on 2001-2012 observer and stranding data (Carretta and Enriquez 2006, 2007, 2009a, 2009b, 2010, 2012, Carretta et al. 2005, Carretta and Chivers 2004, Carretta et al. 2004, 2014a, Jacobsen et al. 2010, NMFS unpublished stranding data). Including estimates from fishery observer programs (16 animals/12 years = 1.3/yr) and strandings data (5 animals/12 years = 0.4/yr), results in an average estimate of 1.7 sperm whale deaths per year due to fishery-related causes for the period 2001 to 2012. The mean annual mortality from strandings represents a minimum value, as not all carcasses come ashore or are detected.

Table 1. Summary of available information on the incidental mortality and injury of sperm whales (CA/OR/WA stock) for commercial fisheries that might take this species. n/a indicates that data are not available. Mean annual takes are based on 2001-2012 data unless noted otherwise.

Fishery Name	Year(s)	Data Type	Percent Observer Coverage	Observed mortality (and serious injury in parentheses)	Estimated mortality and serious injury (CV in parentheses)	Mean annual takes (CV in parentheses)
CA thresher shark/swordfish drift gillnet fishery	2001	observer	20.4%	0	0	1.3 (0.95)
	2002		22.1%	0	0	
	2003		20.0%	0	0

	2011		19.5%	0	0	
	2012		18.7%	0	0	
Unknown fishery	2001-2012	stranding	n/a	5	≥5	≥ 0.4
Total annual takes						≥ 1.7 (0.95)

Sperm whales from the North Pacific stock are known to depredate on longline sablefish catch in the Gulf of Alaska and sometimes incur serious injuries from becoming entangled in gear (Sigler et al. 2008, Allen and Angliss 2011). An unknown number of whales from the CA/OR/WA stock probably venture into waters where Alaska longline fisheries operate, but the amount of temporal and spatial overlap is unknown. Thus, the risk of serious injury to CA/OR/WA stock sperm whales resulting from longline fisheries cannot be quantified.

Ship Strikes

One sperm whale died as the result of a ship strike in Oregon in 2007 (NMFS Northwest Regional Stranding data, unpublished). Another sperm whale was struck by a 58-foot sablefish longline vessel in 2007 while at idle speed (Jannot et al. 2011). The observer noted no apparent injuries to the whale. Based on the size and speed of the vessel relative to the size of a sperm whale, this incident was categorized as a non-serious injury (Carretta et al. 2013). For the most recent 5-year period of 2008 to 2012 for which data are available, no ship strikes of sperm whales were documented (Carretta et al. 2014b) and the mean annual average mortality and serious injury is zero whales. Ship strikes are assessed over the most recent 5-year period to reflect the degree of shipping risk to large whales since ship traffic routes changed in response to new ship pollution rules implemented in 2009 (McKenna *et al*. 2012, Redfern *et al*. 2013).

STATUS OF STOCK

The only estimate of the status of North Pacific sperm whales in relation to carrying capacity (Gosho et al. 1984) is based on a CPUE method which is no longer accepted as valid. Whaling removed at least 436,000 sperm whales from the North Pacific between 1800 and the end of legal commercial whaling for this species in 1987 (Best 1976; Ohsumi 1980; Brownell 1998; Kasuya 1998). Of this total, an estimated 33,842 were taken by Soviet and Japanese pelagic whaling operations in the eastern North Pacific from the longitude of Hawaii to the U.S. West coast, between 1961 and 1976 (Allen 1980), and approximately 1,000 were reported taken in land-based U.S. West coast whaling operations between 1919 and 1971 (Ohsumi 1980; Clapham et al. 1997). There has been a prohibition on taking sperm whales in the North Pacific since 1988, but large-scale pelagic whaling stopped in 1980. Sperm whales are formally listed as "endangered" under the Endangered Species Act (ESA), and consequently the California to Washington stock is automatically considered as a "depleted" and "strategic" stock under the MMPA. The status of sperm whales with respect to carrying capacity and optimum sustainable population (OSP) is unknown. Including both fishery and ship-strike mortality, the annual rate of kill and serious injury (1.7 per year) is less than the calculated PBR for this stock (2.7). Total human-caused mortality is greater than 10% of the calculated PBR and, therefore, cannot be considered to be insignificant and approaching zero mortality and serious injury rate. Increasing levels of anthropogenic sound in the world's oceans has been suggested to be a habitat concern for whales, particularly for deep-diving whales like sperm whales that feed in the ocean's "sound channel".

Revised 7/31/2015

GRAY WHALE (*Eschrichtius robustus*): Eastern North Pacific Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Once common throughout the Northern Hemisphere, the gray whale was extinct in the Atlantic by the early 1700s (Fraser 1970; Mead and Mitchell 1984), though one anomalous sighting occurred in the Mediterranean Sea in 2010 (Scheinin *et al.* 2011) and another off Namibia in 2013 (Elwen and Gridley 2013). Gray whales are now only commonly found in the North Pacific. Genetic comparisons indicate there are distinct "Eastern North Pacific" (ENP) and "Western North Pacific" (WNP) population stocks, with differentiation in both mtDNA haplotype and microsatellite allele frequencies (LeDuc et al. 2002; Lang et al. 2011a; Weller et al. 2013).

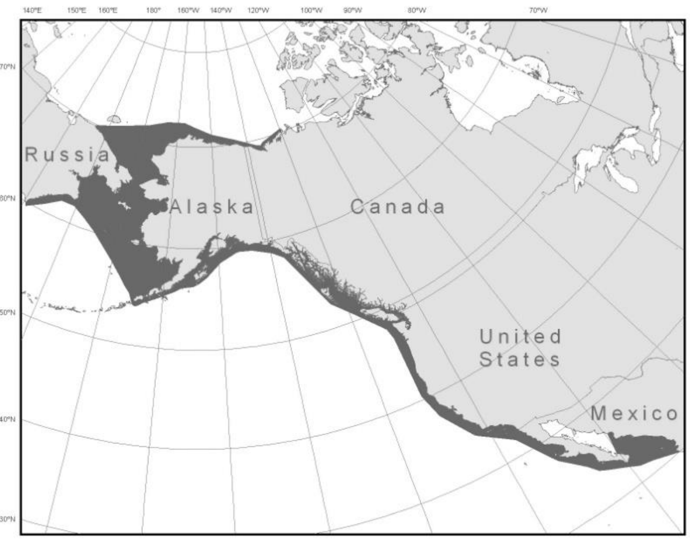

Figure 1. Approximate distribution of the Eastern North Pacific stock of gray whales (shaded area).

During summer and fall, most whales in the ENP population feed in the Chukchi, Beaufort and northwestern Bering Seas (Fig. 1). An exception to this is the relatively small number of whales (approximately 200) that summer and feed along the Pacific coast between Kodiak Island, Alaska and northern California (Darling 1984, Gosho *et al.* 2011, Calambokidis *et al.* 2012), referred to as the "Pacific Coast Feeding Group" (PCFG). Three primary wintering lagoons in Baja California, Mexico are utilized, and some females are known to make repeated returns to specific lagoons (Jones 1990). Genetic substructure on the wintering grounds is indicated by significant differences in mtDNA haplotype frequencies between females (mothers with calves) using two of the primary calving lagoons and females sampled in other areas (Goerlitz *et al*. 2003). Other research identified a small, but significant departure from panmixia between two of the lagoons using nuclear data, although no significant differences were identified using mtDNA (Alter *et al.* 2009).

Tagging, photo-identification and genetic studies show that some whales identified in the WNP off Russia have been observed in the ENP, including coastal waters of Canada, the U.S. and Mexico (Lang 2010; Mate et al. 2011; Weller et al. 2012; Urbán et al. 2013, Mate et al. 2015). In combination, these studies have recorded a total of 27 gray whales observed in both the WNP and ENP. Despite this overlap, significant mtDNA and nDNA differences are found between whales in the WNP and those summering in the ENP (Lang *et al*. 2011a).

In 2010, the IWC Standing Working Group on Aboriginal Whaling Management Procedure noted that different names had been used to refer to gray whales feeding along the Pacific coast, and agreed to designate animals that spend the summer and autumn feeding in coastal waters of the Pacific coast of North America from California to southeast Alaska as the "Pacific Coast Feeding Group" or PCFG (IWC 2012). This definition was further refined for purposes of abundance estimation, limiting the geographic range to the area from northern California to northern British Columbia (from 41°N to 52°N), limiting the temporal range to the period from June 1 to November 30, and counting only those whales seen in more than one year within this geographic and temporal range (IWC 2012). The IWC adopted this definition in 2011, but noted that "not all whales seen within the PCFG area at this time will be PCFG whales and some PCFG whales will be found outside of the PCFG area at various times during the year." (IWC 2012).

Photo-identification studies between northern California and northern British Columbia provide data on the abundance and population structure of PCFG whales (Calambokidis *et al*. 2012). Gray whales using the study area in summer and autumn include two components: **1)** whales that frequently return to the area, display a high degree of intra-seasonal " fidelity" and account for a majority of the sightings between 1 June and 30 November. Despite movement and interchange among sub-regions of the study area, some whales are more likely to return to the same sub-region where they were observed in previous years; **2)**"visitors" from the northbound migration that are sighted only in one year, tend to be seen for shorter time periods in that year, and are encountered in more limited areas. Photo-identification (Gosho *et al*. 2011; Calambokidis *et al*. 2012) and satellite tagging (Mate *et al*. 2010; Ford *et al.*

2012) studies have documented some PCFG whales off Kodiak Island, the Gulf of Alaska and Barrow, Alaska, well to the north of the pre-defined 41°N to 52°N boundaries used in some PCFG-related analyses (e.g. abundance estimation).

Frasier *et al.* (2011) found significant differences in mtDNA haplotype distributions between PCFG and ENP gray whale sequences, in addition to differences in long-term effective population size, and concluded that the PCFG qualifies as a separate management unit under the criteria of Moritz (1994) and Palsbøll *et al.* (2007). The authors noted that PCFG whales probably mate with the rest of the ENP population and that their findings were the result of maternally-directed site fidelity of whales to different feeding grounds.

Lang *et al.* (2011b) assessed stock structure of ENP whales from different feeding grounds using both mtDNA and eight microsatellite markers. Significant mtDNA differentiation was found when samples from individuals (n=71) sighted over two or more years within the seasonal range of the PCFG were compared to samples from whales feeding north of the Aleutians (n=103), and when PCFG samples were compared to samples collected off Chukotka, Russia (n=71). No significant differences were found when these same comparisons were made using microsatellite data. The authors concluded that (1) the significant differences in mtDNA haplotype frequencies between the PCFG and whales sampled in northern areas indicates that use of some feeding areas is being influenced by internal recruitment (e.g., matrilineal fidelity), and (2) the lack of significance in nuclear comparisons suggests that individuals from different feeding grounds may interbreed. The level of mtDNA differentiation identified, while statistically significant, was low and the mtDNA haplotype diversity found within the PCFG was similar to that found in the northern strata. Lang *et al*. (2011b) suggested this could indicate recent colonization of the PCFG but could also be consistent with external recruitment into the PCFG. An additional comparison of whales sampled off Vancouver Island, British Columbia (representing the PCFG) and whales sampled at the calving lagoon at San Ignacio also found no significant differences in microsatellite allele frequencies, providing further support for interbreeding between the PCFG and the rest of the ENP stock (D'Intino et al. 2012). Lang and Martien (2012) investigated potential immigration levels into the PCFG using simulations and produced results consistent with the empirical (mtDNA) analyses of Lang et al. (2011b). Simulations indicated that immigration of >1 and <10 animals per year into the PCFG was plausible, and that annual immigration of 4 animals/year produced results most consistent with the empirical study.

While the PCFG is recognized as a distinct feeding aggregation (Calambokidis et al. 2012; Mate et al. 2010; Frasier et al. 2011; Lang et al. 2011b; IWC 2012), the status of the PCFG as a population stock remains unresolved (Weller et al. 2013). A NMFS gray whale stock identification workshop held in 2012 included a review of available photo-identification, genetic, and satellite tag data. The report of the workshop states "there remains a substantial level of uncertainty in the strength of the lines of evidence supporting demographic independence of the PCFG." (Weller et al. 2013). The NMFS task force, charged with evaluating stock status of the PCFG, noted that "both the photo-identification and genetics data indicate that the levels of internal versus external recruitment are comparable, but these are not quantified well enough to determine if the population dynamics of the PCFG are more a consequence of births and deaths within the group (internal dynamics) rather than related to immigration and/or emigration (external dynamics)." Further, given the lack of significant differences found in nuclear DNA markers between PCFG whales and other ENP whales, the task force found no evidence to suggest that PCFG whales breed exclusively or primarily with each other, but interbreed with ENP whales, including potentially other PCFG whales. Additional research is needed to better identify recruitment levels into the PCFG and further assess the stock status of PCFG whales (Weller et al. 2013). In contrast, the task force noted that WNP gray whales should be recognized as a population stock under the MMPA, and NMFS prepared a separate report for WNP gray whales in 2014. Because the PCFG appears to be a distinct feeding aggregation and may warrant consideration as a distinct stock in the future, separate PBRs are calculated for the PCFG to assess whether levels of human-caused mortality are likely to cause local depletion.

POPULATION SIZE

Systematic counts of gray whales migrating south along the central California coast have been conducted by shore-based observers at Granite Canyon most years since 1967 (Fig. 2). The most recent estimate of abundance for the ENP population is from the 2010/2011 southbound survey and is 20,990 (CV=0.05) whales (Durban *et al*. 2013) (Fig. 2).

Photographic mark-recapture abundance estimates for PCFG gray whales between 1998 and 2012, including estimates for a number of smaller geographic areas within the IWC-defined PCFG region (41°N to 52°N), are reported in Calambokidis *et al*. (2014). The 2012 abundance estimate for the defined range of the PCFG between 41°N to 52°N is 209 (SE=15.4; CV= 0.07).

Eastern North Pacific gray whales experienced an unusual mortality event (UME) in 1999 and 2000, when large numbers of emaciated animals stranded along the west coast of North America (Moore *et al*., 2001; Gulland *et al*., 2005). Over 60% of the dead whales were adults, compared with previous years when calf strandings were more common. Several factors following this UME suggest that the high mortality rate observed was a short-term, acute event and not a chronic situation or trend: 1) in 2001 and 2002, strandings decreased to levels below UME levels (Gulland *et al*., 2005); 2) average calf production returned to levels seen before 1999; and 3) in 2001, living whales no longer appeared emaciated. Oceanographic factors that limited food availability for gray whales were identified as likely causes of the UME (LeBouef et al. 2000; Moore et al. 2001; Minobe 2002; Gulland et al. 2005), with resulting declines in survival rates of adults during this period (Punt and Wade 2012). The population has recovered to levels seen prior to the UME of 1999-2000 (Fig. 2).

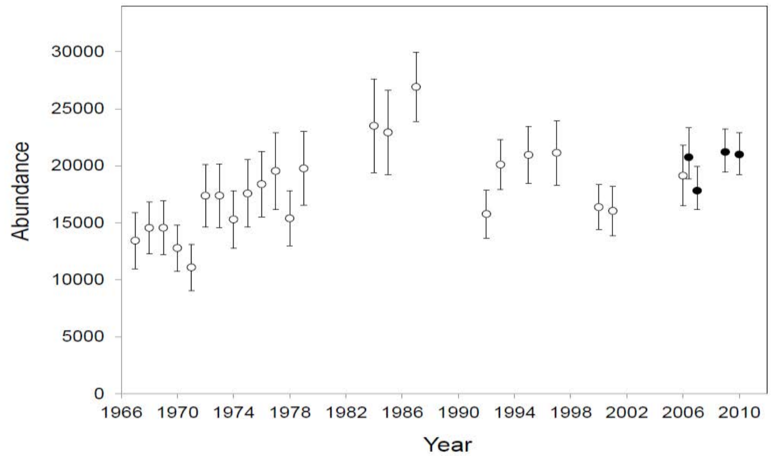

Figure 2. Estimated abundance of Eastern North Pacific gray whales from NMFS counts of migrating whales past Granite Canyon, California. Open circles represent abundance estimates and 95% confidence intervals reported by Laake et al. (2012). Closed circles represent estimates and 95% posterior highest density intervals reported by Durban et al. (2013) for the 2006/7, 2007/8, 2009/10, and 2010/11 migration seasons.

Gray whale calves have been counted from Piedras Blancas, a shore site in central California, in 1980-81 (Poole 1984a) and each year from 1994 to 2012 (Perryman *et al*. 2002; Perryman and Weller 2012). In 1980 and 1981, calves comprised 4.7% to 5.2% of the population (Poole 1984b). Calf production indices, as calculated by dividing northbound calf estimates by estimates of population abundance (Laake *et al*. 2012), ranged between 1.3 - 8.8% (mean=4.2%) during 1994-2012. Annual indices of calf production include impacts of early postnatal mortality but may overestimate recruitment because they exclude possibly significant levels of killer whale predation on gray whale calves north of the survey site (Barrett-Lennard et al. 2011). The relatively low reproductive output reported is consistent with little or no population growth over the time period (Laake *et al*. 2012; Punt and Wade 2012).

Minimum Population Estimate

The minimum population estimate (N_{MIN}) for the ENP stock is calculated from Equation 1 from the PBR Guidelines (Wade and Angliss 1997): $N_{MIN} = N/\exp(0.842\times[\ln(1 + [CV(N)]^2)]^{½})$. Using the 2010/11 abundance estimate of 20,990 and its associated CV of 0.05 (Durban et al. 2013), N_{MIN} for this stock is 20,125.

The minimum population estimate for PCFG gray whales is calculated as the lower 20th percentile of the log-normal distribution of the 2012 mark-recapture estimate of 209 (CV=0.07), or 197 animals.

Current Population Trend

The population size of the ENP gray whale stock has increased over several decades despite an UME in 1999 and 2000 and has been relatively stable since the mid-1990s (see Fig. 2).

Abundance estimates of PCFG gray whales reported by Calambokidis et al. (2014) show a high rate of increase in the late 1990s and early 2000s, but have been relatively stable since 2003.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Using abundance data through 2006/07, an analysis of the ENP gray whale population led to an estimate of R_{max} of 0.062, with a 90% probability the value was between 0.032 and 0.088 (Punt and Wade 2012). This value of R_{max} is also applied to PCFG gray whales, as it is currently the best estimate of R_{max} available for gray whales in the ENP.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for the ENP stock of gray whales is calculated as the minimum population size (20,125), times one-half of the maximum theoretical net population growth rate (½ x 6.2% = 3.1%), times a recovery factor of 1.0 for a stock above MNPL (Punt and Wade 2012), or 624 animals per year.

The potential biological removal (PBR) level for PCFG gray whales is calculated as the minimum population size (197 animals), times one half the maximum theoretical net population growth rate (½ x 6.2% = 3.1%), times a recovery factor of 0.5 (for a population of unknown status), resulting in a PBR of 3.1 animals per year. Use of the recovery factor of 0.5 for PCFG gray whales, rather than 1.0 used for ENP gray whales, is based on uncertainty regarding stock structure (Weller et al. 2013) and guidelines for preparing marine mammal stock assessments which state that "Recovery factors of 1.0 for stocks of unknown status should be reserved for cases where there is assurance that N_{min}, R_{max}, and the kill are unbiased and where the stock structure is unequivocal" (NMFS 2005). Given uncertainties in the levels of external versus internal recruitment of PCFG whales described above, the equivocal nature of the stock structure, and the small estimated population size of the PCFG, NMFS will continue to use the default recovery factor of 0.5 for PCFG gray whales.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Serious Injury Guidelines

NMFS uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases todistinguishserious from non-serious injury (Angliss and DeMaster 1998, Andersen *et al*. 2008, NOAA 2012). NMFS defines serious injury as an "*injury that is more likely than not to result in mortality*".

Fisheries Information

No gray whales were observed entangled in California gillnet fisheries between 2008 and 2012 (Carretta and Enriquez 2009, 2010, 2012a, 2012b, Carretta *et al*., 2014a.), but previous mortality in the swordfish drift gillnet fishery has been observed (Carretta et al. 2004) and there have been recent sightings of free-swimming gray whales entangled in gillnets (Table 1). Alaska gillnet fisheries largely lack observer programs, including those in Bristol Bay known to interact with gray whales. Most data on human-caused mortality and serious injury of gray whales are from strandings, including at-sea reports of entangled animals alive or dead (Carretta et al. 2013, 2014b). Strandings represent only a fraction of actual gray whale deaths (natural or human-caused), as reported by Punt and Wade (2012), who estimated that only 3.9% to 13.0% of gray whales that die in a given year end up stranding and being reported.

A summary of human-caused mortality and serious injury resulting from unknown fishery and marine debris sources (mainly pot/trap or net fisheries) is given in Table 1 for the most recent 5-year period of 2008 to 2012. Total observed human-caused fishery mortality and serious injury for ENP gray whales is 22.25 animals (8 serious injuries, 8.25 prorated serious injuries, and 6 deaths), or 4.45 whales per year (Table 1). Total observed human-caused fishery mortality and serious injury for gray whales observed in the PCFG range and season for the period 2008 to 2012 is 0.75 animals (0.75 prorated serious injuries), or 0.15 whales per year (Table 1). Three gray whales from Table 1 (one death and two serious injuries) were detected in California waters during the known PCFG season, but were south of the area recognized by the IWC as the PCFG management area. It is possible that some of these whales could be PCFG whales, but no photographic identifications were available to establish their identity. They are included in ENP gray whale serious injury and death totals.

Table 1. Human-caused deaths and serious injuries (SI) of gray whales from fishery-related and marine debris sources for the period 2008 to 2012 as recorded by NMFS stranding networks and observer programs.

Date of observation	Location	PCFG range N 41- N 52 AND season?	Description	Determination (SI Prorate value)
13-Oct-2012	Fort Bragg, CA	No	Entangled animal report; animal reported with rope around the peduncle which wasn't seen in photographs but photos did show green gillnet with cuts to the head; animal disappeared and final status is unknown.	SI
31-Aug-2012	Los Angeles, CA	No	Animal first detected near San Diego. Subadult gray whale reported entangled with small gauge, dark-colored line deeply embedded around its tail stock. Little gear trails. Entanglement was once more involved as indicated by scars on the animal's body. Animal in very poor condition - emaciated, scarred and a heavy load of cyamid	Dead

			amphipods. Black line around peduncle, 20 ft trailing; observed off san San Diego on 8/31, completely disentangled off L.A. 9/6, stranded dead 9/14/12.	
22-Aug-2012	Prince William Sound, AK	No	Whale sighted by tour boat. Few details, other than part of a fishing net was observed being trailed from a gray whale's fin. Photos apparently available, but have not been located. Prince william William Sound. Extent and severity of entanglement unknown.	SI (0.75)
16-Jun-2012	Prince William Sound, AK	No	30' gray whale in prince william Prince William Sound entangled in gear. Thrashing at surface and moving at 4-5 knots. No wounds or chafing was observed. Gillnet, corkline (at least 12 floats), and leadline observed over animal's rostrum, body, and tailstock. Both pectoral flippers appeared pinned to body. Animal later appeared tired and was swimming at 2 knots. It was not relocated. Assigned serious injury because gear appears to be constricting movement of whale's flippers.	SI
13-May-2012	Monterey, CA	No	Animal entangled through mouth in at least two sets of suspected pot gear that that hang below. Animal anchored with a short scope in 28 feet of water to suspected pots. Bundle of gear, including 4 buoys lie under animal. Animal having some difficulty getting to surface. Animal eventually disentangled, but results of entanglement may still be life-threatening.	SI
8-May-2012	Eureka, CA	No	Entangled animal report; deep cuts from rope around peduncle and lacerations at fluke notch and lateral edge of fluke; successfully disentangled but long-term survival noted as questionable. Gear was collected and identified as Dungeness crab pot gear. Animal entirely freed of gear. Animal in fair condition and slightly emaciated. Deep cuts (~ 2 inches) from the rope around the peduncle remained. Gear was recovered. Results of entanglement may still be life threatening.	SI
5-May-2012	Monterey, CA	No	Whale watch vessel noticed from images taken of a 20 - 25 foot gray whale they had been observing earlier in the day, that animal was actually entangled. A small gauge line, likely from right side of mouth goes over the animal's back, and over blowholes, to left side of mouth. No buoys or trailing line were observed. Animal in fair condition. Animal sighted next day by whale watch vessel. Confirmed mouth entanglement, appears to be strapping material.	SI (0.75)
28-Apr-2012	Fort Bragg, CA	No	Small gray whale off fort bragg Fort Bragg, CA, in company of two other animals, trailing two buoys.	SI (0.75)
21-Apr-2012	San Simeon, CA	No	Rope like marks on caudal peduncle. Rope impression on pectoral fin. Photos taken.	Dead
17-Apr-2012	Laguna Beach, CA	No	40-foot gray whale reported entangled with approximately 150 feet of line trailing. Four spongex bullet buoys lie along the left side of the animal. Entanglement involves the mouth, a wrap over the head, and the left pectoral flipper. Entanglement appears recent. Partially disentangled on 5/3/12 by fishermen.	SI (0.75)
24-Mar-2012	San Diego, CA	No	Entangled animal report; gillnet gear around peduncle; response effort resulted in successful disentanglement with >100 ft of pink gillnet removed from animal, but animal subsequently observed dead on 03/27 (floating, skin sample taken, no necropsy). Net removed on 03/24 found to contain one dead ca sea lion and three dead sharks.	Dead
28-Jan-2012	San Diego, CA	No	Entangled animal report; towing two orange buoys and at least 150 feet of line; unknown fishery, reported as possible gillnet; no response effort.	SI (0.75)
17-Jan-2012	Unimak Pass, AK	No	A 40' whale was caught in cod pot gear near Unimak Pass. Lines were cut by boat crew and buoys were recovered, however, the pot and some line remained in the water. Any line possibly remaining on animal thought to be minimal. Gray whale species determination made following extensive questioning by local biologist. Determination: prorated serious injury because gear possibly remains on animal.	SI (0.75)
25-Aug-2011	San Mateo, CA	No	One white "crab pot" buoy next to body by left pectoral fin; float stayed next to body and did not change position; animal remained in same position - possibly anchored; only observed for ~2 min; not resighted, no rescue, outcome unknown.	SI
12-Sep-2010	Central Bering Sea	No	Bering Sea / Aleutian Islands flatfish trawl fishery: 12 m animal caught in gear. Photos taken.	Dead
11-May-2010	Orange County CA	No	Free-swimming animal entangled in gillnet; animal first observed inside Dana Point Harbor on 5/11/10; animal successfully	Dead

			disentangled on 5/12/10 & swam out of harbor; animal observed alive in surf zone for several hours on 5/14/10 off Doheny State Beach before washing up dead on beach	
7-May-2010	Cape Foulweather OR	No	Entangled in 3 crab pots, whale not relocated.	SI (0.75)
16-Apr-2010	Seaside OR	No	27-ft long gray whale stranded dead, entangled in crab pot gear	Dead
8-Apr-2010	San Francisco CA	No	Rope wrapped around caudal peduncle; identified as gray whale from photo. Free-swimming, diving. No rescue effort, no resightings, final status unknown	SI
5-Mar-2010	San Diego	No	Free-swimming entangled whale reported by member of the public; no rescue effort initiated; no resightings reported; final status unknown.	SI (0.75)
21-Jul-2009	Trinidad Head CA	Yes	Free-swimming animal with green gillnet, rope & small black floats wrapped around caudal peduncle; report received via HSU researcher on scene during research cruise; animal resighted on 3 Aug; no rescue effort initiated. Photos show rope cutting into caudal peduncle. This whale was re-sighted in 2010 and 2011, still trailing gear. Whale was resighted in 2013 and had shed gear, and was apparently in good health (Jeff Jacobsen, pers. comm.).	NSI
24-Jun-2009	Clallam County, WA	Yes	Whale found entangled in tribal set gillnet in morning. Net had been set 8 pm previous day. Whale able to breath, but not swim freely and was stationary in net. Right pectoral flipper and head were well-wrapped in net webbing. In response to disentanglement attempts, whale reacted violently and swam away. The net was retrieved and found to be torn in two. No confirmation on whether whale was completely free of netting.	SI (0.75)
9-Apr-2009	Sitka, AK	No	Thick black line wrapped twice around whale's body posterior to the eyes was cut and pulled away by private citizen. Animal swam away and dove.	SI (0.75)
25-Mar-2009	Seal Beach CA	No	Free-swimming animal with pink gillnet wrapped around head, trailing 4 feet of visible netting; report received via naturalist on local whale watch vessel; no rescue effort initiated; final status unknown	SI (0.75)
31-Jan-2009	San Diego CA	No	Free-swimming animal towing unidentified pot/trap gear; report received via USCG on scene; USCG reported gear as 4 lobster pots; final status unknown	SI (0.75)
16-Apr-2008	Eel River CA	No	Observed 12 miles west of Eel River by Humboldt State University personnel. It was unknown sex, with an estimated length of 20 ft and in emaciated condition. The animal was described as towing 40-50 feet of line & 3 crab pot buoys from the caudal peduncle and moving very slowly. Vessel retrieved the buoys, pulled them and ~20 ft of line onto the deck and cut it loose from the whale. The whale swam away slowly with 20-30 feet of line still entangling the peduncle, outcome unknown. Identification numbers on buoy traced to crab pot fishery gear that was last fished in Bering Sea in December 2007.	SI

Subsistence/Native Harvest Information

Subsistence hunters in Russia and the United States have traditionally harvested whales from the ENP stock in the Bering Sea, although only the Russian hunt has persisted in recent years (Huelsbeck 1988; Reeves 2002). In 2005, the Makah Indian Tribe requested authorization from NOAA/NMFS, under the MMPA and the Whaling Convention Act, to resume limited hunting of gray whales for ceremonial and subsistence purposes in the coastal portion of their usual and accustomed (U&A) fishing grounds off Washington State (NMFS 2008). The spatial overlap of the Makah U&A and the summer distribution of PCFG whales has management implications. The proposal by the Makah Tribe includes time/area restrictions designed to reduce the probability of killing a PCFG whale and to focus the hunt on whales migrating to/from feeding areas to the north. The Makah proposal also includes catch limits for PCFG whales that result in the hunt being terminated if these limits are met. Also, observations of gray whales moving between the WNP and ENP highlight the need to estimate the probability of a gray whale observed in the WNP being taken during a hunt by the Makah Tribe (Moore and Weller 2013). NMFS has published a notice of intent to prepare an environmental impact statement (EIS) on the proposed hunt (NMFS 2012) and the IWC has evaluated the potential impacts of the proposed hunt and other sources of human-caused mortality on PCFG whales and concluded, with certain qualifications, that the proposed hunt meets the Commission’s conservation objectives (IWC 2013). The Scientific Committee has not scheduled an implementation review of the impacts of the Makah hunt on whales using summering feeding areas in the WNP, but is continuing to investigate stock structure of north Pacific gray whales and may schedule such a review in the future (IWC 2013). In 2012, the IWC approved a 6-year quota (2013-2018) of 744 gray whales, with an annual cap of 140, for Russian and U.S. (Makah Indian Tribe) aboriginals based on the joint request and needs statements submitted by the U.S. and Russian federation. The U.S. and Russia have agreed that the quota will be shared with an average annual harvest of 120 whales by the Russian Chukotka people and 4 whales by the Makah Indian Tribe. Total takes by the Russian hunt during the past five years were: 130 in 2008,116 in 2009, 118 in 2010, 128 in 2011, and 143 in 2012 (source: http://iwc.int/table_aboriginal). Based on this information, the annual subsistence take averaged 127 whales during the 5-year period from 2008 to 2012.

Other Mortality

Ship strikes are a source of mortality for gray whales (Table 2). For the most recent five-year period, 2008-2012, the total serious injury and mortality of ENP gray whales attributed to ship strikes is 9.8 animals (including 7 deaths, 2 serious injuries, and 0.8 prorated serious injuries, or 2.0 whales per year (Table 2, Carretta et al. 2013, Carretta et al. 2014b.). The total ship strike serious injury and mortality of gray whales observed in the PCFG range and season during this same period is 0.52 animals, or 0.1 whales per year (Table 2). One gray whale ship strike in Table 2 was detected in California waters during the known PCFG season, but was south of the area recognized by the IWC as the PCFG management area. It is possible that this animal could be a PCFG whale, but no photographic identification was available to establish its identity. It is included in ENP gray whale serious injury and death totals. Additional mortality from ship strikes probably goes unreported because the whales either do not strand or do not have obvious signs of trauma.

In February 2010, a gray whale stranded dead near Humboldt, CA with parts of two harpoons embedded in the body. Since this whale was likely harpooned during the aboriginal hunt in Russian waters, it would have been counted as "struck and lost" in the harvest data.

HABITAT CONCERNS

Near shore industrialization and shipping congestion throughout the migratory corridors of the ENP gray whale stock represent risks by increasing the likelihood of exposure to pollutants and ship strikes, as well as a general degradation of the habitat.

Evidence indicates that the Arctic climate is changing significantly, resulting in a reductions in sea ice cover (Johannessen et al. 2004, Comiso et al. 2008). These changes are likely to affect gray whales. For example, the summer range of gray whales has greatly expanded in the past decade (Rugh et al. 2001). Bluhm and Gradinger (2008) examined the availability of pelagic and benthic prey in the Arctic and concluded that pelagic prey is likely to increase while benthic prey is likely to decrease in response to climate change. They noted that marine mammal species that exhibit trophic plasticity (such as gray whales which feed on both benthic and pelagic prey) will adapt better than trophic specialists.

Global climate change is also likely to increase human activity in the Arctic as sea ice decreases, including oil and gas exploration and shipping (Hovelsrud et al. 2008). Such activity will increase the chance of oil spills and ship strikes in this region. Gray whales have demonstrated avoidance behavior to anthropogenic sounds associated with oil and gas exploration (Malme et al. 1983, 1984) and low-frequency active sonar during acoustic playback experiments (Buck and Tyack 2000, Tyack 2009). Ocean acidification could reduce the abundance of shell-forming organisms (Fabry et al. 2008, Hall-Spencer et al. 2008), many of which are important in the gray whales' diet (Nerini 1984).

Table 2. Summary of gray whale serious injuries (SI) and deaths attributed to vessel strikes for the five-year period 2008-2012. No vessel strikes were reported in 2012.

Date of observation	Location	PCFG range N 41 - N 52 AND season?	Description	Determination (SI prorate value)
6-Jun-2011	San Mateo CA	No	Massive hemorrhage into the thorax, blood clots around lungs. Lesions indicate massive trauma. Due to carcass position, the skeleton could not be completely examined (lying on back, top of skull in sand).	Dead
8-Apr-2011	San Francisco CA	No	Crushed mandible.	Dead
12-Feb-2011	Los Angeles CA	No	Private recreational vessel collided with free-swimming animal; animal breached just prior to contact, bouncing off side of vessel; dove immediately following contact & was not resighted; no blood observed in water; final status unknown; skin sample collected from vessel and genetically identified	SI (0.14)

			as a female gray whale. Vessel size assumed less than 65 ft and speed unknown.	
22-Jan-2011	San Diego CA	No	Pleasure sailboat collided with free-swimming animal; animal dove immediately following contact & was not resighted; no blood observed in water; final status unknown. Vessel size assumed less than 65 ft. And speed unknown.	SI (0.14)
12-Mar-2010	Santa Barbara CA	No	21 meter sailboat underway at 13 kts collided with free-swimming animal; whale breached shortly after collision; no blood observed in water; minor damage to lower portion of boat's keel; final status unknown; DNA analysis of skin sample confirmed species.	SI
16-Feb-2010	San Diego CA	No	Free-swimming animal with propeller-like wounds to dorsum.	SI (0.52)
9-Sep-2009	Quileute River WA	Yes	USCG vessel reported to be traveling at 10 knots when they hit the gray whale at noon on 9/9/2009. The animal was hit with the prop and was reported alive after being hit, blood observed in water.	SI (0.52)
1-May-2009	Los Angeles CA	No	Catalina island transport vessel collided with free-swimming calf accompanied by adult animal; calf was submerged at time of collision; pieces of flesh & blood observed in water; calf never surfaced; presumed mortality.	SI
27-Apr-2009	Whidbey Is. WA	No	Large amount of blood in body cavity, bruising in some areas of blubber layer and in some internal organs. Findings suggestive of blunt force trauma likely caused by collision with a large ship.	Dead
5-Apr-2009	Sunset Beach CA	No	Dead stranding; 3 deep propeller-like cuts on right side, just anterior of genital opening; carcass towed out to sea	Dead
4-Apr-2009	Ilwaco WA	No	Necropsied, broken bones in skull; extensive hemorrhage head and thorax; sub-adult male	Dead
1-Mar-2008	Mexico	No	Carcass brought into port on bow of cruise ship; collision occurred betweeen ports of San Diego and Cabo San Lucas between 5:00 p.m. On 2/28 & 7:20 a.m. On 3/1	Dead
7-Feb-2008	Orange County CA	No	Carcass; propeller-like wounds to left dorsum from mid-body to caudal peduncle; deep external bruising on right side of head; field necropsy revealed multiple cranial fractures	Dead

STATUS OF STOCK

In 1994, the ENP stock of gray whales was removed from the List of Endangered and Threatened Wildlife (the List), as it was no longer considered endangered or threatened under the Endangered Species Act (NMFS 1994). Punt and Wade (2012) estimated the ENP population was at 85% of carrying capacity (K) and at 129% of the maximum net productivity level (MNPL), with a probability of 0.884 that the population is above MNPL and therefore within the range of its optimum sustainable population (OSP).

Even though the stock is within OSP, abundance will fluctuate as the population adjusts to natural and human-caused factors affecting carrying capacity (Punt and Wade 2012). It is expected that a population close to or at carrying capacity will be more susceptible to environmental fluctuations (Moore et al. 2001). The correlation between gray whale calf production and environmental conditions in the Bering Sea may reflect this (Perryman et al. 2002; Perryman and Weller 2012). Overall, the population nearly doubled in size over the first 20 years of monitoring and has fluctuated for the last 30 years around its average carrying capacity. This is consistent with a population approaching K.

Based on 2008-2012 data, the estimated annual level of human-caused mortality and serious injury for ENP gray whales includes Russian harvest (127), mortality and serious injury from commercial fisheries (4.45), and ship strikes (2.0), totals 133 whales per year, which does not exceed the PBR (624). The IWC completed an implementation review for ENP gray whales (including the PCFG) in 2012 (IWC 2013) and concluded that harvest levels (including the proposed Makah hunt) and other human caused mortality are sustainable, given the current population abundance (Laake et al. 2012, Punt and Wade 2012). Therefore, the ENP stock of gray whales is not classified as a strategic stock.

PCFG gray whales do not currently have a formal status under the MMPA, though the population size appears to have been stable since 2003, based on photo-ID studies (Calambokidis et al. 2014, IWC 2012). Total annual human-caused mortality of PCFG gray whales during the period 2008 to 2012 includes deaths due to commercial fisheries (0.15/yr), and ship strikes (0.1/yr), or 0.25 whales annually. This does not exceed the PBR level of 3.1 whales for this population. Levels of human-caused mortality and serious injury resulting from commercial fisheries and ship strikes for both ENP and PCFG whales represent minimum estimates as recorded by stranding networks or at-sea sightings.
