WORKING GROUP ON AVAILABILITY OF SAMPLES FOR GENETIC ANALYSIS OF SOUTHERN HEMISPHERE HUMPBACK WHALES

The Group had been charged with reviewing three items: currently available tissue samples; identification of sampling needs; disposition of current IDCR samples. Three additional matters were discussed.

(1) Summary of currently available tissue samples
These are summarised in Table 1.

(2) Identification of genetic sampling needs for Southern Hemisphere stocks of humpback whales
The Working Group noted that genetic sampling design must consider two issues: (1) genetic resolution of a given technique; and (2) population heterogeneity (i.e. non-random structuring or associations within populations). Each individual genome offers nearly unlimited historical information at the level of nucleotide variation. For the purposes of most analyses, however, genetic resolution that distinguishes between all individuals in a sample (excluding immediate kin) and allows confidence in the reconstruction of relationships between nucleotypes (i.e., unique DNA sequences) is sufficient. With this level of genetic resolution, a sample of 30–50 individuals (ideally in a non-selective manner) is generally considered sufficient for initial characterisation of a population or seasonal subunit (IWC, 1994). Population heterogeneity is more problematic because the structure or source of this heterogeneity is seldom obvious at the outset of a study. The Working Group noted, however, that heterogeneity is a concern in migratory species. For humpback whales, available evidence demonstrates that migration is stratified or biased by age-sex classes, regional assortment occurs during migration and local fidelity to seasonal habitats is idiosyncratic (Dawbin, 1966; Nishiwaki, 1967; Baker et al., 1986; 1992; Urban and Aguayo-L. 1987; Katona and Beard, 1990; Brown et al., 1994).

Based on these considerations the Working Group recommended that initial characterisation of genetic variation and gene flow in Southern Hemisphere humpback whales should be based on a minimum of 30–50 samples for each of the described seasonal habitats (i.e., feeding grounds, breeding grounds and/or migratory corridors) for each of the described stocks (Group I-VI) or stock components.

To further account for potential population heterogeneity due to temporal or geographic stratification, the Working Group recommended that: (1) samples be collected throughout the migration period along corridors; and (2) in more than one year and as widespread as possible for any given regional habitat (i.e. summering or wintering grounds).

A summary of the distribution of available samples for known or suspected regional habitats is shown in Fig. 1, demonstrating the general need for greater biopsy sampling effort to describe stock structure of humpback whales throughout the Southern Hemisphere. The Group recognised the following examples as among those that are important because of the lack of historical information on stock identity: identification of likely breeding grounds for the formerly large feeding concentrations of humpback whales from Area II, around South Georgia; identification of the primary feeding grounds for the whales formerly killed in large numbers in tropical latitudes along the west coast of Africa; and identification of the feeding grounds for humpback whales currently found wintering throughout the Southwest Pacific (not in priority order).

(3) Current disposition of IDCR samples
The Working Group recognised the need for timely genetic analysis of humpback whale samples collected during IDCR cruises, particularly those from otherwise

Japanese whale research programme under the special permit in the Antarctic.
inaccessible regions (i.e. feeding grounds of Areas I, III and IV). The Group supported the previous recommendation of the Committee (IWC, 1994, p.51) that proposals for the analyses of these samples should be solicited and contracted by the Committee.

(4) Additional issues

(A) Historical sources of genetic information

The Group recognised a number of possible historic sources of material for genetic analysis. Such sources may include tissue (dried, preserved in ethanol or in formalin) bone or baleen held in various institutions including Sea Mammal Research Institute, National Research Institute for Far Seas Fisheries and national museums. Some useful information on the whereabouts of such material may be contained in the IWC data inventories. The Group recommended that an investigation of the availability of suitable material should be undertaken.

(B) Long-term preservation of tissue samples

The Working Group considered the need for establishing protocols for long-term storage of tissue samples for genetic analyses. Previously, the IWC has recommended storage of samples for analysis of DNA in 20% DMSO and saturated salt solution (IWC, 1994; Amos and Hoelzel, 1991). However the Working Group noted that the use of DMSO prevents or inhibits subsequent analyses of isozymes, hormones, natural isotopes and pollutants. Investigators should therefore also consider storage at −70°C for archiving.

(C) Request for tissue samples from strandings

The Working Group recommended that relevant national authorities should be made aware of the need for tissue samples from stranded humpback whales in the Southern Hemisphere and the subsequent protocol required to preserve them.

Appendix 5

AGENDA ITEMS 7.2 ESTIMATES OF ABUNDANCE OF HUMPBACK WHALES, AND 8.2 ABUNDANCE ESTIMATES OF OTHER SPECIES, A COMMENT ON SC/46/SH24, PARTS 1 AND 2

S. Holt

General

In this paper estimates from IDCR cruises carried out south of 60°S are pro-rated by indices of relative abundance for latitudinal zones derived from Japanese scouting vessels (JVSs), which covered latitudes from the ice edge to 30°S. Butterworth et al. state that

'sample sizes for estimating the whale density in the IWC/IDCR survey area obtained from the IWC/IDCR Antarctic surveys are clearly much too small to allow stratification by longitude, so that the latitudinal strata considered are necessarily circumpolar.'

This procedure can give numbers which are biased upwards if the longitudinal distribution of searching effort is such that searching tends to be conducted especially in areas of high whale density and if this feature is stronger in lower than in higher latitudinal strata.

SC/46/SH24, table 12 provides information on searching effort in terms of nautical miles steamed by half-Areas and shows that coverage of the IDCR stratum, in both periods, was relatively evenly spread longitudinally compared with the distribution in strata at lower latitudes. Some of the northern cells were not surveyed at all, and for those that were surveyed the distribution within a stratum by Sub area was very uneven. This raises the specific question of whether the Sub-areas not surveyed at all were known in advance to be regions of very low (effectively zero) whale density, and the more general question of whether, and the extent to which, the survey effort was concentrated more in known higher density regions than in lower density ones.

Fin whales as prime targets

In the earlier period of the JVS data (1965/66–77/78) the primary target species were fin and sei whales in mid- and lower latitudes. How the supposed bias comes into play can be illustrated by the density of fin whales in the 60–50°S stratum relative to the reference density in the IDCR stratum. The unstratified average densities (i.e. total number seen per hundred miles searched) were, respectively, 2.61 and 0.73, giving a ratio of density in the 60–50°S stratum to that in the IDCR stratum of 3.6.

Crude stratified densities would be the arithmetic means of the densities in each Sub-area. These are 0.99 in the 60–50°S stratum and 0.41 in the IDCR stratum, with a ratio of 2.4. Thus the method used by Butterworth et al. might be overestimating the number of fin whales in the important 60–50°S stratum by 50%.

Humpback whales

In their table 14(d), Butterworth et al. give estimates by strata obtained by using the JSV data for 1965/66–1977/78 which total 10,500, from which the grand total is 15,100. If the average densities in each stratum are estimated as the means of densities in each Sub-area of the stratum, as above (ignoring the Sub-areas with no survey effort, which is equivalent to assuming the average density of the whales in them is the same as in the rest of the stratum), the corresponding total is 6,660, giving a grand total of 11,300.

It might be more plausible, however, to assume the densities in the unsurveyed Sub-areas were all zero; that is, they were not surveyed because it was known that the density of baleen whales in them was very low. In this case the total becomes 5,900 with a grand total of 10,500.

It could be argued that as long as the longitudinal density estimates within a stratum constitute a highly skewed set of ratios, a more appropriate estimate of the average density for purposes of pro-rating might, for example, be their geometric mean. In this case the discrepancy with the unstratified estimates becomes even greater.

These calculations are very crude; I have not, for example, allowed for the fact that the Sub areas are sectors of varying angular extent, being generally 30° of longitude but 35° in Area III and 25° in Area II. They are here presented simply to illustrate the fact that unstratified pro-rating can lead to substantial overestimation of total numbers.

Appendix 6

PRELIMINARY REPORT ON THE OCCURRENCE AND PHOTO-IDENTIFICATION OF HUMPBACK WHALES IN BRAZIL

S. Siciliano

Introduction

Abrolhos Bank (17°20' 18°10'S; 38°35' 39°20'W) is an enlargement of the Southern end of the eastern Brazilian continental shelf, predominantly covered with coral communities. The presence of whales in Abrolhos Bank during Austral winter months has been documented since the 19th century (Souza, 1895; Paiva, 1966) and they have been confirmed as humpback whales through bone remains found in the mainland ruins of local whaling station sites. Abrolhos Bank presents all the habitat requirements of a humpback whale breeding and calving ground. The Archipelago on the Bank is composed of five small islands where waters are shallow (0–50m), warm (23°C–26°C) and protected from prevailing northeastern winds. Part of Abrolhos Bank has been protected and was designated as the first Marine National Park in 1983. In 1988, a series of three short boat surveys in the area revealed that humpback whales were visiting Abrolhos Bank seasonally
between June and December. This appendix reports the findings since then on the distribution, group composition and photo-identification of humpback whales in the Abrolhos Bank. In addition, sightings and strandings along the Brazilian coasts are also summarised along with the limited information available concerning local historical whaling.

Materials and methods
Boat surveys were carried out from 1988 to 1992 between July and December throughout the Abrolhos Bank. Shore-based observations were made from the main Island of the Archipelago which provides 360° coverage of the area. Photo-identification of individuals was conducted using the standard techniques for the species. Search tracks were not pre-determined, but observations were standardised and an even coverage of the study area was attempted. Sights were used to calculate the total number of whales observed per hour of effort. Photo-identification data were compared with the comprehensive catalogue for the species housed in the College of the Atlantic, Maine, USA. Stranding and sighting data were collected opportunistically. Whaling records were compiled from the available literature.

Results
Some 120 boat cruises were conducted on the Abrolhos Bank and adjacent waters of the continental shelf off Caravelas (17° 20'S) between 1988 and 1992. Humpback whales usually arrive in Abrolhos Bank in mid-late June and July and can be found in the area up to December of each year, but a single record of a mother-calf pair is known for as late as January in 1991.

Group size and composition
Groups sighted varied from 1 to 9, with humpback whales being rarely found in groups of more than three individuals. The group size most frequently observed was two in all years, reflecting the occurrence of mother-calf pairs with frequencies as high as 50%. Of these, 46% on average are accompanied by at least one escort.

General occurrence of humpback whales in the Abrolhos Bank
Whales were mostly observed in waters of 16-40m in depth, which corresponds to the deeper areas of the Abrolhos Bank. Humpback whales usually avoid waters where coral reefs are abundant. Mother-calf pairs concentrate in the area of the Abrolhos Channel, which separates the two largest coral reef formations (Parcel das Paredes and Parcel dos Abrolhos) of the Bank. This Channel is within the boundaries of the Abrolhos Marine National Park (Fig. 1). Common observations of small calves of about 3.5-4m long indicate the importance of Abrolhos Bank as a calving ground. Humpback whales seem to reach peak concentration during the months of September and October, when smaller calves also seem to increase in numbers. The number of individuals sighted per hour was similar in all years with an overall average of 1.2 individuals per hour of observation, whereas the number of groups per hour decreased gradually to almost half, with 0.8 in 1988 to 0.51 groups per hour in 1992.

Other cetaceans and associations with humpback whales
Humpback whales occasionally associate with other small cetaceans such as the bottlenose and rough-toothed dolphins. During the study period, one observation of a southern right whale mother-calf pair was made during September 1990 in the southern portion of the Bank. With the exception of this record and a potential sighting of a minke whale, humpback whales are the only large cetacean regularly visiting the Bank.

Behaviour
Mother-calf pairs were commonly accompanied by an escort. Adults accompanied by calves (i.e. presumed to be mothers), escorts as well as other individuals were frequently seen exposing their flukes high up from an upside down position. Aggressive behavior between and among escorts is commonly observed during September and October. Deep dives and subsequent fluke up positions are usually not common, considering the shallow waters of the Bank.

Photo-identification studies
A total of 92 individual humpback whales have been identified to date in Abrolhos Bank and photographs are being compared with the catalogue available at the College of the Atlantic, Maine, USA. To date no match has been made between whales photographed in Brazil and the Antarctic.

RESIGHTINGS WITHIN A FIELD SEASON
One whale (no. 035, Brazilian catalogue) was resighted in 1990 up to a 24 day interval. A mother-calf pair was sighted in three different occasions in 1990 with an interval of up 16 days. This preliminary data indicates that at least some whales stay in Abrolhos Bank for a relatively long period of time within a single field season.
RESIGHTINGS BETWEEN YEARS/SITE FIDELITY

A total of five humpback whales (nos 010, 018, 031, 052 and 064) were sighted in more than one field season. One humpback (no. 018) was sighted in three consecutive years indicating some degree of site fidelity.

Humpback whales along the Brazilian coast

The humpback whales migrating through the Brazilian coast to and from Abrolhos seem to follow the coastline and the edge of the continental shelf. This evidence comes from the available sightings of migrating humpback whales along the Rio de Janeiro coast (22°S). Following the shoreline would allow use, particularly for mother-calf pairs, of coastal shallow bays and islands, specially along Rio de Janeiro and São Paulo. A few sightings are known for the oceanic island of Fernando de Noronha (03° 52’S, 32° 28’W), which is slightly north of the former whaling ground off Paraíba coast (at 07° 07’S) and constitutes the northermost record of their occurrence in the Brazilian coast.

Mortality along the Brazilian coast

Siciliano and Lodi (1989) reported on nine humpback whales found dead along the Brazilian coast, between 1980 to 1988. At least nine more records of strandings have been recorded between 1984 to 1993 (Siciliano, unpub. data). From the 18 known strandings these include seven calves measuring between 4.36m to 5.10m and 11 juveniles and sub-adults (all of them physically immature) measuring between 8-15m. Three of the calves are known to have been caught in gillnets (and subsequently stranded). One of the juvenile records was an animal found entangled alive which was successfully released (see Siciliano, 1994) and one stranded alive and pushed back to sea. The apparent increase in numbers of humpback whale strandings recorded since 1989 may be due to a higher observation effort in some areas along the coast, but may be also related to a potential recovery of this species in the Southwestern Atlantic.

Some local historical whaling

Whaling activities started in Caravelas in 1847 (Hart, 1878 In: Paiva, 1966) and ceased in September 28, 1924 due to economic problems (Paiva, 1966). Ruins of the Barra de Caravelas whaling stations can still be traced, with whale bones and tools used in its factory, displayed in many houses, restaurants, hotels and along the beach.

Future work

Research needs include, addressing stock identity, movements and abundance, and the magnitude of bycatch mortality. These could be achieved through:

(i) surveys for estimating population abundance;
(ii) continuation of photo-identification studies;
(iii) collection of biopsy samples for DNA analysis; and
(iv) monitoring mortality along the coast.

All future work can only be implemented with the availability of funding.

HUMPBACK WHALE CATCHES BY AREA AND SEX IN THE ANTARCTIC TAKEN BY THE YURIY DOLGORUKII

D.D. Tormosov

As requested by the sub-committee I asked Cherry Allison to prepare a table of humpback whales taken by the Yuriy Dolgorukii in the Antarctic by season, area and sex. These data are presented in Table 1.

Table 1
Humpback whale catches by the Yuriy Dolgorukii (New data).

Report of the Sub-Committee on Aboriginal Subsistence Whaling

1-3. OPENING REMARKS, ELECTION OF CHAIRMAN, APPOINTMENT OF RAPPORTEURS

The meeting was convened by Reilly. Bannister was elected Chairman. Cawthorn acted as rapporteur.

4. ADOPTION OF AGENDA

The agenda was adopted as in Appendix 1.

The sub-committee agreed that, in the case of bowhead whales, its main task was to assess the Bering-Chukchi-Beaufort Seas stock, but that under Item 6.1 it would consider any new information on other possible stocks. In the case of gray whales, its main task was to assess the North Pacific Eastern stock, but it noted that information from the western North Pacific was relevant to the question of stock identity under Item 7.1.

5. REVIEW OF DOCUMENTATION, DATA AND COMPUTING NEEDS

Documents available to the sub-committee included SC/46/AS1-19, Mg10, NA11, SH18 and several papers provided for information.

In reviewing data needs, it was agreed that past historic catches of bowheads would be reviewed under Item 6.2.

Allison agreed to provide a comprehensive summary of recent aboriginal subsistence catches for all species. It appears as Table 1.

Allison reported that the population dynamics module (BALEEN II) had been validated. Full documentation for the Bayesian synthesis program (BAYSYN 2 and BERGS) had been received by the Secretariat and validation of the programs is in progress. The main routines of the program had been checked but she had not had time to complete the validation process. However, most of the work remaining to be done concerned the standard software routines included in the program. In addition, Punt had written a separate version of the program which had been shown to give near identical trajectories and mean results, thus providing an independent check.

1 Including 6 struck and lost.
2 Humpback (was trapped in a lead in the ice).
3 Humpbacks.
4 Bowhead whales, of which 11 struck and lost.
5 For bowhead whales, these are strikes, not catches; 1 struck whale is presumed to have lived.

6. BOWHEAD WHALES

6.1 Stock identification, migration and distribution

Bering-Chukchi-Beaufort Seas stock

The sub-committee referred to the review undertaken when the stock was last assessed (IWC, 1992b, p.138). There was no new information to alter the conclusion that no evidence of a western Chukchi Sea substock. While there is much evidence for segregation by age and sex, with adults perhaps ranging more widely than subadults, there appears to be a single stock whose movements are governed by food aggregations and ice conditions (Appendix 2). Recent evidence on the animals' distribution in the autumn has come from satellite tagging, mostly related to movements in the Canadian Beaufort Sea. One animal, however, was shown to migrate west of Point Barrow across the Chukchi Sea to the Siberian coast, within 34 days of tagging (Appendix 3).

Other stocks

The only new information available to the meeting referred to the Davis Strait stock (SC/46/NA11). Whales winter in open water as far north as northern Baffin Bay (75°N) and as far south as at least the entrance to Cumberland Sound (64°N). In March 1990, 1991 and 1994 and April 1991 there were 12 sightings (14 animals) from opportunistic observations made during white whale and walrus investigations, with concentrations of bowhead whales between 67°15'N and 68°35'N. During more extensive systematic aerial surveys in March 1981 and 1982, there were 8 sightings (11 animals) in the area bounded by 66°30'-68°15'N and 53°-55°W. The area off West Greenland appears to be one of several wintering grounds for the Davis Strait stock, currently estimated as consisting of 250-
350 animals. Two additional kills from this stock, at least one in April 1928 and another in 1973, both near Qeqertarsuag (Godhavn), Greenland, were reported. Neither had been included in previous catch summaries for this stock.

6.2 Catch history

6.2.1 Commercial catches
Table 1 from the 1991 meeting (IWC, 1992b) was accepted as containing the most up to date information on the commercial, i.e. pelagic, catch, subject to an amendment to the total kill in 1902, to 162. That table, as amended, is reproduced here as Table 2. The sub-committee noted that 'recorded' catches and the presence of zero in the table can as equally refer to no information as to no catch.

The sub-committee accepted that the commercial take reflected the animals' distribution, being taken over the entire range of the stock. The question of uncertainties in the catch history was raised; a working group under Broadhead was charged with reviewing the struck and lost rates applied in arriving at the figures in Table 2, the consequences of their use and what would be required to refine them further.

Table 2 provides an update of the pelagic and shore-based catches tabulated in IWC (1992b). No changes have been made at this meeting in the pelagic kill records. Revisions in the Alaska shore kill and struck and lost, 1973-1993, were from SC/46/AS10. Table 2 shows 'recorded' catches and the presence of zero can as equally refer to no information as to no catch.

Concern was expressed about the degree of variation that might be associated with the estimates of historic pelagic kills. The basic source for these data is Bockstoke and Botkin (1983). They utilised a sample (19%) of logbook records of voyages to the western Arctic, 1848-1914, to estimate catch, struck and lost dying, and struck and lost alive for each year. The estimates of pelagic kill each year were considered to be bowheads caught plus bowheads recorded as struck and lost dying, expanded by the ratio of total voyages to the number of logbook records utilised each year.

The sub-committee recommended that the variability associated with the historic pelagic kill estimates be investigated and taken account of in the modelling process.

6.2.2 Aboriginal subsistence catches
The sub-committee reviewed the 1993 catch (SC/46/AS17) and a revision of data from 1973 to 1993 (SC/46/AS10). The working group under Broadhead reviewed the catch data available at the last assessment meeting (IWC, 1992b).

Revisions in the Alaska shore kill and struck and lost, 1973-1993, from SC/46/AS10, were included in Table 2.

6.3 Abundance and trend estimates
6.3.1 Review of census and estimation procedures
CENSUS
A preliminary report on the results of the 1993 ice-based visual census off Point Barrow, Alaska, was available in SC/46/AS17. Between 10 April and 4 June, in 1,067 hours of watch, observers counted 3,283 whales, including 66 calves. The counts of whales and calves were higher than in any previous census; the raw count of whales was 62% higher than the previous highest count, in 1988. Although some of the increase was likely to have been due to an increase in population size, much was due to the high proportion of animals which came within 4km of the perch (91% in 1993 from acoustic data, see SC/46/AS12). By comparison with earlier years, the 1993 migration appeared to be highly directed and uninterrupted. Of 2,832 sightings for which direction of travel was recorded, 90.7% were heading north, 1.2% south and 8.0% lingered within view of the observers. In 1987 and 1988, 85% and 74% were heading north. A statistically significant association between numbers of whales seen, success of the hunt off Barrow and persistence of easterly winds was noted. A qualitative examination of the acoustic, visual and aerial survey data during spring suggested a positive relationship between heavy ice cover and a broad distribution of migrating whales.

Every effort was made to achieve compatibility of census techniques with those of previous years. Two experiments were conducted to test for possible effects of field procedures, one on the effect of the more southerly perch location, the other on possible bias from the introduction of plotting sheets. No significant effect could be attributed to the former, but the latter suggested that new whales were scored conservatively in 1993.

SC/46/AS19 gave the results of an acoustic study off Barrow in 1993, which since 1984 has complemented the visual census. An acoustic study was conducted in close coordination with the visual census effort during April and May. The 1993 study was the most successful to date in terms of the numbers of hours of acoustic array data collected (>1000 hours), the percentage of the season covered (94%) and the relative quality of the recording conditions.

In order to allow for more rapid analysis of acoustic locations, a new computer system was developed. A preliminary analysis of 469 hours of acoustic array data demonstrated that the majority of vocalising animals (e.g. 75% within 3km, 96% within 6km) were close to the ice edge in contrast to results from previous years. Further ongoing analysis of acoustic data, including more locations, range and bearing errors associated with an acoustic location and determination of call tracks, will clarify the numbers and distributions of vocalising animals.

Aerial surveys off Barrow have been conducted in the spring since 1978 (SC/46/AS4). Some have been designed to study bowhead (and white whale) distribution past the ice-based census area of operation, others to obtain length measurements and individual identifications. The most recent survey, in 1992, was undertaken with 50% or more sea ice coverage. The proportion of the area surveyed with 90-100% ice cover (64%) was higher than for any previous year and the lead was rarely open due to persistent westerly winds. Ice preference differed significantly between juvenile and adult bowheads, with more juveniles seen in ice cover of 60% or more. Bowheads were seen out to 32km from the shorefast ice edge, but with a peak at 6-7km and most sightings within 8km. The results are in contrast to those earlier which suggested that whales migrate in a narrow corridor up to 8km wide, close to the ice edge, although recognition that a significant, but unknown, proportion of animals passes too far offshore to be seen by the visual census led to the abandonment after 1985 of the two-perch visual census in favour of the combined visual and acoustic census (IWC, 1992b, p.141).

ESTIMATION PROCEDURES
SC/46/AS13 reviewed the Bayes Empirical Bayes methodology as used in recent years to estimate bowhead status. While the basic essence has remained unchanged for the past six or seven years, SC/46/AS13 described aspects revised since the analysis of data from the 1988
### Table 2

Catch data, Bering-Chukchi-Beaufort Seas bowhead whales, 1848-1993. These are recorded catches; the presence of zero can equally refer to no information as to no catch. The assignment of 'struck and lost' to the shore kill follows the methodology of Breitwick et al. (1984) which was 1848-1969, 100%; 1970-1980, 50% and a chance of survival for probably died (SC146/AS10) for 1981-1993.

**Total** | 15,684 | 2,153 | 7 | 201 | 2,361 | 1,307 | 22,174
season. When this population was last assessed (IWC, 1992b), the sub-committee agreed that the Bayes Empirical Bayes approach was the most appropriate for estimating current population size. The 1988 census was the most recent and complete census undertaken to that date (1991).

At this year’s meeting, the full methodology was available in Raftery and Zeh (1993) and it was summarised as follows (SC/46/AS13):

(i) the season is divided into time periods that are homogeneous with respect to the type of monitoring (visual only, acoustic only, or both), the conditions (e.g. visibility) under which that monitoring took place, and into three geographical zones (nearshore, offshore and acoustic, shown in fig. 1 of Raftery and Zeh (1993));

(ii) locations are linked together to form tracks using a tracking algorithm;

(iii) for each period and zone, the probability distribution of the number of whales is calculated given the census data, or posterior distribution – this is based on a biological and geometric stochastic model of the census process and whale behaviour;

(iv) the results are combined for different periods and zones to obtain an overall posterior distribution for the entire season;

(v) uncertainty about tracking algorithm and model parameters is incorporated by rerunning steps (ii)-(iv) for a collection of plausible parameter values and combining the results.

SC/46/AS12 and 13 also described the results from an alternative method of estimating population size that does not depend on the tracking algorithm in any way. This estimate is \( N_d/P_4 \), where \( N_d \) is the estimated number of whales that passed within viewing range of the census perch (4km) and \( P_4 \) is the estimated proportion of the population that passed within this range. \( N_d \) is estimated from the visual census counts as described by Zeh et al. (1991). \( P_4 \) is estimated by the proportion of acoustic locations directly offshore from the perch and hydrophone array, averaged over the census period. The variance of \( N_d/P_4 \) is estimated as described by Raftery and Zeh (1993).

6.3.2 Current population size
In 1991, the Committee recommended that a full visual and acoustic census of this stock be conducted as planned in 1992 (IWC, 1992b). The results, however, were poor because of the environmental conditions, with only 291 whales seen. The data were inadequate to support a population estimate.

Environmental conditions in 1993, however, were unusually good, with 3,383 whales seen and at least 49,000 bowhead calls recorded (SC/46/AS13). Less than 10% of whales were outside the visual range in 1993, compared with 23% in 1988. Animals in 1993 were travelling faster, at ca 3km/hr, than in 1988.

Because not all the acoustic data could be analysed in the time available before this meeting, only preliminary results were provided for the 1993 population size, which was estimated as 6,600 (95% CI 5,700–7,600) using the Bayes Empirical Bayes estimation methodology (SC/46/AS13).

The alternative method, using the visual data corrected for whales located acoustically outside the visual range, gave an estimate of 7,992 (95% CI, computed as recommended by Buckland (1992) 6,900–9,200) (SC/46/AS13).

The sub-committee recognised that the lower abundance estimate for 1993 is essentially conservative, particularly by comparison with that for 1988 (7,500, 95% CI 6,400–9,200). The degree of conservatism varies from year to year with the spatial distribution of whales. The 1993 estimate does not imply a reduction in population size over the period, but reflects the concentration of the whales closer to the ice edge in 1993. This sort of distribution causes the tracking algorithm to count very conservatively, linking locations from different whales into single tracks.

Given the number of estimates now available for the population size of this stock, the sub-committee agreed to include Table 3 in which the various estimates are given. Included in the Table are comments on the comparability of the estimates or otherwise.

Notes:
1 The Bayes Empirical Bayes method is not designed to give estimates that are consistent from year to year, but rather to give estimates for each year that are conservative. The extent of the conservatism varies from year to year and depends on the spatial distribution of whales.
2 Thus these estimates are not comparable from year to year and cannot be used to infer population changes (see SC/46/AS13).
3 Preliminary estimate because analysis incomplete.
4 Preliminary estimate because based on partial data.
5 Preliminary estimate because based on partial data and incomplete analysis.

The sub-committee agreed that the 1988 Bayes Empirical Bayes estimate (7,500 with 95% CI 6,400–9,200) was the best estimate to use for assessment purposes. The best available estimate of current population size is the 1993 \( N_d/P_4 \) estimate of approximately 8,000 (95% CI 6,900–9,200).

6.3.3 Recent trends in abundance
SC/46/AS12 analysed trends in annual numbers for the period 1978–1993. The trend in annual numbers passing within viewing range of the perches, estimated by an unweighted regression using \( N_d \) from 10 censuses within this period, gave an increase rate of 4.9% per year (95% CI 1.4–8.5%). An unweighted regression was used to reduce the influence of the high 1993 estimate \( N_d \) of the number of whales that passed within viewing range.

The 1993 estimate was high because, based on acoustic data, 91% of the whales were estimated to have passed within viewing range. In previous years, up to half the whales passed offshore beyond the visual range of the observers.

Acoustic data on the percentage of the population that passed within viewing range were available for the years 1985, 1986, 1988 and 1993 only. A weighted regression using the population estimates \( N_d/P_4 \) for those years, therefore taking into account the whales that passed beyond viewing range, gave an increase rate for 1985–1993...
of 2.5% (95% CI 3.5; 9.0%). The confidence interval was wide since the regression was based on only four data points.

The sub-committee noted that an increase rate of 1.48% (95% CI 0.30–2.80) had been obtained as output from the Bayesian population assessment described in SC/46/AS14. It agreed to defer further consideration of that result pending its discussions under Item 6.6.1, where a revised estimate is discussed.

6.3.4 Historical population size
No new information was available on minimum historical population size apart from an estimate given in SC/46/AS14, derived as a result of the Bayesian assessment and considered further under Item 6.6.1.

6.4 Biological parameters and life history
The sub-committee reviewed new information available at the meeting as follows.

Size class frequency
SC/46/AS3 reported on an update of length structure information obtained from aerial photogrammetry of bowheads off Barrow in 1985, 1986 and 1989–1992. 1,898 animals were measured, averaging 75% of those photographed (range 65–86% per year).

Technical biases such as image distortion and image smear were shown to be small; the largest technical error reported, involving the radar altimeter, had a CV of 0.8–4.1%. Biological biases with a technical component, such as are caused by the position, orientation and behaviour of the whale, were again very small. For example, the average CV for multiple measurements by two observers was 1.9%. Sampling biases may occur through differential measurability of different maturity classes, preferential removal of duplicates of large, well-marked animals from the sample and the behaviour of different maturity classes.

The proportions of adults, juveniles and calves, allowing for the above effects, were 41.1, 53.7 and 5.2% respectively.

Population growth from length class frequency
SC/46/AS9 reported a study undertaken to assess change in population size from length frequency data, themselves derived by transformation from age data. Significant results were obtained from random samples of 1,000 females from populations at high \( r = 0.00 \) and low \( r = 0.03 \) density. To have a reasonable chance of detecting a change in the length frequency distribution, sample sizes of between 500 and 1,000 animals would be required. Such sample sizes are larger than could be obtained from photogrammetry in any one year but survey results from several years could be pooled.

The study recognised several assumptions affecting the results. Only females were considered, while the surveys sample both sexes and the different age at length ratio for each sex may introduce error into the computations; the deterministic model used cannot incorporate such parameters as variable recruitment; there may be potential changes other than the specific density-dependent ones studied.

In discussion it was pointed out that the length structure can be quite sensitive to the growth curve and the age-dependent natural mortality schedule (e.g. de la Mare, 1983). Length structure information is in itself uninformative about the rate of increase in a population unless the natural mortality schedule and growth curve are known. Detecting changes in the population rate of increase, but not the absolute rate, through the length structure may be possible from length data, but the apparent magnitude of change in the rate of increase will be sensitive to the growth curve and natural mortality schedule and possible density dependence used in these parameters.

Pregnancy rates
Examination of 72 mature females taken in the period 1973–1993 gave an uncorrected pregnancy rate of 22% (SC/46/AS17). The value would be biased downwards because foetuses are missed, if the mean length at maturity were higher than that used (13m), or if hunters avoided some mature classes such as pregnant animals.

Some allowance was made for such bias, for example by correcting for missed foetuses by sampling only during the autumn hunt, when small foetuses are unlikely and by using a length at maturity of 13.5m, to allow for stretching of carcasses hauled on to the ice. The resulting pregnancy rate was 34.6%, indicating a calving interval of three years.

The sub-committee was advised that allowing for the lack of lactating females caught would give a calving interval closer to four years.

The sub-committee recalled discussions during the previous assessment (IWC, 1992b, p.145) where calving intervals of 4–7 years were reported, with the possibility of 3–4 years under optimal conditions.

Longevity
Two stone harpoon points of a pattern generally out of use at the turn of the century and certainly since 1920 were recovered from a very large animal at Wainwright in 1993 (SC/46/AS17). Three other primitive harpoon heads have been recovered since 1980. Their recovery suggests that bowheads may be very long-lived, perhaps up to 100 years. Attention was drawn to an earlier study of age determination in bowheads by Nerini (1983).

Mortality
Between 4 and 8% of bowhead whales examined in the catch since 1976 showed evidence of scars from killer whale attack and about 1% had scars from ship collisions (George et al., 1994). The frequency of killer whale scars was considerably lower than for animals in the Davis Strait stock where killer whales are thought to have been partly responsible for the failure of that stock to recover. It was significantly lower for smaller bowhead whales (<13m) in the sample examined from the Alaskan Eskimo take. The latter was attributed to the greater exposure time of larger and hence older whales to the possibility of attack and the likelihood that few smaller whales survive killer whale attacks. The incidence of ship strikes was also lower than for example in north Atlantic right whales, where they are a notable source of mortality.

Growth and age
The sub-committee's attention was drawn to SC/46/SH18 where because of the somewhat controversial nature of the growth pattern of juvenile bowheads described from stable isotope ratios in the baleen plates (Schell and Snape, 1993), eight southern right whale plates had been examined for comparison.

As expected from the more pronounced latitudinal gradient in carbon isotope ratios in the zooplankton in their habitat, the southern right whale plates exhibited oscillations in the carbon isotope ratios of an amplitude (up
to 7ppt) much greater than for bowhead whales (4ppt). The oscillations also appeared far more asymmetrical in the southern right whale, indicating that considerably more of the year was spent feeding in regions of carbon depletion than enrichment. If the oscillations are annual events, then the right whale baleen must be growing faster (28–30cm per year) than in bowheads (16–25cm per year). As right whale baleen grows to 2–2.5m in length compared to 4m in bowheads, there are only about seven growth periods at the most in right whale baleen compared to 20 in bowhead baleen. The utility of right whale baleen for age determination is therefore more limited than in bowheads. Nevertheless, a comparison of the size of right whale calves at four months of age (average 8.2–9m) with the size of the three juveniles estimated from the isotope ratios in their baleen as two years old (9.9m) suggests that as in bowheads a hiatus in body (but not baleen) growth occurs postweaning. This hiatus must be much shorter than in bowheads, as the age at maturity is 6–10 yrs compared with 15+ yrs for bowheads. The shorter hiatus would be consistent with the smaller relative baleen apparatus and faster baleen growth in right whales.

6.5 Indirect effects of human activities

6.5.1 Offshore oil drilling programmes

SC/46/AS6 reviewed the timing of the Alaskan bowhead hunt from 1973 to 1993. While general information on the timing of the spring and autumn migrations is already available, detailed information on the timing of the actual harvest itself was tabulated to help those planning oil exploration and drilling in waters off the North Slope to minimise such impacts on the whales and on the availability of whales to the subsistence hunters.

The sub-committee agreed that information of this kind was useful to managers. It recognised that the probable mechanism for any insidious effect on whales is not the physical presence of oil rigs, for example, but the introduction of noise into the environment.

It was noted that in 1993 ARCO Alaska, Inc. conducted seismic studies and exploratory drilling in the Kuwum Exploration Area off Camden Bay, Alaska directly in the path of the fall migration. This represents ARCO’s fifth year of geophysical activities since 1989. Exploratory drilling commenced on 17 July 1993 and ceased on 10 November 1993. Seismic operations were conducted in the study area between 16 July and 31 August 1993. As required, ARCO supported monitoring studies, which included aerial surveys, surface observations and underwater acoustic monitoring, to determine whether marine mammals (especially bowhead whales) were being adversely affected by the exploratory activities. ARCO has recently submitted a draft final report to the National Marine Fisheries Service concerning the findings of the 1993 monitoring program. A final report should be available in the summer of 1994.

It is unlikely that any geophysical activities in waters off the North Slope will occur in 1994 during the period when bowhead whales are migrating through the Beaufort Sea.

6.6 Assessment

6.6.1 Bayesian synthesis

SC/46/AS14 had been prepared in response to the Committee’s decision last year to recommend the Bayesian synthesis approach for use in this year’s assessment (IWC, 1994, pp.55, 60). It applied that synthesis framework to the BALEEN II population dynamics model. The method relies on a Bayesian combination of the available evidence about the inputs and outputs of a population dynamics model, and weights model simulations on the basis of how compatible they are with the combined evidence. Unlike methods used in previous assessments, the Bayesian synthesis method takes full account of the evidence and uncertainty about bowhead life history, abundance and age distribution.

Concerns over the sensitivity of the Bayesian procedure, particularly to alternative input prior distributions for the values for MSYR and pre-exploitation population size (K), were expressed in SC/46/AS2 and an addendum. A response to those concerns (SC/46/AS5) had led to further discussion.

A working group under Stokes was established to examine these issues and the most appropriate assessment approach. Its report is given in Appendix 4. The sub-committee accepted the conclusions, i.e. that should the sub-committee agree on premodel distributions for model inputs and outputs similar to those used in SC/46/AS14, the consequent assessment would be accepted as a basis for advice at this meeting.

The sub-committee agreed that although the programme had not been completely validated as required under the Committee’s procedures for assessments (see Item 5), it could be used at this meeting.

The pre-model distributions used in SC/46/AS14 were compared with the parameter values accepted at the last assessment meeting (IWC, 1992b, pp.144-6). An agreed set of conclusions was determined as summarised in Table 4.

Most discussion centred on juvenile survival rate (s0), mature survival rate (S), initial stock size (K), the MSYR for the mature stock, the current rate of increase and the maximum historic ratio of calves/mature females.

In the absence of direct evidence of survival rates, there was some discussion of a likely relationship between adult survival and the age at sexual maturity. The higher the latter, the higher the survival rate.

Given the recent evidence from isotope studies of sexual maturity at age 17+ and from photogrammetry of animals becoming adult in their teens or early twenties (Koski et al., 1992), the sub-committee agreed to accept a range for sexual maturity of from 14 to 26 as shown in Table 4. This is considerably later than has been found for other baleen whales and is suggestive of a high adult survival rate.

There was general agreement that the low incidence of killer whale scarring and evidence for ship collision, coupled with the very low incidence of disease found in examined specimens would lead to the conclusion that the adult bowhead survival rate is very high. Further support for that conclusion was provided by the anecdotal information on longevity from recovered harpoon heads (see Item 6.4), aspartic acid racemisation studies (Nerini, 1983) and inferences from Southern Hemisphere right whales. Ages of 120+yrs had been postulated on the basis of Nerini’s work. After considerable discussion, the sub-committee agreed to adopt the distribution for the adult survival rate given in Table 4. In the absence of any information on juvenile survival rates, apart from the general view that it would be lower than adult survival rate, the sub-committee agreed to use the broad distribution shown in Table 4. Butterworth expressed reservations; see Appendix 12.

In respect of MSYR for mature adults, the sub-committee agreed, after considerable discussion, to use a uniform distribution, with values 1–7%. Following
Table 4
Pre-model distributions from SC/46/AS14, consensus sub-committee choices and previous values from IWC (1992a).

Notes:
(1) Schell noted that his data indicated 17 years as the minimum plausible value of this parameter, although a confidence interval for this value might go down to 14 years. He considered values around 20 years most likely. Best noted that the upper limit of 20 used in SC/46/AS14 was based on work of Koski et al. (1992) where 31 was proposed as an upper bound on age of first parturition for any individual whale, but that the parameter used in the Bayesian synthesis assessment represented the average age at sexual maturity. A normal distribution with mean 20 and standard deviation 3, constrained to lie between 14 and 26, was believed by the sub-committee to provide a reasonable pre-model distribution.
(2) IWC (1992a) reported that values calculated from population models ranged from 12,400 to 18,200. These values cannot be used when forming a pre-model distribution since they rely on modelling, however, it is worth noting that these values are within the range of the distribution derived from the CPUE data.
(3) The special meeting of the Scientific Committee on the RMP (IWC, 1993, pp. 221-8) used MSYR$_{mat}$ = 1%, 2.5%, 4% and 7%.
(4) This distribution was accepted by the Scientific Committee in 1991.
(5) Based on best current data.
(6) The SD was increased to reflect the opinion of sub-committee members that very little is known about this parameter.
(7) The centre of this distribution was shifted and the SD was decreased to reflect sub-committee opinion that all biological data suggest very high survival rates, and that the left tail of the distribution used in AS14 was consequently too heavy.
(8) Sub-committee members noted that the development of the CLA had, in essence, required a prior for MSYR$_{mat}$, and that the range of values used in management trials (see Note 3) was an appropriate basis for a pre-model distribution.
(9) The sub-committee agreed that the 1988 Bayes Empirical Bayes abundance estimates was the best to use for assessment purposes because of the preliminary nature and conservative nature of the 1993 estimate.
(10) Sub-committee members felt plausible limits on bowhead calving interval based on pregnancy rate data implied narrower bounds on this parameter.
(11) Let $t_n$ denote a $t$ random variable with degrees of freedom.

Concerns expressed over the validity of that approach and its consistency with previous discussions on MSYR mature by the Committee, a sensitivity trial was undertaken. It used the distribution for MSYR mature given in SC/46/AS14, with greater weight given to values between 1 and 4% and values between 0 and 1% given non-zero, though low, probability. The results of the trial are shown in Appendix 5. They were accepted as confirming that the influence on RY of the MSYR pre-model distribution chosen was not great.

In respect of the increase rate, concerns were expressed over which results, or combinations of them, were most appropriate. Three estimates were available in SC/46/AS12. Two of these, using the visual census results
from 1978 to 1993, were particularly affected by the high 1993 value although account had been taken of that as far as possible. The third estimated rate, since it was based on actual population estimates instead of estimated numbers of whales that passed within viewing range, was not affected by year-to-year variability in the proportion of whales that passed within viewing range but it had high variance, with only four data points. A revised approach was presented, as in Appendix 6, incorporating the available information for the years 1978–1993. The resultant estimate of an increase rate of 3.1% (95% CI 1.4–4.7) was adopted for use in the assessment (but see further consideration of this conclusion under Item 6.6.4).

There was also much discussion of the maximum historic ratio of calves to mature females. An upper bound of 0.5, corresponding to a calving interval of two years, was adopted. A lower bound of 0.25, corresponding to a calving interval of four years, was also adopted. This was supported by the analyses of pregnancy rates described under Item 6.4. Two calving intervals of four years have been observed in photographically identified bowheads and mean calving intervals in the range of 3.3–4.5 years have been estimated, based on rates of occurrence of calves in photographs (Miller et al., 1992).

The pre-model distributions as agreed (see Table 4) were then used in a revised Bayesian assessment with the results shown in Appendix 7. The median and 95% post-model probability intervals obtained in that assessment were as follows:

Initial Stock Size: 12,599 (10,945; 17,431)  
MSYRmax: 4.44% (1.93%, 6.65%)  
Rate of Increase: 2.31% (0.92%, 3.44%)  
RY: 199 (97,300) with 5th percentile 104.

The estimated depletion level is 0.36 with 95% CI (0.27, 0.44) and the probability that the stock is above MSYL is estimated to be 0.002. These estimates are calculated relative to the mature part of the stock.

The results indicate a more robust and fertile stock than shown in SC/46/AS12, because of the less conservative nature of the modifications to the pre-model distributions agreed by the sub-committee. By comparison with SC/46/AS14, there is an increase in the 5th percentile value of RY from 68 to 104.

It was noted that as a function of density RY is generally considered to be a unimodal function with its peak at the MSYL. That is, RY will increase as abundance increases from very low levels to the MSYL and will decrease to 0 as abundance continues to increase from MSYL to K. Thus, if this population continues to recovery, it was recognised that reporting MSY values would be more informative for the purposes of management than continuing to report RY values, for scenarios where the population is assessed to be above MSYL. Therefore, a proposal was made for later consideration that the RY statistic be replaced by one equal to RY for population size below MSYL, but equal to MSY above MSYL.

6.6.2 Other approaches

During its discussions, the sub-committee noted that a simple estimate of RY could be obtained from the estimate of current stock size and increase rate, as has been standard fisheries practice for many years. Although the sub-committee agreed that this approach neither takes into account all the available information nor the associated uncertainty as effectively as the Bayesian synthesis approach it agreed that the results of such an estimate would provide useful comparative information to the agreed assessment given under Item 6.6.2. The results are given in Appendix 8. As expected they are consistent with the view that the Bayesian synthesis approach represents a more complete and conservative method of estimating RY for this population.

Baker had reservations over the choice of the increase rate discussed in Items 6.6.1 and 6.6.2 (see Appendix 12).

6.6.3 Impact of aboriginal subsistence hunt

The sub-committee agreed to deal with this matter under Item 6.6.4.

6.6.4 Management advice

The sub-committee had agreed (Item 6.6.1) a median value of 199 for the RY (95% probability interval 97–300, and the 5th percentile, 104).

In reviewing that value under this item, further concerns were raised over the methodology used in Appendix 6 to obtain a revised estimate of increase rate. The concerns were centred around the use of a weighted regression and the adjustment made to deal with the lack of acoustic data before 1985.

The sub-committee agreed that the unweighted analysis in SC/46/AS12, which was based on visual census estimates (Nt) uncorrected for whales that passed beyond viewing range, was appropriate to allow for the errors contributed by the varying proportion (Pc) of whales within viewing range.

A weighted analysis as in Appendix 6 was appropriate when Pt was accounted for, since there was greater uncertainty associated with the Pt values used when acoustic data were not available.

The sub-committee agreed that the most appropriate way to estimate the rate of increase for bowhead whales would be to estimate the proportion of the population within viewing range for all years for which census data are available. For the years before acoustic data were available, this would involve using information on wind and ice conditions and aerial survey data on offshore distributions of the whales. It was recommended that this analysis be carried out intersexonally.

It was not possible to complete such an analysis at or before this meeting. Therefore, the sub-committee accepted an estimated rate of increase of 3.1% (95% CI 1.4%, 4.7%). This estimate was calculated by applying the average Pt from the years with acoustic data to the estimates for which acoustic data were not available (Appendix 6). An alternative way of dealing with the fact that no estimates of Pt are available prior to 1985 would have been to use the estimate of rate of increase for the period 1985–1993 given under Item 6.3.3, but this would ignore 60% of the visual census data. The approach of Appendix 6 obtained a more precise estimate by using all of the visual census data together with the acoustic data on offshore distribution.

From the agreed Bayesian assessment, the estimated depletion level for the mature part of the stock is 0.36 with 95% CI 0.27, 0.44.

The sub-committee agreed that to provide advice on the effect of the aboriginal catches, population trajectories for the period 1994–1998 would be calculated for assumed annual catches of 0, 47 and 75 animals, based on the present catch quota and half of the difference between the latter and the 5th percentile of the replacement yield, for the period 1995–1998; for 1994 a catch of 52 was assumed.
given the maximum number of strikes allowed under the current quota. The methodology is described in Appendix 9. The results are shown in Table 5.

In view of its concern over the then apparently very low stock size, the Committee had in 1981 recommended the take of smaller animals and avoidance of older animals and reproductive females. The sub-committee agreed that in view of current improved estimates of abundance and its view that the population is increasing towards MSYL, there is no scientific reason to reiterate that recommendation. It recognised that this does not preclude other humanitarian or operating efficiency reasons for making such a recommendation. Given the high modal estimate for adult survival rate obtained from the Bayesian synthesis assessment (0.983), the benefit from such a measure is small.

There was some discussion of the feasibility of increasing the information available on certain parameter values, e.g. adult survival rate, through recommending the catch of certain classes of animals, such as mature adults. Given the current inability to age older animals and the likelihood that for practical reasons, including the effects of weather, the whalers would be unlikely to select the size of their catch, it was agreed not to pursue the matter further.

The sub-committee welcomed the information provided in SC/46/AS10, indicating a continuing increase in hunting efficiency. It also noted that a higher percentage of those whales struck and lost were considered to have died, perhaps reflecting the continuing emphasis on hunting efficiency and weapon improvement. From 1981-86, 49% of whales struck and lost were estimated by hunters to have probably died. From 1987-1993, 80% of the whales struck and lost were reported to have probably died. The sub-committee agreed that every encouragement should be given for the increase in efficiency to be continued.

The sub-committee’s attention was drawn to the results in SC/46/Mg10, where the RMP Catch Limit Algorithm had been applied to the historic catches and the most recent estimate of abundance. SC/46/Mg10 showed that the application of the CLA in the RMP to the bowhead whale stock yields zero catch limit in 1991 and the tuning level yielding the catch limit of 47 whales was 41% of the initial stock size. The sub-committee agreed that until the Commission’s adoption of the RMP there was no context in which to consider the results. It noted also that there has as yet been no development of an Aboriginal Whaling Scheme corresponding to the RMP and that current management advice has therefore to be formulated under the existing Aboriginal Management Scheme, as far as that is possible. The matter would be drawn to the attention of the main Committee meeting.

A question was raised concerning the level of possible genetic interchange between the Bering-Chukchi-Beaufort Seas stock and other, more depleted, stocks. The level that the stock would eventually reach without a catch would be higher than if even a sustainable catch was allowed. This might affect the possibility of movement of even a few individuals between it and those other stocks. The sub-committee agreed that a number of genetic studies should be pursued. It was informed that the results of work on sequence information from the mitochondrial DNA of a small number of whales obtained during the 1992 catch would be available next year.

Conclusions

Under the Aboriginal Whaling Scheme the Committee is required to provide advice on the size of the stock in relation both to the MSYL and ‘a minimum level below which whales shall not be taken’.

The Bering-Chukchi-Beaufort Seas stock of bowhead whales is clearly well above the latter minimum level, given that it has been increasing under a regime of catches of the order of some 30-50 animals since 1978. Although it was unable to provide an estimate for the MSYL in terms of mature females, the sub-committee agreed that on the assumption that the level lies between 0.4 and 0.8, there is a very high probability that the number of mature females is currently below that level. As long as catches are below the RY, the stock will continue to move towards the MSYL, at a rate depending on the level of catch. Table 5 provides information on the rate of that increase under a range of different catch levels.

6.7 Recommendations

In addition to those already agreed, the sub-committee recommended that investigation of ageing techniques be undertaken, including re-examination of the aspartic acid racemisation technique.

7. GRAY WHALES

7.1 Distribution and migration

Distribution

There was no information available at this meeting to alter the conclusion reached at the 1990 assessment meeting that the eastern and western North Pacific populations of gray whales probably represent separate stocks (IWC, 1993b).

The sub-committee noted that efforts were under way to initiate genetic and isotope studies relevant to the question of stock differentiation, including possible biopsy sampling of whales from the eastern and Asian stock this summer.
Migration
There was no new information available to the sub-committee.

7.2 Catch history
Zemsky reported that there had been no Russian catches from this stock in 1992 or 1993.

7.3 Abundance and trend estimates from shore-based censuses
7.3.1 Granite Canyon: 1992/93 and 1993/94 counts
SC46/AS7 provided population estimates derived from the shore counts made in 1992/93 and 1993/94, carried out during the whales’ southern migration past Carmel, California. The 1992/93 estimate, of 17,674 animals (95% CI 15,800–19,800), was significantly lower than that from 1993/94, of 23,109 animals (95% CI 20,800–27,500).

Survey methods were the same as in previous seasons and the method of analysis was consistent with that used for the 1987/88 census data (Buckland et al., 1993b).

Possible reasons for the difference between the two estimates, proposed in SC46/AS7, were: changes in the number of animals migrating as far south as the census point; poor sighting conditions in 1992/93, particularly during the peak of the migration and missing sources of variation. The 1993/94 estimate was not significantly different from the 1987/88 estimate of 20,869 (CV 4.37%).

The sub-committee accepted the results of the assessments presented.

SC46/AS1 presented the results of a study of night migration past the census site, using a US military infrared sensor. Previous studies had, variously, assumed that the night migration rate was slower, faster or the same as during the day. No difference was found in surfacing behaviour or pod size between animals observed during the day or night, although the distribution of animals offshore was not examined. Nor was there any reason to reject the null hypothesis that passage rates did not differ during the day or night.

SC46/AS8 described the results of aerial surveys conducted offshore from Granite Canyon in 1993/94 during the southward migration, complementing four earlier surveys since 1979. Although almost all whales were found to be migrating within 3 n.miles of the shore, there were yearly variations between 1 and 5% beyond that distance. There was a suggestion of a trend for fewer whales to use the nearshore zone, within 1 n.mile of the shore and for more to use the zone between 1.5 and 3.0 n.miles, although the median distance was consistently between 1.5 and 3.0 n.miles.

The sub-committee was informed that similar results had been observed off Oregon and Alaska. The reasons for the change in distribution were not known, but might be associated with avoidance of rough sea conditions near shore.

7.3.2 Other sites
Between 1981 and 1993, seven annual censuses have been carried out near Diablo Canyon California, 70 miles south of the Granite Canyon site, to document nearshore distribution, patterns of abundance and timing of the migration each year in the neighbourhood of the Diablo Canyon Power Plant (SC46/AS1). In 1992/93, the most recent year of the census, the observation period averaged 2.8 hours per day, three days per week, during the migration. The pattern of migration was remarkably consistent from year to year. The first, southbound, animals were usually seen around 28 December each year and the last, northbound, around 3 May; the northbound and southbound migrations overlapped within a one week period in February, with a mean one day overlap period of 10–11 February for the whole study period. The results indicate that the timing of the north and southbound migration have been relatively constant between 1981–1993.

During the northbound migration, a cyclical pattern in nearshore distribution and a bimodal pattern in abundance were observed. Two phases were observed in the latter, the first comprising mainly adult females without calves, adult males and immatures of both sexes, the second mainly females with calves.

7.3.3 Trends in abundance
SC46/AS18 used the 1992/93 and 1993/94 abundance estimates reported in SC46/AS7 (see Item 7.3.1) together with those obtained between 1967 and 1988, to update the earlier estimate, obtained from the latter, by Buckland and Breiwick (1995).

The same assumptions were made as in the earlier study, i.e. that there was no trend in the proportion of pods missed, that passage rate is not different at night or affected by poor visibility or weather, that adjustments for missed pods and biased estimates of pod size are correct for all years, and that the Hermite polynomial model used is appropriate for fitting migration dates and fits the tails of the distribution adequately.

The revised estimate of annual population increase was 2.65% (SE 0.36%). It is lower than the earlier estimate (Buckland and Breiwick, 1995) largely because of the low 1992/93 population estimate. The analysis indicated that the population is still below carrying capacity.

The sub-committee asked that a simple rate of increase be calculated using a logarithmic regression of the estimated population size against time. Since the CV of the residuals from fitting a trend line to the population estimates is more than twice as large as the average of the estimated CVs of the individual population estimates, much of the year to year variability in the population estimates is due to unexplained 'process error'. Therefore, it was argued that equal weight should be given to each population estimate (i.e. an unweighted regression) rather than using a weighted regression as was done in SC46/AS18. Using the data in table 1 of SC46/AS18, this gave a rate of increase (b) of 2.57% (SE = 0.4%). The model used was: \[ \log(n_t) = a + bt \], where \( n_t \) is the population estimate and \( t \) is time.

In SC46/AS16 a Bayesian method had been used to estimate population parameters for this stock, including a rate of increase. In contrast to the results shown in SC46/AS18, it indicated a high probability that the rate of increase had dropped substantially in recent years and that the population had passed the inflection point in the growth curve. Concerns were expressed over the uniform input priors used in the analysis and the lack of discussion in the paper of the basis for their use. In some cases at least the priors used were informative. The results may also have been unduly influenced by the low 1992/93 population estimate. The effects of weather and process errors may not have been fully accounted for.

Although SC46/AS16 estimated a high probability that the population was above MSYL, this conclusion was regarded as questionable because it was based on estimates of sampling precision for the survey estimates. The CVs for these survey results appear to indicate an unrealistically
high level of precision, because they are considerably smaller than the CV of the residuals of a population model fit to these data. The analysis of SC/46/AS18, which takes account of this additional variation, was preferred in this respect. This indicates that it is not yet possible to determine with any great certainty whether or not the population is above MSYL.

The sub-committee recognised that the increase rate obtained was very similar to that already obtained in SC/46/AS18. Given that it was not possible to redo the Bayesian analysis at this meeting, the sub-committee agreed that it would accept the results of the logarithmic regression reported above, i.e. an increase rate of 2.57% (SE 0.4%).

7.4 Biological parameters and life history

7.4.1 Pregnancy rates from aboriginal subsistence fishery
The sub-committee was informed that information was available from material collected since 1980, when a large decrease in pregnancy rate had been observed, but no individual data were available prior to that date. In that event no new estimate of pregnancy rate could be provided.

7.4.2 Calf production from north bound shore count
The sub-committee was informed that a count of calves in the northbound migration was being undertaken during the 1993/94 migration. The results would be available at next year’s meeting.

At least one record of annual breeding was available (Jones, 1990).

There was discussion of the merit of obtaining an estimate of calf production from studies of photo-identified calves in the breeding lagoons. While it recognises that the method will only yield results in the long term, the sub-committee recommends that such studies should proceed.

7.5 Indirect effects of human activities

7.5.1 Contaminants and pollution
Information provided at the meeting (O’Shea and Brownell, 1994) indicated that pollution levels in whales examined from this stock were extremely low.

7.5.2 Other habitat related problems (vessel traffic, whale watching, oil spills, etc.)
A review of tourism and other developments in gray whale critical habitats was developed at the meeting. It appears as Appendix 10.

To plan development compatible with the conservation of the animals and their critical habitats, the effects of past and current potential impacts of development require study. For gray whale breeding lagoons in Baja California, the major aim should be to protect and maintain the integrity of the lagoon habitats. That could be achieved by:

(i) evaluating and considering the effects of lost habitats elsewhere;
(ii) careful comprehensive planning of any development to accommodate the needs of developers and wildlife, e.g. gray whales;
(iii) implementing an ongoing research and monitoring programme to allow detection and analysis of any changes in use of the lagoon by gray whales that could be associated with development, including existing levels of tourism.

The sub-committee agreed that in this way the benefits both of economic development and maintenance of a unique wildlife resource could be achieved, and recommended that such action be continued.

7.5.3 Incidental catches and strandings
The sub-committee recalled that some information from strandings is available in publications at present ‘in press’. It recommended that additional information from strandings be obtained and analysed.

7.6 Assessment

7.6.1 Applications of verified ‘bowhead’ Bayesian method
An attempt to apply the Bayesian synthesis methodology used for bowhead whales to the eastern Pacific gray whale stock had been made in SC/46/AS18. The majority of the population trajectories obtained, however, gave a decreasing population during the period 1967–80. Therefore, very little weight was given to those trajectories. It seems that either the population dynamics model used does not adequately capture the population’s recent and past dynamics, or some of the data inputs are incorrectly specified, e.g. the historic catches and the sex ratio.

The sub-committee agreed that this method could not be applied as it depends on the availability of catch information from the onset of exploitation of the stock. There are considerable problems in this regard, as was recognised during the previous assessment of this stock (IWC, 1993b).

7.6.2 Other methods
The sub-committee agreed that for reasons already recognised (see Item 7.3) it was unable to use results of the Bayesian synthesis approach contained in SC/46/AS16. In addition to reservations already discussed, the analysis relied on assumptions for the population age structure in 1966. The sub-committee recommended that sensitivity to this assumption should be explored.

The sub-committee recognised that this decision did not negate the general validity of a Bayesian approach for this stock and that it possesses more power than the methods used in SC/46/AS18.

7.6.3 Effect of aboriginal subsistence hunt
It was agreed that this item would more appropriately be considered under Item 7.6.4.

7.6.4 Management advice
There was no new information available at this meeting to cause the sub-committee to alter the conclusion reached when the stock was last assessed (IWC, 1993b, p.251), i.e. that:

(1) this stock is not a Protection Stock;
(2) given lack of information on MSYL, no conclusion could be reached on whether the stock was a Sustained or Initial Management Stock;
(3) given the recent history of increase under a regime of constant catches, the stock did not fall within the alternative definition of a Sustained Management Stock;
(4) although the sub-committee was unable to determine the minimum level below which catches should not be taken, as required under the Aboriginal Management Scheme (Schedule para 13), it agreed that the stock was well above such a level.
The sub-committee noted that the calculation of RY, provided in Appendix 11, gave an estimate of 611, which is well above the mean catch over the period 1968–1993.

The 95% CI for this estimate is (484.733) or (452.786) depending on the CV assumed for the 1988 abundance estimate.

7.7 Recommendations
In addition to the recommendations already included in the text, the sub-committee recommended that the possible reasons for the discrepancy between the sampling estimates of CV from the surveys and the CV of the survey estimates about the overall population trend should be explored.

8. WEST GREENLAND FIN WHALES
The sub-committee reviewed SC/46/NA7 which reported progress on genetic analyses based on mitochondrial DNA extracted from samples from 97 fin whales in the Gulf of St Lawrence and 25 from West Greenland. The homogeneity tests revealed no significant level of heterogeneity between the Gulf of St Lawrence and West Greenland samples. Although the results lend no support to the current division of eastern Canadian fin whales (the Gulf of St Lawrence) and West Greenland fin whales, this may be caused by lack of resolution in the method applied.

SC/46/AS15 presents the results of an aerial survey for minke and fin whales conducted off West Greenland in 1993. The design of the survey was similar to earlier years with the exception that blocks 2–5 were further divided into an offshore and a coastal block. Data were analysed with the cue-counting procedure as described by Buckland et al. (1993a) using the program DISTANCE (Anon., 1991). The lack of survey coverage in the central offshore blocks, which in previous surveys have shown a considerable number of fin whales, resulted in a total of only six primary cues from fin whales being recorded. This led in turn to an estimate of abundance for blocks 4–5 of 327 (95% CI 167–551) using the half-normal model. Because of an error in the weighting procedure used for the pooled estimate, a revised estimate was calculated as 178 (95% CI 51–626). It was suggested that consideration is required as to the most appropriate mean and variance cue rate values to use when estimating abundance.

The sub-committee agreed that because of the lack of survey coverage in the central offshore blocks, this estimate should not be considered as applying to the whole of West Greenland. These blocks had contained relatively large numbers of fin whales in earlier surveys.

The most recent estimate of the number of fin whales off West Greenland agreed by the Scientific Committee was 1,096 animals (95% CI 520–2,106) (IWC, 1993a, p.75) based on surveys conducted in 1987 and 1988. The Scientific Committee last considered this stock in 1992. At that time, as in previous years, it had been unable to provide management advice, given the lack of information, particularly on stock identity, but it also stated its belief that it was unlikely that West Greenland fin whales constituted a separate stock. However, if it is a separate stock the small estimate of stock size and its approximate lower bound are a cause for concern. The sub-committee agreed that it was unable to provide any new advice at this meeting.

Information on stock identity is crucial to any understanding of the status of fin whales in this region. The sub-committee therefore recommended that existing plans for stock identification studies, especially employing analyses of nuclear markers, should be implemented as a matter of urgency.

The sub-committee noted the high variance associated with the estimates of abundance and recommended that surveys be continued and expanded.

9. WEST GREENLAND MINKE WHALES
SC/46/AS15 (introduced above) presents information on the distribution and abundance of minke whales off West Greenland in 1993. The distribution of the sightings confirmed the results of earlier surveys that minke whales are predominantly found inshore and in the southernmost blocks. Using the half-normal model an abundance estimate of 8,371 (95% CI 2,414–16,929) was obtained. Although this estimate is potentially biased by the low survey coverage in the central offshore blocks, this is not believed to be a major problem. The author suggested that consideration is required as to the most appropriate mean and variance cue rate values to use when estimating abundance.

In discussion, it was suggested that further studies should examine the fit of a variety of models to the radial distance distribution more closely, to attempt to determine whether or not the shape-inflexibility of the half-normal model used at present might be introducing bias into the resultant estimates of abundance.

The sub-committee concurred with the view put forward by the Scientific Committee when this stock was last considered (IWC, 1992a, p.70). that the West Greenland minke whales do not seem to comprise a separate stock, but are part of a larger stock. Given the lack of knowledge, the sub-committee agreed to reiterate the advice given then, i.e. that although there is no information upon which to determine the status of the stock in relation to MSY, it believes such a stock is above the minimum level below which aboriginal subsistence catches should not be taken. It could offer no advice on the size of catches which would allow the stock to move towards MSY.

The sub-committee recommended the continuation of stock identification studies, including analyses of nuclear markers. It further recommended that the aerial surveys be continued and expanded in order to reduce the large variance associated with the present estimates of abundance.

10. EAST GREENLAND MINKE WHALES
The most recent estimate of stock size is 28,000 (approximate 95% CI 21,600–31,400), obtained in 1990 (IWC, 1993a, p.74). The Committee has not previously given specific advice on this stock in relation to this aboriginal hunt conducted off Greenland.

The sub-committee had no new information to alter the views expressed in 1992 (IWC, 1993a, p.74).

11. HUMPBACK WHALES OFF ST VINCENT AND THE GRENADINES
The sub-committee was informed that in the 1994 season, which ended in March, the whalers had operated but had not struck any whales.

The two whales reported caught in 1993 (IWC, 1994, p.60) were reported to this meeting as a cow and calf, the latter of unknown sex.
As in previous years the sub-committee agreed that a catch of three whales would be unlikely to harm this stock. It again recommended that if whales are taken every effort should be made to collect as much information as possible, in particular photographs of the ventral surface of the flukes and tissue samples for genetic studies. It noted that such information had again not been received from the catch. It further recommended that cows with calves not be taken.

COMMENTS ON THE DISTRIBUTION OF THE BERING-CHUKCHI-BEAUFORT SEAS STOCK OF BOWHEAD WHALES IN THE BEAUFORT SEA DURING SUMMER

J.C. George and J.E. Zeh

The issue of possible stock segregation during the summer in the Beaufort Sea, even if it did in fact occur, is probably not a serious management consideration for the following reasons: (1) all whales that are taken in the subsistence hunt are censused at Barrow, Alaska, and (2) there is no hunting on the summering grounds so there is no possibility that a local aggregation would be depleted. Hunting takes place along the migration route and is therefore restricted to the whales that migrate past Barrow and are counted there.

The whales that migrate past Point Barrow in the spring go on to the eastern Beaufort Sea for the summer. Whales in Alaskan waters in June are generally headed northeast. No whales were seen in the Alaskan Beaufort in July during 21 aerial surveys between 1980 and 1985 (Moore and Reeves, 1993). Moore and Reeves summarise information on intraseasonal movements that indicates that in summer and early fall, bowheads feed in local areas for several days to weeks, then cover relatively long distances (>100km) in a few days. There is much evidence for sex and age segregation, with adults perhaps ranging over larger areas than subadults with great inter-year variability in areas occupied, no doubt in response to food availability and extent of sea-ice cover.

Appendix 3

THE FALL MOVEMENTS OF SATELLITE-MONITORED BOWHEAD WHALES IN THE BEAUFORT AND CHUKCHI SEAS

B. Mate and G. Krutzikowsky

Twelve juvenile bowhead whales were tagged with Argos (satellite-monitored) radio tags off the MacKenzie River in the Canadian Beaufort Sea during a single week in the fall of 1992. Varying amounts of data were obtained from all of the tags, which supplied specifics on dive durations, depths and locations. The tags transmitted upon surfacing 24hrs/day. The longest duration of tag performance was 50 days and at least six tags stopped transmitting due to battery exhaustion.

Three findings from the location data were relevant to the fall distribution of bowheads.

1. Although all whales were tagged in the same area and at roughly the same time, the whales did not all move in unison. Rather, all individuals tracked for more than a few days moved either west, north and/or northeast, suggesting there is not a universally recognised migratory cue which initiates the westward migration.

2. Several individuals spent considerable time in the area of Herschel Island and Demarcation Bay before proceeding west on a very linear route (migration). This supports the contention of local people that these areas may be a staging area where feeding or milling occurs prior to migration.

3. Only one animal provided data west of Point Barrow. It travelled west across the Chukchi Sea to Wrangel Island and then south toward the Siberian coast before the battery was exhausted (34 days after tagging). The route of travel across the Chukchi followed the edge of the heavy ice. This is the first evidence of migration and a specific route from the Beaufort to the Siberian coast in a single season.
Appendix 4

REPORT OF THE WORKING GROUP ON BAYESIAN SYNTHESIS METHODOLOGY

Members: Allison, Butterworth, de la Mare, DeMaster, Givens, Raftery, Stokes (Convenor), Zeh.

1. INTRODUCTION

Last year, the Scientific Committee recommended that the Bayesian synthesis method be used for the current 1994 assessment of bowhead whales. This method will be presented with discussion as the 1994 Applications and Case Studies Invited Paper for the Journal of the American Statistical Association. An assessment of the bowhead whales using the method is presented in SC/46/AS14. However, several criticisms have been presented in SC/46/AS2 and SC/46/AS2(adv), with a partial response made in SC/46/AS5.

The Working Group's remit was to set out the differences between the authors of these papers, to consider what resolution might be possible, to consider what work might be useful inter-sectionally and at this meeting, and to consider how the 1993 recommendation could be implemented at this meeting.

2. METHODOLOGY

The Working Group agreed that the Bayesian synthesis methodology was generally acceptable but three issues were discussed which related either to principle or to the particular implementation. These are discussed below.

2.1 The parameter space explored

SC/46/AS2 and SC/46/AS2(adv) pointed out that the range of biological parameters which may be plausible for many whale populations may include a region where the behaviour of the BALEEN II model depends markedly on assumptions made concerning the population component upon which density dependence acts and to which MSYR refers, and for which oscillatory behaviour may exist.

The Working Group agreed that there are regions of parameter space for which the delay-difference model (BALEEN II) might exhibit oscillatory behaviour but it was noted that the region of the parameter space explored in SC/46/AS14 for bowheads did not exhibit such behaviour. If, therefore, pre-model input and output distributions equal to or similar to those used in SC/46/AS14 are accepted, or their ranges contracted, this should not pose problems at this meeting. If the ranges of any of the prior distributions are increased, then care must be taken to explore fully the behaviour of BALEEN II in the new parameter space.

2.2 Percent calves, percent immature and percent mature

The current implementation (SC/46/AS14) utilises a single step functional form for the age-dependent natural mortality. SC/46/AS2(adv) pointed out that the age-structure information from a population may be incapable of sufficiently unambiguous interpretation to be of value in a management context. Butterworth suggested that the sensitivity of the results (RY in particular), to variations in this assumption, be investigated. Three different mortality scenarios were given in SC/46/AS2(adv) in which the dynamics of the population are the same but the age-distributions are different.

Givens et al. calculated the implications of the three scenarios put forward in SC/46/AS2(adv) as follows: If \( s_0 \) (i.e. \( s_0 = 0.96, s = 0.98 and a = 5, the percentage of the population aged 1 through a in the three scenarios are (a) 9.3%, (b) 10.0% and (c) 10.8%). Raftery et al. (1994) considered a model with a 'typical mammalian' mortality schedule (i.e. with high mortality on the youngest and oldest ages); the results were comparable with those presented in SC/46/AS14. Results from a trial in which the age data were excluded was presented to the Working Group by Givens: the results were very like those in SC/46/AS14.

Butterworth considered that the choice of mortality schedule could be important in estimating certain quantities. Nevertheless, the group considered it unlikely to affect management advice.

2.3 Initial stock size

The current implementation requires an input prior for \( K_{1+} \). \( K \) was estimated using the DeLury (1947) method, which obtains the estimated value from linear regression of CPUE on cumulative catch. Only the early years of commercial exploitation (1848-1870) were used. A probability distribution for the value was obtained by using the approach of Fieller (1954). The details are given in SC/46/AS14.

Butterworth questioned the reliability of the CPUE data upon which the prior for \( K \) is estimated. Only those data from the initial years of the fishery have been utilised, but it is customary in fisheries assessments to omit, or downweight, such data which are likely to be biased as indices of relative abundance because, for example, of the effects of learning and the depletion of those concentrations which are easiest to find. He further questioned the DeLury estimation method on the grounds that it must either produce a result related to a population component other than the 1+, or make an assumption about the value of MSYR, thus implicitly altering the prior for that parameter. (Attempts to estimate both \( K \) and MSYR in such an approach would fail because of the well known property of the 'one-way-trip' in production model analyses for data of the nature considered here – see Hilborn and Walters (1992)). He suggested that the method be modified to use a recent estimate of abundance (e.g. 1988) as an input prior and hence avoid the need to input a prior on \( K \). He noted that the impact of the CPUE data on the results could be investigated as a sensitivity test.

De la Mare suggested that the use of a prior on \( K \) could be avoided if the relative abundance data were used directly in calculating the likelihood. This would probably produce similar results to those obtained using the existing prior but would overcome the assumption of a zero MSYR, implicit in calculating the existing prior. The method used for calculating the relative abundance likelihood should be in accordance with those used currently in the Hitter/Fitter program (Cook and de la Mare, 1994). The Working Group agreed that this could be tried before the next meeting.

Givens, Zeh and Raftery noted that there is some evidence from oil yields that in the earliest years of the fishery, the harvest took more older (larger) animals. By the end of the period of years considered in SC/46/AS14,
all age classes were apparently being taken. Because the period of years considered is a short period during which commercial kills were high, it is reasonable to assume that the effects of recruitment are negligible. Restriction of the take in the early years to mature animals would mean that K estimated from those years was negatively biased. Use of more years, so that recruitment was not entirely negligible, would lead to positive bias in the estimate of K. It is important to note that distributions were averaged over a number of ending years in SC/46/AS14 to ensure that the distribution covered all plausible values instead of being restricted to ones that were biased by either of these effects. Since the resulting pre-model distribution gives relatively low probability to extremely high values of K, it does not give extra weight to extremely low values of MSYR as would, say, a uniform distribution on K.

The CPUE data are data which Givens, Zeh and Raftery believe should not be ignored. Because these are historical data, collected from logbooks of whalers who had no idea they would be used in a CPUE analysis, reporting biases are unlikely. There were no major changes in the nature of the whaling ships and operations during the period considered that would effect the CPUE; the ships were all sailing vessels.

The CPUE analysis was carried out in such a way as to provide a pre-model distribution that included all plausible values of K. It is not crucial that the centre and shape of the distribution be exactly right. As shown in fig. 11 of SC/46/AS14, the model and other data ‘correct’ the pre-model distribution if it is not quite ‘right’, as long as it has some probability in the correct range. Finally, the sensitivity runs in table 2 of SC/46/AS14 indicate that the resulting value of RY is not highly sensitive to the pre-model distribution assumed for K.

Butterworth considered that these responses did not fully address the concerns that he had raised.

3. CONCLUSIONS

Although there are some outstanding issues to be explored inter-sessionally, the Working Group considered that if the sub-committee agrees on input and output priors which are similar to those used in SC/46/AS14 (or which at least do not ‘stretch’ any of the distributions), the assessment presented in SC/46/AS14 should be sufficient to provide a basis for management advice at this meeting. However, if any of the input and output priors are widened, care should be taken to ensure that no untoward population dynamics model behaviour occurs.

REFERENCES

Appendix 5

SENSITIVITY RESULT

G. Givens

The sub-committee requested a Bayesian synthesis trial identical to the one in Annex F, Appendix 7 except replacing the uniform (1% to 7%) pre-model distribution on \( MSYR_{\text{mat}} \) with the original gamma distribution used in SC/46/AS14 which allows values of this parameter down to zero and which gives values in the range of 1% to 4% more weight. The results of this sensitivity trial are shown below: post-model medians and 95% probability intervals are reported.

- Initial stock size: 14,084 (10,945; 18,368)
- \( MSYR_{\text{mat}} \): 3.37% (1.71%, 6.65%)
- Rate of increase: 1.85% (0.77%, 3.44%)
- Replacement yield: 166 (81, 300) with 5th percentile 98.
Appendix 6

REVISED ESTIMATE OF BOWHEAD RATE OF INCREASE

A. Raftery, J. Zeh and G. Givens

Here we present a way of estimating the 1978–1993 rate of increase (ROI) for bowhead whales using both the visual and the acoustic census data. The method is an extension of the method used by Zeh et al. (1991) and AS12. AS12 presented two separate estimates of 1978–1993 ROI, one based on the visual data only for 1978–1993 and the other based on visual and acoustic data from only those four years for which both are available, namely 1985, 1986, 1988 and 1993. Our contribution here is to combine all this information to obtain a single estimate.

We use a subscript \( t \) to refer to (year-1977) and we first consider the four years for which acoustic data are available. Let \( N_4 \) be the estimate of the number of whales passing within visual range (i.e. within 4km), and let \( P_4 \) be the estimate of the proportion of the population passing within 4km of the perch, both as defined in AS12. Let \( n_t \) be the true population, \( m_t \) be the true number of whales passing within visual range, \( \pi_t \) be the true proportion passing within visual range, and \( r \) be the 1978–1993 rate of increase. Then

\[
\begin{align*}
n_t &= n_0(1+r)^t, \\
\pi_t &= P_4 \delta_t^N, \\
m_t &= n_t \pi_t, \\
N_4 &= m_t \delta_t^N,
\end{align*}
\]

where \( \delta_t^N \) and \( \delta_t^P \) are (multiplicative) error terms, the expectation of whose logarithms are equal to zero.

Substituting (1) and (2) into (3), and (3) into (4), yields

\[
N_4 = n_0(1+r)P_4 \delta_t^P \delta_t^N.
\]

Taking logarithms yields

\[
y_t = \beta_0 + \beta_1 t + \lambda_t + \varepsilon_t^N + \varepsilon_t^P,
\]

where \( y_t = \log N_4, \beta_0 = \log n_0, \beta_1 = \log (1+r), \lambda_t = \log P_4, \varepsilon_t^N \) and \( \varepsilon_t^P = \log \delta_t^P \). The change of notation in equation (6) is made so as to recast the model in a more familiar regression notation.

In equation (6) we have \( E[\varepsilon_t^N] = E[\varepsilon_t^P] = 0, \ Var(\varepsilon_t^N) = \text{SE}(\log N_4)^2 \approx \text{CV}(N_4)^2 = (\lambda_t)^2, \) and \( Var(\varepsilon_t^P) = \text{SE}(\log P_4)^2 \approx \text{CV}(P_4)^2 = (\beta_1)^2 \). The values of \( N_4, P_4 \), and their standard errors are shown in Table 1.

For years in which there was no acoustic census, so that \( P_4 \) is not available, we assume that \( \lambda_t \) varies between years in such a way that \( E[\lambda_t] = \lambda \), and the between-year variance is \( \text{Var}(\lambda_t) = \sigma_{\lambda}^2 \). These quantities are estimated from the four years for which we do have acoustic data and hence estimates of \( P_4 \), as \( \lambda = -0.428 \) and \( \sigma_{\lambda}^2 = 0.0573 \). For these years, equation (6) remains valid with \( \lambda_t = \lambda \) and \( \sigma_{\lambda_t}^2 = \sigma_{\lambda}^2 \).

Thus the coefficients \( \beta_0 \) and \( \beta_1 \) in equation (6) can be estimated using weighted least squares regression with dependent variable

\[
y_t^* = y_t - \lambda_t,
\]

independent variable \( t \), and weights \( w_t = [(\varepsilon_t^N)^2 + (\varepsilon_t^P)^2]^{-1} \). Note that \( \exp(y_t^*) \) is our estimate of \( N_4/P_4 \), and the values of this, our effective population index, are shown in Table 1. These values are plotted in Fig. 1, with the fitted curve shown as a solid line.

The resulting weighted regression yields \( \hat{\beta}_1 = 0.0302 \) (SE = 0.0069). We have \( \hat{\beta}_1 = \log(1+r) \) and so confidence intervals for \( r \), the ROI, should be based on the distribution of \( \exp(0.0302+.0069) \), where \( t_0 \) is a random variable that has a \( t \)-distribution with 9 degrees of freedom. This is used as the pre-model distribution of ROI and is shown in Fig. 2. The pre-model point estimate is 3.1%, with a 95% confidence interval of [1.4%, 4.7%].

Appendix 7

REVISED BAYESIAN SYNTHESIS ASSESSMENT

A. Raftery, J. Zeh and G. Givens

A summary of pre-model distributions is shown in Table 1 and changes since the last assessment at the Bowhead Assessment Meeting (BAM) in 1991 (Rep. int. Whal. Commn 42, pp.137-52) are noted. The table shows both the choices made in SC/46/AS14 and those agreed upon by the sub-committee. Graphs of the SC/46/AS14 pre-model distributions can be found in SC/46/AS14, figs 3 and 7. Unless otherwise noted, the sub-committee choices use the same parametric families as in SC/46/AS14.

The medians and 95% post-model probability intervals of key quantities for the assessment using the sub-committee consensus pre-model distributions are:

<table>
<thead>
<tr>
<th>Initial Stock Size:</th>
<th>12,599 (10,945; 17,431)</th>
</tr>
</thead>
<tbody>
<tr>
<td>$MSY_{mat}$:</td>
<td>4.44% (1.93%, 6.65%)</td>
</tr>
<tr>
<td>Rate of Increase:</td>
<td>2.31% (0.92%, 3.44%)</td>
</tr>
<tr>
<td>RY:</td>
<td>199 (97,300) with 5th percentile 104.</td>
</tr>
</tbody>
</table>

These results differ from those in SC/46/AS14 because considerable new evidence was identified by the sub-committee about $s$, $s_0$, $m$, $MSY_{mat}$ and MCM (maximum historic ratio of calves to mature females). In each case, the modifications to the pre-model distributions suggested by the sub-committee for these quantities are less conservative than the choices in SC/46/AS14. The most substantial new evidence identified by the sub-committee is the lower bound of 0.25 for MCM. The change alone rules out about half of the region (and half the sample) identified as plausible by the SC/46/AS14 analysis. The lower bound of 1% for $MSY_{mat}$ is also considerably less conservative than the previous pre-model distribution which permitted values of $MSY_{mat}$ down to zero.

Appendix 8

CENSUS BASED RY ESTIMATE

G. Givens, A. Raftery and J. Zeh

A simple, approximate estimate of 1993 RY is 297, with 95% confidence interval (143, 494) and lower 5th percentile 171. The basic idea is to use the approximate relationship $RY = \text{population size} \times \text{rate of increase}$ and to find the post-model distribution of this quantity. This estimate was obtained using the following Monte Carlo method:

1. Sample an annual rate of increase and a 1988 population size from the sub-committee consensus distributions for these variables (Table 4, this Annex).
2. Starting with the chosen 1988 population size, project the population forward through 1994 by repeatedly applying the chosen annual rate of increase. Estimate RY as the difference between the 1994 and 1993 projections, adjusted for average kill, i.e. $RY = P_{1988} (1 + ROI)^2 - P_{1988} (1 + ROI)^2 + 28$, where 28 is the 1978-93 average annual aboriginal kill.
3. Repeat 1 and 2 50,000 times.

This results in the probability distribution for RY summarised above.

Appendix 9

CALCULATIONS FOR BOWHEAD BCB STOCK MANAGEMENT ADVICE

A. Raftery, J. Zeh and G. Givens

The agreed Bayesian synthesis assessment shows that the stock is almost certainly below MSY level; the estimated depletion level is 0.36 with 95% confidence level (0.27, 0.44), and the probability that the stock is above MSY level is estimated to be 0.002. These estimates are calculated relative to the mature part of the stock. The Aboriginal Whaling Scheme states:

*For stocks below the MSY level but above a certain minimum level, aboriginal subsistence catches shall be permitted so long as they are set at levels which will allow the whole stocks to move to MSY level.* (Schedule, Paragraph 13(a)(2)).

In 1991, the Scientific Committee noted that the stock was clearly well above the minimum level (Rep. int. Whal. Commn 42, p.63) and the agreed 1994 assessment confirms this.

It follows that, as long as subsistence catches are below RY, the stock will continue to move towards MSY, given the assumptions underlying the assessment. The lower the catches, the higher the rate of increase. The 5th percentile of RY from the assessment is 104 and so if hunting mortality is less than 104, the stock will, with 95% probability, continue to move towards MSY.
We now address the question of how fast the stock will increase given specific catch levels. The results of the assessment can be used to calculate an approximate point estimate and approximate confidence intervals for the population in each future year under any schedule of catches. As instructed by the sub-committee, we have done this for the period 1994–1998 assuming annual hunting mortality of 0, 47 and 75 respectively for each of the years 1995–1998. We have assumed hunting mortality of 52 in 1994 as this is greatest number of strikes allowed under the present quota. The results are shown in Table 1.

This is done by a Monte-Carlo method, as follows.

(1) Sample a value of 1993 population size, \( P_{1993} \), and 1993 RY, from their joint post-model distribution.

(2) Calculate the values of \( P_{1994} \), ..., \( P_{1998} \) corresponding to the values sampled in step 1 and the assumed hunting mortality. For example, if the sampled values from step 1 were \( P_{1993} = 8,000 \) and \( \text{RY} = 104 \), the calculations for a 1995–1998 catch of 75 are as follows:

\[
P_{1994} = P_{1993} + \text{RY} - C_{1994} = 8,000 + 104 - 52 = 8,052,
\]

\[
P_{1995} = P_{1994} + \text{RY} - C_{1995} = 8,052 + 104 - 75 = 8,081,
\]

\[
P_{1996} = P_{1995} + \text{RY} - C_{1996} = 8,081 + 104 - 75 = 8,110,
\]

and so on.

(3) Repeat steps 1 and 2 50,000 times.

(4) For each year and each removal schedule in Table 1, calculate the 5th percentile and the mean of the corresponding set of 50,000 simulated population sizes.

We have assumed here that RY remains constant over the period 1993–1998. This does not hold exactly because of the effects of population growth and density dependence, but taking these into account would not change the results appreciably given the short time horizon over which the projections are being made.

Appendix 10

FURTHER THOUGHTS ON TOURISM AND OTHER DEVELOPMENTS IN GRAY WHALE CRITICAL HABITATS

G. Compean J., B. Mate, H. Perez-Cortez M., S. Swartz, P. Ulloa R.

The main point of this Appendix is to emphasize that there are a range of factors and options to be considered when proposing development in or around critical habitats for wildlife to assure that adverse consequences are avoided. Development certainly can (and in most cases will) occur, but the emphasis should be to assure that it is thoughtfully planned and that development plans incorporate scientific information and advice on the habitat requirements of the wildlife (e.g. gray whales), and build on the lessons that have been learned from places and times where people were less concerned with the effects of development on wildlife (e.g. San Diego Bay).

The eastern Pacific stock of gray whales has lost access to some of its former coastal habitat in historical times, it is important to evaluate the effects of these lost habitats for future gray whale population recovery. The failure of gray whales to recoup San Diego Bay is an example of a former gray whale lagoon habitat that is no longer available to gray whales due to industrial growth. In comparison, the gray whale breeding lagoons along Baja California, Mexico are relatively undeveloped and continue to be utilized extensively by gray whales during the winter months. Mexico recognized the value of conserving the gray whale population and the unique natural resources on which they depend in Baja California – the breeding lagoons. Mexico has put a high priority on these critical gray whale habitats, and has given some gray whale breeding and calving areas 'wildlife refuge' status and included them inside a biosphere reserve.

The largest single gray whale breeding lagoon, Laguna Ojo de Liebre (Scammon’s Lagoon) has been the site of the world’s largest solar salt-production operation for many decades. This industry has successfully co-existed with much of the marine wildlife of the region, including gray whales in the winter, largely because the lagoon’s vast interior provides sufficient space for the salt-shipping operations and the whales. The smaller Laguna San Ignacio to the south of Ojo de Liebre was the location of the beginning of commercial whale-watching since the mid-1970s and, with the exception of local fishing, whale-
watching has been the only commercial activity in this lagoon. Despite its smaller size, whale-watching and local fishing has also co-existed with the gray whales and other marine wildlife.

Two of us (Mate and Swartz) studied gray whales in Laguna San Ignacio between 1977 and 1985 and, based on these experiences, we offer several observations on the balance between whale-watching tourism, local fishing and the lagoon’s wildlife. During this period of time, whale-watching tourism and commercial fishing appeared to co-exist well with the wildlife of Laguna San Ignacio (Jones and Swartz, 1984). This was due largely to the unique characteristics of this lagoon, the nature of the whale-watching activity there, and the regulations put in place by the Mexican government to control human activities that occur within the lagoon during the winter.

There are currently proposals to plan development of a solar salt-production operation near to Laguna San Ignacio. Plans for development in the vicinity of Laguna San Ignacio, or within similar habitats or other protected areas, should consider past experiences and ‘lessons learned’ from other countries and in other areas in order to incorporate the knowledge acquired by these experiences when formulating new regulations or when implementing existing regulations for these habitats. In this regard, monitoring of potential impacts from existing activities, such as whale watching and fishing, should continue to identify and to avoid detrimental consequences.

In order to plan development that will be compatible with the conservation gray whales and their critical habitats, both the effects of past and current potential impacts of development need to be evaluated. In the case of the gray whale breeding lagoons of Baja California, the key goal, as we see it, is to protect and to maintain the integrity of the lagoon habitats by:

1. careful comprehensive planning of any development to accommodate the needs of developers and of the wildlife (e.g. gray whales); and,
2. implementing an ongoing research and monitoring program that will allow detection and analysis of any changes in the use of the lagoon by gray whales that could be associated with development, including existing levels of tourism and fishing.

In this way the benefits of both economic development and the maintenance of a unique wildlife resource could be achieved.

Factors unique to Laguna San Ignacio that have encouraged the maintenance of the marine ecosystem

1. There was not a large human population using the area as tourism developed so there was (and still is) a relatively low effect from direct or indirect activities (e.g. sewage, pollution and in water structures);
2. Because of its remote location and the existence of a permit system to regulate visitation, the numbers of tourists are (and have been) limited (no more than two vessels at a time and presently three licensed land operators);
3. Because of its relatively small size and the importance of the upper lagoon to females with calves (Jones and Swartz, 1984), the upper innermost two-thirds of the lagoon is a closed area during the winter and is off limits to all tourists;
4. The skiff operators bringing tour groups to the area have been reasonably stable, providing for experienced skiff (pongola) drivers;
5. With closure of the lagoon to commercial fisheries during the winter whale season, local fishermen have assumed skiff operation activities for tour operators and there has been a good exchange of information with the previously experienced skiff drivers (essentially a guide training program);
6. The local skiff drivers have formed an organization which limits access (prevents too many skiffs), making the available business (no. of customers/boat) economically viable for those drivers (three skiffs/visiting vessel or land operation);
7. This transition has promoted local support for the unique nature of the lagoon ecosystem and for the conservation of the whales now that whale-watching provides a source of income for the lagoon residents.
8. Both land and boat based tour groups are always accompanied by naturalists who explain the natural history of the whales and the lagoon habitat and other natural resources in the area (birds, mangroves, desert ecology, fishing, etc) so there is a broader focus than just whales;
9. The naturalists prepare visitors with expectations that do not overly emphasize the likelihood or importance of a ‘hands on’ experience with ‘friendly’ gray whales, but instead focus on behaviors, their natural history and the importance of the lagoon as a critical habitat for the whales and other wildlife;
10. There is an attempt to have a naturalist aboard each tour vessel or with each land-based excursion group who is bilingual and that can communicate in the appropriate language of the visitors to the lagoon.
11. Laguna San Ignacio is an undeveloped natural area where there have been no permanent physical modifications or developments in the lagoon (marinas, hotels, industry).

REFERENCE

Over the period \( y = y' \) to \( y = y' + n \) assume replacement yield is constant and equal to \( RY \).

The population model is:

\[
P_{y+1} = P_y + RY - C_y \\
P_{y'+n} = P_{y'} + n RY - \sum_{y'}^{y+n-1} C_y
\]

\[
RY = \frac{1}{n} \sum_{y'}^{y+n} C_y + \frac{1}{n} (P_{y'+n} - P_{y'}) = \bar{C} + \frac{1}{n} (P_{y'+n} - P_{y'})
\]

Year \( y' \) is taken to be the first year for which an abundance index is available (i.e. 1968) and \( y'+n \) is taken to be 1994, the year of the most recent census.

The value of \( (P_{y'+n} - P_{y'}) \) is calculated using the ROI and \( P_{98} \). \( P_{98} \) is used as the population series for early years is based on that value to scale values from an abundance index for the preceding years. Estimates of absolute abundance for years subsequent to 1988 are based on the same methodology as used for 1988. The value of \( P_{98} \) used (20,869; SE 913) was taken from Buckland et al. (1993). The mean catch over the period 1968 – 1993, \( \bar{C} \), equals 159.3. The rate of increase used was that obtained from the unweighted regression performed by Breiwick (Appendix 7).

* The convention for denoting the survey year is such that a survey in the 67/68 season is denoted as \( P_{98} \). The catch (and year) convention is straightforward.

\[\text{MINORITY STATEMENTS}\]

(a) Estimation of Rates of Annual Increase (ROI) of the Bering-Chukchi-Beaufort Sea Stock of Bowhead Whales for the Years 1985–93. C.S. Baker

I have reservations about the estimated annual rates of increase (ROI) for Bering-Chukchi-Beaufort Sea stock of bowhead whales used in the BALEEN II, Bayesian synthesis model and in the census based yield rate described in Appendix 8. Zeh et al. (SC/46/AS12) and Raftery (Annex G, Appendix 6) have now provided the sub-committee with five estimates and attached confidence limits (CL) or standard errors (SE) of ROI for bowhead whales:

1. 5.2% (95% CL, 2.5–8%) based on a weighted regression of increase using visual surveys from 1978–93 (derived in SC/46/AS12); (2) 4.9% (95% CL, 1.4–8.5%) based on an unweighted regression of increase using visual surveys from 1978–93 (derived in SC/46/AS12 and used in SC/46/AS14); (3) 3.1% (95% CL, 0.1–6.2%) based on a weighted regression of increase using the visual surveys from 1978–88 (Zeh et al., 1991); (4) 2.5% (approximate SE 1.5%) for the combined visual and acoustic surveys from 1985–93 (derived in SC/46/AS12); (5) 3.1% (95% CL, 1.4–4.7%) for the 1977-93 visual and combined visual/acoustic surveys with an a correction derived from the combined acoustic/visual surveys applied to the visual only surveys (derived in Annex F, Appendix 6).

I conclude that the estimate of 2.5% (approximate SE 1.5%) as calculated in SC/46/AS12 is likely to be the least unbiased estimator of the current ROI for the bowhead whale for the reasons given below.

1. The 2.5% estimate is based on years in which the visual estimates have been corrected by acoustic localization of the number of animals migrating too far offshore to be counted by the visual observers (SC/46/AS19). These estimates are thus unbiased by local environmental conditions which affect the accuracy of the visual counts. The \( P_4 \) correction has ranged from 0.518 to 0.907 across the years 1985–93 resulting in a correction factor ranging from 110% to 190% above the visual (N4) counts.

2. The estimate of 3.1% (95% CL, 1.4–4.7%) accepted by the sub-committee attempts to correct statistically for years without acoustic surveys (1978–83) based on the observed variability in the years for which these data were available (1985–93). This assumes that the variability of the environmental conditions known to influence the visual counts can be modeled based only on the variability of the acoustic correction factor in later years. I believe that this assumption requires further attention and note that in later discussions by the sub-committee reference was made to information on environmental conditions that could be used to
examine further the validity of the model accepted by the sub-committee. These data have not been included in the Bayesian synthesis model.

(3) The 2.5% estimate is based on the last eight years when subsistence kills have been substantially higher than the previous eight years. Total kills averaged 19 animals for the years 1978–85 and 36 animals for the years 1986–93 (AS10). Thus, the alternate estimates of ROI derived from the entire 16 year period do not accurately reflect current population trends under higher rates of subsistence kills.

(4) The empirically derived 2.5% estimate of ROI is most consistent with the ‘post-model distributions’ of 1.48% (95% CI, 0.3–2.8%) provided by the BALEEN II. Bayesian synthesis model recommended by the Scientific Committee for use with bowhead whale assessment. Regarding the results of their own analysis of bowhead whale population parameters, the authors of this model conclude that ‘The pre-weighted distribution shows that it is virtually impossible to find any plausible combinations of input parameters which produce ROI greater than about 3%’ (SC/46/AS14). I interpret this to mean that the Bayesian synthesis model, which includes biological information and uncertainty on a number of life history and population parameters, estimates ROI to be 1.48% despite the ‘pre-model’ distribution of 4.9% (95% CI, 1.4–8.5%) used in the synthesis.

I conclude that caution should be used in considering increases in catch limits for subsistence hunts of bowhead whales. The 95% CI for the unbiased estimate of 2.5% ROI includes negative rates of increase. Thus, one cannot be completely confident that this population is increasing in abundance currently. Although I agree with Zeh et al. (SC/46/AS12), that the power of this trend analysis is low, I believe that this can only be improved by further surveys and increased precision of annual estimates.

REFERENCE

(b) On Reservations Concerning the Results of the Bayesian Synthesis Analysis. Given the Approach Used to Develop Prior Distributions for Natural Mortality Rates. D.S. Butterworth

Without questioning the validity of the Bayesian synthesis approach in principle, it is self-evident that the reliability of the results which it provides depend on the prior distributions required for the input parameters being properly chosen. Even if lack of sensitivity to changes to one or a few of these priors may be demonstrated for certain regions of parameter-prior-space (as in SC/46/AS14), it does not follow that this behaviour will necessarily hold in other regions. Indeed, the differences in the results obtained from the priors agreed by the sub-committee, in comparison to those for the priors assumed in SC/46/AS14, bear testimony to this.

The key constraint imposed by the approach

For a proper understanding of the reasons why the approach adopted by the sub-committee to specify priors on natural mortality rates is not defensible, it is necessary to first appreciate the main difference imposed by the Bayesian synthesis approach, when this is compared to the maximum likelihood procedure customarily used to fit the BALEEN II population model (i.e. the ‘HITTER–FITTER’ procedure).

The key constraint (or ‘check/balance’) provided by the approach is to insist that a bound on the maximum growth rate of the population implied by the values of its demographic parameters is respected. This is illustrated (for the case of stable age-structure and a calving interval of three years) in Fig. 1, which shows the maximum growth rate attainable as a function of the age at first parturition (t_0) and natural mortality rate (M), which is assumed here for simplicity of presentation to be invariant with age. Essentially the Bayesian synthesis approach will reject any population trajectory with parameters inconsistent with the limits shown by such a diagram.

The situation pertaining to B-C-B bowheads is that data-based priors for the stock are available for the (minimum) calving interval and the age at first parturition, but not for ‘juvenile’ or ‘adult’ natural mortality. The primary problems that result arise from this fact. These problems are addressed in turn below. For convenience, no distinction is made between ‘adult’ and ‘juvenile’ natural mortality for the time being, as the same reservations apply to both.

Greater uncertainty implies a wider prior for M?

Consider a thought experiment in which one happens to know exactly the values of pregnancy rate p = 1/3, annual growth rate G = 6%, t_m = 10 yrs and M = 0.02 yr⁻¹ for a population. Note from Fig. 1 that the population concerned is growing at its maximum possible rate.

Now assume that an (idealised) observer is able to measure p = 1/3, G = 6% and t_m = 10 without error, and applies the Bayesian synthesis approach. He does not know the value of M, and happens to use a prior centred on the correct value of M = 0.02. Any value for M > 0.02 within his prior implies a G < 6%, whereas any value for M > 0.02 implies only that G = 6%. The result is that his posterior distribution for G has a central tendency value which drops further below the true value of 6%, the larger the extent of prior uncertainty assumed.

That greater prior variance results in greater posterior variance would be acceptable behaviour for the procedure. However, that the former results in increasing negative bias of the posterior distribution for G seems an undesirable property. This is particularly so in circumstances, as in the sub-committee, when stress is laid on expanding the prior distribution for M to ensure that no conceivably possible value is excluded.

A prior for M independent of other inputs

Given the lack of direct estimates of M for the B-C-B bowhead stock, the basis whereby members of the sub-committee agreed a prior for M was clearly primarily their knowledge of values of this parameter for other baleen whale species.

Now this approach might be defensible if the bowhead was a priori a ‘typical’ baleen whale species. But, as was stressed repeatedly in the sub-committee, bowheads are atypical. Their age at first parturition (t_m) is substantially larger than for other baleen whales and their calving interval appears to be amongst the highest observed. If exact values of t_m, p and M were known for all species and plotted in histogram form, the bowhead values would be in the tails of the t_m, p and M distributions, not near their centres. A priori therefore, one would expect the value for M to be
much more likely to be found in the lower tail of this $M$ distribution, so that this distribution would NOT constitute a defensible prior for a Bayesian synthesis analysis. Thus a prior based on values for other species is inappropriate, and will lead to negative bias in posterior distributions for $G$ and related parameters (such as RY), for essentially the same reasons as explained above (i.e. inappropriate weight given to the upper right region of parameter space in Fig.1, which discriminates against the higher values possible given the prior for $G$).

Inspection of Fig. 1 readily makes apparent that taking this effect into account downweights points towards the upper right of the plot, and hence will result in a lesser (if any) reduction in the posterior mean for $G$ compared to the estimate of $G$ provided by direct observations.

What if a direct estimate of $M$ for bowheads was available? Clearly this would reduce the difficulties alluded to above. But the problem of prior covariance still remains (though to a lesser extent) and it is not at all clear how it should be handled in practice. (Though formally the values of $t_m$, $p$ and $M$ might have been obtained from independent sets of data, prior knowledge of the correlations described above should still be taken into account in the analyses in some way.)

A more defensible approach
Given these circumstances, and particularly the absence of an estimate of $M$ for bowheads based on data, I believe that the specification of a prior for $M$ in the manner that this was done by the sub-committee is indefensible. The arguments above indicate that the choice made could have a marked impact on results and this must therefore lead to reservations about the posterior distributions obtained from the application of the Bayesian synthesis methodology, which pertain to estimates upon which advice for management was based.

What I consider should rather be done, is to modify the approach to treat $M$ as an unknown and estimate a posterior distribution for it without having to specify any prior. This is NOT equivalent to the maximum likelihood approach of HITTER-FITTER, because it would still allow a bound on $M$ (certainly $M > 0$; possibly, for example, $M > 0.01$) to be respected, i.e. the 'checks/balances' aspects of the Bayesian approach is retained.

However, this approach would need considerable time to develop, as the solutions of coupled equations required would be complex to determine numerically. Further, only one further ‘degree of freedom’ is made available by the demographic upper bound on a rate of increase, so that some specification relating to the difference between ‘juvenile’ and ‘adult’ mortality would be required. A prior could be input for this, though I prefer the approach of a test of sensitivity of results to different choices for this value.

Annex G
Report of the Sub-Committee on Small Cetaceans

1. ELECTION OF THE CHAIRMAN
Bjørge was elected Chairman.

2. ADOPTION OF THE AGENDA
The adopted Agenda is given as Appendix 1.

3. APPOINTMENT OF RAPPORTEURS
Martin, Palka, Pinedo, Read, Van Waerebeek and Vidal assisted the Chairman as rapporteurs. After the meeting, the report was edited for clarity and consistency by Donovan and Bjørge.

4. REVIEW OF AVAILABLE DOCUMENTS
The following documents contain information relevant to the work of the sub-committee: SC/46/SM1. 3, 5, 7, 8, 10–14, 16–19, 22, 23, 25, 26; SC/46/O 5, 6, 11, 19, 21, 24, 30 and the SC/46/ProgRep series.

5. REVIEW OF THE STATUS AND EXPLOITATION OF SMALL CETACEANS IN LATIN AMERICA
Borobia provided the sub-committee with the following information on UNEP’s contribution to the conservation of small cetaceans in the region. Some of the Latin American projects providing information to the sub-committee have been initiated by UNEP, channelled through the Global Plan of Action for Marine Mammals (MMAP) in the implementation of the Action Plan for the Conservation of Marine Mammals for the South-East Pacific adopted by the Governments of Colombia, Chile, Ecuador, Panama and Peru in December 1991 (UNEP, 1992). The Action Plan was developed from national reports on the status of marine mammals in each country (e.g. Reyes, 1990; Florez et al., 1992) and from a regional overview (Vidal, 1992). The main objective of the Action Plan is to facilitate an appropriate framework for activities of a character that require regional or global cooperation. Among the recommended priority issues, the Action Plan identified (i) studies on incidental mortality of whales, dolphins and porpoises in all participating countries, (ii) reduction of the illegal utilisation of small cetaceans as bait in the Chilean crab fisheries and (iii) continuation of studies on the incidental mortality in fisheries and intentional exploitation of marine mammals in Peru. To promote an initial phase of implementation of the Action Plan, a number of projects have been supported by the MMAP in Ecuador, Colombia, Peru and Chile. Some of their findings have been provided in advance of publication to the Scientific Committee as a means to report on the preliminary progress achieved since the adoption of the Action Plan and prior to full consideration by participating governments and UNEP.

A similar initiative for the establishment of a Regional Action Plan for the Conservation of Marine Mammals is being developed for the Pacific coast of Central America under the planned expansion of the Regional Seas South-East Pacific Action Plan. National reports on the status of marine mammals have been commissioned and are in preparation. In addition, a volume was produced on the status of marine mammals in the southwest Atlantic (Capozzo and Junin, 1991).

5.1 Vaquita, Phocoena sinus
The sub-committee reviewed four documents (SC/46/SM7, 8, 19 and 23) on the vaquita.

5.1.1 Distribution
Thirty-five sightings (for a total of 59 individuals) of vaquitas were obtained during six cruises carried out in the Gulf of California, Mexico, between July 1992 and November 1993 (SC/46/SM7). Total trackline searching effort was 10,230 n.miles, of which 2,369 n.miles were on a cruise by the Southwest Fisheries Science Center (SWFCS) of the US National Marine Fisheries Service (August-November 1993) and 7,861 n.miles on five cruises (July 1992-October 1993) by the Programa Nacional de Investigacion de Mamiferos Marinos de Mexico (PNICMM) of the Mexican Secretariat of Fisheries (SEPESCA). Vaquitas were identified from body size, colouration and dorsal fin shape and size (see Brownell et al., 1987). All but one sighting (ca. 50 n.miles to the east) occurred in a small area in the northwestern side of the Gulf of California. All vaquita sightings (26) on the SWFCS cruise were made on 8–11 August, while the remaining nine sightings on the PNICMM cruises were made in March, June, July and October. The data presented, plus previous confirmed sightings, collections of osteological materials on beaches and individuals captured incidentally in fishing activities (Brownell, 1986; Silber, 1990; Vidal. 1995) provide additional evidence to support the conclusion that the vaquita is restricted to the upper Gulf of California (Brownell, 1986; Vidal et al., In press). This is the most limited distribution of any marine cetacean. Gerrodette et al. (1993) reported that about 40% of the sightings made by Silber (1990) and of those
obtained during the SWFCS August 1993 survey were made outside the boundaries of the recently declared Biosphere Reserve of the Upper Gulf of California and the Colorado River Delta. This was also the case for sightings made in the PNICMM surveys.

There have been no recent surveys conducted in the shallow waters (<20m) of the northernmost Gulf of California.

5.1.2 Abundance
Until now, little was known on the abundance of the vaquita, although the population size has been considered to be very low (e.g. Silber, 1990). The few previously reported sightings were opportunistic and could not be used to reliably estimate abundance. In September 1991, Barlow et al. (1993) conducted a line-transect aerial survey for vaquitas and obtained only one sighting; no estimate of abundance was made. A new line-transect survey was carried out in the upper Gulf of California during August 1993 (see Item 5.1.1), and SC/46/SM23 reported the results of the first statistically reliable estimate of the size of the vaquita population. Good sighting conditions prevailed during the survey. A preliminary analysis, based on 22 sightings, gave an estimate of the population within the area surveyed of 316 (95% CI 118; 847); further analysis may improve the estimate. Some potential vaquita habitats lie outside the area surveyed (particularly in shallow water) and the true total population estimate might be higher. Nevertheless, the results confirm previous suggestions that the vaquita is very rare. The PNICMM is planning to continue its survey effort.

5.1.3 Migration
There is no evidence for seasonal migration.

5.1.4 Life history
A sample of 56 vaquitas (30 females, 26 males), most of them killed in fishing nets, provided the first opportunity to evaluate the life history of this species (SC/46/SM19). The age structure in the sample was bimodal, with 62% of the specimens from birth to age 2 and 31% from 11-16 yrs; specimens aged from 3-6 were absent. The oldest individual (a female) was estimated to be 21 yrs. Age at sexual maturation could not be estimated because the sample size was too small. However, all males and females less than 3-years old were sexually immature and all greater than 6-years old were mature. The asymptotic length of females was greater than that of males. Near-term foetuses and young calves were seen only between late February and early April, and maximum testes activity occurred from mid-March until at least mid-April. Counting corpora was difficult because the ovaries contained calcified bodies and other structures uncommon in cetacean ovaries. Preliminary counts of the number of corpora relative to estimated reproductive age suggest that the calving interval may not be annual. Preliminary results from histological examination of the ovaries show that an unusual number of oocytes were degenerating, so that fewer follicles proceed to ovulation and females may be relatively infertile. The life history of the vaquita appears to be similar to that of the harbour porpoise (P. phocoena) in a highly exploited population from the Bay of Fundy, Canada, with the important exception that calving does not appear to be annual and thus that the potential rate of increase may be lower.

5.1.5 Genetics
No new information on genetics was presented to the sub-committee, but a recent analysis found no variability in mtDNA, which may represent the results of a population bottleneck or severe inbreeding (Rosel and Rojas-Bracho, 1993). However, the sub-committee recognised that other studies have also revealed low levels of genetic diversity among small cetacean stocks and sub-populations.

5.1.6 Damage to habitat
Some members of the sub-committee expressed concern on the negative effects that the reduction of the Colorado River flow could have caused on the habitat of the vaquita.

5.1.7 Incidental mortality
Gillnets are the most widely used fishing gear within the habitat range of the vaquita and these nets, particularly of large mesh sizes, have been the most important documented cause of incidental vaquita mortality (Vidal, 1995). A minimum of 35 vaquitas was killed in 1985 and 1990 in these fisheries. Until recently, large mesh nets were mainly used to catch totoaba, Totoaba macdonaldi, an endangered sciaenid fish. Although this fishery was banned in 1975, some fishermen in the upper Gulf continued to fish totoaba at least until February 1992 (Vidal, 1995). In February 1992, the Mexican government banned the use of mesh sizes larger than 25cm and on 10 June 1993 declared the Biosphere Reserve of the Upper Gulf of California, mainly to protect the vaquita, the totoaba and their habitat (Vidal, 1993).

SC/46/SM8 presented a preliminary analysis of the incidental mortality of the vaquita in gillnets with mesh sizes of less than 25cm. Fishing activities were monitored in only one (El Golfo de Santa Clara) of the four fishing ports with activities in the range of the vaquita, between January 1993 and March 1994. A total of 14 deaths were reported in gillnets of mesh sizes between 7 and 15cm; one further vaquita was taken, probably in a commercial shrimp trawl. Vaquitas were caught in bottom set as well as driftnets. It was stressed that the figure of 15 vaquitas caught should be considered a minimum since only one fishing town was monitored. SC/46/SM8 concluded that because mortality of the vaquita occurred in gillnet fisheries previously not monitored, the past total mortality may have been higher than previously believed. Vaquitas are being caught in virtually all gillnet fisheries. Several members of the sub-committee noted that the data presented on incidental mortality are still preliminary and that further analyses are required. It is also important to obtain mortality data for the other ports. Compan noted that SEPESCA has monitored the incidental mortality of vaquitas in gillnets during 1993 in two ports (El Golfo de Santa Clara and San Felipe), and reported that new information will be available from the Mexican shrimp trawl observer programme. He also stated that an analysis of vaquita deaths in totoaba experimental fishing conducted in previous years has been completed (Mexican Committee for Vaquita and Totoaba) but the results of the analysis were not provided to the sub-committee.

Considering: (1) the similarities of population parameters with harbour porpoise in the Gulf of Maine/ Bay of Fundy; (2) the information on calcified bodies in ovaries; (3) the indication of a calving interval of more than one year; and (4) that information of incidental takes was provided for only one of four fishing ports, the sub-committee agreed that the vaquita cannot sustain the present levels of incidental mortality in fishing gear.
5.1.8 Recommendations
The sub-committee recognised the importance of recent efforts by the Mexican government to protect the vaquita and, in particular, commended it for the declaration of the Biosphere Reserve in the upper Gulf of California. This is a very important step in the conservation of the vaquita. The sub-committee invited Mexico to provide information on the implementation and development of the Reserve at the next annual meeting.

The sub-committee noted that data on incidental mortality are available for only one fishing town (El Golfo de Santa Clara, Sonora) and thus recommended that the monitoring of fishing activity and incidental mortality of vaquita be conducted throughout the entire range of the species. This monitoring should be sufficient in scope to provide a reliable estimate of total annual incidental mortality.

The sub-committee recommended that census surveys (including shallow waters of the uppermost Gulf of California) be conducted to refine current estimates of abundance and improve understanding of the spatial and temporal distribution patterns of this species. In this regard, the sub-committee welcomed recent joint efforts by Mexican and US government agencies in the study of the vaquita and encouraged further cooperation.

Considering the low estimate of abundance, the limited distribution of the population, the low potential rate of increase and the continuing incidental catches, the sub-committee expressed extreme concern over the status of this species. Although it recognised the utility of further research, in view of the precarious state of the vaquita it recommended that immediate action be taken to eliminate incidental catches in all fisheries. Current evidence indicates that present levels of incidental catches could cause the extinction of the vaquita.

5.2 Franciscana, Pontoporia blainvillei

5.2.1 Distribution, stock identity, life history and abundance
The distribution of the franciscana is known to extend from Itaúnas in Espírito Santo state (18°25’S), Brazil to Rio Negro Province (41°09’S), Argentina (Moreira and Siciliano, 1991; Crespo and Harris, 1992).

Biological data collected from incidental catches in Rio Grande do Sul revealed that seventeen species of bony fishes were eaten, mostly sciaenids of less than 50cm total length (SC/46/SM12). One squid and three shrimp species also formed part of the diet and half of the bony fish species found were observed in the stomachs of franciscanas from both southern Rio Grande do Sul and Uruguay (Pinedo et al., 1989). According to data from Uruguay, sexual maturity occurs at 2–4 yrs for both sexes and a two year breeding cycle has been reported. In Rio Grande do Sul, calving and the peak of incidental mortality occur in the same season. The oldest specimen was 21 yrs old. The ages of 184 franciscanas collected in Rio Grande do Sul from 1976 to 1986 revealed a high vulnerability of the species to gillnets in the first three years of life: 50% of the dolphins caught were less than 4 yrs old, i.e. before, or at the age of, sexual maturation (SC/46/SM12).

Morphometric data revealed two geographic forms of franciscana: a smaller form found between 22°S–27°S and a larger form found between 32°2’–38°S (SC/46/SM12). These two forms should be considered separately for management and conservation purposes (Pinedo, 1991). An increase in fishing effort has been occurring since 1982 in Rio Grande. However, there is no information about possible shifts in fishing grounds (SC/46/SM12). Between 1982–1986 the relative frequency of dead franciscanas older than 3 yrs increased, compared with the catches between 1976–1980. If it is assumed that fishing grounds have remained the same between 1976–1986, the age composition shift may indicate that the franciscana population structure is being affected by these coastal gillnet fisheries (Pinedo, 1994).

5.2.2 Incidental takes
SC/46/SM12 reported that although over a thousand franciscanas have been caught since 1976 along the three southern Brazilian states, it is not possible to evaluate the impact of these catches on the population since, amongst other factors, abundance is unknown. Incidental catches of the species have been assessed in the southern states of Brazil, starting in 1976, 1985 and 1989 in Rio Grande do Sul, Santa Catarina and Paraná, respectively (SC/46/SM12). From 1976 to 1993 at least 1,245 specimens died, 94% of them along the coast of Rio Grande do Sul during the spring, with a mean annual catch of 84 dolphins. Incidental takes in gillnets are the most important human induced cause of death in the Rio Grande do Sul and Santa Catarina coasts (Pinedo et al., 1989; Bittencourt and Zanelatto, 1992; Ximenez and Canella, 1992; SC/46/SM12).

Interviews and visits took place in several localities along the coast of Brazil. In Espírito Santo, fishermen reported franciscanas as a common species in these waters, mainly in the northern coast of the state (SC/46/SM10). Gillnet fisheries in Espírito Santo are concentrated between 1 and 2 miles from the coast and several mesh sizes are used, depending on the boats; the minimum known number of incidental catches is 11. In Atafona, Rio de Janeiro, at least 88 franciscanas have been incidentally caught in gillnets since 1986. There are at least sixty fishing boats operating in the area, usually in coastal waters. Although longlimes are also used, there is no information on bycatches of franciscanas in longlines in this area. In São Paulo, a minimum of 26 franciscanas are known to have been incidentally caught in drift gillnets set for sharks and in beach seines. In Santa Catarina, seven franciscanas were taken in fisheries and in northern Rio Grande do Sul 77 franciscanas were taken between October 1991 to December 1993, while 20 others were caught in the southern portion of the state during a four month study period (SC/46/SM10).

Since 1988, franciscana mortality in nets has been monitored in two fisheries of the southern coast of Buenos Aires Province, Argentina (SC/46/SM25), whilst a recent short study has covered all the fisheries of the area. Gillnets of different mesh sizes set for sharks are the main cause of franciscana incidental takes. The annual mortality estimated for the area was between 230–250 specimens. There appear to be areas with higher concentrations of franciscanas, often within estuarine-sea borders. Corcuera suggested that franciscanas may use these areas as feeding grounds with less risk of predation. High gillnet mortality, however, is not always associated with these areas. In response to questions on possible links between mortality, mesh sizes and fishing location, Corcuera noted that a wide range of mesh sizes are used and that locations are changed frequently. He suggested that one solution might be to replace gillnets with longlines in this area. However, the sub-committee noted that such a shift may not necessarily
result in an ecological improvement: Hall reported that in some areas turtles have been caught in longlines whilst Pinedo mentioned that franciscana have also been entangled in longlines in some areas (SC/46/SM12). The sub-committee emphasized that the ecological impact of any potential gear change needs to be carefully evaluated before any advice on gear change can be given.

5.2.3 Recommendations
The sub-committee concluded that with no estimate of abundance, incomplete information on stock identity within the range of the species and incomplete information on incidental takes, it was not in a position to assess the exploitation and status of the franciscana. The sub-committee therefore identified the following critical research needs that must be addressed before such an assessment can be conducted.

(1) Research should be undertaken to clarify migration patterns and stock identity throughout its range. Morphometric studies and genetic analyses using molecular techniques (e.g. DNA fingerprinting, protein electrophoresis and microsatellite polymorphisms) should be conducted on data and samples from incidentally caught animals. Telemetry methods should be applied to study migrations of free ranging animals (and to collect data on surfacing intervals and surface times – see (2) below).

(2) Abundance estimates should be obtained, following the Committee’s guidelines (IWC, 1994e), for the total population and for those stocks which should be regarded as separate units for management purposes.

(3) Demographic data such as age at sexual maturity, calving intervals and longevity, should be collected from incidentally caught animals, especially from areas where these data are not yet available.

(4) Abundance, demography and vital rates may also be studied using techniques based on individual recognition for localised groups of franciscana showing site fidelity in shallow inshore waters.

(5) Research as identified under 1–3 should be coordinated in Brazil, Uruguay and Argentina to improve abundance estimation and exchange of samples and information across national borders.

The sub-committee further noted that although some incidental takes were documented for Brazil (SC/46/SM10; SC/46/SM12) and Argentina (SC/46/SM25), these were incomplete. Incomplete information on catches was provided in SC/46/ProgRep Brazil and no progress report was received from Argentina. The sub-committee therefore recommended that Brazil and Argentina be requested to establish procedures for recording incidental and directed takes of small cetaceans and to submit all catch statistics to the Commission. The sub-committee requested that the Secretary of the IWC be asked to inform Uruguay on the findings of the sub-committee and to invite Uruguay to submit data on takes and abundance of small cetaceans in their waters.

5.3 Tucuxí, Sotalia fluviatilis
Borobia summarised available information on the tucuxí, Sotalia fluviatilis.

5.3.1 Stock identity
Borobia (1989) distinguished two forms, a coastal marine form and a smaller freshwater form, on the basis of variation in skull dimensions and body size. Further studies are needed to determine relationships among populations in marine and freshwater environments, particularly through genetic analyses.

5.3.2 Distribution and abundance
The marine form has an extensive and possibly continuous distribution from the Florianópolis region, Brazil (27°35'S, 48°34'W), north to Panama (ca 9°22'N, 79°54'W) (Borobia et al., 1991) and more recently it has been found in waters off Nicaragua (Carr and Bonde, 1993). The freshwater form of this species inhabits the Amazon and Orinoco drainages (Best, 1984). It is commonly seen in the Amazon and has been found as far inland as southern Peru.

There are numerous coastal records between 20° and 25°S but this may only reflect a higher observation effort; the lack of records for intermittent stretches of coast is probably due to an absence of observers in those regions, particularly in northern portions of the South and Central America coasts. Despite low sampling effort in these regions, it appears reasonable to assume that at least in coastal Caribbean areas, established populations exist. Marine tucuxí appear to have a mainly coastal distribution throughout their range, inhabiting inshore waters and bays; they are commonly associated with mangrove swamps and estuaries. The limited amount of feeding data from Brazil also seems to support the notion that they prefer coastal habitats (Borobia and Barros, 1989).

Although mostly coastal, some animals have been found about 70km off the coast of Bahia state in Brazil at about 18°S.

Little information on abundance and movement is available for any freshwater or coastal population, although boat-based visual surveys using modern methods have recently been initiated in Columbia, Peru and Brazil, and a radio telemetry project is underway in Brazil on the freshwater form. Da Silva et al., (1984) estimated an average density of 0.51 individuals per km, along a 1.500km stretch between Manaus and Leticia in the Rio Solimoes.

5.3.3 Incidental catches
The information available to date, which has originated mostly from Brazil, indicates that marine tucuxí are commonly caught in artisanal gillnet fisheries along the Brazilian coast and possibly the remainder of its range. Records of catches resulting from opportunistic observations in 47 sites along the coast reveal that at least 322 specimens were incidentally taken since 1986 (see Table 2, SC/46/SM10). The bycatch of tucuxí appears to be generally higher during the austral spring and summer, probably coinciding with greater fishing effort. Characteristics of the gillnet artisanal fishery in Brazil vary widely from region to region. These are coastal fisheries with several types of boats which may be motor- or sail-powered. Most fisheries target more than one species. There is no observer scheme for reporting bycatches onboard fishing vessels, nor is it mandatory to report bycatches. Further, no systematic monitoring of the characteristics of the fishery takes place. Dolphin blubber is commonly used as bait in shark fisheries and the meat used for occasional local human consumption. Preliminary data suggest that the tucuxí may be one of the most commonly caught small cetacean species along the Caribbean coast (Vidal et al., in press).

Martin and Vidal stated that the level of incidental mortality of the freshwater form of the tucuxí appears to be low in the Amazon basin.
It is clear that much remains to be learned about the stock identity, distribution, movements and abundance of the species in freshwater and marine environments. These data are vital to the assessment of the potential impacts of bycatch mortality.

Recommendations
The sub-committee concluded that with no estimate of abundance, incomplete information on stock identity and incomplete information on incidental and directed takes, it was not in a position to assess the exploitation and status of tucuxi. The sub-committee identified the following critical research needs that must be addressed before such an assessment can be conducted.

(1) Research on distribution, migration and stock identity should be conducted; telemetry techniques should be used to track movements of free ranging animals and morphometric and genetic techniques (see Item 5.2.3) should be applied to study stock identity.

(2) Abundance estimates should be obtained following the guidelines provided by the Scientific Committee (IWC, 1994c) or using modified techniques for inshore and riverine waters.

(3) Demographic data including information on age at sexual maturation, calving intervals and longevity should be collected from incidentally caught animals.

(4) Research among countries within the known and potential range of tucuxi (Brazil, Peru, French Guiana, Surinam, Guyana, Venezuela, Colombia, Panama, Costa Rica and Nicaragua) should be co-ordinated.

The sub-committee expressed concern at the possible levels of incidental takes of the tucuxi and as a precautionary action, urges that range states implement steps to reduce incidental mortality. The sub-committee recommended that member countries of the IWC (Brazil, Costa Rica, Peru and Venezuela) be requested to establish procedures for recording incidental and any directed takes of tucuxi and to submit all catch statistics to the Commission. The sub-committee further requests that the Secretary of the IWC be asked to inform the other range states of its findings and to invite these nations to submit data on takes and abundance of tucuxi in their waters.

5.4 Small cetaceans taken for crab bait in Chile
Small cetaceans have been taken deliberately each year since 1974 in the Magellan region of Chile for use as bait in traps set for southern king crab or centolla (Liodes santolla) and centollon or false king crab (Paralolomis granulosa). SC46/SM11 discussed the socioeconomic background, historical sequence of relevant political and economic events and attempted to estimate the numbers of cetaceans that were used in the crab fisheries in recent years. Despite prohibition on the catch, transportation, commercialisation, possession or processing of small cetaceans since 1977, Peale's dolphins (Lagenorhynchus australis), black dolphins (Cephalorhynchus eutropia) and Commerson's dolphins (C. commersonii) continue to be taken. Six factors contribute to the unmanageability of the Chilean crab fisheries, including free access to fishing grounds, state support through credit incentives, growth in export demand, lack of regulation and geographical and cultural factors. The presence of dusky dolphins (Lagenorhynchus obscurus), southern right whale dolphins (Lissodelphis peronii) and Burmeister's porpoises (Phocoena spinipinnis) in the area suggests that those species may have been occasionally taken as bait as well. Special live-capture permits for scientific or cultural purposes have been issued on four occasions. Results indicate that small cetacean mortality in the artisanal sector has declined substantially since 1990 as a consequence of (i) a decrease in fishing effort which lessened the demand for bait; (ii) the significantly diminished demand for illegal bait in 1992 was taken from slaughter houses and industrial fishery which covered the total estimated amount of bait needed; and (iii) dolphins have apparently become less abundant in fishing areas. The authors assume that in the actual crab bait fishery (1992), the take of small cetaceans did not exceed 10% (45 tonnes) of the total demand for bait, or an equivalent of 600 dolphins per year.

Recommendations
Recalling that past levels of small cetaceans taken for crab bait were believed to be substantial and noting that the recent decline in takes seems to be caused by a relative increase in the present availability of other baits for the crab fishery, the sub-committee expressed concern for the status of the small cetaceans taken in this fishery.

Noting that there is a national ban of directed catches of cetaceans and that this ban probably imposes constraints on the access to information on the continuation of the catches, the sub-committee recommended that the ban on takes of cetaceans be implemented or the continued harvest be managed at sustainable levels.

Further, the sub-committee recommended continuation and augmentation of studies monitoring incidental and directed takes. Noting the absence of a national progress report from Chile, the sub-committee recommended that Chile be requested to establish procedures for recording incidental and directed takes of small cetaceans and to submit all catch statistics to the Commission.

5.5 Small cetaceans taken by artisanal fisheries in Peru
SC46/SM16 principally reviewed information on small cetacean mortality in Peruvian fisheries for 1990-1993, i.e. the period after the introduction of a Peruvian national ban on cetacean exploitation and utilisation (Ministerial resolution No. 569-90-PE of 23 November 1990). Most ports along the Peruvian coast were sampled during short visits while Cerro Azul, Pucusana, Chimbote, Ancón and San Andrés were monitored more intensively. The ban was found not to be enforced or at best only partially so. However, fishermen often avoided landing entire carcasses which impeded quantification of kills. Large numbers of small cetaceans were caught directly and indirectly in drift and set gillnets, or were harpooned or netted in purse seines (and often landed alive) by vessels operated by the fishmeal industry. Principal species affected included dusky dolphins, long-beaked common dolphins (Delphinus capensis), Burmeister's porpoise and bottlenose dolphins (Tursiops truncatus) although occasional takes of at least six other small cetacean species (pygmy beaked whales, Mesoplodon peruvianus; short-finned pilot whales, Globicephala macrorrhynchus; short-beaked common dolphins, Delphinus delphis; Risso's dolphins, Grampus griseus; southern right whale dolphins; Cuvier's beaked whales, Ziphius cavirostris; and southern minke whales, Balaenoptera acutorostrata) occurred as well. Estimated annual kills based on mean daily catch rates (±SE) were: 1,651 ±5,3 (1990) at Pucusana; 2,118 ±389 (1992) and 1,956 ±133 (1993) at Cerro Azul; 2,296 ±329 (1991) and
Ex. M-0521

The sub-committee noted with concern the high levels of incidental and directed takes of small cetaceans in Peru reported in SC/46.SM16 and in particular the catch levels and indications of population decline in the dusky dolphin reported in SC/46.SM26. However, without complete information on stock identity and abundance, and with incomplete data on incidental and directed takes of the small cetacean species involved in fisheries, the sub-committee was not in a position to assess the level of exploitation and status of stocks in Peru. The sub-committee identified the following critical research that needs to be addressed before an assessment can be conducted:

(1) Research on distribution, migration and stock identities of small cetaceans involved in Peruvian fisheries should be continued and extended. Morphometric and genetic techniques (see Item 5.2.3) should be used to study stock identity.

(2) Abundance estimates should be obtained following the guidelines provided by the Scientific Committee (IWC, 1994c).

(3) Demographic information such as age at sexual maturation, calving intervals and longevity should be collected from harvested and incidentally caught animals.

The sub-committee further noted that a national ban of cetacean exploitation may have imposed problems in obtaining precise information on the continued takes in Peru. The sub-committee recommended that the ban on cetacean mortality be implemented or the continued exploitation be managed at sustainable levels. The sub-committee further recommended that as a precautionary action, steps be taken to reduce the present mortality level of the dusky dolphin until sufficient information is available to estimate sustainable catch levels. Finally, the sub-committee noted that Peru did not submit a national progress report and recommended that Peru be requested to establish procedures for recording incidental and directed takes and to report catch statistics on an annual basis to the IWC.

5.6 Small cetaceans taken by artisanal fisheries in Mexico

Most available information on incidental mortality of small cetaceans in Mexico was limited to the upper Gulf of California and, therein, to only one species, the vaquita. However, fresh carcasses of common (Delphinus sp.) and bottlenose dolphins are frequently found on beaches in other parts of the Gulf which showed signs of entrapment in gillnets (Vidal et al., 1994). Between 1982 and 1993, there have been 139 records of small cetaceans killed (both incidentally and intentionally) in artisanal fisheries along the Pacific and Atlantic coasts of Mexico (SC/46.SM24). The species reported included common (Delphinus sp.), bottlenose and pantropical spotted dolphins (Stenella attenuata). The sub-committee noted that data presented are preliminary and that much more monitoring effort is needed to further document and to evaluate these takes.

Recommendations

Although the reports indicated takes at a low level, the sub-committee recommended that efforts be made to monitor and evaluate the incidental mortality of small cetaceans along the Mexican coast, with particular emphasis on areas of high fishing effort.
Further the sub-committee noted that SC/46/ProgRep Mexico did not contain information on takes of small cetaceans. Thus the sub-committee recommended that Mexico be requested to establish procedures for recording incidental and directed takes and to submit all catch statistics to the Commission.

5.7 Takes of small cetaceans in Colombia
SC/46/O/30 reviewed and compiled existing and newly collected information on strandings of marine mammals along the Pacific coast of Colombia. A total of 223 stranded animals were recorded for the period 1930 to 1993, of which 105 are supported by photographic or skeletal material. These include *Balaenoptera sp.*., Bryde’s whale (*Balaenoptera edeni*), humpback whales (*Megaptera novangliae*), sperm whales (*Physeter macrocephalus*), melon-headed whales (*Peponocephala electra*), short-finned pilot whales, rough-toothed dolphins (*Steno bredanensis*), bottlenose dolphins, Risso’s dolphins, pantropical spotted dolphins and striped dolphins (*Stenella coeruleoalba*). Twenty-seven fishing towns were visited to determine interactions with artisanal fisheries. Two communities, Charambira and Concherito, were identified as places where fishermen harpoon dolphins for bait in fisheries for shark, cherna (*Serranidae*) and corvinas (*Ophididae*). Harpooning takes place when other sources of bait are scarce. No actual harpooning was witnessed but according to the description from fishermen it is possible that the species captured is the spotted or bottlenose dolphin. Those dolphin species and other marine mammals also become entangled in monofilament gillnets with mesh size 6–8” in the area between Charambira and La Vigía.

The sub-committee informed that UNEP has established a new project to monitor incidental and deliberate human induced mortality of cetaceans in Colombia.

The sub-committee requested that the Secretary of the IWC be asked to (i) inform Colombia of the findings of the sub-committee, (ii) encourage Colombia to submit statistics on their takes of small cetaceans and (iii) invite Colombia to submit such statistics to the IWC.

5.8 Incidental takes in Brazil
SC/46/SM12 reported that besides the franciscana and the tucuxi, the following species of small cetaceans have been involved in interactions with fisheries (mostly incidental takes in gillnets) along the southern Brazilian coast (23°16’S to 33°45’S): bottlenose dolphins; striped dolphins; false killer whales (*Pseudorca crassidens*); killer whales (*Orcinus orca*); long-finned pilot whales (*Globicephala melas*); Atlantic spotted dolphins (*Stenella frontalis*); short-beaked common dolphins; and rough-toothed dolphins. This information was provided by published and unpublished data, collected systematically since 1986, 1985, 1989 in Rio Grande do Sul, Santa Catarina and Paraná states, respectively. The majority of the 178 strandings (81%) were of two species: bottlenose dolphins mostly in Rio Grande do Sul; and tucuxis in Paraná. It was pointed out that for the bottlenose dolphin, only twenty specimens were found with gillnet marks. This may be a low estimate of individual mortality in nets, since carcasses were usually too decomposed to assess the cause of death. The pilot whale deaths were reported as probably related to the longline fishery for tuna which began in Rio Grande do Sul in 1977 by leased Japanese vessels; Taiwanese tuna vessels have also operated since 1991. Effort increased from three vessels in 1977 to 20 vessels in 1993. Pinned reported accounts of predation by killer whales on swordfish hooked on longlines; up to 50% of the catch has been damaged in some fishing trips (Secchi and Vasque, 1992).

SC/46/SM10 reported that thirteen species of cetaceans are known to be caught in fisheries, mainly gillnets along the Brazilian coast. In addition to the species reported in SC/46/SM12, the species reported to interact with fisheries include: spinner dolphins (*Stenella longirostris*), minke whales and humpback whales. The tucuxi and the franciscana are the species most commonly affected by captures in artisanal fishery operations throughout their occurrence in Brazilian waters. The dolphin bycatch is used as bait in shark fisheries in several areas along the Brazilian coast. Ongoing studies are providing information on interactions between small cetaceans and fishery operations in the northern Rio de Janeiro, Paraná, Rio Grande do Sul and three fishing villages (Vigia, Rapose and Taipe) in the north and northeast Brazil. Longline fisheries may also cause the mortality of small cetaceans. Incidental catches of a long-finned pilot whale and a bottlenose dolphin in longlines off the northeast coast of Brazil have been reported. The direct take of dolphins in the north and northeast regions needs to be evaluated and monitored.

Recommendations
The sub-committee concluded that the available information on species composition of incidental takes and the level of incidental mortality in Brazil was incomplete and the sub-committee therefore was not in a position to assess the status of stocks incidentally taken.

The sub-committee recommended that monitoring of incidental mortality of small cetaceans be continued in southern Brazil and extended to cover the entire Brazilian coast, and the species composition and those species subjected to significant incidental takes be identified. For these species the sub-committee recommended that:

1. abundance estimates be obtained following the guidelines provided by the Scientific Committee (IWC, 1994e);
2. demographic data such as age at sexual maturation, calving intervals and longevity be collected from incidentally caught animals;
3. information on take levels be reported to the Commission on an annual basis (see Recommendation 5.2.3).

5.9 Incidental takes in Ecuador
SC/46/O/6 discussed bycatches of cetaceans in artisanal fisheries in Ecuador. In the last decade the fishing fleet has dramatically increased, being ten times higher than in 1982. At a national level there are about 50,000 artisanal fishermen distributed over 70 fishing communities.

Two ports, Puerto Lopez (Manabi province) and Santa Rosa (Guayas) were selected as study sites and in each port a sample fleet of six boats was followed. From December 1992 until December 1993, the two fleets combined made a total of 2,764 fishing trips and incidentally caught 217 small cetaceans. Average daily capture rate and total estimated yearly take was respectively 0.038 ± 0.014 (SE) dolphins/boat/day and 315 ± 60 dolphins/year at Puerto Lopez and
0.1042 ± 0.025 (SE) and 1.446 ± 182 dolphins/year at Santa Rosa. Both drift and set gillnets and longlines are used. These results were extrapolated to two other ports nearby (Anconete and Manta) for which fishery information was available but no cetacean mortality data was collected; this would result in a total bycatch of 5,277. It is speculated that if the sample capture index was the same for the rest of the year, the total national bycatch would be 2–3 times higher. The results of this study showed that at least four species became entangled in surface gillnets: short-beaked common dolphins 86%; short-finned pilot whales 9%; pantropical spotted dolphins 2%; and dwarf sperm whales (Kogia simus) 1%. Target species are mainly large pelagic fishes, including dolphin fish ( Coryphaena hippurus ) several species of tuna and shark, swordfish, marlin and benthic fishes belonging to the Bothidae, Carangidae, Lutjanidae, Serranidae and Sciaenidae families. The incidental capture showed two peaks: one between March and September and another between December and January; it was suggested that it may be related to peak occurrence of small pelagic fish.

The sub-committee commended the effort made by the authors to obtain the first estimates of incidental take in Ecuador. The fleets were from two fishing ports selected, based on the interviews of fishermen from all the ports in the four coastal provinces of Ecuador, as probably being representative. The reliability of the post fishing trip interviews was checked by direct observation aboard some trips. The observed rates were consistent with the interview based bycatch rates for one port, but 2.7 times higher for the other port. The statistical variability in the bycatch rate in the observed trips might be used to test if the difference is statistically significant. In any event, the implications of this difference for the estimates of the total should be considered.

The rates of bycatch for all cetacean species were extrapolated as bycatch/vessel-trip multiplied by the number of vessel-trips to estimate totals. The number of vessel-trips for each port were estimated based on a more general interview study of fishing fleets, accounting for the number of active vessels likely to be using surface gillnets. This includes several levels of judgement and extrapolation, and the statistical uncertainty in the estimates of the number of trips is not accounted for in the final estimates of bycatch.

The estimates of total bycatch for the two sampled ports reflect differences in bycatch rates and amount of fishing. The differences in bycatch rates by port are statistically significant and may relate to differences in fishing areas and species of cetaceans involved.

The two nearby ports used for the extrapolation are thought to have similar numbers of operative boats using surface gillnets and were assumed to have similar fishing grounds to the respective sampled ports. The reliability of this extrapolated total (actual plus extrapolated) is substantially less than the two estimated levels and the uncertainties in areas fish need to be confirmed.

The difference in the bycatch rates by fishing grounds is large, especially in the observer data and this suggests investigating characteristics of the fishing grounds where surface gillnets are used for a wider range of ports.

Incidental takes of bottlenose dolphins in monofilament gillnets set mainly for penaeid shrimp have been reported from the Gulf of Guayaquil (Van Waerebeek et al., 1990; Félix, In press).

**Recommendations**

The sub-committee noted the high incidental take levels indicated in SC/46/O 6. However, with the information presently available, the sub-committee was not in a position to make firm conclusions on the true extent of the mortality in fisheries interactions or to assess the exploitation and status of the respective stocks. The sub-committee therefore recommended that studies to estimate the level of incidental catch be continued and augmented.

Noting that there was no progress report from Ecuador, the sub-committee recommended that Ecuador be requested to establish procedures to record incidental takes and to submit all catch statistics to the Commission.

5.10 Dolphins taken in the ETP purse seine tuna fishery

This subject was included in discussion under Latin America, nevertheless, the sub-committee noted that several countries from outside this region are active in this fishery (SC/46/SM4).

Hall presented SC/46/SM4 and SC/46/SM21. These papers elaborate on the level of incidental catch of dolphins in the ETP tuna fishery and the dolphin populations impacted by this mortality. SC/46/SM21 presented time series of relative abundance estimates of seven dolphin populations that have been subject to varying levels of mortality in this fishery. Most populations showed a decline in abundance during the late 1970s, with numbers levelling off at, or just after, the end of the decade and remaining fairly constant since then. In contrast, the abundance index of the northern stock of common dolphins showed a strong decline in the study area from 1980 to 1993, even though mortality of this stock due to the tuna fishery has recently been very low. Independent information indicates that animals of this type have simultaneously been seen more commonly off California, perhaps as a result of oceanographic changes. The sub-committee noted that this was an example of how abundance estimates from only part of a population's range can give misleading results if considered in isolation. A further anomaly highlighted by this paper was a series of significant positive correlations between dolphin abundance and both the number and proportion of net sets on dolphins, indicating that the index may be biased. Most likely, operational changes in the fishery itself were responsible for these anomalies. Further work will attempt to correct this situation.

SC/46/SM4 reported that total dolphin mortality in the ETP tuna fishery was 3,605 animals in 1993. This represents a decrease of 97% since 1986 and 77% since 1992. Most of this improvement was due to changes in fishery performance. The observer coverage was 100% in 1993.

The level of relative mortality ( incidental deaths/ estimated population size ) for each of the populations affected by this fishery was also presented in SC/46/SM4. Hall reported that mortality rates for all species were considerably below conservative estimates of sustainable losses for these populations. The highest figure was of 0.16% ( for the northeaster spotted dolphin ).

The sub-committee's attention was drawn to the fact that net sets on free-swimming tuna schools or logs, while reducing dolphin mortality, dramatically increased both
the level of incidental mortality of other organisms (such as turtles and sharks) and the tonnage of discarded tuna.

It was noted that the tuna-dolphin association is still poorly understood. At the present level of dolphin mortality, the involved agencies may wish to give higher priority to ecological studies of the tuna-dolphin association, rather than to further dedicated sighting surveys to assess dolphin abundance. The sub-committee noted, however, that abundance estimates for ETP dolphins were now six years old and there are no plans for further surveys. Hall stated that estimates of relative abundance will be continued based on sightings on tuna vessels.

The sub-committee welcomed the continued rapid decline in the size of dolphin bycatch in the ETP tuna fishery and reiterated its appreciation on the achievements made by the IATTC and collaborating nations, and on the considerable effort of the fishermen conducting the release operation of entrapped dolphins. The sub-committee encouraged the effort to continue to further reduce mortality levels.

5.11 Information on other stocks and areas

A preliminary review of mortality of small cetaceans in gillnets in Central America and the Caribbean was recently conducted (Vidal et al., 1994). The review covers 26 of the 36 nations in the area, but data on incidental mortality were available from only eight nations (Colombia, the Dominican Republic, French Guiana, Honduras, Panama, Surinam, Trinidad Tobago and Venezuela). The lack of mortality records for the other countries reflects poor or non-existent documentation. At least 10 species of small cetaceans were reported caught in fishing nets: short-beaked common dolphins, bottlenose dolphins, tucuxis, Atlantic spotted dolphins, pantropical spotted dolphins, spinner dolphins, striped dolphins, Clymene dolphins (Stenella clymene), Pacific white-sided dolphins (Lagenorhynchus obliquidens), Risso’s dolphins, killer whales, short-finned pilot whales, false killer whales, pygmy sperm whales (Kogia breviceps) and botos (Inia geoffrensis). From the limited information available, it is evident that considerably more data are needed to assess the effects of gillnet fisheries on small cetaceans in this large area.

Vidal reported that a research project on the ecology, abundance and fishery interactions of botos and tucuxis was carried out in the Colombian-Peruvian Amazon between March-December 1993, as part of the Action Plan for the Conservation of Marine Mammals of the Southeast Pacific supported by UNEP. A final report was recently submitted to UNEP.

Recommendations

The sub-committee endorsed previous recommendations (see 1WC, 1994; Vidal et al., 1994) given for this large area: (1) to further document existing gillnet fisheries and those that may develop, by soliciting cooperation from local fishery officers and biologists; (2) to identify and stimulate interested local biologists and organisations to become actively involved in the monitoring of small cetaceans in gillnet fisheries; and (3) to develop studies to assess the abundance of small cetaceans incidentally killed in order to understand the impact of mortality due to fisheries.

Special attention should be given to the coastal populations of the tucuxi. This may be the most commonly killed small cetacean in the Caribbean and along the northeastern coast of South America.

5.12 General recommendations

5.12.1 Telemetry

Little information is available on distribution, migration and stock identity for several of the small cetacean species directly harvested or incidentally caught in Latin America. The sub-committee has made recommendations for the use of telemetry to address these research needs. At present technology is not readily available for satellite-linked radio transmitters suitable for use on the smallest cetacean species. The sub-committee therefore recommended that the potential of the current methodology is explored and studies expanded to include the construction of satellite-linked transmitters suitable for application on species such as the franciscana, porpoises and other small dolphins.

5.12.2 Fishing performance and fishing gear

The present review has identified incidental takes of small cetaceans as a problem for most of Latin America; these incidental catches are a global problem for many net fisheries. The sub-committee recalled that the substantial reduction of dolphin mortality in the ETP purse seine fisheries for tuna was achieved by adjustment of fishery performance and gear modifications. The sub-committee therefore recommended that efforts to minimise incidental mortality of non target species and adverse ecological effects be considered when new types of fishing gear are developed. Present gear types and fishing operations should attempt to increase selectivity for target species.

5.12.3 Implementing routines for recording bycatch data

The sub-committee noted the extensive small cetacean bycatch problems occurring in many countries where different fishery practices and fishery legislation exist. The sub-committee recommended that a comprehensive observer schemes as the most reliable way of obtaining bycatch data. However, in some countries, certain fishing practices are such that observer schemes may not be practicable. In such circumstances, the sub-committee recommended that either a monitoring programme and/or modified observer schemes should be instated: if this is not possible reporting schemes by fishermen should be formalised. However, the sub-committee cautioned that data collected by any means other than full observer schemes, are generally less reliable. All the schemes recommended, where appropriate, should be administered nationally and be adapted to local circumstances.

6. THE HARBOUR PORPOISE IN THE NORTH ATLANTIC AND BALTIC SEA

6.1 Northwest Atlantic

Harbour porpoises (Phocoena phocoena) were discussed in two papers, SC46/SM3 and SC46/SM18. The first paper contained a theoretical discussion about predator-prey factors that could influence the abundance and distribution of harbour porpoises in the Northwestern Atlantic. Those factors are: (1) the population of a prey species, herring (Clupea harengus) that has an expanding distribution, increasing abundance and variable energy content; and (2) the populations of harbour porpoise predators, large sharks are declining. Because little evidence for these ideas
were presented, the sub-committee was unable to evaluate them, except that on a theoretical basis the proposed factors may influence the abundance and distribution of harbour porpoises.

The second paper (SC/46/SM18) summarised the findings of a workshop to assess the status of harbour porpoises in the northwest Atlantic and presented an international collaborative proposal to investigate population structure. During the workshop recent information on population structure, estimates of abundance, bycatch and potential population growth rates were reviewed. The findings of the workshop were described in detail.

The workshop review indicated that there was presently no evidence to accept or reject the hypothesis proposed by Gaskin (1984) that there were three sub-populations in the area—Gulf of Maine/Bay of Fundy, Gulf of St. Lawrence and Newfoundland. However, results from recent genetic studies, two abundance surveys and tagging individuals indicated that the putative sub-populations may not be as discrete as was thought in the past.

During the workshop it was reported that abundance estimates for harbour porpoises in the Gulf of Maine/Bay of Fundy region during 1991 and 1992 were 32,750 (95% CI 26,700 to 41,000) and 67,500 (95% CI 32,900 to 104,600). A weighted average estimate was 47,200 (95% CI 39,500 to 70,600), where each annual estimate was weighted by the inverse of its variance. The reason for the nearly two-fold, but statistically non-significant inter-annual difference was unknown, but may reflect either a real change in abundance due to a distribution change or methodological errors. No abundance estimates for the Gulf of St. Lawrence and Newfoundland were presented.

Bycatch estimates were reported to the workshop for the US Gulf of Maine and Gulf of St. Lawrence gillnet fisheries. In the US Gulf of Maine, bycatch levels were estimated to be 2,400 (95% CI 1,600 to 3,500), 1,700 (95% CI 1,100 to 2,500) and 900 (95% CI 700 to 1,200) for 1990, 1991 and 1992. The 1993 estimate was not complete. During the workshop, various potential biases of the US Gulf of Maine bycatch estimates were explored e.g. due to harbour porpoises falling out of the net before being observed. For the Gulf of St. Lawrence in 1989 and 1990, the results of mail surveys to fishermen suggested that approximately 1,000 harbour porpoises are killed. The reliability of this number was questioned because of the low return rate of the mail survey. No bycatch estimates were presented for the US mid-Atlantic coast, the Bay of Fundy or Newfoundland.

During the workshop, a new method to estimate the potential population growth rate which incorporated uncertainties in age of sexual maturity, age-specific reproduction and other life history parameters was presented. This simulation method led to a distribution of potential population growth rate values which indicated that the annual growth rate was unlikely to be greater than 10%. If the median of the distribution represents the best estimate, then the value is about 4%.

During the workshop it was concluded that because of the uncertainties in population structure, seasonal movements, estimates of abundance, bycatch levels and population growth rate, it was not possible to assess the status of harbour porpoises in the western North Atlantic. To complete an accurate assessment of harbour porpoise status the workshop recommended the following work: (1) determine genetic population structure and seasonal movements, (2) estimate summer abundance in the Gulf of St. Lawrence and around Newfoundland, (3) estimate bycatch in the US mid-Atlantic region, Bay of Fundy and around Newfoundland and (4) update estimates from the Gulf of St. Lawrence and re-calculate Gulf of Maine estimates to incorporate the possible bias of animals falling out of the net.

After the presentation of the paper it was noted that there was a petition to list harbour porpoises in the US as threatened under the Endangered Species Act and there was presently a proposal to reduce bycatch by closing three large areas of the Gulf of Maine for one month in each area. In addition, it was noted that the only reason bycatch estimates for the Gulf of Maine were available was a mandatory observer programme was instigated. A voluntary reporting scheme was inadequate to produce accurate bycatch estimates.

Recommendations
The second half of paper, SC/46/SM18, described a research proposal (a summary is given in Appendix 3) for collaboration on North Atlantic harbour porpoise population structure. This proposal will also be presented to ICES and ASCOBANS during September 1994. The sub-committee commended the plans for an international programme to study the population structure for the North Atlantic harbour porpoise and recommended that they be implemented. It also urged that the international cooperation be extended to other questions such as methods to modify fishing gear and practices in order to reduce the cetacean bycatch.

In light of the high estimates of incidental mortality in the Gulf of Maine/Bay of Fundy, the sub-committee welcomed the information on plans for reducing the bycatch in the Gulf of Maine by temporal closure of fishing areas. The sub-committee recommended that actions be taken to implement the proposed plans for the Gulf of Maine and that plans be developed and implemented in the Bay of Fundy and other areas of high incidental mortality of harbour porpoise in the western North Atlantic.

6.2 Northeast Atlantic and Baltic Sea
Two papers described aspects of the biology of harbour porpoises around the British Isles. SC/46/SM13 summarised findings of autopsies of 295 (142 males and 121 females) stranded and incidentally caught animals between 1985 and the present from England and Wales (and from Scotland before 1992). Approximately a quarter of the stranded animals were assessed as having been caught in fishing gear from autopsy examinations (SC/46/ProgRep UK). Morphometric measurements were taken, body condition assessed and ages determined for each animal. The animals ranged from neonates to 24 yrs old. For comparison, some animals off California have been recorded to be over 20 yrs old, while the oldest recorded animal in the Gulf of Maine/Bay of Fundy was 17 yrs old, with most below 10 yrs of age. It was also found that for animals in their first year in the British sample, there were over twice as many males as females.

The maximum sizes recorded for individuals were 163cm and 189cm length in males and females respectively, with maximum weights of 54kg and 81kg respectively. The birth size appeared to be 65–70cm length and 5kg weight.

It was found that juveniles (1–2 yrs old) had thicker blubber than did adults and newborns and that pregnant females were heavier and fatter than lactating and anoestrous females.
The female reproductive data have not been completely analysed and were thus not reported. The data on testes weight from the males indicated that the males start puberty at 3 yrs of age when they are greater than 130cm long. In addition, seasonal changes in testes weight suggest that breeding probably occurs in July. The pattern of peak neonate recoveries during the year suggests that most births take place in June and thus that there is a 10-11 month gestation period.

The sub-committee discussed the possibility that the large testes sizes seen in some months might indicate sperm competition. It also considered the idea that the high mortality rate in the first year might be due to the bycatch problem. To investigate this it was suggested that the age/area/sex distribution of the animals be examined, particularly those incidentally caught animals and those assessed as bycaught from the autopsy examinations. It was also noted that there were problems with using ages of incidentally caught and stranded animals to estimate survival rates and that inherent inconsistencies in the data would result in inaccurate estimates. The potential sources of mortality discussed for the first year of life will be sensitive to diseases and genetic defects. It was noted that the UK has started pathological studies using the same animals as in this study (SC/46/ProgRep UK); genital herpes has been documented for the harbour porpoise and might reduce reproductive success (SC/46/ProgRep UK).

SC/46/SM14 presented results from a preliminary analysis (using mtDNA) of the genetic patterns of 50 out of 124 stranded and incidentally caught animals from the Shetland Isles, eastern England, the Channel and western England. These four areas constitute four hypothesised sub-populations (three of which correspond to Gaskin's (1984) putative populations). The methods used were amplification by PCR (polymerase chain reaction) of the non-coding control region followed by direct sequencing of the double-stranded product for 390 bases. The genetic distance between pairs of haplotypes was calculated as the percent difference in nucleotides. Using these techniques, 26 variable sites were found of which 19 occurred only once. In a pairwise comparison between putative sub-populations, there were no differences between Shetland and eastern England or eastern England and western England. However, differences between western England and Shetland animals were significant. Overall, 95% of the diversity in the 50 sequences was found within populations and 5% between populations. Taken as a whole the results do not show significant divisions in population structure (p=0.09).

The sub-committee recommended that studies such as these should continue and be expanded; the population structure of harbour porpoises needs to be estimated in order to assess the impact of bycatches (see Item 6.1). In addition to the above study, UK scientists are investigating population structure using skull morphology (for both harbour porpoises and common dolphins – SC/46/ProgRep UK).

The sub-committee discussed the question of harbour porpoise bycatch estimates. It was noted that Denmark has an observer programme for several fisheries in the North Sea. During 51 observed trips, 117 harbour porpoises were caught. Using these data, a preliminary annual estimate of 4,630 harbour porpoises killed in Danish turbot and cod set nets fisheries were obtained. It was also noted that Norway has not reported bycatches in its progress report this year. Observer programmes should result in less biased bycatch estimates than other methods but it was also noted that for some fisheries in some countries, conducting an observer programme is difficult for logistical reasons.

The establishment of an observer programme to estimate bycatch levels in fisheries around the UK has been suggested and a trial was carried out during 1993 off Cornwall. It has been shown that the present voluntary reporting programme for bycatches is not working and a new reporting scheme is to be launched ‘soon’. The sub-committee suggested that until a formal observer programme can be initiated, a voluntary programme should be promoted and incentives given to encourage fishermen to land the carcasses of incidentally caught animals.

**Recommendations**

Range states in the northeast Atlantic, Baltic and North Seas should set up observer programmes or modified observer programmes to estimate cetacean bycatches. Those states should then report levels of observer effort, spatial and temporal coverage and methods used to obtain at least approximate total bycatch levels, in reports to the IWC. Data on life history parameters should be collected and abundance estimates obtained to allow for an assessment of the impact of bycatches on the populations.

Several methods of reducing bycatch levels were discussed including modifications to fishing gear and fishing practice, as well as time/area closures. The best method or combination of methods was not determined. However, the sub-committee recommended that bycatch numbers be reduced by whatever means possible given the particular situation of the individual fisheries and national legislation.

The sub-committee noted that bycatch problems existed for IWC member nations who were also parties or range states to ASCOBANS (the Agreement on the Conservation of Small Cetaceans of the Baltic and North Seas). The ASCOBANS Agreement requires parties to work towards methods for reducing small cetacean bycatch levels, to implement national reporting schemes on bycatches, collate such data and modify fishery practice and gear to reduce bycatch levels.

The sub-committee urges the parties of ASCOBANS to act on implementing the aims of the Agreement as soon as possible. To this end and recognising the other important aims of ASCOBANS regarding matters of conservation and management of small cetaceans, the sub-committee encourages ASCOBANS range states who are not yet party to the Agreement, especially IWC member countries (France, Norway, Finland and Russia) to co-operate fully with ASCOBANS. ASCOBANS is discussed further under Item 9.2.

6.3 Response to the 1993 Resolution on harbour porpoise

The IWC adopted a resolution on North Atlantic harbour porpoises in 1993 (IWC, 1994b). The resolution requested all range states to (1) collect and analyse additional data on population distribution and abundance, stock identities, pollutant levels and bycatch mortality levels; (2) give high priority to reducing bycatches; (3) report to the 1994 meeting on their progress in implementing the above recommendations; and (4) exchange information with the Interim Secretariat of the ASCOBANS. In response to this resolution scientists from 12 countries (Canada, Denmark, Germany, Greenland, Iceland, Ireland, Netherlands, Norway, Sweden, UK and USA) provided the subcommittee with reports on progress in implementing at least some of the above recommendations.
A summary of current research activities from the above countries is compiled in SCI/46/SM17. The countries were asked to provide information on programmes pertaining to harbour porpoise research on a number of topics including population structure, abundance and distribution, life history characteristics, feeding ecology and anthropogenic effects. For each programme, the following information was requested: descriptive title; status of programme; principal investigators; collaborators; sources of materials; methods; and a list of recent publications or manuscripts in preparation. A total of 61 programmes was reported, covering all of the above research activities to some degree. Populations being investigated ranged from the Baltic Sea to the mid-Atlantic coast of the USA. As noted earlier, an international cooperative programme has been proposed to use standardised methods on sufficient sizes of samples from all putative sub-populations (Appendix 3). Abundance estimates have only been made for a few areas: the summer population in the Gulf of Maine/Bay of Fundy, Norwegian waters (Bjorge and Oien, 1995) and selected sections of the North Sea and western Baltic (Heide-Jørgensen et al., 1993). However, during July 1994, a comprehensive survey of the North Sea and Baltic will be conducted. Total bycatch estimates have been made only for the US Gulf of Maine and Danish fisheries. In most countries, samples from incidentally captured and stranded animals are, or were, being collected to investigate life history and feeding characteristics and to determine pollutant levels. However, samples sizes are currently still very low. Other aspects of biology that are investigated by Germany, Ireland, Netherlands, Norway and the UK include parasitology, pathology, virology and histopathology. Canada, Denmark, Germany, UK and USA are currently investigating methods to reduce bycatch levels, such as acoustic alarms on nets, time/area closures and alternative net characteristics.

The specific responses to the IWC Resolution were from Germany, Netherlands, Norway, Sweden and USA given in IWC/46/33 covered management actions and administrative questions. They were therefore not discussed in the sub-committee but would be considered by the Commission (IWC/46/33).

### 7. STRIPED DOLPHIN FISHERY OFF JAPAN

Information on directed takes of striped dolphins was presented in SCI/46/ProgRep Japan. In the Chiba and Wakayama prefectures a total of 94 striped dolphins was taken by the hand harpoon fishery; 450 striped dolphins were taken by drive fisheries in the Wakayama prefecture. The total of 544 striped dolphins taken in 1993 was about half the level of catches in 1992 (1,045 dolphins). Nomura explained that this reduction was due to strict quota regulations. The sub-committee welcomed the information provided and commended the substantial reduction in kills achieved by domestic quota regulations in 1993. No further documentation on biological studies or abundance estimates was presented at this meeting. The sub-committee was informed that a programme involving sighting surveys in an extended area, biopsy skin sampling and biological studies of caught animals will be continued and that genetic samples will be exchanged between Japanese and US scientists. The programme will provide more information on stock identity, distribution and abundance estimation.

The sub-committee recommended that such information be presented as soon as possible in order to facilitate an assessment of the striped dolphin as defined at last year’s meeting (IWC, 1994a).

### 8. REVIEW OF OTHER AVAILABLE INFORMATION ON SMALL CETACEANS

#### 8.1 Incidental takes at the Canadian west coast

SCI/46/O 5 reported on 57 records of eight species of cetaceans that stranded or were entangled in fishing gear on the west coast of Canada in 1993. Twenty-four of these records were from an unusual mortality event of porpoises (Dall’s porpoise, *Phocoenoides dalli* and the harbour porpoise) around the southern Vancouver Island; seventeen of these animals were necropsied but no underlying cause for this event was found.

#### 8.2 Incidental takes in California

Estimates of mortality in California gillnet fisheries for 1993 for pinnipeds and cetaceans are reported in SCI/46/O 11. The halibut set net and swordfish/shark driftnet fisheries are monitored and observer coverage is 15% and 13.5%, respectively; however, in some areas both fisheries have coverage rates less than 5%. Estimates of total effort are calculated from fishing vessel logsbooks, NMFS (US National Marine Fisheries Service) observer data and sales receipts of landed fish (SCI/46/SM2). Observed mortality is extrapolated to total estimated mortality using mean-per-unit and ratio estimators. For the calendar year 1993, the bycatch in the set net fishery was estimated to be 12 harbour porpoises and over 2,000 pinnipeds. The estimated bycatches in the drift net fishery are 22 Cuvier’s beaked whales, 170 common dolphins (*Delphinus sp*.), 37 short-beaked common dolphins, 52 northern right whale dolphins (*Lissodelphis borealis*), 15 Pacific white-sided dolphins, 30 Risso’s dolphins, 67 Dall’s porpoise, 81 short-finned pilot whales, 22 sperm whales, 7 pygmy sperm whales, 7 unknown whales and 192 pinnipeds.

#### 8.3 Antarctic beaked whales

SCI/46/SM15 summarised present knowledge on the distribution, abundance, migration, morphology, vital rates, diving behaviour and diet composition of beaked whales (family Ziphiidae). The information was obtained during the Japanese whale research programme (which includes special permit catches of minke whales in the Antarctic) from 1987/88 and from the IWC/IDCR sighting surveys. These surveys have revealed that beaked whales, primarily southern bottlenose whales (*Hyperoodon planifrons*) are abundant and widely distributed in the Antarctic. When presenting SCI/45/SM15, Ohsumi concluded that the southern bottlenose whale is likely to play an important role in the Antarctic ecosystem and that it may be an important indicator of environmental changes in the Antarctic. He therefore emphasised that the present state of knowledge on southern bottlenose whales is insufficient to utilise fully its potential as an ecosystem indicator. He underlined the need for biological sampling of this species and encouraged the sub-committee in the future to also focus its attention on cetaceans of the higher trophic levels in the Antarctic. Nomura stated that Japan had no immediate plans for the biological sampling of beaked whales in the Antarctic.
8.4 Incidental mortality of small cetaceans in Mediterranean driftnet fisheries
SC/46/O 21 reported on continuation of the use of driftnets averaging 10–12km of length for swordfish in the Mediterranean Sea. The Italian fishery may have taken as many as 8,000 cetaceans per year in the Mediterranean Sea (Di Natale and Notarbartolo-di-Sciarra, 1994).

According to SC/46/O 21, the current fishery is mainly conducted by European Union (EU) nations (Italy and Spain) and Moroccan vessels and the activity is a contravention of the UN General Assembly Resolution 46/215 and for the EU countries this activity violates the European Community Regulation 345/92 which prohibits EU vessels from using driftnets in excess of 2.5km length in the Mediterranean.

The Mediterranean driftnet fishery takes the striped dolphin among other species. IWC (1994f) concluded that the Mediterranean striped dolphin could not sustain the reported levels of exploitation. The sub-committee further noted that the striped dolphin suffered significant mortality during an epizootic in 1990 and 1991 and the long term impact of the epizootic on the population is not clear.

The sub-committee expressed concern over the status of the striped dolphin in the Mediterranean and recommended that the EU be requested to implement action to reduce mortality of striped dolphins and bring the Mediterranean driftnet fishery in accordance to the UN resolution and EU regulations and the general provisions outlined in the Action Plan for the Conservation of Cetaceans in the Mediterranean Sea adopted by the parties to the Barcelona Convention.

Further the sub-committee recommended that the EU be requested to establish a programme for recording incidental takes of cetaceans in the Mediterranean Sea and to report all catch statistics to the Commission.

8.5 Other information of relevance to the sub-committee
8.5.1 Equipment for acoustic surveys of harbour porpoise
The development of equipment for acoustic surveys of harbour porpoises was described in SC/46/SM20. The sub-committee asked whether the technique could work for other dolphins and porpoises such as the vaquita which are difficult to visually detect. Palka and Bjørge had seen a demonstration of the technique which indicated it was promising. However, there were concerns as to whether it was feasible given our present knowledge of the characteristics of harbour porpoise sound and behaviour. In the absence of the authors these and other questions could not be answered. The sub-committee encouraged continuance of this work and, if successful, expansion of the technique to other species.

8.5.2 Information from China, Taiwan
Chen reviewed the cetacean research activities occurring in China, Taiwan. He reported that for two years they have been interviewing captains in many harbours around the country to determine which species are present. 22 species have been identified thus far in China. Taiwanese waters. This information has been used to design a line transect survey which will be conducted soon following the guidelines (IWC, 1994e). Marine mammals have been protected since 1989. There are no directed takes and bycaught animals cannot be brought to port. Strict penalties have been given if these rules are violated. Chen underlined that such regulations do not reduce bycatch levels but rather reduce the amount of scientific information that can be collected which may help to reduce the bycatch. The sub-committee noted that similar problems occur in Latin America (e.g. Van Waerebeeck and Reyes, 1994).

The sub-committee welcomed information on this recently started research and urged that it be continued and the results reported to the Scientific Committee.

8.5.3 Southern Hemisphere killer and pilot whales
Abundance estimates for killer and pilot whales in the Southern Hemisphere were presented in SC/46/SH24. The data used came from two circumpolar sets of surveys which were conducted from 1978/79 to 1983/84 and from 1985/86 to 1990/91. The methodology used to estimate abundance (and its CV) was the same as agreed and used by the Committee for minke whales in the Southern Hemisphere. The abundance estimates for pilot whales had high CVs due to the small number of sightings (<20 in the 13 cruises): 1978/79 – 1983/84, 130,000 animals (CV=80%); 1985/86 – 1990/91, 43,000 animals (CV=104%). One potential problem is that one atypically large school was seen and this one sighting greatly influenced the resulting abundance estimate. Killer whale estimates have lower CVs: 1978/79 – 1983/84, 64,000 animals CV=30%; 1985/86 – 1990/91: 53,000 animals CV=30%). One potential problem with these estimates is that the size of groups (mean about 23 individuals) near the ice was about twice as large as for groups away from the ice (about 10). If this pattern is incorporated into the analysis, then the abundance estimate is lowered by 10% and the CV to approximately 20%. It was noted that the coverage (about 80%) of the second circumpolar set of surveys covered the area below 60°S more extensively than during the first set of surveys (coverage about 65%). The effect of this difference on the abundance estimate for these two species was not specified.

8.5.4 Implications of cohesive social structure on the sustainable yields of cetacean populations
In an attempt to address the possible implications of cohesive social structure on the sustainable yields of cetacean populations, SC/46/SM9 reported on a simulation which modelled their life history in a manner which might be applicable to the long-finned pilot whale. Some of the key whaling factors that were modelled included the fact that entire schools were harvested and that large schools were preferred to small schools. The only life history characteristic which had an effect on the sustainable yield of this simulated population was the decision rule that when large schools broke into two groups, one of the new groups would contain younger, smaller– sized animals that were less efficient at protecting their calves. Overall, the taking of entire pods under the simulation conditions had only a small effect on the sustainable yield. It was also found that when life history information from smaller and younger pods was excluded, estimates of sustainable yield based on life history parameters for larger pods alone could be misleading. In addition, it was observed that the simulated population abundance oscillated around a central value, under harvesting, rather than approach it smoothly as in simpler population models. The authors asked the sub-committee if it had suggestions for alternative population life history mechanisms which could be examined in the future.
Much of the discussion centred around the question of the splitting of large schools. Alternative and/or expanded rules suggested included: (1) that sperm competition is an important factor in the pilot whale reproduction strategy, animals that split off from a large group should be closely related; (2) pilot whale schools should be modelled to merge together for mating as is thought to be the case for animals around the Faroe Islands; (3) the trigger for pod splitting should be related to food supply, distribution and abundance. It was not possible to rank the likelihood of these hypotheses and the sub-committee believe that an examination of the effect of all of them on the sustainable yield would be informative. In response to a question as to why many of the biological life history parameters were not the estimated values obtained from field studies, Butterworth explained that these ‘exact’ values were compressed in the simulation so that the joint relationship was a surrogate of the actual measurements. This was done to increase the computer efficiency of the program and was unlikely to affect the results.

9. OTHER BUSINESS

9.1 Nomenclature
The sub-committee noted that Heyning and Perrin (1994) proposed the division of the common dolphin into two common dolphin species: the short-beaked common dolphin, *Delphinus delphis*, and the long-beaked common dolphin, *Delphinus capensis*. The sub-committee recommended that the Committee's List of Recognised Species and Common Names be amended accordingly.

9.2 ASCOBANS
The progress on ASCOBANS was reported by Lockyer on behalf of the Interim Secretariat. The Agreement came into force on 29 March 1994 with six Parties (Belgium, Denmark, Germany, Netherlands, Sweden and the UK). The first full meeting of Parties and Range States would be held in Stockholm, 26-28 September 1994.

A preliminary meeting of Range States was held in Cambridge in October 1993, when it was agreed to collaborate closely with the IWC on matters concerning small cetaceans, especially on action plans addressing the status of the harbour porpoise in the North Atlantic and Baltic Sea. Progress on implementation of the Survey on Small Cetacean Abundance in the North Sea (SCANS) was reported and it was noted that participating countries included Denmark, France, Germany, Ireland, Netherlands, Norway, Sweden and the UK, all IWC member nations. The programme, co-ordinated by the UK, was 50% funded by the EU.

The full cost of the programme was over 1,500,000 ECU (about £1.160,000). A successful preliminary survey took place in April 1994. The main surveys throughout the North Sea, Channel, south-western approaches (south of Ireland) and south-western Baltic Sea, would take place in June-July this year. It was anticipated that there would be a report of the survey’s findings ready for consideration by the sub-committee in 1995.

Lockyer reiterated the aims of ASCOBANS regarding habitat conservation and management, surveys and research, use of bycatches and strandings, legislation and information and education. It was intended that a Scientific Advisory Committee to ASCOBANS would be established at the September meeting later this year and that a primary goal would be to formulate and then implement an action plan for small cetaceans in the Agreement area.

9.3 Ways by which the sub-committee identifies stocks for review
At its 44th meeting, the IWC established a Working Group to consider a mechanism to address small cetaceans in the IWC (IWC, 1993a). This Working Group met prior to the 45th Annual Meeting and at this meeting the IWC passed a Resolution on Addressing Small Cetaceans in the IWC (IWC, 1994d). The resolution identified four topics for future discussion within the Working Group, including the way the small cetacean stocks are identified for review.

Past and current practices of the sub-committee in this regard are summarised below. The sub-committee identifies stocks for review by selecting priority topics for its meetings. Each year since 1982 the sub-committee has proposed priority topics for its following meeting. In recent years, the sub-committee has identified priority topics for more than one year ahead to facilitate more time for relevant research and documentation to be completed ahead of meetings.

9.3.1 Guidelines for setting priorities for the work of the small cetaceans sub-committee
When setting priorities for future work, the sub-committee has, in the past, given priority to species or stocks which were subject to direct harvest or incidental mortality by fishery operations. The 1990 and 1991 IWC Resolutions on Small Cetaceans (IWC, 1991a; 1992a) which also provided guidelines for the future work of the sub-committee, confirmed that this practice was in agreement with the then priorities of the Commission.

Following these guidelines, the sub-committee has continued to propose priority topics that focus on directed and incidental takes. However, there are different ways to define such priority topics. Examples of three types of priority topics recently proposed are:

(1) a species or stock(s) that is or may be influenced by exploitation (example: dolphin stocks harvested by Japanese drive fisheries – 1992);

(2) a geographical area where there are indications or evidence of incidental or directed exploitation on populations of small cetaceans, but where information on takes or impact on specific stocks are limited (small cetaceans in Southeast Asia, Indo-Malay region – 1993; small cetaceans in Latin America – 1994);

(3) a global review of a species or taxonomic group (example: Monodontidae – 1992).

However, from a conservation point of view it may be questioned whether strict focus on stocks subject to significant directed or incidental takes is sufficient to unveil important threats to small cetacean populations. Several small cetacean stocks are confined to coastal, inshore, estuarine or riverine waters. Such stocks may be particularly exposed to pollutants, habitat degradation and disturbances caused by human activities. In 1991, the sub-committee stressed that these factors should be emphasised in any comprehensive assessment of threats to small cetaceans (IWC, 1992b). The 1993 IWC Resolution on research on the Environment and Whale Stocks (IWC, 1994e) and in particular the 1992 IWC Resolution on Small Cetaceans (IWC, 1993b) opened up the way for a broadening of the scope for future priority work of the sub-committee.
9.3.2 Sources of information for discussion within the sub-committee of priorities for its future work
In principle, the sub-committee has three potential sources of information for discussion of priority topics for its next meeting. These sources are:

(i) information provided by submitted National Progress Reports from IWC member nations;
(ii) information provided by submitted scientific papers;
(iii) personal knowledge of the sub-committee members (via published or unpublished literature, threats revealed by other scientific organisations or information provided by colleagues not present in the sub-committee).

In addition to addressing newly identified problems, the sub-committee may want to evaluate any progress made upon advice or recommendations it has previously made.

9.3.3 Present procedure for adopting priority topics for the small cetaceans sub-committee
Proposals for priority topics are discussed within the sub-committee and the agreed proposal is put to the full Scientific Committee for discussion and amendment or adoption as the Scientific Committee’s priority for its sub-committee. The Scientific Committee’s proposal is then forwarded to the Commission and unless changed by the Commission, is adopted as the Priority Topic for the next meeting of the sub-committee.

An atypical situation occurred in 1990. The sub-committee proposed narwhals and white whales (alternatively a review of Lagenorhynchus and Lissodelphis, and dolphins involved in the ETP tuna fishery) as priorities for its meeting in 1991 (IWC, 1991b). However, at the Commission meeting the Scientific Committee was asked to begin to draw together the available information on the status of the stocks of small cetaceans which were subjected to significant directed or incidental takes, assess the impact of those takes on the stocks, and assess the threats facing the stocks concerned (IWC, 1991a). The Commission agreed to present the report of the first year of this process to the United Nations Conference on Environment and Development in 1992 (IWC, 1991a). The sub-committee responded to the request by a global review of stocks of small cetaceans which were subjected to significant directed or incidental takes (Bjorjko et al., 1994). The review of narwhals and white whales was deferred to 1992.

9.4 Takes of small cetaceans in 1993
Reported directed and incidental takes are summarised in Appendix 2. Information is provided in national progress reports from Argentina, Brazil, France, Germany, Japan, USA and in documents submitted to the sub-committee. The sub-committee emphasised that these statistics are incomplete and that in addition there are significant directed and incidental takes in areas for which there are no records available.

The sub-committee noted that despite previous practice, no information was provided on the directed takes of small cetaceans in the Faroe Islands and Greenland. The sub-committee therefore recommended that the Secretary of the IWC be advised to request Denmark to provide catch statistics for these ongoing fisheries.

No information on incidental takes was provided in the progress reports submitted by Ireland, Mexico, Norway and Spain. In addition, several member nations failed to submit progress reports. The sub-committee reiterated its recommendation that IWC member countries be requested to establish procedures for recording incidental and directed takes of small cetaceans and to submit all catch statistics to the Commission.

9.5 Priority topics for the 1995, 1996 and 1997 meetings
In discussing priority topics for forthcoming meetings, the sub-committee recalled: (1) priorities discussed at its meeting in 1993; (2) the IWC 1993 resolution on harbour porpoise in the North Atlantic and the Baltic Sea and this year’s discussion of the species (Item 6); (3) the IWC 1993 resolution on directed takes of striped dolphins and this year’s discussion of striped dolphin takes off Japan (Item 7).

Borobia provided the sub-committee with a description of UNEP programmes under the Marine Mammal Action Plan which in the near future may substantiate information on small cetaceans in coastal waters of Africa.

Members of the sub-committee referred to this year’s review of small cetaceans in Latin America and problems arising in other areas and emphasised the urgent need for further review of the genus Lagenorhynchus and the genus Lissodelphis.

Other members draw the sub-committee’s attention to the plans for a comprehensive small cetacean survey in the North Sea (SCANS), the high incidental take levels of harbour porpoise in Gulf of Maine/Bay of Fundy and in the North Sea called for a comprehensive review of this species in the North Atlantic region.

The sub-committee agreed to give priority to the following topics:

1996—(A) Review of small cetaceans in coastal waters of Africa.
        (B) Global review of the genus Lagenorhynchus and the genus Lissodelphis.
        (B) Global review of the striped dolphin, Stenella coeruleoalba.

9.6 Publication of documents
The sub-committee reviewed submitted documents and made recommendations to the Editorial Board for some of the papers to be considered for publication: a number of these were to be considered for publication in the special issue on Gilthead and Cetaceans.

10. ADOPTION OF REPORT
The report was adopted as amended by the sub-committee on 9 May 1994.

AGENDA

1. Election of Chairman
2. Adoption of Agenda
3. Appointment of Rapporteurs
4. Review of available documents
5. Review of the status and exploitation of small cetaceans in Latin America
   5.1 Vaquita, Phocoena sinus
   5.2 Franciscana, Pontoporia blainvillei
   5.3 Tucuxi, Sotalia fluviatilis
   5.4 Small cetaceans taken for crab bait in Chile
   5.5 Small cetaceans taken by artisanal fisheries in Peru
   5.6 Small cetaceans taken by artisanal fisheries in Mexico
   5.7 Takes of small cetaceans in Colombia
   5.8 Incidental takes in Brazil
   5.9 Incidental takes in Ecuador
   5.10 Dolphins taken in the ETP purse seine tuna fishery
   5.11 Information on other stocks and areas
   5.12 General recommendations
6. The harbour porpoise in the North Atlantic and Baltic Sea

6.1 Northwest Atlantic
6.2 Northeast Atlantic and Baltic Sea
6.3 Response to the 1993 Resolution on harbour porpoises
7. Striped dolphin fishery off Japan
8. Review of other available information on small cetaceans
   8.1 Incidental takes at the Canadian west coast
   8.2 Incidental takes in California
   8.3 Antarctic beaked whales
   8.4 Incidental mortality of small cetaceans in Mediterranean driftnet fisheries
   8.5 Other information of relevance to the sub-committee
9. Other business
   9.1 Nomenclature
   9.2 ASCOBANS
   9.3 Ways by which the sub-committee identifies stocks for review
   9.4 Takes of small cetaceans in 1993
   9.5 Priority topics for 1995, 1996 and 1997 meetings
9.6 Publication of documents
10. Adoption of the report

Appendix 2

Official statistics have been taken to be those provided in the Progress Reports or official catch records submitted to the Secretariat. Values given in scientific papers submitted to the Committee and data obtained during the Committee meeting are provided for information only and their sources indicated.

REPORTED CATCHES OF SMALL CETACEANS IN 1993

The table has been divided into two sections. The main table is overleaf. This table provides a breakdown of the heading 'Other' in the main table.

### REPORT OF THE SCIENTIFIC COMMITTEE. ANNEX G

REPORTED CATCHES OF SMALL CETACEANS IN 1991

Catches are presented by nation, rather than ocean area, except in the case of the data submitted by the IAATC for the eastern tropical Pacific (ETP). In this case, the submitted estimated catches are not broken down by country, except for the USA, and a summed total incidental catch for the following countries is given: Colombia, Ecuador, Honduras, Mexico, Panama, USA, Vanuatu and Venezuela.

HARBOUR PORPOISES IN THE NORTH ATLANTIC

The sub-committee received a proposal for collaboration in research on North Atlantic harbour porpoise population structure provided in SC/46/SM18. The sub-committee endorsed the proposal and recommended that international collaboration be extended to address other research needs on harbour porpoises as identified by the sub-committee.

Bjørge, Lockyer, Palka and Read agreed to act as contact persons to facilitate further work in implementing the research proposal. The proposal is described below.

Draft Description of Research Proposal: Collaboration on Atlantic Porpoise Population Structure (CAPPSS)

Introduction
The bycatch of harbour porpoises, *Phocoena phocoena*, in the North Atlantic has increasingly been recognised as a major environmental problem in the waters of several nations. Where both the level of bycatch and abundance have been estimated, the levels have exceeded likely sustainable levels although the information needed for a complete assessment of the status of the populations involved has been lacking.

These concerns are reflected in the 1993 IWC resolution on harbour porpoises in the North Atlantic (IWC, 1994). The resolution calls for a number of scientific research activities relating to the status of harbour porpoises and asks member states to provide information on progress to the Commission at its 1994 meeting. At the end of March 1994, the Agreement on the Conservation of Small Cetaceans of the Baltic and North Seas (ASCOBANS) comes into force. This agreement includes, as one emphasis, the issues of the bycatches of small cetaceans.

To promote resolution of this problem, ASCOBANS has agreed to support the action and direction of the IWC on problems related to small cetaceans (Report of the Preliminary Meeting of ASCOBANS Range States, October 1993, Cambridge).

Gaskin (1984) suggested the existence of 14 separate populations of harbour porpoises in the North Atlantic (Table 1), although more recent work has raised uncertainties about the degree of interchange among animals in some of these areas (Rosel, 1992; Andersen, 1993; Wang, 1993). Improving our understanding of the population structure of this species is essential in order to interpret bycatch and abundance estimates in the future. If biologically separate populations are not recognised, there is a danger of underestimating the biological significance of the bycatch from one of the populations. If on the other hand, separations are assumed that are not real there is a danger of overestimating the actual significance, which might result in unnecessary restrictions on fishing activities. However, it is likely that harbour porpoise occupying some of the adjacent areas may not be genetically distinct but nonetheless have ecologically significant levels of interchange only rarely from an ecological perspective. To be sure that management actions in response to bycatch levels are well designed, it is important to understand the nature of the population structure of harbour porpoises, be it discrete populations with limited exchange or groups of animals with variable interchange rates.

The resolution of this uncertainty will require the collection, analysis and integration of information from several types of harbour porpoise samples from throughout the North Atlantic. An international collaboration of scientists in this region is proposed, coordinated through the IWC Scientific Committee, in collaboration with the International Council for Exploration of the Sea (ICES), ASCOBANS and cooperating organisations. The project is planned to take two years and to produce an integrated description of the population structure of this species in the North Atlantic.

Hypothesis
Gaskin (1984) proposed fourteen sub-populations of harbour porpoise in the North Atlantic, based largely on distribution data. These data were supplemented by major biogeographic boundaries which might serve as barriers to movements. As a starting point for an examination of population structure of this species in the North Atlantic it seems reasonable to consider four alternative hypotheses:

H₁: one panmictic population unit across the North Atlantic
H₂: less than or equal to fourteen units with considerable exchange
H₃: less than or equal to fourteen units with little exchange
H₄: fourteen discrete population units

Here discrete means that the amount of exchange between units is small enough that the units have been isolated from one another over recent geological time. H₁ suggests that the number of migrants per generation is very small, so that the units could be discriminated using standard genetic techniques. H₂ suggests that the units are ecologically distinct, but that sufficient exchange occurs among them that they cannot be distinguished using genetic techniques or morphological measurements.

There is some information to suggest that H₃ and H₄ have been invalidated by morphological and genetic evidence. This proposal, therefore, is for a set of studies using a range of complementary methods to determine both the number of population or sub-population units and the degree of interchange among them, and thereby to distinguish between H₁ and H₂.

Study design
A range of scientific methods of determining population structure will be applied to existing and new biological samples from across the North Atlantic. Analysis of incidentally caught and stranded samples from each of the 14 hypothesised population areas will be attempted, with sample sizes to be determined separately for each of the methods being used.

Five methods or groups of methods will be emphasised: movements, biological processes, chemical indicators, morphology and genetics. These tools each have different strengths depending on the actual population structure. Analyses will be conducted by scientists in several laboratories throughout the North Atlantic and the North and Baltic Seas. Workers applying methods in each of these four groups will collaborate to ensure adequate sample sizes and consistent application of the methods. Results from individual laboratories will be published as appropriate, with full participation and recognition of the contributions of individuals collecting samples and conducting analyses. The collaborating groups will assemble the data from the individual laboratories into common databases and these databases will be jointly analysed by representatives from the individual collaborations.

Overall coordination of the study will be by representatives of the collaborating methodological groups and others. Specifics of the collaborating methods groups and of the overall coordination will be developed within the sub-committee on small cetaceans. The matter of organisation and management of the programme is considered below.

Identification and initial analyses of samples will not commence until the later half of 1994, but are expected to be completed within 12 months. Specialty-specific databases will begin to be created by mid-1995, with feedback for obtaining further samples to fill gaps as they emerge. Individual specialty study groups should meet before the end of 1995 and results of those meetings will be analysed at a workshop in 1996 and compiled into a report.

Application of results
The results of the study will be of primary importance in determining the correctness of the hypothesised population structure for North Atlantic harbour porpoise (Gaskin, 1984). The conclusions will provide the necessary information for interpreting information on bycatch and abundance levels in terms of the biological significance of the bycatch. These results will especially important in areas where porpoise are subject to bycatch mortality by fishermen from more than one country and will provide a sound basis for management in general.

The comparison of the results obtained from the simultaneous application of several methods which have been used in studies of the population structure of cetaceans, will improve our understanding of the applicability and statistical power of the several methods in different situations. For example, the relative power of the two principal genetic methods to be used to detect the degree of population discreteness will be illustrated, allowing selection of the more effective and cost efficient method in future studies of cetaceans. Similarly, results from methods which emphasise interchange of animals on ecologically relevant time scales will be compared with those emphasising interchange on evolutionary time scales. This comparison will improve our understanding of the appropriateness of these two types of approaches in determining population structure. More generally, the results will help us to understand the degree to which different methods are complementary.

Finally, the extensive collaboration among scientists using the same research methodology will result in improvements in the consistency of application of the methods. This will allow improved technical capabilities among scientists throughout the North Atlantic countries.

3. ADOPTION OF AGENDA
The agenda adopted is given as Appendix 1.

4. g(0)

4.1 North Atlantic minke whale analyses
SC/46/NA8 contains a re-analysis of some of the data from the independent observer experiments used in Schweder et al. (1993) for estimating g(0) in the 1988/89 Northeastern Atlantic minke whale sighting survey. The paper presented (1) additional developments in the basic theory for estimating g(0) developed by Schweder and Host (1992) and in Schweder et al. (1991b; 1992; 1993); (2) simulation results on the performances of the estimator; and (3) a detailed discussion of the input data with respect to the classification of surfacing into trials or non-trials and the problems of identifying duplicate surfacings and whales.

With respect to the theory, SC/46/NA8 presented a Poisson approximation for the whale surfacing rates that can be used in estimating the likelihood for the surfacing detection probability function (SDPF). It also fitted the full two-dimensional hazard rate function when data on the initial sighting positions were included in the estimation procedure. Finally, it developed an additional model (referred to as the product model) for estimating the SDPF.

The simulation study examined the effect of model misspecification for the SDPF, the use of the Poisson approximation, estimation errors in surfacing distances and angles and whale movements. The effects of model mis-specification and the use of the Poisson approximation were small. Estimation error and whale movements resulted in negative biases in the estimates of g(0). The simulations were not an exhaustive set of tests for possible and/or expected deviations from the assumptions of the theory.

The paper noted that there was a greater number of recorded surfacing times with zero seconds (i.e. whole minutes) than would be expected if all times had been recorded on the tape as planned. The excess was presumed to represent times that were not on the tapes and which had been recorded to the nearest minute at best. This was taken into account in making duplicate judgements for these cases.

With respect to the treatment of the input data, SC/46/NA8 noted that it is necessary to classify each surfacing identified by one platform into one of the following four categories (although cases C and D do not need to be explicitly distinguished from one another):

(A) surfacing not seen by platform 2 and whale also not seen previously by platform 2 (Bernoulli trial with a ‘failure’ outcome);
(B) surfacing seen by platform 2 and whale not previously seen by platform 2 (Bernoulli trial with a ‘success’ outcome);
(C) surfacing not seen by platform 2, but whale previously seen by platform 2 (no Bernoulli trial);
(D) surfacing seen by platform 2, but whale also previously seen by platform 2 (no Bernoulli trial).

The paper discussed the problems in performing such classifications and developed a set of criteria which were used for classifying the 1990 independent observer data. The criteria were based on estimates of the time of surfacing, the position of the surfacing relative to vessel, the orientation of the whales and the number of whales in each surfacing, combined with information on the uncertainties associated with each of these estimates. The paper presented summary statistics for these various criteria for surfacings classified into the different categories.

The Working Group noted that SC/46/NA8 represents a significant contribution to the development and application of the method used for estimating g(0) in Schweder et al. (1993).

For the data set that was used in SC/46/NA8 (i.e. the 1989 survey plus the 1990 experimental data), g(0) was estimated to be 0.587 with a CV of 0.063 compared to 0.36 (CV 0.079) in Schweder et al. (1993) which used the 1989 survey data and the combined 1989 and 1990 experimental data sets. The Working Group reviewed in detail the source of the difference in the estimates of g(0) and identified five potential factors in the two analyses which contribute to the difference in the estimates. These are:

(1) the data set used in the analyses (i.e. Schweder et al. used the combined data set from the 1989 and 1990 independent observer experiments while SC/46/NA8 only used the data from 1990);
(2) the method used for classifying surfacings into successes, failures and non-trials;
(3) the model used for estimating the SDPF;
(4) the fitting method and criteria used when initial sightings data were included in the estimation.
There was extensive discussion of the source of the difference in Table 1. One of the major factors appears to be how the two methods classified potential duplicate whales from non-simultaneous surfacings in which estimated positions suggested that the surfacings were in close proximity to each other. SC/46/NA8 identified most of these as duplicate whales (10 cases). The method used in Schweder et al. made no explicit assumption about such surfacings, but the classification method generally (if not always) identified these surfacings as coming from different whales. Another important source of the difference in the classification was the treatment of surfacings where the radial sighting distance and/or angles were missing. SC/46/NA8 excluded all such surfacings from its analysis, while Schweder et al. included some of these surfacings when they were part of a sequence of surfacing. In such cases, the position of the surfacing was interpolated based on the other surfacings in the sequence with positional information. Two other sources for the differences in classification were also identified: (1) how surfacings with possible inaccurate times were evaluated; and (2) sequences of surfacing in which one team identified a pod of two whales and the other team identified surfacings of single whales which could be interpreted as the same whales. These latter two differences resulted in SC/46/NA8 classifying an additional four pairs of duplicates that were not judged to be duplicates in the data set provided by Schweder. 

There was discussion, but no agreement, concerning the merits of the different classification approaches and on the use of plots of sightings and vessel position to classify sightings. The Working Group noted the importance of explicitly identifying the criteria used to classify surfacings and recommended that a full description of the criteria should be included in any future analyses. The Working Group noted uncertainties will exist with any classification system and that some errors in classification (i.e. false duplicates and missed duplicates) will occur, especially in high density areas. Accurately collected data on time and position of each observed surfacing will minimise the extent of the uncertainty. The Working Group strongly recommended that any future estimates of g(0) need to include quantitative analyses of the error in duplicate classification and their effects on the estimates of g(0). It also recognised that this may not be a simple task and that methods and procedures need to be developed for performing such analyses.

The only direct comparisons that could be made of the effect on g(0) for the two different classification methods was for the 1990 data based only on the Bernoulli trial data and for the r-x and the r-logx models. In this case the effect of the different methods for classification was relatively small. The classification method used in SC/46/NA8 resulted in g(0) estimates of 0.634 for the r-x model and 0.590 for the r-logx model. The classification method in Schweder et al. yielded estimates of 0.65 and 0.547 respectively (Schweder and Host, 1992; Schweder et al., 1992). However, the committee noted that this comparison could not be generalised with respect to the overall effect that the two different classification methods might have on the estimates of g(0) if the 1989 data were included in the analyses or if the initial sighting data were also included in the analyses. This is because of the differences noted above in how the 1989 data were collected and because of possible interactions when the initial sightings data are included in the analyses. The sensitivity of the g(0) estimate to the inclusion of the initial sightings data set may depend on the
exact Bernoulli data set used which is determined by the classification method.

Based on comparisons of results in SC/46/NA8 and Schweder and Host (1992), there also may be an interaction between the classification method used and the estimation procedure (i.e. the use of the traditional or simulated likelihood and the fitting criteria) when the initial surfacing data are used. Results in SC/46/NA8 suggest that the estimate of $g(0)$ is relatively insensitive to the inclusion of the initial sighting data from the 1989 survey when only the 1990’s experimental data are used with the classification method developed in that paper. In contrast, results in Schweder and Host (1992) suggest that the estimate of $g(0)$ is sensitive to the inclusion of the 1989 survey when only the 1990 experimental data are used with the classification method from Schweder et al. (1992; 1993). SC/46/NA8 used the traditional likelihood method with the two dimensional fitting criteria while Schweder and Host (1992) used the simulated likelihood estimation method with the marginal fitting criteria (as noted below, Appendix 2 indicates that the estimates of $g(0)$ are insensitive to the fitting criteria for the results in SC/46/NA8). It is not clear why the results in SC/46/NA8 and Schweder and Host (1992) exhibit this apparent difference in sensitivity to the inclusion of the initial sightings data and further analyses are required. It should be noted that the results in Schweder and Host (1992) were preliminary and that subsequent changes that have been made to the fitting procedure could yield different results.

Concerning the identification of duplicate sightings, it was noted that the development of an automated system for identifying duplicate sightings by independent observers would be useful. Further, the analytical use of measurement error in estimated surfacing times, distances and angles in classifying sightings as duplicates in SC/46/NA8 was considered an important and useful step in developing an automated process. However, there was disagreement as to whether field trials to estimate measurement error in sighting distances and angles was representative of actual sightings conditions in a survey mode. It was noted that in some experiments there appeared to be substantial errors in the measurement of the ‘true’ angles used to calibrate the observer estimates. The Working Group agreed that in general errors in angle and distance estimates in field trials would tend to be less than measurement errors that occur during sighting surveys.

Concerning differences in model selection for the detection function, it was agreed that additional information was needed to evaluate the merits of each model. This information included, but was not limited to, a comparison of the predicted detection function and the histogram of observed perpendicular distances, and a comparison of the reduction in the Bernoulli likelihood relative to the combined likelihood. Some of this information was made available during the Working Group’s meeting for the analyses in SC/46/NA8 (see Appendix 2). Based on these findings and those in SC/46/NA8, the Working Group agreed that for these data both the product and the $r$.logx model provided similar fits to the data, with the product model providing a slightly (but not significantly) better fit to the Bernoulli data alone, and the $r$.logx model providing a somewhat better fit to the combined experimental and survey data. The resulting estimates of $g(0)$ for the different models were similar (e.g. 0.584 for the product model compared to 0.543 for the $r$.logx model when the combined data are used). Overall, the Working Group thought that the difference in model selection did not have a major effect on the $g(0)$ estimates. Nevertheless Butterworth suggested investigation of the introduction of an additional parameter into the distance component of the product model used in SC/46/NA8, to allow for the possibility that the detection function decreased closer to the vessel.

Concerning the effect of the difference in fitting criteria, calculations were performed during the meeting which indicated that the choice of fitting criteria had little effect on the $g(0)$ estimates (Appendix 2) or the resulting goodness of fit. The fitting criteria used in SC/46/NA8 yielded a reasonably ‘good’ fit to the marginal distributions of perpendicular and forward initial sightings data (Appendix 2).

The $g(0)$ estimates in SC/46/NA8 did not account for measurement error in angles and distance. Schweder et al. included measurement error when estimating $g(0)$.

The Working Group also noted that the inclusion of the survey data along with the Bernoulli trials data did not have a substantial effect on the estimates of $g(0)$ in SC/46/NA8. It had the largest effect when the $r$.logx model was used to fit the SDPF, with $g(0)$ being reduced from 0.590 when only the Bernoulli trials data were used to 0.543 when the combined data were used. This is in contrast to the results in Schweder et al. (1993) in which the inclusion of the combined survey and Bernoulli trial data had a large effect on the estimate of $g(0)$.

The discussion of SC/46/NA8 highlighted the importance of accurate and careful data collection procedures and methods for duplicate identification when independent observer experiments are to be used for estimating $g(0)$. The Working Group felt it was important that a set of guidelines be developed for future surveys and analyses. A small group was set up to draft a set of recommendations. Their recommendations were adopted by the Working Group and listed in Appendix 3. These recommendations may need to be considered for incorporation into the Guideline for surveys under the RMP (IWC, 1994b).

In addition to the above, during the course of the discussion a need for research and information on the distribution of swimming speeds and its impact on identifying duplicate sightings from independent platforms was identified. Appendix 4 contains information on swimming speeds for North Atlantic minke whales that was supplied to the Working Group.

Butterworth advised the Working Group that he hopes to investigate the possibility that comparison with analyses for Southern Hemisphere minke whales might provide insight in regard to likely values for, or biases in, estimates of $g(0)$ for North Atlantic minke whales.

4.2 New approaches

The Working Group also reviewed SC/46/O 23. It was noted that the paper presents a theoretical development of estimators for $g(0)$ and effective strip width (ESW). The Working Group agreed that the proposed approach was biased due to unresolved problems of heterogeneity and that the bias would be positive. While the approach begins from the perspective of a discrete detection function in two dimensions (i.e. the same approach discussed under Item 4.1), the paper uses approximations that reduce the problem to a one-dimensional continuous function. While the derivation is different, the estimators in SC/46/O 23 are similar to those used previously (Butterworth and Borchers, 1988). However, to some extent stratification by
pod size and sighting conditions, as recommended by the author, may reduce some of the effects of heterogeneity at the expense of increased variance. However, the basic effect of heterogeneity due to diving behaviour cannot be eliminated by this approach (Schweder et al., 1991a).

5. AVOIDANCE/ATTRACTION

SC/45/NA8 was reviewed by the Working Group. This paper suggested that vessel-attraction behaviour could be biasing shipboard line transect estimates for North Atlantic minke whales. The Working Group noted that there was no quantifiable data available for assessing whether attraction or avoidance behaviour does occur. It was noted that occasional observed examples of attraction behaviour cannot be used to conclude on average whether attraction, avoidance or no reaction is occurring. It was also pointed out that behaviour observed in relationship to stationary or slow moving vessels cannot be extrapolated to the expected behaviour in relation to survey vessels travelling at 10–12 knots.

It was suggested that simulation models might be helpful in elucidating the possible magnitude and direction of bias that could be introduced into abundance estimates due to the response of minke whales in the North Atlantic to survey vessels. The range of such simulations might be constrained by incorporating existing estimations of the observed two dimensional hazard rate function. However, such simulations would probably require better information on minke whale behaviour in order to provide useful results. Schweder noted that at least six continuous tracks of radio-tagged minke whales were currently being analyzed and may provide useful information on possible vessel reaction behaviour. Results from these radio tagging studies would be available at next year’s Scientific Committee meeting.

There was some discussion regarding whether information on avoidance/attraction of Southern Hemisphere minke whales to survey vessels could be applied to the North Atlantic. There was general agreement that the comparative approach was unlikely to produce reliable results. Rather, some direct approaches were identified: (1) radio-tracking studies of individual animals; (2) independent platforms of observation for observing the response of individual animals approached by survey vessels; (3) analyses of information on swimming directions at the time of initial sighting and (4) analyses of implied swimming tracks derived from linked observing surfaces (e.g. using the data from the g(0) independent observer experiments). The Working Group noted that there were problems with all of these approaches. There was no agreement on what would be the best approach for investigating this problem or what priority should be placed on determining if significant reaction behaviour occurs in North Atlantic Minke whales with respect to approaching survey vessels. Improved methods for estimating whether attraction or avoidance behaviour is occurring would be desirable.

6. NEW ABUNDANCE ESTIMATES

The Working Group noted several abundance estimates as identified in working papers under this agenda item. The Working Group did not have time to review these estimates and noted that if the Scientific Committee was to use them in its future work they would need to be reviewed. The following documents pertain to the corresponding agenda items: (6.1) fin whales (eastern North Atlantic) – SC/46/NA6; (6.2) humpback whales (eastern tropical Pacific) – SC/46/NP4; (6.3) North Pacific minke whales – SC/46/NP6.

7. SURVEY PLANS

7.1 North Atlantic minke whale

A cooperative project between the Institute of Marine Research and the Norwegian Computing Centre (Research Council of Norway) has been initiated to conduct a survey for North Atlantic minke whales starting in July 1995. The intention is to survey the same area as covered by Norwegian vessels in 1989 (see SC/46/NA4) and also the western part of the Norwegian Sea including the Jan Mayen area. No decision has yet been taken with regard to methodology and coverage, other than that the survey will be a vessel survey and two independent teams of observers will be on each vessel. Comments on the potential use of adaptive survey designs have been solicited. Duplicate identifications will be automated to a large extent using objective criteria. The first stage of the preparations for this research are scheduled to be completed by the end of 1994. Results from the survey will be available in the spring of 1996.

The Working Group supported the general survey as proposed and the plan to incorporate independent observers on each survey platform in order to estimate g(0) as part of the normal survey operations. Smith noted that a cetacean survey in the western North Atlantic east to Sable Island, Canada has been scheduled for the summer of 1995 which will be focused on porpoises, dolphins, beaked whales, pilot whales and large whales such as right and humpback whales. There was agreement that the principal investigators directing these surveys should communicate with one another to ensure to the degree possible that the data be compatible and that survey effort was distributed in time and space in an efficient manner.

It was noted that Iceland also plans to conduct a survey for minke whales in 1995 (SC/46/NA10). The Working Group noted the desirability of having the results of such a survey available to the IWC. However, it felt that the mechanism for achieving this and any possible interaction of IWC with this survey was outside the terms of references of the Working Group and would be more appropriately discussed by the full Scientific Committee.

Several issues were discussed regarding the development of adaptive sampling techniques (i.e. where the distribution of searching effort is adjusted based on the encountered density of whales) for cetacean sighting surveys. The Working Group noted that the IWC would be interested in the general development of this methodology for cetacean surveys and there would be a need for the Scientific Committee to review the adaptive sampling methodology if it were to be used.

7.2 North Pacific minke whale

Sighting surveys in the North Pacific have been scheduled by the National Research Institute of Far Seas Fisheries (NRIFSF) of Japan for the summer of 1994. Line transect methods will be employed. The proposed area of study includes the Sea of Japan, the east China Sea, the Yellow Sea and other areas in the western Pacific including the EEZ of some countries (see SC/46/Q 22). The primary target species include minke whale, Bryde’s whale, Dall’s porpoise, short-finned pilot whale and Mesoplodon spp. In addition to whale sightings, biopsy skin sampling will be
8. ADOPTION OF REPORT

The report was adopted as amended.

REFERENCES

Schweder, T., Host, G. and Øien, N. 1991a. A note on the bias in capture-recapture type estimates of g(0) due to the fact that whales are diving. Rep. int. Whal. Commn 41:397-3.

The results are shown in Table 1. One of the statistics used in SC/44/NAB12 involves the proportion of sightings with $y\geq 0.5$ n.miles. To fit this statistic, the truncation at 0.5 n.miles was waived. For comparison, the results of using the two-dimensional fit without truncation are also shown. All other fits have truncation at $y=0.5$ n.miles.

Since less than 4% of the sightings have $y\geq 0.5$ n.miles, the choice of statistics in SC/44/NAB12 is perhaps not too appropriate, but in this case it does not seem to affect the results.

With this data set the choice of fitting criterion does not seem to have much influence on the results.

### Bernoulli likelihood for different data sets and fitting criteria

Table 1 also shows the log-likelihood of the Bernoulli trials for the various fits to the product model using the Poisson approximation. The greatest log-likelihood, -98.87, is of course obtained when the Bernoulli trials alone are fit. The log-likelihood of the Bernoulli trials is reduced by 2.1 when the full survey data are fit: the difference is not significant ($p = 0.1$, df $= 2$). The mean $x$-value in the survey was 0.232 n.miles (SE 0.006) as against 0.254 (SE 0.012) in the experiment. The difference is not significant ($p = 0.1$) but may be sufficient account for the slight reduction in the $g(0)$ estimate compared with using the experimental data alone.
Operational procedures and data recording
The group noted that standard procedures for accurate data collection on line transect surveys should be followed on IO surveys. It concentrated, however, on procedures and data specific to IO surveys in general and IO surveys where the intended analysis involves estimation of two dimensional detection hazard functions in particular. The following recommendations were made in this regard.

Precise sighting times
Use of electronic recording devices is considered critical for obtaining precise sighting times, which are in turn critical for reliable duplicate identification.

As it is not always possible to record precise times, even when electronic recording devices are used, it is also important that there is a facility for recording the fact that a recorded time is not precise when this is the case.

Precise positions
Distance and angle estimation training should be conducted at the start and during surveys in the interests of obtaining as precise positional data as possible.

Estimates of the bias and precision of position estimates are essential for the evaluation of the duplicate status of sightings. Estimated distance and angle calibration experiments must be conducted to obtain these estimates. The observer making the estimates should be identified both in the calibration experiment data and in the survey data. Determination of the best design and conduct of these experiments requires further work. One factor to be considered is obtaining a sufficient range of combinations of angles and distances, bearing in mind typical distributions of angles and distances obtained during the survey.

Tracking procedures
Tracking teams should consist of more than one observer. Data records for each pod/animal track should contain some information on the level of certainty that the resightings are of the same pod/animal. (For example, if there was uncertainty whether or not a particular cue in the series of cues comprising the track was from the pod/animal being tracked, this should be indicated.)

There is a trade-off between obtaining complete tracks from both platforms for reliable duplicate identification on the one hand, and maximising g(0) by not diverting search effort into tracking sightings on the other hand. More work needs to be done before the nature of this trade-off is properly understood.

Whale heading
Information on the direction of movement of pods/whales at the time of sighting should be recorded for each detected cue.

Pod fragmentation
Pod fragmentation (when a previously detected pod of more than one animal splits into more than one pod/animal) and pod formation (when more than one previously detected pod/animal joins together to form a single, larger pod) should be explicitly recorded. Data forms should be designed to accommodate the recording of these data. The number of animals associated with a sighting/resighting should be recorded for every sighting/resighting. Explicit criteria for recording more than one cue as a single sighting/resighting should be specified and used in recording data. (For example, cues from different animals in a single pod should be recorded as a single sighting/resighting if they occurred within a specified small time period of each other.)

Additional data
Each sighting/resighting record in the data forms should have a field for comments, in which additional data (such as details of pod/animal behaviour) should be recorded.

Duplicate judgement reporting
The group recognised that there were many ways of making decisions on the duplicate status of sightings/resightings. It also noted that what may be a useful/reliable method of duplicate identification for one species/area/survey procedure, might be an inappropriate method for another species/area/survey procedure. It did not, therefore, address the question of how best to do duplicate classification, but instead restricted its attention to how the classification procedure and the associated data should be reported. The following recommendations were made in this regard.

Data from IO survey analyses which are or have been presented to the IWC should contain a full record of all sightings and resightings, together with the status of each of these. ‘Status’ in this context refers to the duplicate classification of each sighting/resighting (as Bernoulli trial with a ‘failure’, Bernoulli trial with a ‘success’, or no Bernoulli trial) as used in the analysis, as well as details of whether or not the sighting/resighting was excluded from the analysis altogether, or was excluded from a part of the analysis.

The criteria which were used for duplicate judgement should be specified as explicitly as possible, the object being to make each duplicate decision intelligible to someone not involved in the actual decision making.

Some descriptive data/statistics on the distribution of sightings/resightings with respect to the duplicate identification criteria should be presented. For example, if proximity in time was a primary criterion for duplicate identification, a histogram of times between resightings of the same pod/animals might usefully be presented.

It is required to classify each surfacing observed by a platform into one of the following categories (although C and D need not be distinguished from each other):

(A) surfacing not seen by platform 2 and whale also not seen previously by platform 2 (Bernoulli trial with a ‘failure’ outcome);
(B) surfacing seen by platform 2, whale not previously seen by platform 2 (Bernoulli trial with a ‘success’ outcome);
(C) surfacing not seen by platform 2, but whale previously seen by platform 2 (no Bernoulli trial);
(D) surfacing seen by platform 2, but whale also previously seen by platform 2 (no Bernoulli trial).

Some quantitative analysis of the errors in duplicate judgement and their effect on the estimate of g(0) should
be reported. For example, say a particular classification procedure yielded three classes of sightings: definite duplicates (because of simultaneous cues at similar positions, say), uncertainties (no simultaneous cues, but potentially a resighting of a pod/animal previously seen by the other platform) and definite non-duplicates (too far in space and time to be candidates for duplicates). Say also that the uncertainties were then examined further and allocated to either the duplicate or non-duplicate class. In this example an analysis of duplicate judgement error might reasonably consist of classifying all uncertainties as duplicates and estimating $g(0)$, then classifying all uncertainties as non-duplicates and estimating $g(0)$. This would provide a crude estimate of the magnitude of misclassification errors and their effect on the estimate of $g(0)$. Methods and procedures need to be developed for performing analyses of the errors in duplication judgement and their effects on estimates of $g(0)$.

Appendix 4

SWIMMING SPEEDS OF MINKE WHALES FEEDING OFF THE COAST OF NORTHERN NORWAY AND SPITSBERGEN

L. Walløe and A. Blix

Folkow and Blix from the University of Tromsø, Norway, record swimming speeds and dive sequences of minke whales as part of their work on minke whale energetics (Folkow and Blix, 1995). The investigations continue.

Three methods are being used to record swimming speed of minke whales with lengths of approximately 7–8m ('average-sized').

(1) Instantaneous swimming speeds are recorded by VEMCO (Type V4PS – 4HI – CPU – 500 PSI) sonic swim speed and dive depth transmitter, a V-11 hydrophone and a VR-60 ultrasonic receiver. The transmitter is towed 10m behind the whale.

(2) Surfacing positions of whales with VHF-transmitters are determined by triangulation and average horizontal speed between surfacings is calculated.

(3) On a few occasions horizontal swimming speed of whales with VHF-transmitters swimming on a constant course with a constant speed during night (sleeping?) has been estimated from the speed of the following boat.

Preliminary conclusions
(1) Range of speeds is 2–9 knots (1–4.5 ms$^{-1}$).
(2) Respiratory rate is approximately constant for swimming speeds below 7 knots ('basal metabolism'), and it increases rapidly with increasing speed above 7 knots.
(3) 'Sleeping' whales are swimming at about 2 knots.
(4) During day-time 'normal' swimming speeds of minke whales are 4–7 knots both during feeding and when travelling between feeding areas.

REFERENCE
Annex I

1. RECOMMENDATIONS ARISING FROM THE 1993/94 CRUISE REPORT (SC/46/SH3)

1. Biopsy sampling of cow-calf pairs
The Working Group felt that biopsy sampling of cow-calf pairs in the Antarctic, when most calves would be several months old and in the process of weaning, was unlikely to be unduly disruptive. For the purpose of mtDNA analysis, sampling of either animal would produce identical results, so sampling the calf was unnecessary. If in terms of national legislation a permit was required for such activities, then participants should inform the relevant authorities at the time of permit application.

Ideally the target for biopsy sampling should be the dorsal surface of the rear half of the animal. The Working Group recommended that both biopsy guns should be thoroughly tested before the cruise and the possibility of a back-up gun on each boat should be investigated.

Because biopsy samples are stored in a domestic refrigerator on board ship, it was suggested that they should be kept in a small polystyrene container therein to avoid contamination and inadvertent thawing.

2. IMMARSAT telephone and facsimile communication
As it facilitated communication regarding ice-edge data, the Working Group recommended that both vessels be equipped with IMMARSAT telephone and facsimile facilities, as last year.

3. No direct computer entry of effort and weather data
Although the Working Group referred this matter to the planning meeting, they noted that if the recommendation from the cruise was accepted then it would have implications for software design and this should be communicated to Joyce in good time.

4. Continued use of data entry software and computers used on last cruise
The Working Group agreed with this recommendation.

5-7.
Referred to planning meeting.

8. West-to-east direction of survey
In passing this recommendation on to the planning meeting, the Working Group believed that it should apply to all survey Areas, not just Area I.

9-10.
Referred to planning meeting.

11. Adoption of alternative sightings data form
In passing this recommendation on to the planning meeting, the Working Group suggested that the analyst should be involved in its discussion and that a copy should be sent to the Secretariat.

12. Sea surface temperature at each sighting
The Working Group agreed with the recommendation that this should be recorded and noted that it would involve a minimal increase in effort for participants.

13. Use of CTD equipment
After considerable discussion, the Working Group agreed in principle that further environmental monitoring could be potentially useful in improving the precision of population estimates, if there was prompt and thorough analysis of the data. On the 1993/94 cruise an experimental use of CTD was tried on one vessel and it was recommended that, as a minimum, a similar apparatus should be installed on the second vessel for the forthcoming cruise. In addition, Kato undertook to investigate the possibility of obtaining XBTs from his institute for experimental use on at least one vessel during the 1994/95 cruise.

The Working Group understood that Japanese scientists had expressed an interest in analysing the data.

14. Maintenance/replacement of SM2 computer
The Working Group understood that no new computer was required at this stage, but agreed to include an item for computer maintenance on the cruise budget.

15. Problems with computer software on SM2
The problems experienced on SM2 had not yet been documented, but the Working Group recommended that, once received, they should be referred to Joyce directly.

16. Notification of ships’ owners regarding modifications to vessels
The Working Group took note of the September 1994 deadline for such modifications. At this stage it was not envisaged that there would be any major modifications.

* Numbers refer to those in SC/46/SH3.
17. Omissions in usage notes
These omissions had not yet been documented but should be brought to the attention of the planning meeting.

18–20.
Referred to planning meeting.

2. NEED FOR SPECIALIST MEETING
The specialist meeting held in 1993 in conjunction with the planning meeting proved very successful in establishing contact between the Scientific Committee and the IDC cruise participants, and the presence of Ensior at this year's Scientific Committee meeting should further improve this communication. The Working Group did not believe, however, that such a specialist meeting should necessarily be an annual event, and as no major changes in survey design or experiments were planned for 1994/95, it did not consider there was a real need for such a meeting before the forthcoming cruise.

However, the Working Group considered that there was value in extending the duration of the normal planning meeting to allow some dedicated discussion between the analyst, Secretary, cruise leader and other participants before the more detailed logistic meeting with inter alia ship’s personnel. It was therefore recommended that the planning meeting should be extended from two to four days duration, and that funds should be provided to enable the analyst, Secretary and cruise leader to participate.

3. NUMBER AND IDENTITY OF VESSELS OFFERED AND LENGTH OF CRUISE
Kato announced that the Japanese Government was offering two vessels, Shonan Maru and Shonan Maru No. 2, and that the maximum duration of the cruise (from home-port to home-port) was 60 days. Both vessels must return to Japan by 30 March 1995. The Working Group expressed its appreciation for this generous offer.

4. CHOICE OF SURVEY AREA AND ITS SIZE
Each Area was reviewed using the information in Table 1. Although the priority in chronological order would be Area II (last surveyed in 1986/87), the complex ice-edge in this Area made a survey with two vessels very difficult. As the survey of Area III in 1992/93 had been incomplete, extending only from 0° to 40°E, a strong case could be made to complete this Area and continue into the western half of Area IV, so covering the extent of Prydz Bay in one season. This had been proposed at last year’s meeting but discounted because of a possible conflict between the cruise and the activities under JARPA in Area IV: this potential conflict would not be an issue in 1994/95 because JARPA activities would be carried out in Arca V.

The Working Group therefore recommended that the region to be surveyed in 1994/95 should be Area III east of 40°E, extending into Area IVW. If Cape Town and Fremantle were the home ports, 44 days would be available for the survey. As 40° of longitude had been covered in the 1993/94 cruise in 43 days, it was recommended that the target Area should extend as far as 80°E, with possible extension into the stratum 80°–90°E if time permitted. The question of whether the northern boundary should be 60° or 61°S was deferred to the planning meeting.

5. TIMING OF CRUISE, HOME PORT
Following the Scientific Committee’s recommendation of two years ago, it was proposed to delay the start of the cruise by about a week, with the objective being to improve the chances of the ice-edge receding before the survey commenced. The scheduled date of arrival in the first home port would then be 2 January 1995, with the date of return to the home port being 6 March 1995. The Working Group recommended this revision to the timing of the cruise, believing it would have little effect on the comparability of the results with those of previous cruises. However, there may be logistic difficulties for participants in travelling

Table 1
Best estimates of Southern Hemisphere minke whale population sizes. CM = closing mode estimate, PM = passing mode. 'Pseudo' is the 'pseudo-passing' estimate, i.e., the closing mode estimate divided by the closing mode/passing mode calibration factor 0.751 (CV 0.152). P is a inverse-variance-weighted average of CM and Pseudo estimates. Original figures are taken from Rep. int. Whal. Commn 44: 198.

*The IVW(70°-100°E) survey in 1984/85 has been omitted because PM in that survey did not include the IO and therefore is not comparable to subsequent PM results.
during the period between Christmas and New Year, but these could be minimised if early bookings were made.

Two options for home ports were considered, Fremantle-Fremantle and Cape Town-Fremantle. The former would result in 39 operational days and the latter 44 operational days. It was therefore recommended that the home ports be Cape Town (2-5 January) and Fremantle (6-10 March). This would also mean that the survey was carried out in an easterly direction and that Prydz Bay would be reached later in the cruise with better chances of the pack ice having receded.

6. SURVEY METHODOLOGY

Following its success in the 1993/94 cruise, the Working Group recommended the continuation of the use of alternating-pass-in-IO mode and closing mode, with a maximum duration of 100 n.miles in any one mode, throughout the cruise. Details of the track design should be left to the planning meeting, but it was suggested that consideration might have to be given at that meeting to adopting a separate track design to survey Prydz Bay.

There was discussion over the accuracy of angle and distance estimation procedures currently in use on the cruises, and it was suggested that possible alternative procedures such as that described in SC/46/G29 should be considered by the planning meeting.

7. EXPERIMENTS

The estimated distance and angle experiment should be carried out as last year.

Natural marking and biopsy work should be confined to blue, humpback and right whales, and should only be carried out in closing mode if possible. The advice of the bosun should be sought to decide when pursuit of a whale should be called off, but generally 30 minutes was considered the maximum chasing time allowed to obtain biopsy or photo-identification material.

Data on marine debris should continue to be collected as in previous cruises.

The deployment of CTD devices would take place when the boats were off effort, whereas XBTs could be deployed at any time. It was recommended that planning of the collection of the environmental data be left to the planning meeting.

Behavioural data would continue to be collected as before. The Working Group believed that (as in previous cruises) the entry of such data should have a lower priority so that in high density areas its recording might be discontinued. In this way there was almost no interference with the main duties of the participants. Although the Working Group appreciated that as yet no interest had been expressed in analysing the behavioural data, many participants felt positively disposed towards its collection so the Working Group did not recommend the discontinuation of the collection of behavioural data at this time.

7.1 Implications of experiments for cruise design

The Scientific Committee had requested the Working Group to provide some indication of the implications that the proposed experiments might have for the survey, so that the trade-offs in time lost versus information gained could be evaluated. This is given below.

<table>
<thead>
<tr>
<th>Experiment</th>
<th>Time lost</th>
</tr>
</thead>
<tbody>
<tr>
<td>Estimated distance and angle:</td>
<td>0.5 day (?)</td>
</tr>
<tr>
<td>Biopsy (based on last cruise):</td>
<td>1.67 hr/sample</td>
</tr>
<tr>
<td>Natural marking (based on last cruise):</td>
<td>0.25 hr/whale</td>
</tr>
<tr>
<td>Marine debris:</td>
<td>0</td>
</tr>
<tr>
<td>Deployment of CTD:</td>
<td>0</td>
</tr>
</tbody>
</table>

There was some interaction between the collection of biopsy and natural marking material, as both could be done simultaneously. Hence the time lost for these experiments was not a simple addition of the two values given. The values for the biopsy samples was also inflated by three trials when the gun malfunctioned; omitting these would result in a figure of 1.17 hr/sample.

The time taken for completion of these experiments had to be balanced against the value of the material, particularly the biopsies, where a limited sample size could provide valuable information on stock identity. Consideration also had to be given to the otherwise general inaccessibility of these populations to researchers. The matter was referred to the Scientific Committee for guidance.

8. POSSIBLE PARTICIPANTS

A total of six researchers is required for the cruise. Japan will supply two researchers, including Shimada. Ensor tentatively agreed to act as cruise leader. Other researchers will be selected after completing their applications through the Secretariat. All applications, including a CV, indications of previous appropriate experience and including the names of two referees (preferably from the Scientific Committee), should be at the Secretariat by 1 September 1994 and the selection process will be undertaken at the planning meeting.

9. LOGISTIC PLANNING

The extended planning meeting proposed under Item 2 above will last 4 days, possibly in mid-late October, and will be held in Tokyo. Participants will include the cruise leader, the analyst, the Secretary of the IWC, Japanese researchers and relevant ships’ personnel. The IWC Secretariat will be responsible for circulation of the draft and final reports.

The home port organisers will be Best (Cape Town) and Bannister (Fremantle). Kato will act as organiser for the Tokyo planning meeting.

The Secretariat will write to the appropriate South African and Australian authorities for permission to undertake closing mode surveys in national EEZs, port access and permission to bring biopsied cetacean material into port.

10. DISPOSITION OF BIOPSY SPECIMENS AND INDIVIDUAL IDENTIFICATION PHOTOGRAPHS

The question of the disposition of the IDCR biopsy specimens was handled in another Working Group of the Southern Hemisphere Baleen Whale sub-committee. The Secretary announced that all available photo-identification material from IDCR cruises was held in the Secretariat.

11. INTERACTION WITH BLUE WHALE RESEARCH PROGRAMME

As this matter was still to be discussed in the Plenary, the Working Group could make no useful comments.

12. CRUISE REPORT FORMAT

Ensor stated that the guidelines given last year had proved useful and that there had been no problems with preparing the cruise report.

13. BUDGET

A preliminary budget was prepared for the cruise (Table 2). This was substantially less than that requested last year (£68,755), due mainly to the reduction in the number of participants (7 to 6) and the decision not to hold a specialist meeting this year.
Annex J

Report of the Research Proposals Working Group

INTRODUCTION

Kato was elected Chairman and Cawthorn agreed to act as Rapporteur.

The Working Group reviewed eight research proposals submitted to the meeting (SC/46/RP1-8). Each was considered on the basis of: (i) its relevance to the objectives of the Scientific Committee and the work of the Commission; (ii) the scientific quality of the project; (iii) its chances of success; (iv) the competence of the proposers; (v) the feasibility of the work schedule and (vi) the reasonableness of the budget. As is customary, proposers and those associated with proposals were absent during discussion of their projects and subsequent ranking.

The Working Group agreed that the Scientific Committee should be asked to consider developing more specific guidelines concerning attendance of proposers, associates and cooperators during Research Proposal discussions.

After consideration of the proposals, reviewer’s comments and the proposer’s responses, the Working Group decided that seven of the proposals satisfactorily fulfilled most of the above criteria.

PROPOSALS

(1) Evolution, genetic structure and molecular ecology of the North Atlantic fin whale, Balaenoptera physalus – SC/46/RP1. Principal proposer: Martine Bérubé, University of Copenhagen, Denmark. Amount requested: US$22,000

Strong support for this proposal was expressed by the Working Group. It agreed this proposal is well structured and meets the established criteria.

An extensive genetic survey of fin whale populations from seven locations across the North Atlantic and from one location in the North Pacific is proposed. Comparison of variation among these putative populations should provide important information on the genetic structure of North Atlantic fin whale populations.

Ranking: HIGH

(2) Photo-ID and behaviour study of humpback whales in New Caledonia (South Pacific) – SC/46/RP2. Principal proposer: Claire Garrigue, Orstrom, New Caledonia. Amount requested: US$10,500

This proposal met the required criteria as the proponents had concurred with the reviewer’s comments to place more emphasis on biopsy sampling. The Working Group was advised that there has been a pilot study in the survey area and the chances of collecting biopsies, sightings and whale songs are good. It was generally agreed that, where possible, all biopsies should be accompanied by photo-identification. The project will make a significant contribution to current knowledge of the east Australian, Tonga – New Zealand humpback stock.

Ranking: MEDIUM

(3) Genetic analysis sub-project – Years of the North Atlantic Humpback Whale – SC/46/RP3. Principal proposer: Per Palbsbøll, University of Copenhagen, Denmark. Amount requested: €10,000

This project is a subset of a large project (YONAH). It meets all the required criteria. The proposal was strongly supported by the Working Group. The genetic analyses proposed will complete a significant portion of the YONAH work which has Scientific Committee input and is relevant to the aims of the IWC. The entire project provides genetic information coupled with photo-identification and other aspects giving it an excellent chance of success.

Ranking: HIGH

(4) Histo-pathology of kidney and liver tissues of the pilot whales off the Faroe Islands, related with high levels of cadmium and mercury – SC/46/RP4. Principal proposer: Florence Caurant, Université Nantes, France. Amount requested: £26,950

This project is well designed and presented and meets all required criteria. Those involved have considerable experience having participated in a larger pilot whale project.

The Working Group agreed that this was a well designed and presented proposal which outlines an attempt not only to examine pollutant loads but also to answer important questions regarding the long-term toxicological effects of pollutants on Cetacea. The Working Group endorsed the project in principle and agreed it should be reviewed at the forthcoming pollution workshop, (see Plenary Item 7) for consideration for funding.

Ranking: (MEDIUM) referred to pollution workshop.

This proposal is well designed and meets most of the established criteria. Some concerns were noted in the Working Group regarding sample size and heterogeneity problems. Members believed that unless the sample size could be expanded, particularly in certain regions, important aims of the project are unlikely to be met. The Working Group also noted that some of the work of YONAH and this project overlap. The Working Group
recommends that the proposer be asked to reassess the number of samples available in relation to the number required and that the proposal be resubmitted next year.

Ranking: (MEDIUM) to be considered next year.

(6) Survey of humpback whale breeding grounds in Southern Madagascar and their relationship to other breeding grounds in the southwest Indian Ocean – SC/46/RP6. Principal proposer: Peter Best, Mammal Research Institute, Cape Town, South Africa. Amount requested: £7,520

This proposal is well designed and meets the required criteria. The project will provide new information on humpback whales in a poorly known area of the IWC’s Indian Ocean Whale Sanctuary. Strong support for the primary proposal was expressed by the Working Group. It was advised that 16 of the 20 contributing participants have already confirmed their participation thus making it highly likely that the primary proposal can go ahead. During discussion of a reviewer’s comments regarding acoustics, the Working Group was advised that a simple two element acoustic array could be easily deployed from the vessel proposed and would meet the reviewer’s concerns.

The Working Group agreed that it should endorse the primary funding proposal.

Ranking: HIGH

(7) Improving information resources in the IWC/IDCR program: A proposal – SC/46/RP7. Principal proposer: Gerald Joyce, Seattle, WA, USA. Amount requested: US$11,000

This proposal is comprehensive and meets most of the established criteria. This proposal to produce an instructional manual for IDCR and software for data entry was endorsed by the IDCR cruise leader and would assist in facilitating data recording and entry on IDCR cruises. Some concerns on some aspects of this proposal were made by one of the reviewers and these require further consideration. The Working Group was advised that some chapters in the IWC Special Issue on the IDCR cruises will be relevant to this proposal.

The Working Group agreed that this proposal should be deferred to the October IDCR planning meeting for further review. These comments should be conveyed to the proposer who should be encouraged to submit a revised proposal submitted next year.

(8) Satellite-monitored radio tracking of tagged gray whales, right whales and bowhead whales in the Sea of Okhotsk – SC/46/RP8. Principal proposer: Bruce Mate, Oregon State University, Corvallis, OR, USA. Amount requested: US$50,000

This proposal had been developed during discussions on bowhead whales at this meeting. Although the subject matter was of interest to the Committee, the proposal was not presented in time for the normal review and referee process, and the cost of capital equipment was high. The Working Group agreed that the proposal should not be funded this year.

SUMMARY

The Working Group therefore recommends as highest priority: SC/46/RP1 - £15,000; SC/46/RP3 - £10,000; SC/46/RP6 - £7,520.

The Working Group recommends as medium priority SC/46/RP2, provided the Committee’s recommendations are taken into account.

The Working Group recommends that SC/46/RP5 be resubmitted next year if the problem of sufficient samples is solved. Two proposals were referred for further consideration. SC/46/RP4 to the pollution workshop and SC/46/RP7 to the IDCR planning meeting.
Annex K
Matters Arising on the Effects of Environmental Change on Cetaceans

ANNEX K1. ISSUES RELATING TO CHEMICAL POLLUTION TO BE CONSIDERED AT THE INTERSESSIONAL WORKSHOP ON THE EFFECTS OF ENVIRONMENTAL CHANGE ON CETACEAN POPULATIONS

Members: Anderson, Brown (K), Fujise, Nomura, Reijnders (Chairman), Simmonds, Walloe

Objective: To make a full multi-disciplinary assessment of the significance of chemical contamination for cetaceans and thus facilitate the work of the IWC.

(A) Agenda items

1. Direct effects
   1.1 Lethal impacts
   1.2 Sub-lethal (‘disease’)
   1.3 Reproduction and early development
   1.4 Immune system
   1.5 Cancer induction and mutagenic impacts
   1.6 Behaviour

2. Indirect effects (related to cetacean food chain)
   2.1 Lethal impacts in prey
   2.2 DNA damage to prey
   2.3 Other toxic impacts
   2.4 Shifts in plankton composition

3. Research implications (i.e. what needs to be done to further elucidate threats)
   3.1 Consideration of synergistic/cumulative effects
   3.2 Is present monitoring adequate?
   3.3 Can the relationship between toxic loadings and impacts be further clarified?
   3.4 Future trends in global contamination
   3.5 Identification of new/future areas of concern

(B) Identification of necessary areas of expertise

1. Toxicology (including consideration of the state of the art of interlaboratory calibration).
   1.1 Halogenated hydrocarbons (including ‘exotics’ – i.e. compounds not routinely assessed)
   1.2 Metals
   1.3 Methyl sulphonates
   1.4 Non-aromatic and polynuclear aromatic hydrocarbons

2. Cetacean/Marine mammal toxicokinetics

3. Cetacean/Marine mammal endocrinology

4. Cetacean/Marine mammal reproductive physiology

5. Cetacean pathology

6. Cetacean biology/veterinary investigations/epizootic investigations

* In some topic areas, data from cetaceans is limited and it may be appropriate, with all necessary caution, to consider data concerning or derived from other animal species.

7. Epidemiology

8. Biomarkers (i.e. suites of biochemical and/or physiological indicators of exposure to contaminants)

9. Contaminant trends

Notes
To be comprehensive and fully effective, the proposed workshop on chemical pollution will require detailed forward planning. Therefore, it is recommended that as soon as the workshop is sanctioned an organising committee is established by the IWC.

One major aim of the meeting must be to determine if the relationship between pollution loadings in cetaceans and impacts can be further clarified.

All participants should be made aware that: (i) they are required to explain what the outcome of their particular discipline means for future research efforts; (ii) the meeting will be reporting to the Scientific Committee of the IWC.

It is recommended that the chemical pollution workshop occurs at a date before the next annual IWC Scientific Committee meeting and which would also allow adequate time for the results of the Workshop to be fully considered by Scientific Committee members.

Workshop participants should be made aware of the information concerning environmental threats which has previously been made available to the IWC Scientific Committee.

Suggested participants
Organisations: ICES, IOC, IMO, UNEP.

Suggested experts (i.e. names proposed by Working Group participants to date) and Agenda Items most relevant to their expertise:

- Aguilar (1,2,6)
- Baker (5)
- Beland (1,2,6)
- Bergman (5,6)
- Boer (1,9)
- Boon (2)
- Boyd (3,4)
- Brouwer (2,8)
- Colborn (3)
- Fossi (8)
- Gaskin (1,6)
- Hartmann (5)
- Kennedy (6,7)
- Law (1)
- Norstrom (1,2)
- Martinneau (1,2,5,6)
- Olsson (1,2,6,9)
- Osterhaus (6,7)
- Reijnders (1,2,3,4)
- Skaare (1)
- Simmonds (1,6)
- Tanabe (1,2,9)
- Tatsukawa (1,2,9)
ANNEX K2. IS CLIMATE CHANGE A CONCERN FOR THE MANAGEMENT OF WHALE POPULATIONS?

Workshop objectives
The IWC should be provided with the best available advice on the question: relative to other issues related to the management of whales, are the potential ecological effects of climate change and ozone depletion of concern?

Potential topics to be considered
(I) Summary of trends and predictions for the marine environment related to climate change and ozone depletion.
   (a) Physical environment (e.g. temperature profile, circulation patterns).
   (b) Primary production (e.g. species composition, productivity).
   (c) Secondary production (direct and indirect effects).
(II) Review of trophic couplings between cetaceans and autotrophs in marine ecosystems.
(III) Evaluation of possible effects of climate change and ozone depletion relative to other issues related to the management of whaling and the conservation of whales.

(IV) Identification of alternative management strategies to account for the potential effects of environmental change on whale populations.
(V) Identification of future work by the Scientific Committee.
(VI) Synthesis – What research on the effects of environmental changes on whales is needed to provide advice to the Commission regarding the appropriate response strategies to these new challenges?

Notes
Format: 2-3 day symposium followed by 2-4 day workshop.

Relevant organisations: IWC Scientific Committee and Commission members; IPCC of UN; CCAMLR Scientific Committee members; ICSU – GLOBEC; SCAR; SCOR; UNEP; IOC; WMO.

Schedule: October 1995 (information being summarised in a report being prepared by the IPCC is crucial to the success of this workshop. Report availability is mid-1995).

---

* Contribution is possible.
1 Contribution may be difficult.
? Contribution is impossible.
1 Holm-Hansen et al. (1993) reported no substantial effect on primary production by UV-radiation and consequently negligible effects on whales.
2 Melting ice might have different effects on ice-dependent species (e.g. Adelie penguins and Crabbeater seals) and ice-independent species (e.g. Chinstrap penguins and Antarctic fur seals), with the former species increasing while the latter decreasing.
3 Indirect effects (accumulation through prey organisms) are far important than direct effects.
Conclusions

(1) The effects on whales by global environmental changes including pollution appear first as changes in health, nutrition, growth, reproduction and mortality (e.g. see Lockyer, 1987), and trends in abundance are usually noticeable too late.

(2) We suggest that data from lethal surveys (or under the RMS) are more appropriate to monitor the effects.

Annex L

1. OPENING REMARKS

Kato welcomed the participants1 (listed in Appendix 1) to the intersessional meeting hosted by Japan.

Gambell explained that after discussions between the Convener of the Steering Group, the Acting Chairman of the Scientific Committee and the Secretary of the Commission, it had been agreed that an intersessional meeting of the Steering Group as proposed by the Government of Japan should be held in Tokyo immediately after the IDCR Southern Hemisphere Minke Whale Assessment Cruise Planning Meeting.

This was on the understanding that any report or conclusions reached by the Steering Group would be distributed to all Steering Group members before submission to the next meeting of the Scientific Committee.

A statement on behalf of the Commissioner for Japan, Mr Shima, was read by Komatsu. He referred to the large catches of blue whales taken by many nations from the Southern Hemisphere in the past and the apparent failure of the stocks to recover. Japan believed that a positive approach should be taken now towards rebuilding the numbers of this species.

2. ELECTION OF CHAIRMAN, APPOINTMENT OF RAPPORTEURS; ARRANGEMENTS FOR MEETING

Bannister was elected Chairman and Gambell appointed Rapporteur. The practical arrangements for the meeting were outlined.

3. TERMS OF REFERENCE

At its 1993 meeting the Scientific Committee identified three possible objectives for a research programme to help determine the reasons for the low abundance estimates for Southern Hemisphere ‘true’ blue whales and their apparent lack of recovery from commercial exploitation. These were to:

(1) refine estimates of abundance in feeding areas;
(2) evaluate the potential for competition for krill between blue whales, other baleen whales and other high-level predators;
(3) determine the distribution of breeding areas and whether animals that utilise a particular low-latitude breeding area utilise particular feeding areas in the Southern Ocean.

The present meeting reviewed the discussion recorded in the Report of the Scientific Committee (Rep. int. Whal. Commn 44:52–3, Item 8.3) leading to these objectives, and the wider context of available information and research needs.

The Steering Group was established by the Scientific Committee to:

(a) identify a set of objectives for research on Southern Hemisphere blue whales;
(b) identify individuals who could contribute to the development of a research proposal at next year’s meeting.

The Scientific Committee suggested that at the 1994 meeting a Working Group could then be convened to develop a revised research programme proposal, including: an outline of objectives; methodology; the chances of success; and short- and long-term financial implications.

Should the Commission approve the revised proposal in principle and be willing to make funds available, a detailed programme should be developed at a subsequent meeting. At its 45th Annual Meeting the Commission approved a Resolution (IWC/45/38) which:

(1) adopted the recommendation of the Scientific Committee to establish an intersessional steering group to identify objectives for research on Southern Hemisphere blue whales and financial implications;
(2) decided that the research programme for large whales in the southern oceans should be afforded high priority in the Scientific Committee’s activities next year; and
(3) decided further to examine mechanisms to finance implementation of this research programme.

4. ADOPTION OF AGENDA

A draft agenda circulated by Bannister after consultation with some members of the Steering Group was re-ordered and amended in light of detailed discussion on the terms of reference. Comments by two members unable to be present, Kock and Holt, were taken into account. The agenda as adopted is shown in Appendix 2.

5. RELEVANT DOCUMENTS

Working Papers for the meeting are listed in Appendix 3. Documents 4, 6, 8, 11 and 13 are to be treated as confidential until this restriction is lifted. Similarly, the report of the meeting is for use only by the members of the Steering Group before submission to the Scientific Committee.

1 All members of the Steering Group as nominated in Kyoto were invited to participate in the meeting. Those able to attend are indicated in Appendix 1.
6. OBJECTIVES, INCLUDING RESEARCH METHODOLOGY AND FEASIBILITY

The three possible objectives suggested by the Scientific Committee were considered.

(a) To refine estimates of abundance in feeding areas

This objective can be related to the Scientific Committee’s Comprehensive Assessment of Whale Stocks, particularly since such estimates are needed to establish rates of change over time. Meeting this objective should include a review of IDCR and similar sightings data, as well as correlation with environmental/hydrographic data and examination of historical records. Japanese scientists believed that new research is needed because the existing data and analyses are inadequate to provide sufficiently reliable abundance estimates.

The number of primary sightings of blue whales during January-February on the IDCR cruises 1978/79-1990/91 was only 39 schools (composed of about 60 whales), with very high coefficients of variation for the abundance estimates in each Area. These months have been shown to be the peak of blue whale abundance in the Antarctic (SC/45/SHB/a4). This gives estimates of abundance of about 450 (CV approximately 0.5) for part of the area (two-thirds and 80% in the two circumpolar sets of surveys respectively) south of 60°S. Extrapolation over the unsurveyed areas using 1965/66-1977/78 Japanese sightings vessel (JSV) data has been attempted, but it is confounded by the mixing of true and pygmy blue whales. Assuming that north of 50°S at that time of year the animals are pygmy blue whales, the sightings correspond to total abundance estimates of some 700 true blue whales and 5,000 pygmy blue whales (SC/43/M/34).

There is poor survey coverage in the JSV data for middle latitudes in the Pacific and (to a lesser extent) Atlantic Ocean regions, leading to imprecision in the extrapolation process. However, the blue whale abundance as currently estimated is clearly very low. This conclusion would not be altered qualitatively even if adjustments could be made for the absence of JSV coverage in some areas and the negative bias introduced by assuming g(0)=1.

Any improvement in estimates could be achieved only by much greater sightings effort. An alternative is to understand better the distribution on the feeding grounds (and elsewhere) before refining abundance estimates. To this end, efforts should be concentrated firstly on analysing existing data, including biological and physical characteristics of ‘preferred’ blue whale habitat, in order to direct future fieldwork (including abundance estimation, where to go to place satellite tracking equipment, do biopsy sampling, etc.). It was suggested that sightings surveys, coupled with acoustic surveys, in areas such as the Solomon Islands might provide valuable information on the possible location of the breeding grounds (WP6).

Identification of areas of sufficiently high aggregations of blue whales in low latitudes was thus seen as a key issue.

It was agreed that the primary reason to refine estimates of abundance in feeding areas is to improve our ability to detect trends. Two promising topics for this refinement arc:

1. improved differentiation of true blue whales and pygmy blue whales (especially in the allocation of sightings by locality from IDCR and JSV cruises);
2. selection of a sub area of the Southern Ocean for close scrutiny. This selection should be based on improved stock structure information.

Important points raised in discussion included the need for accurate identification of true blue whales, as distinct from pygmy blue whales. Without such information, new analyses of data would have to be restricted to south of 50°S to assess true blue whales alone. With such information, it should be possible to refine the latitude at which the distinction should be made and to apply that latitude to the analysis of both old and new data.

This is one facet of the wider question of stock structure, as the total abundance estimate includes as many separate populations of blue whales as exist in the Southern Hemisphere. Biopsy sampling for genetic studies is, therefore, relevant either separately from or together with the sightings programme. Acoustic techniques might also be used to distinguish between true and pygmy blue whales, as well as between different blue whale populations.

Feasibility studies must be carried out to test the utility of any of these techniques before they are implemented on a large scale.

Refinement of the estimates using the IDCR surveys would include better combination of the IDCR research vessel data with those from JSV and special permit vessel sightings south of 50°S. This would be achieved using linear models once all available data have been stored in the database currently being developed by the IWC Secretariat (Rep. int. Whal. Commn 43: 111-112). Improvements may also be possible if better g(0) estimates become available.

Improvement of the CVs associated with the present circumpolar IDCR abundance estimates for blue whales to values of about 0.2 (typical of estimates for minke whales by Area) would require perhaps four times as much effort to be devoted in the Antarctic south of 60°S. It was noted (Rep. int. Whal. Commn 44:100, Item 8.1) that the present cycle of 6-year circumpolar IDCR cruises will take a further 25 years to give growth rate estimates for species of low abundance (such as true blue whales) with standard errors of less than 2% (but 95% confidence limits ±1 to ±7%).

These considerations suggest that it might be more practical to limit the extent of survey effort to allow more frequent surveys of a smaller area or population unit, if such can be identified. This would allow a specified precision in the estimate of the population increase within that area to be achieved within a shorter time frame.

Breeding areas are not though to be suitable for estimating abundance in general, although particular localities may be appropriate for specific studies, e.g. cow/calf ratios. The difficulties of combining line transect surveys with other studies were recognised. Research cruises in the lower latitudes are probably better focussed on stock identification and structure. Because of the greater area of ocean in middle latitudes relative to higher latitudes which could not be covered completely at an adequate level of survey intensity, it would first be necessary to determine the distribution and extent of such breeding areas and their relation to feeding grounds before they could be surveyed for abundance estimation purposes so that the areal extent of surveys could be limited to achieve reasonable levels of precision.

(b) To determine the distribution of breeding areas and whether animals that utilise a particular low latitude breeding area utilise particular feeding areas in the Southern Ocean

It was agreed that discussion of this possible objective flowed naturally from the previous one. Detailed techniques and methodologies should be considered at the
next full meeting of the Scientific Committee. The difficulties of even finding blue whales given the very low sightings rate in high latitudes (39 schools seen by 2-3 vessels over 12 years) suggest that acoustic or other searching techniques will be necessary over and above purely visual sightings. Emphasis was placed on the need to:

(1) discover the location and extent of the breeding grounds;
(2) determine the structure of the stocks; and
(3) relate the breeding and feeding grounds.

Techniques highlighted to be considered in detail include satellite tracking of movements; biopsy sampling for linkages; acoustics for locating the breeding grounds and distinguishing the true and pygmy forms; photo-identification.

All such procedures will need considerable development before their full potential can be realised.

Possible sources of existing data which could be re-examined to help identify the breeding areas include the merchant vessel sightings collected by the UK, Netherlands and others, e.g. New Zealand. While they can produce useful information, these data have to be treated with caution because of difficulties in identification of species and quantification of effort.

Historical catch and sightings records from low latitudes are mainly from coastal whaling operations and do not give good coverage in oceanic waters. The breeding stocks may extend beyond the range of the coastal observations, but they could be correlated with hydrographic conditions such as upwelling and such features could be investigated as potential areas of concentration.

The peak of the seasonal occupation of putative breeding areas also needs to be considered when planning surveys.

The meeting took note of the proposal by Japan to search for blue whales in Melanesian waters and around the Solomon Islands using the two vessels in transit to the 1993/94 IDCR Antarctic minke whale survey (WP11). This could serve as a useful pilot study for low latitude surveys, although the meeting noted that the timing (November-December) is not in the breeding season.

**Biopsy sampling**

It appears that only three biopsy samples from blue whales have been collected in the Southern Hemisphere on IDCR cruises. Pygmy blue whale samples may have been obtained from some Australian strandings and analysis of such samples would be useful for assessing genetic differences between the two sub-species and evaluating the usefulness of such sampling in the future.

Any future sampling programme for true blue whales also could be combined with a radio satellite tracking programme.

Existing collections of blue whale baleen plates may provide useful material for genetic analyses. An inventory of available tissue samples, e.g. in museums and other collections which may be suitable for analysis, should be compiled.

**Satellite tagging**

Tagging for at least 6 months or preferably 12 months to cover the migration period is required for blue whales. A Japanese initiative (WP8), with the potential for international cooperation, was welcomed as an important development to be encouraged and supported. The multi-disciplinary character of this programme was recognised.

A review and re-analysis of the historical Discovery marking data would be useful to see what new insights they might provide on migrations and linkages.

**Photo-ID**

This technique has potential for individual stock identification and other studies. The existing material should be reviewed and its value assessed.

**Acoustics**

It is believed that blue whales are able to produce sounds of 200 decibels at 20Hz. It is further assumed that the whales indulge in such vocalisation prior to and during the breeding season. It follows that acoustics may aid in the identification of blue whale breeding grounds and possibly also in separating true blue whales from pygmy blue whales.

(c) To evaluate the potential for competition for krill between blue whales, other baleen whales and other high-level predators

Direct estimates of krill abundance are only available for a small part of the Antarctic Ocean, mainly from the FIBEX programme around the Antarctic Peninsula. Additional estimates will come only over a long time-scale. Quantitative studies of species interactions are at an early stage and have yet to produce useful results. The potential for competition for krill may be evaluated through modelling, using both historical and current data. It was noted that animals feeding in the same area on the same food may or may not be in competition with one another. Four possible approaches to resolving the issue were discussed:

(i) comparison of consumption by predators with krill production;
(ii) investigation of possible response of some species to a ‘krill’ surplus;
(iii) direct observation of ‘competition’ between individual animals (including comparison of diet data: present/historic);
(iv) development of multispecies models (possibly as an extension of (i)).

No conclusion was reached as a result of this exchange of views and preferences.

7. RELATIONSHIP BETWEEN THE PROPOSED RESEARCH AND THE CURRENT COMPREHENSIVE ASSESSMENT OF SOUTHERN HEMISPHERE BALEEN WHALES

This matter was addressed in the discussion of Agenda Item 6, objective (a).

The Scientific Committee identified the objective of the original Japanese proposal (SC/45/SB/H22) as a plan of research to help determine the reasons for the low abundance estimates for true blue whales and their apparent lack of recovery. The title of that proposal and comments by Japanese scientists at the present meeting referred to an international action plan for recovery of large whales – towards recovery of blue whales.

The meeting noted, however, that the Scientific Committee Report and Resolution IWC/45/38 do not refer to such an action plan to assist blue whale recovery and that the Steering Group2 had been asked only to identify

2 The Steering Group did not have an opportunity to review the following text under this agenda item.
objectives, financial implications and possible contributors. The Scientific Committee had suggested three possible objectives which this meeting used to aid its discussion. Discussions (see Item 6) had focussed upon a natural sequence of possible work:

(i) improving knowledge of stock structure;
(ii) refining abundance estimates and estimating trends;
(iii) investigating 'competition'.

It was noted that items (i) and (ii) deal essentially with blue whales and as such relate to the Comprehensive Assessment only in so much as decisions regarding priority species would need to be taken. If, however, item (iii) is also emphasised, then the relationship to the Comprehensive Assessment is more complicated as a complex multispecies programme would need to be mounted which would involve cooperative work with other organisations such as CCAMLR.

8. POTENTIAL RELATIONSHIP TO THE PROPOSED WORKSHOP WITH CCAMLR ON FEEDING ECOLOGY

Discussions in this meeting reinforced the need for close cooperation and coordination of activities with organisations such as CCAMLR and SCAR. It was noted also that there will be a joint ICES/NAFO symposium next year.

It was agreed to recommend that, should the Scientific Committee wish to develop the approaches identified in Item 6 objective (c), an approach should be made to CCAMLR with a proposal for a more specific agenda as a follow-on to previous contacts which have been made concerning joint activities.

9. POSSIBLE BUDGET AND FINANCIAL IMPLICATIONS

Topics to achieve objective (b) and which the Steering Group identified are:

(1) satellite tag development;
(2) 'in transit' research cruises;
(3) biopsy sampling – (a) analysis of existing data; (b) collection of further data;
(4) Discovery marks analysis;
(5) surveys to find wintering whales (including acoustics as a special technique);
(6) historic catch data analysis;
(7) analysis of environmental data and other Discovery data;
(8) analysis of historic sighting rate data;
(9) satellite tag deployment;
(10) photo-ID studies.

A number of projects are already in hand (development of satellite tags, ‘in transit’ surveys of breeding grounds, biopsy work). These are important and should be continued. The analysis of historical data (Discovery marks, catches, environmental and other Discovery data, sightings rates) should also be undertaken in order to improve the efficiency of future surveying, both on feeding grounds to assess abundance and to locate breeding grounds and their linkages to feeding areas. Satellite tag deployment, further biopsy and photo-ID work could then take place. Whilst analysis of historical data is undertaken, however, any surveys to locate breeding grounds and supply new data should be regarded positively. Opportunities to conduct such work ‘in transit’ should certainly be taken. Table 1 summarises a possible sequence of work.

The question of costs was briefly considered. The meeting noted that the considerable cost of ship time requires that information on the best timing and location for research cruises is obtained beforehand.

The results from achieving objective (b) and other considerations (e.g. logistics) should lead to identification of reduced areas to achieve objective (a) – perhaps using two vessels for two months a year, i.e. in the region of the cost of a current IDCR-type exercise.

A multispecies study, as identified in agenda Item 7, would be appropriate to achieve objective (c). It would, however, be a relatively complex undertaking.

The Steering Group in the time available was unable to consider this or other relevant topics under this item in further detail.

10. ANY OTHER BUSINESS

Japanese financial contribution

The Steering Group was informed that the Japanese Ministry of Agriculture has requested ¥40 million for the financial year commencing 1 April 1994 to send out a research vessel and carry out data analysies, including ¥3 million for development of the satellite tracking system. This budget is subject to approval by the Cabinet and Diet. The use of these funds may be adjusted in the light of the priorities developed by the IWC.

Priority of blue whale research
This question was raised relative to the present emphasis by the Scientific Committee on its Comprehensive Assessment programme and humpback studies. The matter was referred to the Scientific Committee, bearing in mind the Commission's decision to afford the research programme for large baleen whales in the Southern Ocean high priority in the Committee's activities next year.

Stock identity
This topic arose in a number of discussions throughout the meeting. Because of its importance to so much of the total programme under review and development, the Steering Group considered whether the item should be clearly identified by the Scientific Committee as a fourth objective in its own right.

The conclusion was that in the present meeting, discussion of stock identity and population structure had been essentially subsumed in objective (b), although the Steering Group believes that the Scientific Committee might wish to consider whether the item should be a fourth objective in its own right.

11. ADOPTION OF REPORT
In the time available and given that not all Steering Group members could be present, it was agreed that no specific conclusions or recommendations should be formulated by the meeting.

In adopting the Report, comments provided by Butterworth on the draft available on the final day were taken into account up to the end of agenda Item 6(a).

The remainder of the draft Report up to and including Item 10 was amended and approved by the meeting.

Given the composition of the meeting and in the context of the Secretary's Circular Communication of 5 August 1993, the Report and Working Papers were circulated to all participants and other Steering Group members as soon as possible. Responses were sent to the Convenor and submitted together with the Report for consideration by the Scientific Committee.

Thanks to the Japanese hosts for their support and hospitality were given on behalf of the overseas participants by the Chairman. The Chairman in turn was thanked for his leadership of the meeting. Appreciation was also expressed to the Rapporteur, the interpreters and the Secretariat for their hard work.

Matters Arising out of the Discussion of Blue Whales

ANNEX M1. APPLICATION OF US NAVY UNDERWATER HYDROPHONE ARRAYS FOR SCIENTIFIC RESEARCH ON WHALES.

C.W. Clark

Background and overview
In the fall of 1992, the United States Navy initiated the Whales '93 program. This program used existing passive hydrophone arrays to study the acoustic behaviours and seasonal distributions of whales in the North Atlantic Ocean.

Whales '93 was an extraordinarily successful program (Clark et al., 1993). On the first weekend (6 November, 1992) that the Navy analysts officially began to systematically document the occurrence of the whales, there were so many acoustic detections (an acoustic detection is the equivalent of a visual sighting) that the database system overloaded and crashed. In the first six weeks of the program there were more whale sounds detected than whales counted in all years for all the gray whale census and bowhead whale census efforts combined! More acoustic material was acquired in the first year than exists in all the cetacean sound libraries combined.

This relatively small, conscious effort to apply passive acoustic systems to basic research and environmental monitoring yielded an unprecedented amount of information about the ocean-scale, seasonal distributions, movements and behaviour for three species of whales (blue, fin and minke whales).

The initial results do not indicate that there are more whales, only that the application of ocean-scale listening systems provides the unique opportunity to learn about their natural behaviours, seasonal movements and population distributions on a scale that was once thought beyond possibility.

The results from the Whales '93 program support the conclusion that a large-scale survey of blue, fin and minke whales can be successfully conducted using a combination of passive acoustic array systems (IUSS and others), traditional visual survey methods (e.g. the pending North Atlantic Sighting Survey, SC/46/NA10) and biopsy sampling methods.

Whales '93 results
Passive hydrophone arrays are part of the US Navy's Integrated Undersea Surveillance System (IUSS). The IUSS consists of mobile towed hydrophone arrays, referred to as SURTASS (Surveillance Towed Array Sensor System) and bottom-mounted, fixed hydrophone arrays, referred to as SOSUS (Sound Surveillance System). A network of these arrays has been installed and operated over the past 30 years as a means of acoustically detecting and tracking enemy submarines throughout the North Atlantic and North Pacific oceans. These acoustic listening systems are particularly well adapted for the low-frequency (10-100Hz) calls of baleen whales.

Some of the primary questions addressed in the Whales '93 program were: (1) How many different species of whale can be reliably detected? (2) Can individual whales be tracked? (3) Is there evidence of seasonal distributions and movements for the different species? (4) Can we follow the migration of humpback whales in the western North Atlantic?

A brief summary of the results from Whales '93 is given here.

In the first months of the programme, acoustic confirmations of blue, fin, humpback and minke whale were made (Schevill et al., 1964; Cummings and Thompson, 1971; Winn and Perkins, 1976; Thompson et al., 1979; Edds, 1982; Thompson and Friedl, 1982; Watkins and Wartzok, 1985; Watkins et al., 1987). Confirmations were based on published descriptions and recordings for these species' vocalisations and not on any simultaneous visual/acoustic detections. There was one unusual acoustic detection, tentatively identified as a bowhead whale, from the area north of Norway, south of Spitsbergen.

Blue whales were located and tracked throughout the North Atlantic, but were primarily found around the Grand Banks region of Newfoundland and west of the British Isles. Vocal activity is seasonally protracted, beginning in early August, peaking from September through February and ending in late May – early June. Most sounds are long, patterned sequences of infrasonic 'moans' in the 10-20Hz band, with each moan lasting between 15-25 seconds. Sequences last in the region of 15-20 minutes, with regular inter-sequence pauses that might be periods when the animal is breathing at the surface.

Blue whale sounds are routinely detected at ranges of up to 1,000 miles and can be tracked quite effectively out to ranges of many hundreds of miles. Individual animals are tracked based on the specific characteristics of their vocalisations (e.g. acoustic structures and call timing patterns) and the consistency in the coordinates of consecutive locations. Long-range detections and locations are possible because blue whale sounds are often extremely loud (>185dB re 1 microPascal 1m), there are relatively few blue whale vocalising at any one time and the same sounds are detected on several arrays. Fig. 1 is a schematic for a typical blue whale location in the western North Atlantic using just two arrays. Fig. 2 shows the acoustic locations and tracks for blue whales around the Newfoundland region for September 1993. Fig. 3 illustrates the track for one blue whale that was followed acoustically for 43 days as it travelled over 1,700 miles throughout the western North Atlantic (Gagnon and Clark., 1993).
There is some evidence to suggest that there are vocal differences between blue whale vocalisations from different regions of the North Atlantic and there are distinct differences between the blue whale sounds from the North Atlantic and eastern North Pacific, and between those from the eastern and western North Pacific. These differences might be used for discriminating between individuals from different populations.

Fin whales are the most vocally abundant whale in the North Atlantic and can be detected throughout the year in the Norwegian Sea. Fig. 4 is a scatter plot of detections in the northeastern North Atlantic from a few weeks during the winter of 1993, where almost every detection north of 60°N is from a fin whale. In the western North Atlantic, their seasonal vocal activity patterns are similar to those for the blue whale in that there is a distinct increase in vocal behaviour in the late summer, peaking in the winter and diminishing by the late spring. This coincides with a definite southward flow of whales during the fall and northward flow during the spring. In the western North Atlantic, the southward flow pattern is from the Labrador–Newfoundland region south past Bermuda and into the West Indies, while in the eastern North Atlantic, the flow is from the British Isles region south to the coasts of Spain and Gibraltar. During the winter when fin whales can be heard throughout the deep water of the North Atlantic Ocean, there is persistent activity in the Norwegian and Barents Seas.
There is some preliminary evidence for fin whales that whales in different regions of the North Atlantic have different vocal patterns. For example, fin whales recorded off Bermuda or the West Indies sound different to those recorded in the Norwegian Sea. These differences might eventually be of value for discriminating between different populations. Differences have also been observed between fin whale vocalisations from the North Pacific and North Atlantic Oceans.

Minke whales are primarily detected in the southern part of the western North Atlantic during the autumn, winter and spring. There are some preliminary detections of minke whales off the British Isles, but they are rarely, if ever, detected in the Norwegian Sea region. Fig. 5 illustrates the seasonal trend in the flow of whales through the western North Atlantic. Whales appear to move through the West Indies region from the northeast to the west during the autumn to mid-winter period and then westward and northward during the mid-winter through spring period. Fig. 6 shows monthly levels of detection from one of the array sights (array 2) depicted in Fig. 5.

Humpback whales, like minke whales, are vocally active seasonally and regionally. This is especially true in the western North Atlantic. This was not well documented in the eastern North Atlantic, primarily because of the limited effort on the part of the Whales '93 team in that part of the ocean. However, there were definite detections of singing humpback whales off the British Isles. During the winter months in the North Pacific, they have been recorded singing in the Gulf of Alaska and off the Northwest US coast, well north of the wintering grounds where singing is traditionally reported. Also, throughout the entire West Indies region, singing whales were consistently detected during the winter in deep water, 50–100 miles offshore of the islands.

It was not possible to follow the humpback migration southward through the western North Atlantic as originally planned. This was surprising given the relatively small area involved (in geographical terms) and the relatively good acoustic array coverage. The primary reason for this inactivity is that the humpback population is relatively large. Consequently, humpback whale song is usually only detectable out to ranges of <50 miles, although there was one occasion when a singer was detected at almost 100 miles range.

REFERENCES

ANNEX M2. JAPANESE SIGHTING CRUISE FOR BLUE AND BRYDE'S WHALES AROUND THE SOLOMON ISLANDS IN 1994.
T. Miyashita, H. Kato and S. Nishiwaki

Objectives
To obtain the sighting information on blue and Bryde's whales in the waters around Solomon Islands. Skin biopsy samples will be collected. Sightings of cetaceans other than above whales will be recorded.

Research area and cruise track
The research area almost covers the waters where blue whales were previously confirmed by Ohsumi and Shigemune (1993). It is bounded by 4°S and 13°S, and 154°E and 164°E, including the EEZ of the Solomon Islands, Papua New Guinea and Vanuatu (Fig. 1).

Research vessel and personnel
'Shonan-maru No. 2 (916.44 GRT) will be used and at least two Japanese scientists will join the cruise. The scientists on board will transmit the daily survey report to the IFS.

Research Items
All cetacean sightings will be closed with, and species and school size recorded. Survey effort, weather and water temperature profile obtained from XBTs will be recorded. Photographs will be taken for individual identification of blue whales, right whales and humpback whales if encountered. We plan to collect skin samples from blue and Bryde's whales using biopsy air gun and darts. Permission for both sampling and bringing the biopsy equipment and samples to Guam Island is required.

Research procedures
The survey will be conducted by two top mast observers and several additional observers on the front of wheel house. They will estimate radial distance and angle from the bow to whales sighted. The vessel will keep to a speed of 11.5 knots and follow a predetermined track line during the survey. The research will principally begin at 30 minutes after and finish at 30 minutes before sunset. The daily research hours will not exceed 12hrs. The survey will be conducted in wind speeds <20 knots and/or meteorological visibility over 2-3 n.miles.

Submission of cruise report and data
All data and samples from the cruise will be kept by the IFS for future analysis. A cruise report will be submitted to the corresponding countries and the next IWC meeting, and submission of original data will be considered on request.

Participation of foreign researchers
Foreign researchers are welcomed onboard as the capacity of the vessel allows.

REFERENCE
Annex N
Revisions to Annotations to the Revised Management Procedure (RMP) for Baleen Whales

(1) Annotation 9
On lines 8/9, replace implementation trials with Implementation Simulation Trials.

Add the following text as a third paragraph:
Implementation Simulation Trials involve identifying the range of plausible hypotheses relevant to recommending an Implementation or Implementation Review and formulating simulation models which conform with these hypotheses. Computer simulations are used to evaluate the effect under these models of applying the CLA to designated Management Areas with various Catch-cascading and/or Catch-capping options. If none of the options tried produces satisfactory performance on conservation criteria across the range of hypotheses it may be that Management Areas are inappropriately defined. If the range of plausible hypotheses is very broad, it may be that additional information is required to narrow the range of plausible hypotheses before application of the RMP can be recommended. Further explanation is given in Rep. int. Whal. Commn 45:117-9.

(2) Annotation 12

(3) Annotation 23
On line 5, replace ‘implementation simulation trials’ with Implementation Simulation Trials.
Annex O
Guidelines for Data Collection and Analysis under the Revised Management Scheme (RMS) Other than those Required as Direct Input for the Catch Limit Algorithm (CLA)\(^1\)

1. SCOPE

These guidelines form part of the RMS of the International Whaling Commission. Their main purpose is to specify, as far as possible, methods of data collection and analysis, and reporting procedures for types of data other than those required for the CLA, to ensure their availability throughout the period of application of the RMP, and to identify the issues that these data are intended to address.

In terms of the RMP\(^1\), biological data are of particular value in Implementation Reviews in terms of reducing uncertainty in the identity of stocks and specifying verifying Management Areas, and providing information on levels of mixing between them. In addition, analyses of biological and other data may play an important role in providing an independent check on the overall status of populations (e.g. IWC, 1993b, p.61; IWC, 1994a, p.45).

This Annex discusses both data required or encouraged to be collected whenever whales are caught and data which can be collected during other research activities. The exact manner of using the data described here is not explicitly defined in the RMP and thus precise requirements cannot be specified. Specific procedures for collection and analysis of these data are expected to change, particularly in the field of molecular genetics. It is envisioned that the Scientific Committee will update these guidelines from time to time.

Implementation Review shall take account of the available biological and operational data (IWC, 1994b). It is also envisaged that these data will form part of the more general information to be used by the Scientific Committee as part of its consideration of the actual application and further development of the RMP. The Committee should use these data to conduct research that, as far as possible within the context of applying the RMP, ensures that the general principles of management originally developed in 1980 (IWC, 1981), which are listed and discussed in IWC (1995), Item 9 are met.

The results of this research will ensure that data are available for (and, where appropriate, new methods developed for) periodic reviews of the overall condition of the harvested stocks of a given species in a Region. Such reviews will need to be conducted less frequently than Implementation Reviews.

2. REQUIREMENTS UNDER THE RMS

Contracting Governments shall arrange for the collection, archiving and analysis of such biological samples, tissue samples, specimens and data from whales caught as the Commission shall from time to time decide, on the advice of the Scientific Committee. The results of the analyses of such data shall be reported to the Commission in a timely fashion (the appropriate time will vary according to the data and the analysis required) to ensure their availability for use by the Scientific Committee.

The data described in this section are recommended to be required for each whale caught. The value of retaining these recommendations should be assessed on a regular basis by the Scientific Committee, on a time scale linked to that for Implementation Reviews. Additional recommendations for collection may be made by the Scientific Committee as circumstances warrant. Conversely, the Scientific Committee may recommend that some data cease to be required under this section. Recommendations may be for all whales caught or be species and Region specific.

2.1 Stock identity

Information on stock identity is important in ascertaining the adequacy of Management Area definitions and in suggesting improvements.

2.1.1 Tissue samples

The value of genetic information which can be obtained from tissue samples for reducing uncertainty in stock identity is clear and harvested whales provide an opportunity for collecting suitable samples. Collection of samples requires trained personnel, but is not difficult.

At least 5cm\(^2\) of skin shall be collected from each whale caught. Long term archiving of all samples with appropriate identifying information is the responsibility of the harvesting nation. A list of archived samples shall be forwarded to the Secretariat at the end of each season.

Samples should be archived using standard methods such as storage in 20% DMSO (Amos and Hoelzel, 1991) or freezing at \(-70^\circ\)C.

The Committee will recommend specific analyses for these archived samples. The results shall be reported to the Committee within a specified time and included in the IWC databases. Further analyses may be recommended from time to time as techniques develop and specific uncertainties are identified.

Scientists seeking access to these samples for analysis should submit a research proposal for review by the Scientific Committee, i.e., the procedure adopted for biopsy samples collected during IDCR cruises (IWC, 1993b, p.82).

2.1.2 Other

A number of items discussed under Item 2.2 may also provide information on stock identity.

\(^1\) Catch Limit Algorithm (CLA): This is the process used to calculate a catch limit for a Management Area. Revised Management Scheme (RMS): This includes all scientific and non-scientific aspects of management, as covered in the Commission's resolution (IWC, 1993a). RMP: the Revised Management Procedure as detailed in IWC (1994b).
2.2 Biological rates
The Committee recognises the potential problems of extrapolating rates, calculated from data from catches, to populations as a whole and thus interpretation of observed changes in these over time. Nonetheless, it believes the data outlined below should be required.

2.2.1 Length
The value of length data is twofold: (1) direct – major changes over time in the length distributions of catches by Small Area would warrant the attention of the Committee; (2) indirect – length information is valuable and perhaps essential, in interpreting the other data specified in this section.

The length of all animals caught shall be obtained, measured in a straight line parallel to the whale from the tip of the upper jaw to the notch of the flukes. These data shall be reported to the Secretariat at the end of each season and included in the IWC database.

2.2.2 Age
As for length data, the value of age data is twofold: (1) direct – major changes in the age distribution of the catch over time would warrant the attention of the Scientific Committee; (2) indirect – age information is valuable and perhaps essential, in interpreting the other data specified in this section. In many baleen whale species, ages can be estimated from earplugs or other material suitable for ageing. Bullae are an acceptable alternative in the case of Northern Hemisphere minke whales. Collection requires trained personnel. Attention is drawn to the need for ages to be estimated by trained personnel according to the recommendations in IWC (1980; 1984). It may be more appropriate to estimate ages from material collected over several years rather than each year.

Where possible, at least one earplug (or bulla) shall be collected from each whale caught. The resultant age estimations and the identity of the reader shall be reported to the Secretariat sufficiently in advance (normally one year) of the next Implementation Review for the species and Region, and included in the IWC database.

2.2.3 Ovaries
Major changes over time in pregnancy or ovulation rates would warrant the attention of the Scientific Committee. Such rates can be estimated from analysis of ovaries. Trained personnel are required to collect these tissues although collection is not difficult. Laboratory examination of ovaries is required to determine numbers of corpora, from which the reproductive history of individual females can be inferred.

Where possible, both ovaries shall be collected from each female caught. Corpora counts shall be reported to the Secretariat within one year of the close of the season and included in the IWC database.

2.2.4 Foetus
Foetal data may help interpret apparent pregnancy rate data and/or provide some information on stock identification. To ascertain whether small foetuses are present requires careful searching by trained personnel. Determining the sex of small foetuses is difficult and requires trained personnel or the collection of tissue (for genetic analysis).

If sufficiently trained personnel are present, recording of the presence, length and sex of foetuses is recommended. If it is not possible for such personnel to be present, these data should still be recorded where possible and the lack of trained personnel noted. A sample of tissue from the foetus should be collected if possible (see Section 2.1). These data shall be forwarded to the Secretariat at the end of the season and included in the IWC database.

2.2.5 Lactation
Lactation forbids the taking of whales accompanied by calves (Paragraph 1C). Traditionally, if a lactating female is taken this is regarded as an infraction and reported to the Commission. Determination of lactation is already specified in the Schedule (Chapter 1, section C).

Lactation shall be recorded and reported to the Secretariat at the close of the season and included in the IWC database.

2.3 Operational data
Operational data may allow detection of differential exploitation of stocks if there are multiple stocks within a Small Area. Such data may also be of value in monitoring and should be obtained from the start of any whaling operation. Given the difficulties with the interpretation of such data identified by the Committee in IWC (1988), the Committee should refine specific data needs.

Pending such review, the operational data currently specified in the Schedule shall be collected and reported to the Secretariat within one year of the close of the season. Arrangements for reporting the data in electronic format should be made.

3. OTHER DATA

Despite the uncertainty about their interpretation, the Committee encourages contracting Governments (and other Parties) to collect and analyse data other than those specified in Section 2. The types of data described below are included because they are potentially useful. The collection of these data shall be reported in National Progress Reports. The analysis of such data may be reviewed by the Scientific Committee as part of Implementation Reviews, provided the collecting country makes the data available to the Scientific Committee sufficiently in advance and requests the topic to be on the Scientific Committee agenda.

It should be stressed that the examples provided in this section are not intended to restrict the type of research that should be carried out.

3.1 Data from captured whales
Many types of data can be collected from captured whales. In addition to providing general biological knowledge, several of these have provided information on issues related to the RMP such as the question of stock identity (e.g. morphometry, parasite and pollutant burdens, see review by Donovan, 1991). Other types of data such as information on stomach contents and measurement of body condition such as blubber thickness may relate to the quality of the environment.

3.2 Data not obtained during harvesting

Stock identity
Samples for genetic analyses collected from whales from areas and seasons where whaling does not occur may be of great value to stock identity questions. Possible sources
include biopsy samples collected during abundance surveys or other field activities and samples collected from stranded animals. Collection of such data should be reported in National Progress Reports. Other types of data that have potential use in stock identity studies include individual identification data and data from telemetry studies.

Physical environment
Information on environmental conditions may be useful in the context of the RMS in various ways. The topic of long term changes in environmental conditions is being addressed by the Scientific Committee and such discussions will include identifying types of information which may be useful in this regard under the RMS.

Information on environmental conditions collected during sighting surveys may be useful in understanding variations in spatial distribution and in abundance estimates from survey to survey. More generally, data from remote sensing such as satellite-based sea surface temperature data or ice-edge locations may be of value in planning sighting surveys or interpreting their results.

The collection of oceanographic data during sighting surveys is encouraged. The analysis and reporting of remote sensing data may be useful in specific situations.

Several other types of data, for example relating to feeding ecology (feeding behaviour and prey distribution and abundance), may be of interest for management (IWC, 1992b, pp.59–60; IWC, 1992a, pp.638–40). The collection and analysis of such data is encouraged.

Annex P

Intersessional Working Group on g(0)

Members: Smith, Palka, Cooke, Schweder, Hammond, Borchers, Laake, Miyashita, Polacheck (Convenor).

TASKS TO BE COMPLETED BEFORE 1995 IWC SCIENTIFIC COMMITTEE

(1) Identify the source of the differences between the g(0) estimates in Schweder et al. (1993) and SC/46/NA8 and quantify the contribution and sensitivity of g(0) to each of the sources (including possible interactions). The factors that need to be examined include:

(a) inclusion of the 1989 experimental data;
(b) method of fitting (simulated versus regular likelihood and fitting criteria);
(c) method of classification of duplicates;
(d) models for the two dimensional detection function;
(e) inclusion of measurement errors in angles and distances in the estimate of g(0);
(f) the dive sequences used and stratification of dive sequences by time of day.

(2) Examination of duplicate classification for the 1989 experimental data and evaluation of the usefulness of these data for estimating g(0).

(3) Presentation of descriptive statistics on the distribution of sightings/resightings with respect to the duplicate identification criteria for the classification of the data used in SC/46/NA8; Schweder et al. (1993) and any additional classifications that are performed.

(4) Presentation of information on the goodness of fit to the underlying two-dimensional detection function used for estimating g(0) - e.g. histogram of observed and predicted perpendicular sighting distances, likelihood statistics.

(5) Initiate development of objective criteria for duplicate identification; development of methods for translating these criteria into automated procedures; and development of quantitative estimates for the probabilities of misclassification.

(6) Conduct simulation studies to evaluate the performance of the objective procedures developed in (5).

(7) Analyses of existing data and any new data that become available as a result of the 1994 SCANS survey with respect to reactive behaviour of North Atlantic minke whales to approaching survey vessels.

SPECIFIC MATERIAL AND WORK THAT NEEDS TO BE CARRIED OUT IN ORDER TO COMPLETE THE ABOVE TASKS

(1) Submission of the data files used to estimate g(0) in Schweder et al. (1993) and SC/46/NA8 to the IWC Secretariat (including identification of duplicates and the actual trials used in the analyses) by 1 September 1994.

(2) Exchange of the programs used in Schweder et al. (1993) and SC/46/NA8 for estimating g(0) among the members of the Working Group. The authors of SC/46/NA12 and SC/46/NA8 should submit their programmes to the IWC Secretariat who will in turn distribute the programs to members of the Working Group on request.

(3) The dive time data presented in Folkow and Blix (1993) and used in Schweder et al. (1993) should be submitted to the IWC Secretariat by 1 September 1994.

(4) Submission of a computerised data file from the 1989 parallel ship experiment to the IWC Secretariat which includes all surfacing recorded during the experiment and relevant documentation about the experiment that would help with the interpretation of the data (e.g. variance in the inter-vessel distance; asynchrony between vessel clocks; etc.) by 1 September 1994.

(5) Submission of data files that contain any additional classification of the 1989 and 1990 experimental data that will be used in analyses of g(0) that will be presented to the 1995 IWC Scientific Committee Meeting as early as possible but at least one month before the beginning of the 1995 meeting.

(6) Submission of any additional data on dive time sequences that will be used in analyses of g(0) that will be presented to the 1995 IWC Scientific Committee Meeting by 1 December 1994.

Those members of the Working Group that will be attending the Survey Design Workshop in Tromsø, Norway in November agreed to meet in order to review progress to date and plan how to complete the remaining work in time for the 1995 meeting. They will prepare a short report of their discussions that will be distributed to members of the Working Group that are unable to attend this meeting.

Annex Q
Report of the Steering Group to Advise on the Comprehensive Assessment of North Pacific Bryde’s Whales at Future Meetings

Members: Brownell (Convener), Kato, Hatanaka, Ohsumi, Ogiso.

The Steering Group met to discuss future work towards a Comprehensive Assessment of Bryde’s whales in the North Pacific. Two documents were discussed (SC/46/NP5 and SC/46/O 22).

SC/46/NP5 examined the available data on the recent distribution of Bryde’s whales in the western North Pacific using sighting data and oceanographic data collected from 40 sighting surveys in August and September from 1983 to 1993. The area of coverage was between 10°N to 50°N and 120°E and 130°W. A total of 701 Bryde’s whales in 436 groups were recorded during the surveys. Bryde’s whales were only sighted south of 45°N. The southern limit was not determined, but the authors believed the southern boundary to be south of the survey area (10°N). Sighting density was low in the Kuroshio Current and higher in the areas both west and east of the current.

SC/46/O 22 outlined plans for Japanese sighting surveys in the North Pacific in 1994/95 and in the Southern Hemisphere low latitudes in September-October 1994. The National Research Institute of Far Seas Fisheries plans to conduct a total of seven cruises with other relevant organisations. The cruises will last about two months each. Standard line and transect sampling method will be used. Skin biopsy samples will be collected on an opportunistic base. One cruise by the Shonan-Maru No. 2 is especially relevant as it will investigate the southern boundary of North Pacific Bryde’s whales. The Steering Group recommended the proposed set of cruises but noted that a critical issue for the success of these surveys is the research or entry permits into the EEZ of the relevant countries.

The draft agenda for the Comprehensive Assessment remained the same as that agreed to at last year’s meeting (Appendix 1). The tentative list of potential data sources was expanded from last year’s meeting (Appendix 2). The Steering Group also reviewed the preliminary analyses required (Appendix 3) from the 1993 meeting.

At the 1990 and 1993 meetings of the Committee, during discussions on priority stock groups it was agreed

‘that given the uncertainties with respect to stock identity, any in-depth assessment of Bryde’s whales should consider the whole North Pacific’ (Rep. int. Whal. Commn 41: 69).

The Steering Group agreed with this area of coverage.

The major analyses still needed for the Comprehensive Assessment include: genetics, Japanese survey and scouting vessels, age-related analyses, including considerations of age-determination methods and ecosystem and habitat considerations. Kato and Ohsumi expected that work on most of these analyses would be undertaken before next year’s Annual Meeting. Therefore, the Steering Group recommended that the Scientific Committee should begin the Comprehensive Assessment process for North Pacific Bryde’s whales at the next annual meeting.

Appendix 1
AGENDA

1. Opening remarks, election of Chairman, appointment of Rapporteur(s)
2. Adoption of agenda
3. Review of available documents and computing facilities
4. Review of available data
   4.1 Catches and search effort
   4.2 Sightings and search effort
   4.3 Biological data
   4.4 Marking data
5. Stock identity, distribution and migration
   5.1 Genetic analyses
   5.2 Morphological analyses
   5.3 Distribution patterns
   5.4 Mark-recapture analyses
5.5 Other information
6. Estimation of abundance and trends
   6.1 Sightings estimates
   6.2 Mark-recapture estimates
   6.3 Other
7. Biological parameters
8. Ecosystem and habitat considerations
   8.1 Diet and prey community changes
   8.2 Oceanographic data
9. Assessment
   9.1 Use of HITTER/FITTER
   9.2 Other assessment approaches
10. Future research
11. Management advice
12. Recommendations
Appendix 2

POTENTIAL DATA SOURCES

1. Catches
   1.1 Japan
      1.1.1 Historical net whaling
      1.1.2 Pre-war whaling
      1.1.3 Post-war coastal whaling
      1.1.4 Post-war pelagic whaling (1946–1952)
         (1971–1979)
   1.2 Republic of Taiwan
      1.2.1 Post-war pelagic whaling (1976–1980)
   1.3 USSR
      1.3.1 Post-war pelagic whaling (1970–1979)
   1.4 Philippines
      1.4.1 Local coastal whaling
      1.4.2 Coastal whaling (1983–1985)
   1.5 Korea
   1.6 People’s Republic of China
   1.7 Mexico
   1.8 North Pacific forms

2. Sightings and search effort
   2.1 Japan
      2.1.1 Platforms of opportunity
      2.1.2 Dedicated surveys since 1983
      2.1.3 Dedicated surveys pre-1983
      2.1.4 Scouting boats
   2.2 USA
      2.2.1 Platforms of opportunity
      2.2.2 SWFSC directed surveys
   2.3 USSR
      2.3.1 North Pacific ship surveys (status unknown)
   2.4 Mexico
      2.4.1 Platforms of opportunity

3. Biological information
   3.1 Japan
      3.1.1 Genetic materials
      3.1.2 Catch-related length, sex, foetus, stomach contents
      3.1.3 Gonad data
   3.2 USSR
      3.2.1 Genetic materials
      3.2.2 Catch-related length, sex, foetus, stomach contents
      3.2.3 Gonad data
   3.3 Other countries
      3.3.1 Genetic materials

4. Marking data
   4.1 Japan
   4.2 USSR
   4.3 Others

5. Species identification problems
   5.1 Catches
   5.2 Sightings

6. Other data

Appendix 3

ANALYSES NEEDED TO CONDUCT THE ASSESSMENT

1. Stock identity, distribution and migration
   1.1 Morphometric comparisons
   1.2 Genetic analyses
   1.3 Spatial patterns from sightings
      1.3.1 Japanese directed surveys
      1.3.2 Japanese scouting boats
      1.3.3 Soviet directed surveys
      1.3.4 US directed and incidental surveys
      1.3.5 Mexican incidental surveys
   1.4 Spatial patterns of catches
   1.5 Mark recaptures
   2. Abundance and trends

2. Stock structure
   2.1 Japanese survey and scouting vessels
   2.2 Other surveys

3. Biological parameters
   3.1 Age-related analyses and age-determination methods
   3.2 Analyses of length at maturity
   3.3 Review

4. Ecosystem and habitat considerations
   4.1 Review of diet and prey community changes

5. Assessment
   5.1 HITTER/FITTER analyses
   5.2 Other assessment approaches
Annex R

Minority Statements

ANNEX R1. STATEMENT OF THE JAPANESE DELEGATION CONCERNING SMALL CETACEANS

The position of the Government of Japan, as stated in the last Annual Meeting of the Scientific Committee, has not changed on the matter of small cetaceans. That is, the activities of the Commission with the population management of whales should be limited to the matters concerning whales listed on the Nomenclature of the International Whaling Conference Final Act (1946).

However, we can support the Resolution adopted by the IWC at its 32nd Annual Meeting in 1980 that the Scientific Committee of the IWC is recommended to consider the status of small cetaceans and provide such scientific advice as may be warranted to Contracting Governments.

ANNEX R2. MANAGEMENT RECOMMENDATIONS FOR SMALL CETACEANS

F. Hester, F. Larsen, M. Komatsu and H. Perez-Cortes

Sub-committees of the Scientific Committee provide recommendations that fall into three categories:

(1) Recommendations of work to be done, methodological studies or data needs of interest to the sub-committee. Such recommendations are directed to scientists and groups with competence on the matters of concern.

(2) Recommendations of work needed to be done under the auspices of the Scientific Committee and placed on the Agenda.

(3) Recommendations to the Scientific Committee that become recommendations of the full Committee and are passed onto the Commission. These are nearly always in response to a request by the Commission and may involve management advice.

The sub-committee on small cetaceans is in an unusual situation with respect to the third category. This sub-committee was established to consider the status of small cetaceans and provide such scientific advice as may be warranted to Contracting Governments. This role has not been broadened by the Commission, in fact, the role is still subject to debate; see Resolution on Addressing Small Cetaceans in the IWC (Rep. int. Whal. Commn 44, 1994, p.31). Here the Commission speaks of identifying a framework under which the matter can be addressed in IWC without prejudice to the views of member states on the regulatory competence of the IWC, mechanisms for encouraging and ensuring coastal state participation, including non-member countries, mechanisms for improving data availability, examining the role of the IWC in respect to small cetaceans, etc.

To further distinguish it from other sub-committees of the Scientific Committee, the sub-committee meets in parallel with other sub-committees. It does not perform formal assessments, nor has it developed any management procedures with which to deal with small cetaceans. Even if it did, the Commission Schedule lacks provisions for listing any measures that might be recommended and agreed to.

Therefore, it is inappropriate for this sub-committee to offer recommendations to the Commission that involve management actions. Included would be recommendations that member or non-member states take actions to limit takes, to establish data collection systems, or to submit all catch statistics to the Commission. Instead, the sub-committee should make recommendations only of type (1) research recommendations to scientists and groups working within the sub-committee and type (2) recommendations to the Scientific Committee for future Agenda Items. For matters that normally would be covered by type (3) recommendations (management measures and national statistics) the sub-committee should advise the Scientific Committee properly and through it the Commission, of its concerns. What actions to take should be left up to the Commission.
Progress Reports
This report refers to work involving: the Australian Nature Conservation Agency (ANCA), formerly Australian National Parks and Wildlife Service (ANPWS), the Australian Fish Management Authority; the Bureau of Rural Resources, Canberra; Australian Capital Territory; New South Wales; National Parks and Wildlife Service, Sydney, New South Wales; Department of Environment and Conservation, North Quay, Queensland; South Australian National Parks and Wildlife Service, Adelaide; South Australia; Conservation Commission of the Northern Territory; Darwin, Northern Territory; Department of Conservation, Forests and Lands, Melbourne, Victoria; Department of Parks Wildlife and Heritage, Hobart, Tasmania; Department of Conservation and Land Management, Como, Western Australia; University of Sydney, New South Wales; James Cook University of North Queensland, Townsville, Queensland; University of Tasmania, Hobart, Tasmania; Australian Museum, Sydney, New South Wales; South Australian Museum, Adelaide, South Australia; Western Australian Museum, Perth, Western Australia; Queensland Museum, Brisbane, Queensland; Queensland Boating and Fisheries Patrol, Queensland Fish Management Authority; Sea World Australia Limited, Brisbane, Queensland; Taronga Zoo, Sydney, New South Wales; Pet Porpoise Pool, Cofts Harbour, New South Wales; Defence Science and Technology Organization, Sydney, New South Wales; Australian Oceanic Research Foundation, Windsor, New South Wales; Australian Whale Conservation Society, Brisbane, Queensland (AWCS); Pacific Whale Foundation, Maui, Hawaii (PWF); ORRCA NSW and a number of unaffiliated individuals.

Species and stocks studied

(i) Southern right whale, *Eubalaena australis* – southern coast of Australia.

(iii) Minke whale, *Balaenoptera acutorostrata* (dwarf form) – northeast Australia.

(iv) Pygmy right whale, *Caperea marginata* – South Australia.

(vi) Various species sighted or stranded around the Australian coast.

A review of all cetaceans in Australian waters is also being prepared for ANCA under the Endangered Species Program, with a report due in late 1994.

Field observations and collections

Stranded specimens

Universities and Museums have continued where possible to collect material from animals stranded or incidentally killed and have obtained skeletal, parasitological, pathological and other material.

Marking

Artificial markings

Freeze branding of stranded cetaceans returned live to the sea has continued in Western Australia, with a total of 30 animals branded up to 1992. None were marked in 1993.

Natural markings

A number of cetacean studies in Australian waters now make use of natural markings for individual identification of animals. Studies of particular note include those on humpback whales, southern right whales and inshore bottlenose dolphin populations. A study has continued on common dolphins off Hobart, Tasmania. Development continued of national catalogues of photo-identification material for southern right and humpback whales. A partial catalogue of humpback whale fluke photographs, with a preponderance of east coast animals, has now been published by PWF with support from ODEH and ANCA.

Laboratory work

Analyses of reproductive material obtained from dolphins killed in the northern gillnet fishery, which closed in 1986, are still incomplete, as is age determination of the same animals through analysis of tooth sections. Analysis of samples obtained opportunistically from stranded cetaceans for heavy metal, pesticide and other residues continues, with the development of a national programme continuing under the National Contingency Plan for Stranded Cetaceans. C. Kemper (SA Museum) has collated information on currently available analyses of stranded cetacean material. Large numbers of stranded pilot whales during late 1991 and through 1992 in Tasmanian and mass strandings of false killer whales have resulted in a considerable backlog of material awaiting analysis in 1993/94.

Genetic material is being collected from within and outside Australia to determine relationships of inshore and offshore forms of bottlenose dolphins. Cranial material is being collected for comparisons of smaller inshore forms in the two South Australian gulfs with those in other areas.

Development of techniques

Development of biopsy techniques to obtain samples for molecular genetic and pollutant level studies of inshore dolphins, dugong and humpback whales off the Queensland east coast continued. Some biopsy samples were obtained from southern right whales. Refinement of super-telephoto shore based photography continued, producing identification photographs of very high quality, some of which have allowed identification of many first year calves. Land based census techniques have included long-shore visual tracking. A catalogue of identified southern right whales is being maintained, linking digitised photographs with database information. The identification catalogue is computer based, with a capacity for searching for callusity patterns based on pattern recognition software currently under development and providing encouraging results.

Research results

Pygmy right whale study

C. Kemper (SA Museum, Adelaide) is continuing studies of the biology and systematics of pygmy right whales. Estimation of body length from skeletal measurements and development is close to completion and should allow existing material to be assigned to relative age categories and so examine possible ontological differences in stranding occurrence. Frozen tissue samples are being collected and are sought from all freshly dead baleen whales for genetic research.
Taxonomy of Irrawaddy dolphin
This study, carried out by G. Heinsohn (Dept. of Zoology, James Cook University), uses skeletal material (primarily skulls) from Irrawaddy dolphins stranded near Townsville or caught in local shark-nets. The collection is held at the Museum of Tropical Queensland. The first aim of the study is to document adequately the osteology of the species. The main sample is 15 animals of known age and sex, ranging from new-born to 28+ dentinal growth layers; 115 cranial characters have been measured.

The second aim is to assess the relationship of Orcaella to other delphinoids. Comparative cranial material of Delphinapterus, Monodon, Phocoena, Pseudorhiza, Phereca, Pseudorca, Globicephala, Sousa, Lagorhynchus, Lagenodelphis, Delphinus, Grampus, Tursiops and Stenella has been examined.

Acoustic studies
During 1993, research was conducted in Areas IV and V in Australian waters, continuing work started in 1982 on a comparative study of song on east and west coasts, the compilation of photographs for identification and aspects of migration rates and behaviour. W. Dawbin of the Australian Museum, volunteer helpers P. Gill, L. Eyre and others, supported by staff of the Port Porpoise Pool, Coffs Harbour and the Australian Museum. Sydney recorded sounds of northward migrating whales off Coffs Harbour (30°18'S, 153°09'E) and at Hervey Bay, Queensland (25°06'S, 152°49'E), with some recordings from further north in the Great Barrier Reef Region. The Oceanic Research Foundation (P. Gill) in cooperation with ORSTOM Noumea carried out sightings and acoustic surveys off the Chesterfield reefs. In eight days of surveys, 20 humpbacks were sighted, with photo-identification of 12. The survey is planned to continue in 1994. Additional acoustic recordings were obtained opportunistically by a number of groups. The total number of humpback whale songs collected since 1990 for the WA population is 31. Six recordings were made in 1990, seven in 1991, ten in 1992 and eight in 1993.

Behaviour
Humpback whales
A commercial whale-watching industry was established in Hervey Bay in 1987 as the result of observations of numbers of humpback whales in the Bay in late August to early October. Research was begun in 1988 to assess the numbers and distribution of whales, the effects of tourist boats on whale behaviour and the residence times of individual whales in Hervey Bay and this continued in 1993.

Southern right whales
Extensive behavioural observations and photo-identification work continued in 1993 from cliff-top observation areas at the Head of the Bight. South Australia as part of comparative studies of southern right whales in areas adjacent to oil exploration leases off the Victorian coast, 1994 will represent the fourth year and expected completion of this intensive field study into the ecology and behaviour of southern right whales on the coast of Southern Australia. The data collected involves detailed analyses of mother and calf behaviour patterns in calving grounds as well as observations of behaviour, including mating, of unaccompanied adult whales. Information about partitioning of calving sites has also been collected and interactions between southern right whales, and other species including humans, noted. The study also investigated temporal changes in behaviour over the calving season with some environmental correlations.

A relatively detailed life history of southern right whales has been achieved through this study and includes records of weaning and juvenile site fidelity. Cliff-top vantage points have allowed high quality photographic identifications of over 120 adult and approximately 40 southern right whale calves.

Inshore bottlenose dolphins
Behavioural and acoustic research begun in 1990 in Moreton Bay on the inshore dolphins also continued. Projects included studies of acoustic behaviour of inshore dolphins; estimation of population size; and comparative studies of behaviour and nutrition of free ranging and captive dolphins. Studies of acoustic behaviour and behaviour of free ranging dolphins continued in 1992, with some aspects continued in 1993. Compilation of a catalogue of identified individuals continues for the area.

A study of patterns of habitat use by bottlenose dolphins in Jervis Bay (NSW and ACT Territory) was completed in 1993 (F. Mandelc, Macquarie University, Sydney). The study was designed to allow quantitative assessment of the use of different inshore habitats by resident and transitory animals. Commercial dolphin watching cruises begun in 1989 are a potential disturbance.

The study in Port Phillip Bay, Victoria has continued with a number of volunteers working on projects related to individual identification, movements and behaviour. Some 35 individuals have been identified, with an estimated peak abundance of about 20 bottlenose dolphins. Some concerns have been expressed over possible effects of commercial operations including dolphin watching and scallop trawl fisheries on the resident Tursiops (Port Phillip Bay Dolphin Research Group). Harassment of dolphins has been reported.

Work also continued on a longer-term study of behavioural ecology of Tursiops truncatus in an area of approximately 60sq/km in Port Adelaide, Adelaide, South Australia (M. Bosley, South Australia). More than 80 individuals have been identified from dorsal fin and other marks, with habitat use and behaviour of solitary and group-living individuals now being mapped.

Research is continuing into the social organisation, behaviour and aspects of the ecology of bottlenose dolphins at Monkey Mia (25°55'S, 113°32'E) in Western Australia. Monkey Mia has been regularly visited by a number of wild dolphins for many years and development of a major tourist attraction is continuing with a variety of associated problems. In other developments in Western Australia, the Bunbury Dolphin Trust organised an observation and information programme involving wild dolphins that had been fed in the past to encourage interactions. The Trust has been issued with a licence to study the dolphins and their interaction with sonic devices. One other commercial operator organises tours based on swimming with dolphins.

Biopsy sampling
Analysis of humpback whale biopsy samples obtained in 1991 and 1992 continues. Some additional southern right whale biopsy samples were obtained in 1993.
Sightings data

Southern right whales: Southeastern Australia

Aerial surveys funded by Broken Hill Proprietary Limited (BHP) Petroleum Division continued in the 1993 calving season, in June-September, along the southeastern Australian coast south of Adelaide to Victoria, with one flight (6 September 1991) to Botany Bay, NSW (Kemper, SA Museum). Small numbers of southern right whales were seen; analysis of photographs is continuing to eliminate resights on successive surveys and to provide indications of movement between east coast and South Australian and Western Australian data. Data from flights in 1992 and 1993 are being analysed.

Southern right whales: Victoria

From collation of a series of 209 sightings between 9 June and 8 October 1993, Warnecke estimates five cow-calf pairs were present in Victorian waters in 1993, with an unknown number of single animals contributing to the overall total. One cow and a well developed calf, both distinctly marked, were sighted in January 1994.

Southern right whales: New South Wales

Recent incidental sightings are being collated (NSWNPWS/ORRCA)

Southern right whales: Tasmania

There were 34 sighting reports for southern right whale off Tasmania for 1993, the first on 1 June, the last on 4 October, with two reports of newly-born calves. As part of the broader aerial survey of the southeastern coastline, five flights were undertaken, with one cow/calf pair sighted.

Southern right whales: South Australia

Three aerial surveys were carried out by J. Ling and P. Needham (South Australian Museum) in 1991 west of the Eyre Peninsula between 136° and 126°E but funds were not available to repeat these surveys in 1992. Needham records 149 individual right whales recorded from 1970 to 1992 for South Australia and Victoria in a partial catalogue, with additional identifications from work at the Head of the Bight and from other surveys in 1992. No aerial surveys were carried out west of Adelaide in 1992, but in 1993 Needham sighted 22 adults and 20 calves from Port Lincoln to Nullarbor and return (6hrs survey), with an additional two surveys at the Head of the Bight (27 adults, 19 calves). There are currently 370 entries in the South Australian catalogue, with 1992 and 1993 analysis incomplete. The individually-identified whales total 164 (78 female, 9 known males, 57 unknown adults and 20 calves). Table 1 summarises peak counts for the Head of the Bight areas. J. Ling has produced an estimate of the total population in the SA sector of 208–253 for 1991, based on several simplifying assumptions.

Southern right whales: Western Australia/South Australia

Two surveys were conducted in 1993 in late July, late August and late September (Bannister, WA Museum). The area covered in surveys flights from 1976–1992 (Cape Leeuwin to east of Israeliite Bay) was extended eastwards to Ceduna (32°08'S 113°41'E) to incorporate areas at the Head of the Bight in particular. These areas were formerly covered in surveys flown from South Australia. In 1993 there were again concentrations of sightings in the Gordon Inlet-Pt Ann-Pt Charles and East of Israeliite Bay areas.

For the two areas with the longest time-series, 'C Leeuwin-C Arid' and 'C Leeuwin-Israelite Bay', the addition of a further year's data has again slightly reduced the values of the increase rates (1977–1992: range of point estimates 10.8–13.3%; 1977–1993 10.1–12.8%). It has also again narrowed the confidence intervals (1977–1992: range of interval ±4.9– ±8.0; 1977–1993 ±3.4– ±8.0): intervals are still unacceptably wide, reflecting the relatively small numbers continuing to be observed each year.

For the area with the shortest time-series, 'C Leeuwin-East of Israeliite Bay', with data only available from 1983, the increase rate for 'other animals' is still higher than for the other two classes, though by somewhat less than before (14.7 cf. 18.4%); the confidence interval (±11.6%) is still, however, very wide. The rate for 'all animals' is slightly higher than previously, and that for cow-calf pairs is also rather higher than before (9.8 cf. 7.7%), although its confidence interval is now narrower (±4.8 cf. ±5.6%).

Bannister provided an updated estimate of current population size, including animals off southwestern South Australia, of in the region of 800 animals, based on a figure of 189 reproductively active females, a sex ratio of 1:1, and an allowance for non-reproductive adults and the minimum of young animals likely to be present in the population.

A total of 113 animals individually identified from photographs was obtained in 1993, of which 90 were from the WA sector, compared with 59 from that area in 1992. Thirty 'matches' with animals identified in 1993 or earlier. The number included those observed on the survey flights in the WA and SA sectors. For WA alone, 18 matches were recorded. Of those, three were animals seen more than once in 1993 but not identified in earlier years; they were thus new 'within-year' matches. Of those already in the catalogue, eight represented existing matches. The remaining seven were new 'between-year' matches, i.e. they had been identified only once before. 'Between-year' matches obtained from animals identified off WA, including those 18, now represent 84 individuals. Of those, 49 (58%) are known to be adult females, having been recorded at least once with calf.

An important aim of the project has been to compare animals identified off the WA coast with those identified elsewhere, in particular off SA, to provide information on the extent of possible interchange between the two areas. A four day workshop held in Perth on 13–16 January 1994 provided an opportunity to exchange information and ideas, and compare catalogues from as many areas as possible. Comparisons were made between animals identified off WA, off SA (including Head of the Bight) and off Victoria. A small number of photographs was also...
available of animals off NSW and Tasmania. No new matches were obtained between animals photographed off WA and SA (east of Adelaide), Victoria, NSW or Tasmania.

Twenty-one matches were confirmed between animals in the WA catalogue and those identified at the Head of the Bight, SA by S. Burnell. The WA catalogue includes animals photographed in the SA sector on the flights. Excluding those, seven matches represent animals identified at the Head of the Bight from 1991 to 1993, and identified previously off WA. A further 23 matches, obtained at the workshop or otherwise, represent animals identified at that or other localities and/or other times off SA.

The information now available on movement between the two areas, the southern WA coast and the western SA coast, can be summarised as follows:

(1) 30 animals show evidence of movement between years and there are three examples of an animal moving within one year;
(2) most information is from 1983 onwards, but there are three earlier records, from 1976, 1978, 1979;
(3) the three examples of 'within year' movement were all westwards, i.e. from SA to WA;
(4) two-thirds of the animals recorded are female (having been recorded once or more with a calf) whilst one animal has been identified as a male, from observations at the Head of the Bight;
(5) 13 of the known females were first seen without a calf, and may therefore have not been adult at the time; and
(6) half (15 animals) were first recorded from WA, suggesting an equal degree of movement in either direction. But if the records from 1983 are divided into two equal periods, 1983–88 and 1988–93, there is clearly a higher proportion of first records in WA in the first period than in the second (12/20 cf 17/7). This reflects the unequal effort in both areas since 1983, with relatively little off SA in the earlier period, and considerably greater effort there more recently, particularly at the Head of the Bight since 1989.

The conclusion drawn last year, that for future estimates of increase rate and population size both areas should be considered together, is reinforced by the larger number of records now available that demonstrate movement between them.

Humpback whales: Tasmania
There were nine reports of humpback whales off Tasmania, between 2 June and 24 December. There were two reports of animals with newly-born calves, on 4 and 24 December.

Humpback whales: Western Australia
In 1993, identifying photographs of humpback whales were obtained from several sources off the Western Australian coast including:

1. operations of commercial whale-watching vessels off the coast just north of Perth;
2. opportunistic operations of Museum, other State Government staff and private individuals off the WA coast in the course of official duties or recreational activities;
3. Dampier Archipelago research project;
4. Pacific Whale Foundation activities under State and Commonwealth Government research permits and opportunistically with commercial whale watching operations. (It is a requirement of those permits that copies of photographs obtained are provided to the relevant authorities).

In 1993, 107 animals were identified off Perth, bringing the total identified there since 1986 to 480.

Research on humpback whales off Western Australia began in 1990 (Jenner and Jenner, based at Dampier Archipelago), was continued in 1993 (Table 3). The project is a five year boat-based study to obtain a population estimate of the Group IV humpback whale stock.

1 Number of whales identified and number of 'new' whales are the same because there is only one computer record for whales seen within a season.

2 Totals include Montebello Island effort.

Table 3
Effort and number of humpback whales seen since 1990 from the Dampier Archipelago and the Montebello Islands (in 1992).

Comparison off animals identified off Perth and off Dampier up to 1992 has given 18 resightings, comprising 1 year interval – 6 resights, 2 year interval – 5 resights, 3 year interval – 7 resights. In addition, the first resight between Antarctica and WA was recorded. Identified from a distinctive right flank pattern, it was photographed as an 'adult' at 64°20'S, 101°12'E on 14 February 1993 and matched with an 'adult' photographed off Perth almost three and a half years earlier, on 30 September 1989.

In 1991, an aerial survey was again flown off the coast of Western Australia to provide a comparison with a series of
surveys flown during the northward migration since the last commercial sightings flights in 1963. Bannister (Rep. int. Whal. Commn 44:309–310) gives an estimated increase rate of 10.9% ± 3.0% of a previous estimate of 8.8% (±5.8%), with a likely minimum estimate of total population, based on comparisons with 1963 sightings figures, of at least 3,000. The survey is scheduled to be flown again in 1994.

**Humpback whales: Queensland**

The Queensland Department of Environment and Conservation has a small programme for humpback whale research and monitoring being conducted by field staff responsible for the day-to-day management of the Great Barrier Reef Marine Park (GBRMP), especially in the southern region of the Great Barrier Reef. Field staff have continued to collect photographs of tail flukes and body colouring of individual humpback whales in the Mackay/ Capricorn section of the GBRMP and opportunistically in the Whitsunday region. In 1993, as in earlier years, however, because of the rapid development of commercial whale watching operations in the area, most effort was put into Hervey Bay and to some monitoring of the Whitsunday area.

R.A. and P. Paterson continued their long-term assessment of the east Australian (Area V) humpback whale stock from Point Lookout on North Stradbroke Island (23°5′S 150°45′E). Observations were made again during the northward migration in 1993 and are in press. Paterson (SC/45/SHB/18) provided an estimate of total stock size of 1,900 (1,650: 2,150), with an annual rate of increase calculated at 11.6% for the period 1987–1992.

M. Bryden, P. Corkeron and M. Brown carried out shore-based surveys from Stradbroke Island during the 1993 northward migration, repeating observations carried out in 1988 and 1991/92. Offshore aerial surveys have been flown to provide an estimate of the width of the migratory pathway. Preliminary analysis provides an estimate of total population of about 1,400 animals, with additional work undertaken in 1993 still to be taken into account (see SC/46/SH2).

The Pacific Whale Foundation continued their boat-based and underwater photographic research efforts for the purposes of individual identification and the determination of population parameters for humpback whales off the east and west coasts of Australia.

In 1993 individual patterns of fluke and lateral body markings were photographed from small boats working from Platypus Bay, in Hervey Bay and off Perth and Exmouth, WA. The effort is summarised in Table 4 for the period up to 1993.

Following circulation of a request for access to photo-id material for humpbacks in May 1990, a total of 1,173 individually identified whales had been documented up to November 1991 and are included in a catalogue now published (Kaufman et al., 1993). The bulk of the photographs are from East coast animals. The catalogue does not include one of the major Western Australian fluke photograph collections or lateral body photographs, but does include limited material from Tonga and the Antarctic.

**Other sightings**

Sightings of pilot, humpback, right, blue and sperm whales have also been reported to ANCA from Coastwatch and Defence Force, and private aircraft and vessels, and collation of a national sightings database continues.

Compilation of sightings reports has continued in ANCA, with eight years of radio reports of cetacean sightings from the southwestern Pacific and some 2,500 records in the national sightings database.

### Strandings

ANCA continued to receive and collate stranding reports from the States, the Northern Territory and the External Territories; those recorded in the Jervis Bay annex to the Australian Capital Territory have been included in the NSW totals. A total of 102 individuals was reported in 96 stranding incidents.

### Pollution studies

Analysis continues of material collected during 1991/92 from several mass strandings. One major series of samples was collected from a mass stranding of long-finned pilot whales (* Globicephala melas*) in Tasmania, where 178 animals stranded on 13 November 1991, with additional material collected from subsequent strandings of 69, 198, 76 and 26 individuals, of which only 16 were returned to the sea alive. The majority of animals were extremely stressed when found and those animals returned to the sea restranded and died. Kemper et al. (1994) have reviewed available information on analysis of pesticide and heavy metals from strandings in Australia.

### Statistics and data for small cetaceans

The Scientific Committee has requested that information on the catches of small cetaceans be presented by calendar year. Table 5 summarises all the directed and incidental takes of cetaceans for 1993, with preliminary estimates provided for some areas for which there is little or no other information.

### Captures for public display and holding of captive animals (see Table 6)

The dolphin release programme conducted by WA Utilities (Atlantis Marine Park) has been concluded (Gales and Waples, 1993). Of the nine animals at the start of the rehabilitation program, two wild caught animals appear to have been returned successfully to the wild. Three, one of which was born in captivity, were recaptured after not being able to forage successfully and losing weight. One, a calf born in captivity, is known to have died. Three other dolphins had not been sighted again by early 1993. The three remaining captive dolphins, an adult male and female...
Reported incidental and deliberate catches of cetaceans 1993 calendar year (incomplete information). Included in the Table are records for stranded animals where entanglement or other human interference was recorded as the likely cause of death, as well as animals taken deliberately or accidentally but not recorded in the strandings database (successful releases in parentheses).

and a subadult female born in captivity, are being maintained in sea cage facilities, with supervised sea release still being considered. The adult female has now given birth to a female calf, her third in captivity.

Fisheries interactions and incidental catches (see Table 5)
ACCIDENTAL CAPTURES IN PROTECTIVE SHARK NETS
Protective netting of recreational beaches is undertaken in Queensland and New South Wales; cetacean catches appear to be rare in NSW, although further information is being sought on recently reported catches. In Queensland, where the Queensland Shark Meshing Programme seeks to protect barracuda from sharks, there is an increasing use of drumlines in some areas, but catches of cetaceans, primarily hump-backed and bottlenose dolphins continue, with an estimated 8 (mainly bottlenose) taken in the 1993 calendar year; identification and carcass retrieval remain problematic. A cause for concern, with the increase in humpback whale numbers off the eastern Australian coast, has been entrapment of young humpbacks. A programme of attaching sonic alarms to the nets has been implemented in an attempt to reduce the rate of entanglement.

OTHER INCIDENTAL CATCHES
Reports from the Western Australian Department of Conservation and Land Management in 1989 indicated that there have been a number of catches of dolphins (possibly bottlenose) through entanglement in demersal shark nets. There is still no reliable information on the number or species taken in the shark fishery in 1993, with previous estimates ranging from 1 to 10-12 in total per annum. There are also known but undocumented catches of small cetaceans in inshore legal and illegal barramundi and threadfin bream netting in shallow northern waters of Queensland, the Northern Territory and northwestern Australia, the species involved are most likely to be hump-backed and Irrawaddy dolphins.

In several areas in which there is tuna longline activity, particularly in the Coral Sea, East coast Queensland and the southwest coast grounds, Japanese vessels fishing under an access agreement have reported significant losses to killer, false killer and pygmy killer whales. Whale damage was reported for albacore and yellowfin tuna, with damaged fish constituting from 11-57% of landed numbers in some areas. Entanglement, however, is rare. In 1993, one false killer whale was hooked but released alive.

Another increasing trend has been capture of both inshore dolphin species (bottlenose and common) in salmonid and tuna mariculture cages. While in most cases the animals are found and released alive, there have been some fatalities. Measures adopted to reduce seal damage may reduce entanglement of cetaceans, but there are also reports of baleen whale entanglement (humpback in 1993, southern right whale in 1992).

Illegal dolphin killing
Reports have continued on illegal shooting or spearing of cetaceans of South Australia, Victoria and Western Australia, involving primarily the more common inshore species (common and bottlenose) as summarised in Table 5. The Table incorporates those individuals included in the strandings records for which there were good indications
that deaths had been the result of entanglement or deliberate shooting or spearing. Traditional fishing vessels from Roti in Indonesia, travelling to Australian waters to fish in accordance with the Indonesian-Australian Memorandum of Understanding, are known to take dolphins on occasion. Two takes were detected in December 1993, species indeterminate, but possibly bottlenose. In both cases a successful prosecution followed.

Publications (excluding IWC references)

BRAZIL: PROGRESS REPORT ON CETACEAN RESEARCH, 1993–1994

A number of governmental and non-governmental organisations (NGOs) contributed to this report, including: the Laboratory of Marine Mammals of the Oceanographic Museum/Federal University of Rio Grande (MOPURG/LMM); the Brazilian Institute for the Environment and Renewable Natural Resources/Manatee Center (IBAMA/PAP/PE); National Institute for Amazonian Research/Laboratory of Aquatic Mammals (INPA/LMAq); Federal University of Rio Grande/Institute of Oceanography (FUcri/DOc); State University of Rio de Janeiro/Department of Oceanography (UERJ/DOc); Federal University of Bahia/Cetacean Study Group (UFBA/GECET); Federal University of Paraíba/Wildlife Biology Center (UFPRE/CEBIMAR); Federal Rural University of Pernambuco/Aquatic Mammals Group (UFRPE/GMA-FAUNE); Federal University of Santa Catarina/Laboratory of Aquatic Mammals (UFSC/LAMAQ); Brazilian Foundation for Nature Conservation (FBCN – NGO); Rio Grande do Sul Aquatic Mammals Study Group (GEMARS – NGO); Pro-Noronha Institute/Sponge Dolphin Project, International Wildlife Coalition-BR (INT. WILD. COAL.-BR. NGO); Center for Education and Environment Monitoring (NEMA – NGO).

Species and stocks studied
The following species/stocks were studied: southern right whale, Eubalaena australis (MOPURG/LMM; UFRPE/CEBIMAR; INT. WILD. COAL); minke whale, Balaenoptera acutorostrata (MOPURG/LMM; UERJ/DOc; UFRPE/GMA-FAUNE; GEMARS); sei whale, B. borealis (UFRPE/GMA-FAUNE); Bryde’s whale, B. edeni (UFRPE/CEBIMAR; UFRPE/GMA-FAUNE); fin whale, B. physalus (UFRPE/GMA-FAUNE); humpback whale, Megaptera novaeangliae (UERJ/DOc; UFRPE/GMA-FAUNE; FBCN); Cuvier’s beaked whale, Ziphius cavirostris (MOFURG/MM; FURG/DOc; UFRPE/CEBIMAR; UFRPE/GMA-FAUNE); Amazon river dolphin or boto, Inia geoffrensis (INPA/LMAq); La Plata river dolphin or franciscana, Pontoporia blainvillei (FURG/DOc; MOFURG/LMM; FBCN; GEMARS); sperm whale, Physeter macrocephalus (UFRPE/GMA-FAUNE); pygmy sperm whale, Kogia breviceps (UFRPE/GMA-FAUNE); short-finned pilot whale, Globicephala macrodus (UFRPE/GMA-FAUNE); long-finned pilot whale, G. melas (MONFURG/LMM); killer whale, Orcinus orca (MOFURG/MM); melon-headed whale, Peponocephala electra (UFRPE/GMA-FAUNE); false killer whale, Pseudorca crassidens (GEMARS); common dolphin, Delphinus delphis (UERJ/DOc; UFRPE/GMA-FAUNE); rough-toothed dolphin, Steno bredanensis (UFRPE/CEBIMAR; UFRPE/GMA-FAUNE); South American dolphin or tucuxi, Sotalia fluviatilis (INPA/LMAq; UERJ/DOc; UFRPE/GMA-FAUNE); striped dolphin, Stenella coeruleoalba (GEMARS); spinner dolphin, S. longirostris (UFRPE/GMA-FAUNE; FBCN); Atlantic spotted dolphin, S. frontalis (UERJ/DOc); and bottlenose dolphin, Tursiops truncatus (FURG/DOc; MOFURG/LMM; UFRPE/CEBIMAR; UFRPE/GMA-FAUNE; GEMARS).
Field observations and collections
Biological and physiological research on the boto and the
tucuxi in the Amazon basin has been carried out by INPA/
LMAq. Samples of blood and skin for DNA analysis were
collected from five and nine botos, respectively, in the
Estação Ecológica do Mamirauá, Amazonas, Brazil.

Beach observations were undertaken on the
northeastern coast by UFRPE/GMA-FAUNE, the
southeastern coast by UERJ/DOc; FBCN and the
southern coast by FURG/DOc; MOFURG/LMM; UFPR/
CEBIMAR; UFSC/LMA; GEMARS (mainly from
29°20' S to 33°40' S). Observations were also made from
boats or from fixed points and included monitoring of
interactions between fishing activities and cetaceans
(FURG/DOc; MOFURG/LMM; GEMARS). In a four
month period, 20 franciscanas (caught in gillnets set for
croakers) were collected by MOFURG/LMM from just
10% of the gillnetting regional fleet; females and juveniles
were predominant. Skulls, teeth or complete skeletons
were collected as well as parasites, stomach contents and
tissue sample, some for genetic analyses. Osteological
material collected by most of the institutions has been
preserved in their own collections: FURG/DOc (Turistops
trunca tus, Ziphius cavirostris); MOFURG/LMM (a
diminutive form of Balaenoptera acutirostris, Eubalaena
australis, Globicephala melas, Orcinrus orca, Mesoplodon
densirostris, Pontoporia blainvillei, Tursiops truncatus,
Ziphius cavirostris); UERJ/DOc (Megaptera novaeangliae,
Delphinus delphis, Stenella plagii, Stenella frontalis;
UFPR/CEBIMAR (Balaenoptera edeni, Delphinus
delphis, Pontoporia blainvillei, Stenella plagii, Steno
broadnose, Turisops truncatus); UFPE/GMA-FAUNE
(Balaenoptera edeni, Globicephala macrorhynchus,
Peponocephala electra, Phistisay macrocephalus, Stenella
plagii, Stenella longirostris, Tursiops truncatus, Ziphius
cavirostris); GEMARS (Pontoporia blainvillei, Stenella
coerulescens).

Studies on interactions in southern Brazil between killer
whales and tuna and swordfish longline fisheries were
continued by MOFURG/LMM.

Markings
Natural markings
Studies of natural markings occurred only in southern
Brazil: fifteen right whales were photo-identified by their
callosities from aerial surveys (INT. WILD. COAL. - BR).
Thirteen tucuxis were photo-identified from their dorsal fin
marks (UFSC/LMAq); and thirty-five bottlenose
dolphins were photo-identified also from their dorsal fin
marks in the estuarine region of the Patos Lagoon
(MOFURG/LMM). Photo-identification of humpback
whales from the colour patterns of the ventral portion of
their flukes was continued by FBCN.

Artificial markings
INPA/LMAq marked and released nine botos at Estação
Ecológica do Mamirauá. Eight were marked with a VHF
radio-transmitter, plastic tag mark and freeze brand whilst
one was marked only with a plastic tag as it was very young.

Laboratory work
Morphometric, parasitological and osteological studies
were made, age evaluated and stomach contents analysed
by most of the institutions already mentioned. Chemical
analysis of lipid tissues as well as radiological studies were
pursued (UERJ/DOc: MOFURG/LMM and GEMARS).
The latter two institutions sent biological material to other
institutions under a common programme of pollution
analysis (see 'Pollution studies').

Development of techniques
VHF radio-transmitters were developed and designed by
INPA/LMAq to track botos.

Traditional techniques continued to be followed. The
aerial photo-survey used 400ASA colour film and a
computer system designed to help with the photo-
identification of southern right whales (INT. WILD.
COAL. - BR). Bottlenose dolphin and tucuxi mark-
recapture studies were continued by MOFURG/LMM and
UFSC/LMAq respectively. Dentine and cementum
rings (GLG) were analysed (FURG/DOc; UFPR/CEBIMAR).

Research results
A different species of the genus Inia was described for the
upper Madeira and Beni/Mamoré river basins by INPA/
LMAq (see da Silva, 1994).

The impact of fishing activities on cetacean behaviour
and survival were studied and critical areas were
determined (FURG/DOc; MOFURG/LMM; UFPR/
CEBIMAR; UFPE/GMA-FAUNE; FBCN;
GEMARS).

Over a period of years, variation in the diet of
franciscanas has been demonstrated by FURG/DOc.

Preliminary results concerning the degree of
contamination from organochlorinated pesticides in
franciscanas (collected along the southern coast of Brazil
and the northern coast of Argentina) reveal
contamination, but at low levels: mean DDTs = 0.87 ppm
(SD = 1.7; n = 14); mean PCBs = 3.00 ppm (SD = 4.4; n = 14).
It is important to note that most animals were
juveniles (integrated programme MOFURG/LMM and
Museo Argentino de Ciencias Naturales de Buenos Aires).

Sightings data
During 1993, the most important sightings data refer to
three different groups of a significant number of right
whales (about 20 including mothers and calves: 12m –
32'00' S and 51°50' W); long-finned pilot whales (about 20
including mothers and calves; 977m – 30°49' S and
48°53' W) and common dolphins (about 20; about 900m –
30°56' S and 49°11' W). They were observed and
photographed in the second week of October from the
oceanographic vessel Atlântico Sul (MOFURG/LMM).

Throughout the year MOFURG/LMM has permanently
monitored bottlenose dolphins in the Rio Grande area and
now considers some animals definitely as residents.

Along the southeastern coast, groups of 2–50 tucuxis
were sighted as well as one right whale and two
franciscanas (UFPR/CEBIMAR).

UERJ/DOc observed humpback whales from on board
Brazilian Navy vessels, as well as a number of tucuxis from
fixed points in the Bay of Guanabara.

FBCN continued studies of humpback whales on their
wintering grounds (Marine National Park of Abrolhos
Reefs).

Strandings
Strandings data were recorded by most of the institutions
mentioned, but a considerable effort to monitor beaches
occurred along the southern and northeastern coasts of
Brazil (notably FURG/DOc; MOFURG/LMM; UFPE/
GMA-FAUNE and GEMARS). The following species
were recorded: Bryde’s whales (UFPR/CEBIMAR; UFRPE/GMA-FAUNA); minke whales (UFPR/GMA-FAUNA); right whales (FURG/DOC; MOFURG/LMM); sperm whales (UFPR/GMA-FAUNA; GEMARS); killer whales (MOFURG/LMM); long-finned pilot whales (FURG/DOC; MOFURG/LMM); short-finned pilot whales (UFPR/GMA-FAUNA); melon-headed whales (UFPR/GMA-FAUNA); false killer whales (GEMARS); common dolphins (UFPR/CEBIMAR); striped dolphins (GEMARS); spinner dolphins (UFPR/GMA-FAUNA); tucuxi (UFPR/CEBIMAR; UFRPE/GMA-FAUNA); rough-toothed dolphins (UFPR/CEBIMAR); bottlenose dolphins (FURG/DOC; MOFURG/LMM; UFRPR/CEBIMAR; GEMARS); franciscanas (FURG/DOC; MOFURG/LMM; GEMARS); and Cuvier’s beaked whales (FURG/DOC; MOFURG/LMM; UFRPE/GMA-FAUNA).

Pollution studies

Heavy metal concentrations in small cetaceans were studied by UERJ/DOC.

Samples of lipid tissue from stranded and incidentally killed cetaceans have been collected and analysed to evaluate the degree of contamination from organochlorinated pesticides as part of an integrated programme (MOFURG/LMM, Museo Argentino de Ciencias Naturales de Buenos Aires). The same programme is now evaluating the degree of contamination from heavy metals in liver and kidney tissues, also collected from stranded and incidentally killed cetaceans. Most of the other institutions are collecting tissue samples for the same purpose.

DENMARK. PROGRESS REPORT ON CETACEAN RESEARCH, MAY 1993 TO APRIL 1994

This report refers to work involving: Danish Fisheries Research Institute (DFRI), Charlottenlund Slot, Jægerborg Allé 1B, 2920 Charlottenlund; Department of Population Biology (DPB), Zoological Institute, University of Copenhagen, Universitetsparken 15, DK-2100 Copenhagen Ø, Denmark; Greenland Fisheries Research Institute (GFRI), Tagensvej 135, DK-2200 Copenhagen N, Denmark; National Forest and Nature Agency (NFAN), Ministry of the Environment, Haraldsgade 53, DK-2100 Copenhagen Ø, Denmark; Zoological Museum, University of Copenhagen, Universitetsparken 15, DK-2100 Copenhagen Ø, Denmark (ZM). The report was compiled by F. Larsen (GFRI).

Species and stocks studied

Studies were conducted on the following species in the following areas: fin whale (*Balaenoptera physalus*) – West Greenland; humpback whale (*Megaptera novaeangliae*) – West Greenland; minke whale (*Balaenoptera acutorostrata*) – West Greenland; and the harbour porpoise (*Phocoena phocoena*) – Danish waters.

Cetaceans occurring in Thai waters were studied within the framework of a Thai-Danish cooperation (ZM).

Field observations and collections

**Greenland**

A photo-identification survey primarily aimed at humpback whales was conducted as a part of the Years of the North Atlantic Humpback whale project (YONAH) by GFRI off West Greenland in July-August, 1993. Usable ID-photos were obtained from 99 humpback whales and one sperm whale and skin biopsies were collected from 36 humpback whales. An additional 14 humpback whales were photo-identified during a seabird survey conducted by Greenland Environment Research Institute off West Greenland in August.

Around 90 hours were spent in July-August during an aerial survey for minke and fin whales off West Greenland. Estimates of abundance for minke and fin whales are presented in SC/46/AS15 (GFRI).

The catch of minke and fin whales in Greenland in 1993 is shown in Table 1. In addition to these figures, six minke whales and two fin whales were incidentally caught in fishing gear in West Greenland and one humpback whale, trapped in a lead in the ice, was taken at Kangatsiaq.

Denmark

Bycatch of harbour porpoise was recorded by observers on board Danish fishing vessels during 51 commercial fishing trips into the North Sea in 1992 and 1993 (DFRI).

Marking
No returns of artificial marks have been recorded. Photographs of natural markings of humpback whales from West Greenland have been sent to the central catalogue for the North Atlantic (GFRI).

Laboratory work
Determination of gender and analyses of the nucleotide sequence in the mitochondrial D-loop were carried out for humpback, fin, narwhal and white whale specimens collected in the North Atlantic (DPB).

Development of techniques
Development of a simple and reliable system for collecting skin biopsies from free ranging large cetaceans has been continued by GFRI.

Tri- and tetramer micro satellite loci are currently being isolated from humpback and fin whales (DPB).

Research results

Denmark

An estimate of the total bycatch of harbour porpoises was derived using a survey of 51 fishing trips representing a total effort of 1.546km net set for cod, turbot and sole. No animals were recorded caught in the nets set for sole. A total of 117 animals was taken in the nets set for cod and turbot. Catch rates in cod nets were 45, 35, 173 and 23 animals per 1,000km net for the four quarters of 1993, respectively. For turbot nets the catch rate was 129 animals per 1,000km net in the second quarter of 1993, the only quarter during which turbot was caught in this area. Extrapolation to the total effort in these fisheries, i.e. 62,891km of net, results in an estimated total bycatch of harbour porpoise of 4,629. As the sampling was not representative of the entire fishery, the estimated catch rates and total should be considered preliminary (DFRI).

17 cetacean species have been recorded from Thai waters: Balaenoptera edeni, Physeter macrocephalus, Kogia sima, Mesoplodon ginkgodens, Steno bredanensis, Sousa chinensis, Tursiops aduncus, Delphinus delphis, Stenella coeruleoalba, Stenella attenuata, Stenella longirostris, Globicephala macrorhynchus, Pseudorca crassidens, Peponocephala electra, Orcinus arca, Orcaella brevirostris and Neophocaena phocoenoides. B. edeni from Thailand and presumably much of the adjacent Sunda Shelf represent a small ecotype of B. edeni for which the original name 'Sittang' whale is proposed. Specimens of adult size lay between minke whales and large B. edeni (ZM).

Sightings data

Sightings recorded during the aerial survey off West Greenland in July-August 1993 included 72 humpback, 15 fin, 27 sei, 66 minke, 2 sperm, 9 killer, 7 northern bottlenose and around 460 pilot whales (GFRI).

Sightings recorded during the photo-identification survey off West Greenland in July-August 1993 included 192 humpback, 14 minke and 2 sperm whales and 4 white-beaked dolphins (Lagenorhynchus albirostris) (GFRI).

Stranding:
Focal institutions are the Zoological Museum of the University of Copenhagen and the Esbjerg Fishery Museum in cooperation with the National Forest and Nature Agency.

FRANCE. PROGRESS REPORT ON CETACEAN RESEARCH, APRIL 1993 TO APRIL 1994

This report refers mainly to work conducted by or in cooperation with IFREMER (Institut Français pour l’Exploitation de la Mer) and concerning the survey of the French albacore tuna drift net fishery in the temperate waters of the eastern North Atlantic.

Species and stocks studied

In 1993, IFREMER completed the study requested by the French Ministry of the Seas, following a European Council regulation. This study was based on the analysis of incidental cetacean catch data collected during two observer campaigns in 1992 and 1993 (GERDAU programme), and on the results of a sighting survey (MICA) for delphinid populations undertaken in summer 1993. As recommended by the study group who defined the programme, the ecological risk associated with drift net fishing was assessed by addressing the impact of incidental catches at the population level for two dolphin species: the striped dolphin (Stenella coeruleoalba) and the common dolphin (Delphinus delphis).

Field observations and collections

In summer 1992, 18 observers monitored one-third of the French tuna drift net fleet. They were asked to count and sample all incidental catches (a total of 475 cetaceans was reported). When possible, autopsies were performed on
dolphins and the following samples were collected: teeth (290), gonads (287), skin (321), stomachs (207) and parasites (47).

During the 1993 fishing season, 18 observers covered 27% of the total driftnet fleet and reported 377 catches of cetaceans.

A number of skin samples were collected in 1992 and 1993: Stenella coeruleoalba (371); Delphinus delphis (151); Tursiops truncatus (4); Globicephala melas (7); Grampus griseus (4); Stenella attenuata (2).

A line transect survey to assess cetacean abundance was conducted in the temperate waters of the eastern North Atlantic during summer 1993. Three different cruises were carried out between 3 July and 22 August, by a team of 10 observers from France, Spain, Belgium and Italy. The area surveyed (almost 205,000 n.miles²) was delimited by the continental slope of the Bay of Biscay, 21°W and 51°30’N and 43°N.

Laboratory work
Gonads, skin and parasites were studied by the laboratory of the Centre de Recherche sur les Mammifères Marins (CRMM) La Rochelle. Teeth were prepared for age reading in the laboratories of IFREMER (Brest) and CRMM (La Rochelle). Arrangements were made with American laboratories for DNA analysis of skin samples taken during 1992 and 1993 from common and striped dolphins.

Research results
Data from the 1992 and 1993 tuna seasons were analysed together. Bycatches were extrapolated to the total fleet by using their ratio to the albacre catches. The estimated total cetacean incidental catch amounted to about 1,700 individuals each year. The two species principally concerned were the striped dolphin (69% of the total incidental catch of cetaceans in 1992 and 64% in 1993) and the common dolphin (24% both years).

Biological parameters for these species were estimated from length frequency data, age data from tooth reading and reproductive data from gonad samples. The results revealed that catches of calves were predominant in 1992 for both species, whereas catches of 1 year olds were predominant in 1993, suggesting the progression of a strong 1992 cohort in the catches of the two species. Gonad analysis suggested an age at first reproduction of 9–10 years for common dolphins and 7–8 years for striped dolphins.

Population abundance of both species was estimated from the sightings survey, assuming that the populations were entirely confined to the sample area. Mean estimated population sizes of common and striped dolphins were estimated as 61,888 and 73,843 respectively. The mean population size of the fin whale (Balaenoptera physalus) in the surveyed area was estimated as 7,407 animals.

A comparison of the total catch to the estimated abundance population size gave average ratios of 0.7% and 1.6% for common and striped dolphins respectively. A model was established to simulate annual changes in population size due to fishing mortality. This model used parameters such as age at first reproduction, calving interval and annual rate of survival of calf and non-calf individuals. Under an initial balanced population assumption, fishing mortalities of 1.4% and 3% (the worst cases as defined by the 95% upper confidence limits) respectively for common and striped dolphins would lead to an annual rate of population decrease of 1%.

Sightings data
Sightings (number of schools) made by observers on board the driftnetters (A) and during the sightings survey (B) are given in Table 1.

Unidentified whales were not systematically recorded and only 16 were recorded.

Strandings
Strandings of cetaceans on the coasts of France are recorded by the CRMM in La Rochelle where strandings data are available.

Pollution studies
Samples of tissues and organs (blubber, liver, muscle, kidney, gonads and sometimes milk and blood) were taken from the common and striped dolphins incidentally caught by the French tuna driftnet fishery, for the purpose of organochlorine, mercury and cadmium measurements. These samples (n=200) are to be analysed during 1994 by IFREMER.

Statistics and data for cetaceans
The incidental catches of cetacean species reported by the observers on board the driftnetters are given in Table 2.

Publications (excluding IWC volumes)
GERMANY. PROGRESS REPORT ON CETACEAN RESEARCH, JUNE 1993 TO MAY 1994

This report was compiled by Karl-Hermann Koch, Institut für Seefischerei, Bundesforschungsanstalt für Fischerei, Palmiilei 9, D-22767 Hamburg and Harald Benke, Forschungs- und Technologiezentrum Westküste, Werfstrasse 10, D-25761 Büsum. As in previous years cetacean research in the Federal Republic of Germany in 1993/94 focused on small cetaceans. In addition, historical aspects of whaling were investigated.

History of whaling
Studies on the history of whaling were continued under the auspices of the 'Deutsches Schifffahrtsmuseum' and associated researchers and groups and dealt primarily with medieval whaling in northern Europe, the iconography of stranded whales and South African whaling off Durban (in collaboration with De Jong). Contact address: U. Schnall and K. Barthelmess, Deutsches Schifffahrtsmuseum, Van Ronzelen Strasse, D-27568, Bremerhaven.

Species and stocks studied
Studies centred on smaller toothed whales, in particular the harbour porpoise, Phocoena phocoena, in the Baltic and the North Sea. In addition, bottlenose dolphins, Tursiops truncatus, and dusky dolphins, Lagenorhynchus obscurus, were subject to investigations by German scientists.

Field observations and collections
Small cetaceans—general
The project to investigate stocks, health status and migration of small cetaceans, mainly harbour porpoises in German waters was completed. Individuals drowned in fishing gear or found dead on beaches were examined at the University of Kiel or the Marine Museum at Stralsund. Samples were collected for studies on pathology, contaminant levels, parasitology, age determination, diet and reproduction. Exchange and close cooperation with a number of European institutions provided an optimal utilisation of these samples. All sightings of cetaceans in German waters were collected and analysed at the University of Kiel. Contact address: H. Benke, Forschungs- und Technologiezentrum Westküste, Werfstrasse 10, D-25761 Büsum.

Studies on parasites and analyses of stomach contents of small cetaceans were continued at the University of Kiel. Contact address: R. Lick, Forschungs- und Technologiezentrum Westküste.

Studies on the biology and conservation of cetaceans and seals along the coast of Mecklenburg-Pomerania (Baltic Sea) were continued. For many years, the Marine Museum at Stralsund has collected information on the distribution of harbour porpoises, harbour seals, ringed seals and grey seals along the southern shores of the Baltic Sea. Furthermore, the museum is responsible for the collection of all specimens found dead along the shores of Mecklenburg-Pomerania and the analysis of the state of marine mammal populations in that area. Contact address: G. Schulze and K. Harder, Meeresmuseum Stralsund, Katharinenberg 14a, D-18439, Stralsund.

Harbour porpoise
The project to monitor variations in local abundance and migrations of harbour porpoise off the Isle of Sylt, launched by the Society for the Protection of the Wadden Sea and World Wide Fund for Nature-Germany in 1990, was continued. An observer network collected data obtained by standardised sighting methods at 18 different locations at two week intervals. In addition, information on behaviour (swimming speed, diving times, etc.) was also collected. The feasibility of photo-identification was tested. Contact address: L. Koch, Schutzstation Wattenmeer, Norwegener Steinl, D-25997 Hörnum/Sylt.

Studies on seasonal appearance, movements, social behaviour, group and social structure of harbour porpoise off the Isle of Sylt (North Sea) were continued. A project was started to study the effects of boat traffic and aquatic sport activities on harbour porpoise and seals at the Lister Tief north of the Island of Sylt. Contact address: R. Schmidt and B. Hessel, Schutzstation Wattenmeer.

WWF-Germany (Wadden Sea and North Sea Programme) continued two projects with respect to harbour porpoise: fisheries interactions and the drift of carcasses in relation to hydrographical conditions within the German Bight (North Sea). Contact address: S. Lutter and P. Moreno, WWF-Wattenmeerstelle Niedersachsen-Bremen, e/o Okologieämter, Am Güthpol 9, D-28757 Bremen.

A project to develop new techniques and thus improve precision of age determination in harbour porpoises was continued. Contact address: H. Kremer, Hohenbergstrasse 13, D-24105 Kiel.

Methods to attach time depth recorders and satellite tracking devices were tested on harbour porpoises in captivity. Contact addresses: R.A. Kastelein, Dolphinarium Harderwijk, The Netherlands; H. Benke, Forschungs- und Technologiezentrum Westküste.

Bottlenose dolphin
Studies on a population of bottlenose dolphins, their social behaviour, social organisation, population dynamics and ecology in the Sado River estuary (Portugal) were continued. Contact address: S. Harzen, Novotel Setubal, 2900 Setubal, E.N. 10 Monte-Belo, Portugal.
Dusky dolphin
Investigations on age determination and reproduction were conducted on a population of dusky dolphins from Peruvian waters. Contact address: L. Chavez, Zoologisches Institut und Museum, Martin Luther King Platz 3, D-20146 Hamburg.

Marking
No marking using artificial marks was conducted. No investigations using natural marks were carried out on large cetaceans. Attempts to identify harbour porpoises and other small cetaceans by means of photos were continued.

Laboratory work
Investigations on the skin and on the anatomy and morphology of the head of different species of toothed whales were continued. Contact address: G. Behrmann, Alfred Wegener Institut für Polar- und Meeresforschung, Columbusstrasse, D-2758 Bremerhaven.

Pathological-anatomical and histopathological investigations on small cetaceans from the North Sea and the Baltic collected by the University of Kiel were continued; the necropsies were carried out at the University of Kiel whilst histopathology was undertaken at the Institute of Veterinary Pathology of the University of Giessen. Contact address: K. Frese and U. Siebert, Institut für Veterinär-Pathologie, Justus-Liebig-Universität, Frankfurter Strasse 96, D-35392, Giessen.

Veterinarian investigations (parasite infestation, body condition, health state etc.) were routinely carried out on cetaceans stranded or drowned in fishing gear. Contact addresses: H. Bohlen and U. Siebert, Institut für Haustierkunde, Christian-Albrechts-Universität Kiel, Ohshhausen-strasse 40-60, D-24118 Kiel, for North Sea coast and Western Baltic coast of Schleswig Holstein; G. Schulze, Meeresmuseum Stralsund; (see above) for Central Baltic coast of Mecklenburg-Vorpommern; M. Stede, Staatliches Veterinäruntersuchungsamt für Fische und Fischwarten, Schleusenstrasse, D-27472 Cuxhaven, for North Sea coast of Lower Saxonia.

Pollution
Ecopathological monitoring of marine mammals in the coastal waters of Lower Saxonia was continued. Autopsies of deceased and stranded marine mammals were conducted with special reference to: contagious diseases, possible effects of human activities (e.g. organophosphate infections and skin diseases, parasitology, and pollutants). Contact address: M. Stede, Staatliches Veterinäruntersuchungsamt für Fische und Fischwarten (see above).

Studies on heavy metal and organochlorine levels in various tissues of harbour porpoises and the relationship between pathological changes and toxic levels were continued. Contact address: U. Siebert, Institut für Veterinärpathologie, Justus Liebig Universität Giessen, Frankfurter Strasse 96, D-35392 Giessen.

An evaluation of existing methodologies for the accurate determination of individual congeners in complex polychlorinated biphenyl (PCB) mixtures was undertaken as part of studies related to the impact of PCB’s on marine mammals. Clean-up procedures for extracts of liver, blubber, brain and blood using alkali, acid treatments and separation on alumina were tested. Contact address: Prof. J.C. Dinkler and R. Bruhn, Institut für Meereskunde, Abt. Meereschemie, Düsternbrooker Weg 20, D-24105 Kiel.

Strandings
Stranded specimens are collected and dissected by the Institut für Haustierkunde at the University of Kiel (North Sea coast and Western Baltic coast of Schleswig Holstein), the Marine Museum Stralsund (Central Baltic coast of Mecklenburg-Pommerania) and the Staatliches Veterinäruntersuchungsamt für Fische und Fischwarten at Cuxhaven (North Sea coast of Lower Saxonia).

Contact addresses: H. Benke, Forschungs- und Technologiezentrum Westküste, Werftarre 10, D-25761 Büsum; G. Schulze, Meeresmuseum Stralsund, Katharinenberg 14a, D-18439 Stralsund; M. Stede, Staatliches Veterinäruntersuchungsamt für Fische und Fischwarten, Schleusenstrasse, D-27472 Cuxhaven.

Statistics and data for small cetaceans
Statistics on strandings and bycatches are collected and stored by the institutions mentioned above and are given in Table 1.

IRLAND. PROGRESS REPORT ON CETACEAN RESEARCH, MAY 1993 TO APRIL 1994

This report summarises cetacean research conducted through May 1993 - April 1994 by: University College Cork (UCC), Fisheries Research Centre, Department of the Marine (FRC), Radiological Protection Institute of Ireland (RPI), Free University of Belgium (FUB), Veterinary Investigation Laboratories, Belfast (VIL), Sea Mammal Research Unit, UK (SMRU), the Irish Whale and Dolphin Group (IWDG) and the International Fund for Animal Welfare (IFAW). All studies are UCC unless otherwise stated. This report was compiled by Simon D. Berrow, UCC.

Species and stocks studied
During this period there have been on-going studies on stranded small cetaceans, mainly harbour porpoise (*Phocoena phocoena*) and common dolphins (*Delphinus delphis*). A study of bottlenose dolphins (*Tursiops truncatus*) in the Shannon estuary also continues.

Field observations and collections
A visual and acoustic survey for cetaceans was carried out during 1993 off the coast of County Mayo by IFAW and the IWDG. The study (IWDG) in the Shannon estuary involves boat and land based surveys to determine the pattern of use of the estuary by bottlenose dolphins. Field observations on Fungi, a ‘friendly’, wild bottlenose dolphin in Dingle, County Kerry are also being collected.

Two studies of incidental capture of cetaceans in fishing gear have been carried out. A quantitative study of incidental capture of marine mammals in the offshore gillnet fishery operating on the Celtic shelf has been completed in collaboration with the Cornish Trust for Nature Conservation and SMRU. A pilot study to assess ecological risk in the Irish albacore tuna (*Thunnus alalunga*) fishery was carried out during the 1993 season.

Marking
Photographic identification of individual bottlenose dolphins in the Shannon estuary using natural markings has recently started.

Laboratory work
Age determination, dietary analysis, reproductive condition and parasite load of stranded and incidentally caught small cetaceans is ongoing at UCC. Post-mortem examination has been carried out on 15 harbour porpoise (eight bycaught), 13 common dolphins (six bycaught), 4 striped dolphins, 2 white-sided dolphins, 3 white-beaked dolphins (*L. albirostris*) and one bottlenose dolphin. Samples were taken for the analysis of contaminants, age determination, reproductive condition, dietary analysis and parasite load. Post-mortem examination of known incidentally caught harbour porpoises and common dolphins has been carried out in an attempt to identify the pathological characteristics of death by immersion. Skin samples from harbour porpoises (*n* = 26) have been sent to SMRU and stranded dolphins (*n* = 4) to University of Valencia for DNA analysis.

Post-mortem examination on stranded cetaceans is carried out in Northern Ireland by S. Kennedy at the VIL. Some of these animals are recovered, under licence, from the Republic of Ireland.

Research results
Most post-mortem studies are on-going and results are not yet published. No evidence of exposure to morbillivirus infection has been found in cetaceans screened using histological and immunoperoxidase tests (VIL).

As part of the Shannon Estuary Dolphin Project, 25 bottlenose dolphins are individually recognisable using photo-identification and between 56 and 68 dolphins were counted during a ‘minimum number’ estimate survey in October 1993. No large whales were seen during a visual and acoustic survey off County Mayo during June and July 1993, even though whaling records suggested high catches had been taken off County Mayo during these months. Dolphins (common and white-sided) were recorded acoustically on 16% of monitoring sessions, pilot whales on 14% and unidentified cetaceans on 29%. Unfortunately weather conditions during the survey period were not favourable and conclusions therefore tentative (IFAW/IWDG).

Results from the bycatch studies are not yet published.

Sightings data
A sighting scheme which collects incidental sighting records of cetaceans in Irish waters has been established and coordinated by the IWDG. A quantified effort sighting network has also been established in Ireland. A sightings database (Apple Mac – Cetacea) is maintained by the IWDG for all sightings records.

Strandings
A stranding scheme operates in Ireland, coordinated by the IWDG and in collaboration with the Office of Public Works, National Parks and Wildlife Service, 32 cetaceans were reported stranded on the Irish coast between May 1993 and April 1994, mainly harbour porpoise and common dolphins. Two strandings were alive including a female sperm whale. All verifiable stranding records are published annually in the Irish Naturalists’ Journal.

Pollution studies
Cetaceans incidentally caught in fishing nets and stranded in good condition have been analysed for contaminants. Analysis of organochlorines (PCBs and pesticides) in liver, kidney, muscle and blubber from incidentally caught cetaceans (*n* = 15) have been analysed by FRC and organochlorines (PCBs and pesticides) and heavy metal levels (Cd, Pb, Cu, Mn, Zn, Cr, total and organic Hg, Se, metallothioneins) from stranded cetaceans (*n* = 50) are being analysed by the FUB. Heavy metal levels (Cd, Pb, Cu, Mn, Zn, Cr) in ribs (*n* = 46) are being analysed by the
FRC and SRTC. Samples of muscle from 20 incidentally captured and stranded harbour porpoises from Britain and Ireland have been analysed for radioceasium by the RPI.

**JAPAN. PROGRESS REPORT ON CETACEAN RESEARCH, APRIL 1993 TO MARCH 1994**

*National Research Institute of Far Seas Fisheries, 5–7-1, Orido, Shimizu, Shizuoka 424, Japan*

This report summarises cetacean research conducted from April 1993 to March 1994 by the National Research Institute of Far Seas Fisheries (NRF) and Japan Fisheries Agency of the Ministry of Agriculture, with the cooperation of other related organisations.

**Species and stocks studied**
2. Bryde's whales: stocks in the North Pacific.
3. Pygmy blue and true blue whales in the Southern Hemisphere.
5. Right whales in the Southern Hemisphere.
7. Short-finned pilot whales: northern and southern stocks off the Pacific coast of Japan.
8. Risso's dolphins: off the Pacific coast of Japan.
10. Dolphins and porpoises taken by the Japanese drifnet fisheries.
11. Additional species and stocks taken during small-type whaling operations.
12. Additional species and stocks sighted during sighting cruises conducted in the North Pacific and Southern Hemisphere.

**Field observation and collections**
The Government of Japan issued the Institute of Cetacean Research, Tokyo (ICR) a permit to take no more than 330 Southern Hemisphere minke whales for research purposes and provided partial financial support.

The IFS and NRF conducted a total of ten research cruises between April 1993 and March 1994 in the North Pacific and two cruises in the Southern Hemisphere. Of those in the North Pacific, seven cruises were primarily engaged in sightings surveys with limited opportunistic biopsy skin sampling whilst the remaining three cruises were primarily conducted for biopsy sampling.

Details of the sighting cruises are given in the 'Sighting data' section of this report and are summarised in Table 1. T. Miyashita (IFS) and H. Shimada (IFS) planned the cruises including designing the cruise tracks and specifying searching methods as well as acting as researchers on board. Table 1 also provides an outline of the biopsy sampling cruises. During all cruises the following biopsy samples were collected: striped dolphins, 27; Pacific whitesided dolphins, 5; northern right whale dolphins, 3; common dolphins, 10; bottlenose dolphins, 5; melon-headed dolphins, 2; Risso's dolphins, 1; minke whales, 5; and Bryde's whales, 13. All samples were preserved in a freezer at the IFS.

The Government of Japan provided two research vessels for two months for the 1993/94 IWC/IDC/brake Southern Hemisphere minke whale assessment cruise. H. Kato (IFS) acted as organiser of the programme and Shimada participated on the cruise as senior scientist on the Shonan maru No. 2. Before the 1993/94 cruise, the vessels carried out a survey in the waters off the Solomon Islands as part of a Japanese National Project with the cooperation of the Government of Solomon Islands. Details of the cruise are given under 'Sighting data'.

The national quota for Baird's beaked whales was 54 whales, as last year, with permitted operation periods of 1 July – 31 August (two land stations at Ayukawa and Wadaura on the Pacific coast) and 1 – 20 September (Abashiri station on the Okhotsk coast). A total of 54 whales (2 off Abashiri, 25 off Ayukawa and 27 off Wadaura) were taken using four catcher boats and the three land stations. T. Kishiro (IFS) organised the field data collection from the fishery and the animals were examined and sampled by a number of biologists (Kishiro, T. Iwasaki (IFS), J. Okajima (JFA) and M. Inaba (JFA) and T. Nakazato (JFA)).

The national quota of northern form short-finned pilot whales for small-type whaling was 50 whales with a permitted season from 5 October – 30 November for two boats (Koei-maru No. 75 and Taiyo-maru No. 28). A total of 44 whales was taken by the two catcher boats and one station in Ayukawa. All animals caught were examined and sampled by biologists (Kishiro and Inaba). The national quota for southern form short-finned pilot whales for the small-type whaling was also 50 whales with permitted operation periods from 16 May – 30 September. A total of 47 whales was taken using three catcher boats (Katsu-maru, Sumitomo-maru No. 31, and Seiwa-maru) and two land stations (Tajji and Wadaura). All animals caught were examined and sampled by biologists (Kishiro, Inaba, Okajima, M. Amano (JFA) and M. Yoshioka (JFA)). The JFA also set a national catch quota of 30 Risso's dolphins for small-type whaling in Tajji in May, June and September. A total of 30 individuals were taken by Katsu-maru, Sumitomo-maru No. 31 and Seiwa-maru, and examined by Kishiro, Inaba, Amano and Yoshioka. Iwasaki and his colleagues from JFA (T. Kage, M. Fujimoto, T. Hara, M. Furus) collected samples for life history and genetic studies from catches made by the drive and hand harpoon fisheries in Tajii during operations from 1 – 24 December 1993 and 8 January – 28 February 1994. They examined a total of 734 individuals comprising 280 striped dolphins, 162 short finned pilot whales (southern form), 113 bottlenose dolphins, 94 Risso's dolphins and 85 spotted dolphins.

The research team consisted of T. Kasuya (IFS), Kato, A. Kawa (Mic University), Miyashita, Shimada, Iwasaki and staff of the Toba Aquarium (Mic Prefecture) and Minami-Chita Beach Land Aquarium (Aichi Prefecture). Sighting surveys were made in Jse and Mikawa Bay in April, September and January.

Two northern right whale dolphins which were incidentally caught during experimental driftnet (large mesh) operations (100 tan x 16 times) were examined by M. Hisano (JFA) and Iwasaki.

Marking

No whale marking using artificial marks was conducted and no marks were recaptured. Although many photographs which may be suitable for natural marking studies were taken during the sighting cruises, the photographs have not yet been analysed.
Table 3
Whales sighted by Japanese dedicated surveys (Kyo-maru No. 1, Shonan-maru No. 2, Toshi-maru No. 18, Toshi-maru No. 25, Shinsho-maru, Sunamoto-maru No. 31 and Shinyo-maru) operated in the North Pacific during 1993 Summer season (July to September 1993). Number of sightings by 10 degree square are based on the noon position of the vessels. Key: Dist. = Distance surveyed (n.miles); Ba = Baird's beaked whale, Zi = Cuvier's beaked whale, Ps = southern form short-finned pilot whale and Pn = northern form short-finned pilot whale. For other species key see Table 2.

K. Masuda (Faculty of Science, Hokkaido University) and Kato started to examine mitochondrial DNA haplotype composition of Baird's beaked whales collected in waters off Japan.

Kishiro, Inaba and A. Chiba (School of Dentistry, Hokkaido University) have begun preparing the teeth and gonads of Baird's beaked whales collected in waters off Japan during the operations in 1992 and 1993.

Iwasaki aged 77 striped dolphins taken off the Pacific coast of Japan under the scientific permit in 1993.

Ichii, C. Tamura (Hokkaido University) and Y. Fujise (ICR) examined the contents of 100 minke whale stomachs collected during the 1989/90 and 1991/92 Japanese research permit cruises in Area IV.

T. Kobayashi (NIA; National Research Institute of Aquaculture), T. Okazaki (NIA), Kato and Kishiro carried out a preliminary examination of mitochondrial DNA from 52 minke whales taken by the past whaling operations off Japan for stock identity studies.

Development of techniques
Iwasaki, Miyashita and Kasuya developed a modified hand harpoon with a biopsy dart on its head to obtain skin samples from small cetaceans; a total of 68 skin samples were collected using the harpoon. They are continuing to examine modifications of the dart in order to improve its efficiency.

Laboratory work
Kato and R. Zenitani (ICR) aged 305 of 327 ordinary form of southern minke whales taken by the ICR for scientific purposes in the 1992/93 Antarctic season.

Research results
Kato and M. Yoshioka (University of Tokyo) examined biological parameters and their geographical and temporal variation in Bryde's whales. While they found apparent

local variation in certain parameters such as length at sexual maturity, pregnancy rate and length at physical maturity, they believed it was not possible to conclude that the differences were due to stock differentiation; they believed they were probably caused by sampling bias due to different whaling regulations by area.

Kato, S.B. Reilly (Southwest Fisheries Science Center, USA), Miyashita and Shimada examined the segregation of two subspecies of southern blue whales and the current distribution of pygmy blue whales using all available sighting information collected by the JSV, Japanese national sighting project and IWC/IDCR research vessels.
Table 6

Summary of cetacean strandings and catches by Japanese fisheries in 1993, by species and type of fisheries. For further details see Table 5.

They found that the pygmy blue whales appear to segregate north of the Antarctic convergence with true blue whales further south in mid-summer in the Indian Ocean. This is also true in the South Pacific and the South Atlantic. Some local resident stocks of the pygmy blue whale appear to exist in waters off Peru.

Ichii and their co-workers examined the stomach contents of 100 minke whales collected during the 1988/89 and 1990/91 Japanese research take cruises in the Ross Sea and found that the minke whales had a strong preference for larger or sexually mature krill over smaller krill.

Fujise, Kato, Zenitani and Kishino analysed the age structure and reproductive status of 615 ordinary form minke whales taken during the Japanese research programme in 1991/92 and 1992/93 found some changes in the age structure to occur with time during the feeding season.

Miyashita and Kato analysed sightings data collected by the R/V *Shuyo-maru* during the 1991 and 1992 cruises off the Pacific coast of Japan and estimated the abundance of Baird's beaked whales to be 5,029 (CV 0.36).

Shimada examined the current population size of Bryde's whales using sightings data collected from the cruises which took place from 1988 to 1991, and obtained a preliminary estimate of abundance of 11,386 (CV 0.163). He believed the estimate may be biased downwards because the survey did not cover the entire summer distribution.

Ichii, Tamura, Fujise and their co-workers examined the stomach contents of 100 southern minke whales collected under the Japanese research take in 1989/90 and 1991/92; *Euphausia crystallorophias* was the dominant food species in the Prydz Bay region.

**Sighting data**

In 1993/94, an IWC/ICDR minke whale assessment cruise was conducted in Area 1. Japan provided two vessels and crews for the programme as in previous years. Shimada participated in the cruise as senior scientist on *Shonan-maru No.2* and L. Pastene (ICR) was a researcher on *Shonan-maru*.

Sightings were also conducted by the two vessels before the IDCR cruise in waters off the Solomon Islands, mainly for Bryde's and blue whales. The cruises were conducted with the cooperation of the Government of Solomon Islands and carried a governmental observer; Shimada and Pastene were on board throughout the cruise.

Of the nine research cruises conducted in the North Pacific, seven were mainly for sightings in the western North Pacific (using four catcher boats, two tuna long-liners and one R/V of the IFS) while the remaining two were for obtaining skin biopsies (using one small-type whaling boat and a tuna long-liner). The names of the vessels, scientists on board and period of each cruise are given in Table 1.

The results from the sighting cruises above are given in Tables 2.3 (summer surveys) and 4 (in winter).

Sightings of cetaceans were also recorded during northern fur seal research in the Okhotsk Sea (*Shuyo-maru*) and off the Pacific coast of Japan (*Kanki-maru No.38*); N. Baba (Seal section, IFS) was on board *Shuyo-maru* from May 29 – June 24, 1994 and *Kanki-maru No.38* from April 3–29 1994. Cetacean sighting information was also recorded by six salmon research vessels in the 1994 season. These sightings data are not included in Tables 2–4.
Stranding
Information on stranded cetaceans has been collected by the Coastal Division of the Fisheries Agency, 1-2-1, Kasumigaseki, Tokyo 100, Japan; the Institute of Cetacean Research, Tokyo Suisan Building, 4-18 Toyomi, Chuo-ku, Tokyo 104, Japan; T. Yamada, National Science Museum, Hyakunin-cho, Shinjuku-ku, Tokyo 164, Japan. Details can be obtained from these institutions.

Pollution studies
Tissue sampling from striped dolphins for pollution study was carried out during the Shinhoyo-maru cruise.

Statistics of small cetaceans
Catch statistics of direct and incidental takes of small cetaceans are given in Table 5 by prefecture and type of fisheries and summarised in Table 6.

Small-whale whaling statistics were collected by the Far Seas Division of the Fisheries Agency; other statistics were provided by the Coastal Division of the Fisheries Agency.

During the 1993 season, the harpoon fishery for porpoises was permitted for nine months (February to October) in Okinawa prefecture, seven months (February to August) in Wakayama, six months (January to April, November to December) in Miyagi, Iwate and Chiba, 4.5 months (May - 15 June and August to October) in Hokkaido and 3 months (April, November, December) in Aomori. The drive fishery was allowed for 7 months in Wakayama (January to April, October to December) and Shizuoka (January to March and September to December).

National quotas for 1993 by species were as follows: 9,000 dali-type Dall's porpoises; 8,700 true-type Dall's porpoises; 1,270 Risso's dolphins; 1,100 bottlenose dolphins; 950 spotted dolphins; 725 striped dolphins; 400 southern form short-finned pilot whales; and 50 false killer whales.

The seasons for small-type whaling are detailed in the section on field observations and collections.

Publications (excluding IWC volumes)

Priority was given to research projects on the distribution, biology and management of the vaquita (Phocoena sinus). A series of five seasonal cruises was completed and scientific observers were located in two fishing towns to assess the incidental mortality of this endemic species.

Regarding the dolphins associated with the yellowfin tuna in the Eastern Tropical Pacific, studies of the local distribution and natural history of spinner dolphins (Stenella longirostris) have been developed as well as an investigation on the distribution and movements of common dolphins (Delphinus delphis) in the Gulf of California, the offshore waters of Baja California and other North American waters. In a cooperative research programme, short term movements of offshore spotted dolphins (S. attenuata) were tracked (see SCI/46/ProgRep USA).

Field observations and collections
As in previous years, the use of several platforms at sea permitted sightings of cetaceans present in Mexican waters to be obtained: these included the use of tuna fishing boats, research and military vessels and small boats with outboard engines. The main effort was directed at cetaceans in the Gulf of California. Data on the observations of cetaceans present in the tuna fishing areas of the Eastern Tropical Pacific and the Gulf of Mexico were also collected through the information provided by PNAAPD.

Fresh samples from dead specimens were collected after two mass strandings, one of sperm whales and the other of spinner dolphins (see ‘Strandings’).

Marking
In a cooperative research effort between the National Tuna Dolphin Program of Mexico, NMFS-NOAA-USA and IATT/CICAT, a marking programme for yellowfin tunas (Thunnus albacares) and offshore spotted dolphins was conducted. VHF radio tags were implanted on five dolphins and four tunas were also marked. After tracking the cetaceans for one night, the radio tags were all recovered the following day (for more details and results see SCI/46/ProgRep USA).

Laboratory work
Materials collected from the strandings referred to above are being analysed for various studies. The following institutions: Universidad Autónoma de Nuevo León, Universidad Autónoma de Sinaloa and Universidad Nacional Autónoma de México are involved in cooperative research projects with materials collected by PNICM

Development of techniques
The reaction of dolphins to air bubble curtains during tuna fishing operations is currently being studied as a method of reducing dolphin capture whilst maintaining fish production. The potential use of the bubbles as sound deflectors is also being analysed. Positive results on both experiments have been obtained and more field work is planned.

Research results
At present data on distribution, abundance and habitat utilisation of several whale species and other cetaceans is either 'in press' or 'under review'.

Sightings data
A series of seasonal cruises designed to study the distribution and abundance of the vaquita (Phocoena sinus) were performed and various observers from Mexican institutions and NOAA-USA participated in this effort.

Sighting information on several cetacean species obtained through the research projects and platforms mentioned above is currently under review. Species including sperm, fin, Bryde's, minke and humpback (M. novaeangliae) whales were observed in different seasons in the Gulf of California and other Mexican waters.

Strandings
A mass stranding of sperm whales in the Gulf of California, at the Bay of La Paz, allowed us to gather some information on the behaviour of these cetaceans during this particular event. This stranding can be considered unique due to the successful rescue of 15 out of 18 of the animals involved, due to prompt action taken by the rescue team led by Mexican Marine Mammal Program (PNICMM) personnel.

Other stranding events were recorded during the year along several Mexican coasts. Another mass stranding occurred at La Paz Bay, this one consisted of a group of spinner dolphins. Approximately one half (69 dolphins) of the animals involved died while the other half were rescued. With the participation of several national institutions, various studies are being conducted on the materials collected.

Pollution studies
Collaborating with experts from the Marine Sciences Institute of the National University (ICMx UNAM) who have studied vaquita samples before, several tissues from spinner dolphins from the mass stranding mentioned above are currently being analysed for heavy metals and pesticide traces.

Publications (excluding IWC volumes)

This report summarises research by the Netherlands Institute for Sea Research (NIOZ), the National Museum for Natural History (NMN), the Institute for Forest and Nature Research (IBN-DLO), Leiden University (RUL), Institute for Public Health and Environmental Protection (RIVM), Netherlands Institute for Fisheries Research (RIVO-DLO), Information Technology Group, Technical University Delft (TUD) and the Harderwijk Marine Animal Park (HMAP). Compilation by K. Lankester, NL-1054 DT 18G-III Amsterdam.

Species and stocks studied

The species of primary interest were harp seal porpoise (Phocoena phocoena) and Lagorchynchus spp. Other species included sperm whales (Physeter macrocephalus), killer whales (Orcinus orca), long-finned pilot whales (Globicephala melas), River dolphins (Inia spp., Sotalia fluvialis) and Commerson’s dolphins (Cephalorhynchus commersonii).

Field observations and collections

Several dedicated surveys were carried out during line-transect surveys for birds in the North Sea (IBN-DLO, RIVO-DLO, NIOZ). In addition, regular sightings from research vessels are made on an opportunistic basis throughout the year. Data have been catalogued in a database, which comprises data from the period 1972–1994 from shipboard surveys, coastal sightings and various other sources (NIOZ). In an ongoing bycatch research programme, the behaviour of killer and pilot whales was described (RIVO). Some bycatch victims were collected. Stranded animals have continued to be reported and samples were collected for analyses (NMN). Several live stranded harp porpoises were rescued. In their recovery period, experiments were conducted in pools on reactions to fishing gear, before the animals were returned to sea (HMAP).

Laboratory work

Various experiments on sound production were undertaken on several cetacean species (TUD). Work continued on virus isolation and characterisation in various cetacean species (RIVM).

Development of techniques

Experiments on interactions between harp seal porpoise and fishing gear, on sound production and the design of telemetry attachment devices were undertaken (HMAP). Various other experiments were conducted on live stranded harp porpoises in the period of their recovery.

Sightings data

There was one confirmed sighting of a bowhead whale (Balaena mysticetus) on 11 August 1993 (80°25’N, 52°2’E) off Franz Josef Land. Sightings are recorded during the research programme on incidental catches in Dutch freeze trawler operations (RIVO-DLO). Sightings data reported from the North Sea are published on a regular basis in the ornithological journal SULA (NIOZ). These are also entered in the existing database. In June/July 1994, the SCANS-survey took place (a large scale cetacean survey programme in the North Sea, inter alia for harp porpoise): three Dutch vessels took part (RIVM, RIVO-DLO).

Strandings

Registration of strandings was continued (NMN). Live stranded animals are, when possible, moved to the HMAP for treatment.

Pollution studies

Tissue samples of stranded harp seal porpoises were collected and analysed for studies on pollutant burden and pathology. Dissections on 65 specimens from bycatches of P. phocoena (4), L. acutus (47), L. albirostris (1), D. delphis (11), T. truncatus (2) have been conducted (RIVO-DLO). Samples from bycatch victims were distributed inter alia for contamination analyses and biological and pathological studies.

Statistics and data for small cetaceans

NEW ZEALAND. PROGRESS REPORT ON CETACEAN RESEARCH, APRIL 1993 TO MARCH 1994

M.F. Donoghue

Department of Conservation (Te Papa Atawhai), PO Box 10420, Wellington, New Zealand

This report summarises studies on cetaceans which have been carried out in New Zealand between April 1993 and March 1994. Contributions have been received from staff of the Department of Conservation; the National Museum of New Zealand; Auckland, Massey and Otago Universities; the Crown Research Institute for Environmental Health and private consultants.

Species studied
During the past year, studies have been conducted on the following species in the New Zealand region: sperm whales (Physeter macrocephalus), southern right whales (Eubalaena australis), humpback whales (Megaptera novaeangliae), bottlenose dolphins (Tursiops truncatus), dusky dolphins (Lagenorhynchus obscurus), common dolphins (Delphinus delphis), Hector's dolphins (Cephalorhynchus Hectori), long-finned pilot whales (Globicephala melas), killer whales (Orcinus Orca) and several species of beaked whales (Ziphiidae spp.).

Field observations and collections
A tissue bank containing samples from stranded cetaceans, is held by A. van Helden at the Museum of New Zealand, Te Papa Tongarewa, PO Box 467, Wellington. A. van Helden also maintains the collection of skeletal material for the Museum of New Zealand, which specialises in ziphid whales.

The plotting of historical whale sightings in the South Pacific onto new charts has been commenced by M.W. Cawthorn, using information from the Townsend data base.

Data from strandings have been collected by Department of Conservation staff, Museum of New Zealand and university personnel. In association with a research programme to investigate humane euthanasia of cetaceans, staff of Massey University have developed a collection of casts, X-rays and CAT scans of skulls and tissues of a number of species.

Observations and the development of photo-identification catalogues continue for right whales in the sub-antarctic, sperm whales at Kaikoura, Hector's dolphins off the east coast of the South Island and killer whales nationally. A catalogue of tail flukes of humpback whales in Tonga has also been established.

The Hector's dolphin research program, started by E. Slooten and S. Dawson in 1984, has been joined by S. Brager who is studying the population biology of the species for his PhD at Otago University. Aside from continued work at Banks Peninsula, where most research on Hector's dolphins has been carried out so far, Brager will be working at two other sites on the east coast of New Zealand and at three sites on the west coast.

The central aim of the work at Banks Peninsula is to assess whether the Marine Mammal Sanctuary is an effective solution to gillnet entanglement problems in the area (Dawson and Slooten, 1993). To achieve this, survival and reproductive rates are estimated using photographic identification. The Department of Conservation is also assessing trends in population size, using aerial surveys.

Marking
No whales have been marked or tagged with permanent markers between April 1993 and March 1994. In February 1994, three Hector's dolphins were temporarily tagged with a 'Remora' suction cup radio-transmitter.

Laboratory work
Tissue samples of stranded cetaceans have been analysed for planar chlorinated hydrocarbons (PCHs) by P. Jones at the Institute for Environmental Health. A summary paper has been provided to the Scientific Committee.

E. Slooten and S. Dawson have continued their anatomical studies of Hector's dolphin.

D. Blackmore and colleagues at Massey University have carried out investigations into the anatomy and morphology of a number of cetaceans stranded on the New Zealand coastline and have assessed the effectiveness of several methods commonly used to kill or euthanise whales.

C.S. Baker (Auckland University) has continued his analyses of nuclear and mitochondrial DNA of cetaceans, especially the molecular genetic identification of sex and stock identity among humpback whales of the Southern Oceans (Participants: C.S. Baker, School of Biological Sciences, University of Auckland and S.R. Palumbi, University of Hawaii in collaboration with B. Abernethy, J. Bannister, R. Slade, L. Flores-Gonzalez, P. Corkeron and H. Rosenbaum). Humpback whales in the Southern Hemisphere are considered to form five or six distinct feeding aggregations, (Groups I-VI), distributed more or less discontinuously around the Antarctic continent during the austral summer feeding season. The longitudinal boundaries of these feeding grounds are largely coincidental with the division of Antarctic waters into six broad zones. To evaluate the genetic basis of stock structure among Southern Hemisphere humpback whales, work is continuing on the analysis of sequence variation in the mitochondrial DNA control region from samples of 110 individuals collected in Groups IV, V and VI-I. Funding for this programme has been provided by the IWC.

Genetic variation and population structure of Hector's dolphins is also under investigation (Participants: C.S. Baker, F. Pichler, School of Biological Sciences, University of Auckland, S. Dawson and E. Slooten, Department of Zoology, University of Otago). Hector's dolphin is a coastal species endemic to New Zealand with an estimated total population of 3–4,000. To assess current levels of genetic variation and to describe population structure, single-copy nuclear and mitochondrial DNA sequences amplified by the polymerase chain reaction are being analysed from samples collected as bycatch and beach-cast specimens. This programme was initiated in late 1993 with funding from the Department of Conservation and is expected to continue through early 1995.

Development of techniques
Development and refinement of biopsy equipment by M.W. Cawthorn continues, with the emphasis on sample
retention and release of darts from whales’ skin. Cutting
hands have been designed specifically for some species of
whales.

A group of scientists of different disciplines from
various institutions and organizations including Massey
University, the Department of Conservation and the
New Zealand Meat Research Institute, led by D.K.
Blackmore, has been working on dead stranded whales in
order to investigate and develop the most appropriate
techniques for the euthanasia of stranded cetaceans in
extremis.

To assess the practicality of euthanising whales by the
use of electricity, equipment has been produced which will
inject a known electrical current into the carcasses of
whales and will measure both the impedance of various
cetacean tissues and the current flow through the carcass,
including both the brain and the heart. Cetaceans studied
include common dolphins, long finned pilot whales, pygmy
sperm whales, beaked whales and sperm whales. Domestic
stock studied as models for certain techniques include
sheep, pigs and cattle.

The interactions between tourist vessels (permitted to
operate ‘swim-with-dolphins’ trips) and groups of dusky
dolphins are being studied at Kaikoura by K. Barr,
supervised by B. Würsig (Texas A&M University, Galveston)
and E. Slooten (University of Otago). Dolphin
movements are tracked from shore by a teledoscope
interfaced with a laptop computer to log data and ‘Big Eye’
25x150 large-ocular binoculars, which allow for accurate
determination of behaviour at distances of up to 12
kilometres. Data on dolphin speed, direction of travel,
frequency of direction changes, group size and aerial
activity will be post stratified by time of day and number of
tourist boats into a factorial Analysis of Variance design.
Data have so far been collected from 55 days of
observations and will continue to be collected to the end
of April 1994. Further data will be collected over the six
months from October 1994 to April 1995. Research results
will be available in 1995 and will be used to assess whether
the current guidelines for behaviour of vessels around
dolphins are effective and appropriate.

Behavioural responses of bottlenose and common
dolphins to commercial swim/watch programmes in the
Bay of Islands are being studied by C.S. Baker, D.
Helweg and R. Constantine, School of Biological
Sciences and Department of Psychology, University of
Auckland and N. Gales, Department of Conservation.
Commercial swim/watch programmes focusing on wild
populations of bottlenose and common dolphins have
developed recently in the Bay of Islands, New Zealand,
under permits from the Department of Conservation.
Behavioural, acoustical and photo-identification methods
are being used to document the exposure of individual
dolphins to commercial operations and to monitor
changes in the behaviour of dolphins during approaches
by swim/watch boats and the subsequent swimming by
passengers. The monitoring programme was initiated in
late 1993 and is expected to continue at least through
early 1995.

As part of ongoing cooperative studies between the New
England Aquarium and the Department of Conservation,
G. Stone successfully deployed further ‘Remora’ suction
cup radio tags on Hector’s dolphins at Banks Peninsula,
the most successful of which provided uninterrupted data
transmission for 15 hours. Groups of dolphins were also
studied through the use of underwater video recordings
and surface observations. This research is part of a long-
term study aimed at examining movement and dolphin
characteristics. Full results of the study will be
available in 1995.

S. Bruger (Otago University) will be using stereo-
photography to assess the population structure of Hector’s
dolphins at Banks Peninsula and at five other study sites.
Two precisely aligned, downward-looking cameras will be
used to take stereo photographs of dolphins as they ride the
bow wave of the 4.5m research boat. The system will
provide precise measurements of individual dolphins and
employs a simultaneous underwater video to sex each
individual measured. Data on age versus sex are available
from the examination and tooth sectioning of more than 70
dolphins which had been killed in gillnets or found dead
ashore. This work will allow more accurate population
modelling via incorporation of age structure and sex ratio
of the free-ranging animals and will provide insights into
the effects of gillnetting and other human impacts in
different areas.

K. Schneider (Otago University) is starting his PhD
study on the bottlenose dolphin population of Doubtful
Sound in April 1994. In addition to continuing the photo-
ID work, a downward-looking stereo camera and
simultaneous video system (as described above) will be
used to document population structure and to extend
current work on social organisation. Schneider’s work will
also focus on foraging and acoustic behaviour. The very
recent development of suction cup tags which record dive
time and depth holds considerable promise in studies of
foraging. However, the effect of such tags on behaviour
has not been studied quantitatively and without such
studies tag results are of unknown value. Schneider,
Dawson and Slooten will investigate the effect of the tags
using a controlled experiment comparing behaviour in
tagged and untagged animals. If, despite high statistical
power, tags have no significant effect, or that effect is
temporary, tag data will be used to determine where
dolphins are foraging. Examining those areas/depths with
a remotely operated diving vehicle (owned jointly by
Television New Zealand and Otago University) will
provide information on what prey species are available in
those places.

Schneider will also study the acoustic repertoire of free-
ranging bottlenose dolphins using wide band recording
equipment. These studies may help to put into context the
considerable amount known about sonar and whistles in
this species, and help to elucidate the role each might play
in communication.

C.S. Baker has developed a field-based technique for
amplification of DNA, using a portable laboratory for the
polymerase chain reaction. Amplified DNA from a variety
of biological sources (e.g. commercial products, bycatch,
strandings) can then be sequenced and used to identify the
species and geographic origin of the samples.

A team at Auckland University, led by D. Helweg, is
currently investigating the role of acoustical factors
implicated in the mass strandings of long-finned pilot
whales on New Zealand beaches, starting at Golden Bay,
Nelson. The physical structure of stranding sites and strong
social bonds of the pods which are, in part, maintained by
whistles, suggest that acoustic factors are central to the
cause of mass strandings. To date, these hypotheses have
not been carefully investigated. New Zealand has one of
the highest rates of pilot whale strandings in the world,
providing reliable opportunities to attend strandings with
the goal of understanding why they happen and
establishing methods for stranding prevention.
The proposed research involves systematic studies of the role of acoustics in mass strandings at the site of at least two strandings of pilot whales in 1994. At the stranding sites, systematic recordings will be made of social whistles, echolocation clicks and other vocalisations of the stranded whales, using an extremely sophisticated digital sound recording system that is being custom made in the Department of Psychology at the University of Auckland. These vocalisations, combined with data on the gender, genetic relatedness and identity of the vocalising individuals, will give an insight into the function of different vocalisations in relation to stranding behaviour. At the strandings, studies of the usefulness of acoustic playback methods in reversing and preventing stranding will be initiated, using a sophisticated, durable acoustic playback system that has also been developed in the Department of Psychology at the University of Auckland. Details of acoustic equipment are available on request.

E. Slooten (Zoology Department, Otago University), B. Taylor (National Marine Fisheries Service, La Jolla) and D. Fletcher (Department of Mathematics and Statistics, Otago University) are currently working on a population viability analysis for Hector's dolphins.

O. Jake (MSc student at Otago University) is conducting trials to quantify the range at which whales are detected using a directional and omni-directional hydrophone, to calculate the 'width' of current acoustic transects and hence to derive quantitative estimates of whale abundance. Preliminary analysis with a Bruel & Kjaer precision level recorder shows that faroof proof click detection requires the clicks to be about 4dB above the background noise. Spherical spreading of the signal and attenuation, means that this 4dB signal to noise ratio is achieved at a range of about two nautical miles. He is now using digital signal processing hardware and software to improve the ability to detect clicks in noise. This approach should significantly extend the range at which clicks can be detected and hence widen effective search width on acoustic transects. These methods promise far greater accuracy and lend themselves naturally to automation.

Research results
Blackmore et al. have demonstrated that detailed anatomical studies of 12 species of cetaceans including CT scans, conventional radiography and computer-generated illustrations, could be used to make decisions on where best to disrupt cerebral function by ballistic or explosive devices. Further work in shooting the isolated heads of pigs, cattle, dolphins, pilot whales and live large pigs with a shotgun and a multiple projectile has resulted in an effective and safe method for destroying small cetaceans. Work on the intra-oral positioning of small explosive charges for the destruction of large cetaceans is promising.

The electroencephalograms (EEG) of live sheep have been studied to evaluate the effects of projectiles fired through the spinal cord at the occipito-atlantal junction. Severance of the spinal cord at this level has no effect on consciousness. Techniques are being developed to study the EEG of live whales. Acrylic casts of the blood vessels from the heart to the brain of two immature pilot whales have been prepared. These confirm that the common carotid arteries play virtually no role in the blood supply to the brain.

Abundance and habitat use of humpback whales in Tonga is under investigation by C.S. Baker, P. Jenkins, School of Biological Sciences, University of Auckland and M. Donoghue, Department of Conservation, in consultation with B. Abernethy, South Africa Museum and M. Cawthorn. The Tongan Archipelago is considered a winter breeding ground for humpback whales that migrate from Area V of the Antarctic past the coast of New Zealand and eastern Australia. Monitoring the abundance of humpback whales in this region is of particular interest because of the observed increase in the numbers of whales migrating along eastern Australia, the absence of any increase along the coast of New Zealand and the recent history of subsistence whaling in Tonga. A paper describing Tongan humpback whale song recorded in 1993 by P. Jenkins will be presented by D. Helweg on 3 May 1994 at the Symposium on Marine Sensory Systems in Harderwijk, Holland.

Following the approach used in recent surveys of this region humpback whales were observed, photographed for individual identification and their song recorded for population analysis during seven days of non-systematic surveys in the Vava'u and Ha'apai Island groups. Consistent with previous results, the numbers of whales observed was low. A total of 14 groups were sighted, including 15 adults and 5 calves. In contrast to Hawaii where the majority of cow/calf pairs are escorted by one or more adults, the five cow/calf groups observed in Tonga were not escorted. A fragment of one song was recorded and one biopsy sample was collected.

Recent data on behaviour and social organisation of Hector's dolphins (Slooten et al., 1993) indicate that sexual behaviour is more common when previously separate groups meet. This could lead to increased fertilisation rates in high density areas and decreased fertilisation rates in low-density areas.

A review, comparing levels of PCBs and DDTs in Hector's dolphin with those found in marine mammals elsewhere has been completed recently by D. McCutchen (Diploma of Wildlife Management, 1992).

Work on the distribution, abundance and population structure of sperm whales at Kaikoura continues. Between 1988 and 1993, 85 individuals have been identified from nicks and marks in the trailing edge of their flukes and so far all individuals photographed have been uniquely identifiable. Resightings show that some whales spend several weeks or months in the area. About half (49%) have been seen in more than one field season. One individual has been seen every year from winter 1989 to summer 1992/93 and, like several others, appears to return to the area regularly. Others (29%) have been photographed on one day only and appear to be transients. Mark-recapture analyses by S. Childerhouse (Diploma of Wildlife Management student, Otago University) suggest that between 50 to 100 whales use the Kaikoura area.

A low-cost stereo photographic system was developed to estimate the sizes of individuals from measurements of the distance from the blowhole to the dorsal fin (SC/45/O 2). Stereo pairs of 41 individuals have been analysed. Calculated total lengths of these whales ranged from 9.32 to 15.83m. Without underwater observation or genetic analysis, it is not possible to sex subadult sperm whales. However, over half of the whales measured were considered too large to be female (>11.3m) confirming the impression that most (perhaps all) whales at Kaikoura are males.

This summer's fieldwork on sperm whales (by Dawson, Jake, Childerhouse and Slooten; all from Otago University), included collection of 21 samples of sloughed skin - collected with a dip-net while following whales at the
surface before they fluke-up. In collaboration with other researchers, these will be used for mtDNA analyses to look at the relationships between the Kaikoura ‘stock’ and those in other areas.

Bottlenose dolphins have mostly been studied in shallow tropical or semi-tropical environments. Doubtful Sound (Fiordland, New Zealand), is very near the southern limit for bottlenose dolphins and offers a uniquely contrasting environment. J. Williams (MSc student, Otago University) found that a population of approximately 60 dolphins is resident in Doubtful Sound (Williams et al., 1993). They appear to neither leave the area nor exchange members with other groups of dolphins. More than 60% of the population has been photographically identified (Williams et al., 1993).

Sightings data
M.W. Cawthorn continues to maintain an active sightings network throughout the South Pacific. NZ region and Tasman Sea.

C. Jowett regularly surveyed cetacean distribution and abundance in the Hauraki Gulf from a barge travelling between Auckland and Great Barrier Island. Common dolphins were the most frequently sighted species.

An aerial survey of the sub-antarctic Campbell and Auckland Islands to count southern right whales (Eubalaena australis) was carried out by an RNZAF Orion on 5 August 1993. Forty two adults and one calf were counted at Port Ross in the Auckland Islands, and eight adults were counted at North-West Bay, Campbell Island.

I. Visser continued her research into the seasonal abundance and distribution of killer whales in New Zealand waters. Thirty individual animals have now been identified, most of which have been sighted more than once. Individuals have been re-photographed on up to six different occasions. Most pods move between North and South Islands.

Strandings
All strandings in New Zealand are entered on a database maintained by the Museum of New Zealand. Table 1 provides a summary of all stranding events from 1 April 1993 to 31 March 1994.

Table 1
Stranding record for the period 1 April 1993 - 31 March 1994. Key: A = number of stranding incidents; B = number of individuals; C = individuals resighted; D = individuals restranded; E = individuals saved.

The percentage number of single strandings from April 1993 to the end of March 1994 is 71% of the total number of incidents. The number of strandings involving five or more animals is 16% of the total number of incidents for the period. The number of species represented is at least 10 and could be as high as 14.

The terms ‘Beaked Whale, Dolphin, Mesoplodon sp. and Whale’ in Table 1 are used when an animal or animals have only been identified to that level. Of the families represented for the period the greatest percentage of representation is for Delphinidae at 74% of the total incidents, followed in order by Ziphiidae (10%), Physeteridae (8%), Balaenopteridae (7%) and lastly Balaenidae (1%).

The greatest number of incidents for a species is for common dolphins with 30, which represents 41% of the total number of incidents.

The greatest number of individuals stranded for a species, is the long-finned pilot whale with 471, which represents 82.5% of the total number.

Pollution studies
P. Jones et al. (Crow Research Institute for Environmental Health) have continued their analyses of tissues of stranded cetaceans and have shown that planar chlorinated hydrocarbons (PCHs) are present in marine mammals beach casts on the New Zealand coastline. The concentrations of PCHs are related to both food habit and proximity to the coast. Concentrations of polychlorinated biphenyls (PCBs) were lowest in open ocean baleen whales, intermediate in open ocean carnivores (beaked whales and common dolphins) and highest in Hector’s dolphins, which have very limited coastal distribution. Concentrations of PCBs in common dolphins and beaked whales in New Zealand are lower than those reported for similar species in the Northern Hemisphere. Further details are available in SC46/0.12.

Statistics and data for small cetaceans 1993
No permits were issued in New Zealand for the directed take of small cetaceans during the past year.

The total number of incidental takes reported by Ministry of Agriculture and Fisheries Observers aboard deep sea fishing vessels in New Zealand fisheries waters and by Department of Conservation staff for the period 1 April 1993 to 31 March 1994 is as follows: common dolphin 27; Hector’s dolphins 3; Gray’s beaked whale 2; bottlenose dolphin 1; dusky dolphin 1; killer whales 1; pilot whale 1; humpback whale (released) 1; and sei whale 1.

Publications (excluding IWC volumes)

This report summarises the Norwegian research on cetaceans conducted during the period April 1993 to March 1994. Since 1989, most research on marine mammals in Norway has been organised through the national Marine Mammal Research Programme funded by government grants through the Research Council of Norway. The programme is coordinated by a Research Council Steering Committee headed by Professor Lars Walløe, University of Oslo.

Research on cetaceans is taking place at the following institutions/laboratories: the Institute of Marine Research, Bergen (IMR); the Norwegian College of Veterinary Medicine/National Veterinary Institute (NCVM-NVI); the Norwegian Computing Center (NCC), Oslo; the Norwegian Institute for Nature Research (NINA), Oslo; the Norwegian Polar Research Institute (NPI), Oslo; the Department of Chemistry, University of Bergen (DC-UB); the Bioenergetics Group of the Department of Animal Physiology, University of Oslo (BEG-UO); the Department of Marine Zoology, University of Oslo (DMZ-UO); the Department of Arctic Biology, University of Tromsø (DAB-UITØ); the Institute of Medical Biology, University of Tromsø (IMB-UITØ) the Norwegian College of Fishery Science, University of Tromsø (NCS-UITØ); the Norwegian Institute of Fisheries and Aquaculture, Tromsø (NIFA); the Department of Zoology, University of Trondheim (DZ-UNIT); the Department of Chemistry, University of Trondheim (DC-UNIT); the Center of Veterinary Medicine, Tromsø (CVMNT).

Species and stocks studied

(i) Minke whale, *Balaenoptera acutorostrata* – northeastern and central Atlantic waters.

(iv) Humpback whale, *Megaptera novaeangliae* – in the northeastern Atlantic (the Norwegian part of the YONAH collaborative project to estimate abundance and stock structure).

Field observations and collections

During three periods in 1993; April-May, June-July, August-September, a special permit catch of 69 minke whales was carried out as part of a comprehensive study on the ecological importance of minke whales in the northeast Atlantic. A description of the scientific whaling operations and the collections is given in SC/46/NA2 (NIFA).

Samples for scientific purposes were also collected from the 157 minke whales taken during traditional minke whaling in Norwegian waters during June-September 1993. The collections were carried out by trained official inspectors who were all veterinary surgeons. The recorded data include total length of all animals and length and sex of foetuses; both bulae were taken for age readings and both ovaries and testes for studies of reproductive biology. Tissue samples, skin, liver and kidney, were collected for stock identity analyses. Times to death and other related data were also recorded.

Catch data for the special permit catch as well as the traditional catch have been submitted to the IWC Secretariat from IMR.

In September 1993, attempts were made to deploy satellite transmitters on minke whales off the coast of northern Norway. One transmitter was successfully deployed and a total of 32 uplinks were received from the tagged whale over an eight day period; at the end of this period the animal was still in the area where it had been tagged. Improvements of attachment technique have been made during this winter and further tagging experiments will be conducted during spring and summer 1994 (DAB-UITØ).

As part of YONAH, an international programme to estimate abundance and stock structure of humpback whales in the North Atlantic, field work to collect fluke photos for individual identification and biopsies was conducted in the Bear Island-Hopen area of the Barents Sea in August – September, in the Central Barents Sea in September and in the Norwegian Sea in July. The work was carried out using vessels from the Norwegian Coast Guard and research vessels from the Institute of Marine Research. Approximately 50 photos of tail flukes were taken and 22 biopsies were collected (IMR).

Marking

No artificial marks have been released and no returns have been recorded during the past year. Natural marking photographs for humpback and killer whales are discussed elsewhere in this report.

Laboratory work and results

Age readings of the 92 minke whales caught under special permit in 1992 have been carried out using *bullae tympanicae*. The age distribution in the catch was between 1 and 15 years. The youngest animals were caught in the coastal areas in Lofoten, Vesterålen and Finnmark, while older animals, especially females, were caught further north. Sexual organs from 41 females and 44 males collected from the 1992 catch have been analysed. About half (51.1%) of the sampled females were sexually mature, all of them eight years and older. Foetuses were recorded in 16 females (76.2%). Four of the mature females had a corpora lutea graviditatis in the ovary, but no foetus was registered. Including these four females gives an apparent pregnancy rate of 95.3%. Histological analyses of the testes showed that 59.1% of the males were sexually mature, 15.9% were maturing and 25% were immature. Age readings and analyses of sexual organs from the 1993 scientific and traditional catches are underway (IMR).

Reproductive endocrinology of minke whales is being studied in a project at the Norwegian College of Veterinary Medicine (NCVM).

Stomach content samples from the 63 minke whales caught under special permit in 1993 have been analysed. The preliminary results are presented in SC/46/NA2. The results indicate that the diet was dominated by fish, but that the species composition varied with geographical area and sampling period. Gadoid fish species dominated in spring. In summer and autumn, krill was the most important food item in the northernmost areas, with the addition of smaller amounts of capelin (*Mallotus villosus*). In the coastal areas of northern Norway, the minke whales had been feeding mostly on herring (*Clupea harengus*) and to a lesser extent on gadoid fish; 0-group fish seemed not to be important as food for minke whales in the area surveyed (NIFA, IMR).

The baleen from minke whales caught under special permit in 1992 and 1993 will be analysed for isotopic concentrations of $^{13}$C/$^{12}$C and $^{15}$N/$^{14}$N for the possible evaluation of diet and trophic position of minke whales (DAB-UITØ). The digestibility of different prey types in minke whales has been studied. The method is based on the naturally occurring marker manganese (Mn). Samples of colon contents and fresh prey specimens have been analysed for energy density and Mn concentration. The results have been submitted for publication (DAB-UITØ).
The energy cost of fat deposition is being studied by estimating the energy equivalent of the amount of fat that is deposited seasonally in blubber, muscle, skeleton and around the intestinal organs of minke whales. The energy content and the relative and absolute amounts of the different tissue types, have been determined for animals caught in early spring and late autumn. The total energy content of each whale is calculated and related to body size, and the amount of energy deposited from spring to autumn is then calculated by subtraction. Data from whales caught in spring are few and additional data from the scientific catch in 1994, both from spring and autumn, are needed before reliable estimates can be made (DAB-UITØ).

The energy cost of growth and reproduction in minke whales is being studied. Samples of foetuses, placenta, muscle, blubber and visceral fat collected during the scientific whaling, have been analysed for energy density (DAB-UITØ).

The insulative value of minke whale blubber has been assessed by recording the thermal conductivity of the tissue. Blubber samples from different sites of the whale body have been collected during the scientific whaling in order to determine whether seasonal and/or body regional variations exist. The lipid content of the blubber samples is being determined in order to investigate the relationship between the composition of the blubber and its thermal conductivity. The results of this study are important for the interpretation of heat loss model data and in evaluating whether minke whales may have extra thermoregulatory expenses at some time of the year. The combined results from the feeding ecology studies and the energetic studies will ultimately be used to determine the daily energy and food requirements of northeastern Atlantic minke whales (DAB-UITØ).

The chemical composition of minke whale blubber has been studied. The blubber contains 41–67% fat, 6–15% protein and 24–25% water. The lowest amount of fat and highest amount of protein and water were found in blubber from the anterior ventral part (ventral grooves) of the body. The composition also varied with the depth of the blubber. The outer half has almost twice the content of fat found in the inner half adjacent to the muscle. The fatty acid composition of oil produced from minke whale blubber is distinct from that of fish oil, e.g. cod liver oil. The whale oil consists of approximately 60% mono-unsaturated fatty acids, compared to about 50% in cod liver oil. The oxidative stability of minke whale oil was also found to be high compared to other marine oils and work is ongoing to identify possible antioxidant components in minke whale blubber and oil. Clinical trials have been performed to study the effects of moderate intake of minke whale oil and seal oil on humans. One clinical trial period with 140 healthy persons is completed and a new study with 240 persons is under way. Changes in coagulation, fibrinolysis and cellular activation are being measured (NIFA/IMB-UITØ).

Fatty acids in blubber from 63 minke whales caught in 1993 have been chemometrically determined. Clearcut differences were detected in the composition of fatty acids between the different layers of the blubber. The fatty acid composition also appeared to vary with season, but not with location of the catch. Currently fatty acids in heart tissue from the same animals are being analysed for seasonal and geographic variations (DC-UB).

The nematode (Anisakis) infection in minke whales caught during scientific catch in 1992 and 1993 is being studied in relation to geographical area, sex, age and diet of the whales (DMZ-UO). Serum samples from 75 minke whales caught in 1992 and 54 caught in 1993 have been tested for antibodies against PDV (phocine distemper virus). No antibodies against PDV have been found (VMCT).

Sightings data
During 1993, a total of 733 observations of cetaceans were recorded by species and position (IMR). Killer whale surveys and photo-identification were performed during several cruises in the Lofoten – Vesterålen area in 1993 (IMR/NCF-S-UITØ).

Strandings
Information on stranded cetaceans has been collected at the Institute of Marine Research Bergen and at the Norwegian College of Veterinary Medicine (IMR, NCVM-NVI).

Pollution studies
Levels of chlorinated organic pollutants (PCBs, DDTs, Chlordanes, HCH, HCB) have been measured in blubber samples from 35 female and 37 male minke whales caught during the scientific catch in 1992. PCBs had the highest concentrations. In all the samples ΣPCBs > ΣDDTs > ΣChlordanes > HCB > ΣHCHs with the levels of ΣPCBs ranging from 0.5–8.0 ppm (average 4.5 ppm) in males and 1.1–9.5 ppm (average 2.5 ppm) in females. Animals taken in the Lofoten area seemed to have higher levels of organochlorines than animals taken in the Finnmark, Kola, Bear Island and Svalbard areas. Males taken outside Bear Island differed from the other groups in the composition of DDT-components and metabolites by having much lower relative amounts of the main metabolite p,p'-DDE. Samples from the 1993 catch are now being analysed (NCVM-NVI).

The levels of PCBs in blubber of minke whales from Greenland and Jan Mayen are being compared with samples from minke whales taken in the northeastern Atlantic during the scientific catch. The results so far have shown no significant differences between the western and the eastern areas (DC-UNIT).

Selected heavy metals (Pb, Cd, Cu, Hg) and radionuclides (137Cs, 89Sr, Pu) have been determined in organs of minke whale from the scientific catch in the Barents Sea, off the coast of the Kola peninsula in 1992. 137Cs concentrations were slightly lower than in animals caught off the coast of northern Norway in 1988. Results for 89Sr and Pu are not yet available. Heavy metal concentrations were similar to those found in 1988. Compared to minke whales from the Antarctic Ocean, the Barents Sea minke whales showed substantially lower Cd levels and slightly higher Hg levels. Levels of other heavy metals did not differ between whales from the two areas. Studies on the Hg/Se ratio are planned to see whether Se plays a role in Hg detoxification as previously shown for other marine mammals (DC-UNIT).

Small cetaceans
Contaminants in porpoises incidentally caught in 1988–1990 have been analysed. The concentration of PCB and other organochlorines in blubber of male porpoises were determined and concentrations of mercury (Hg) and selenium (Se) in liver and kidney of males and females
were analysed. Total PCB, Hg and Se all showed a decreasing trend from south to north along the Norwegian coast (NCVM-NVI and NINA).

Studies of foraging ecology and habitat use of porpoises in Norwegian coastal waters indicate that porpoises have a preference for foraging in shallow waters where benthic fish species dominate their diet. When porpoises are foraging in deeper waters the diet consists of pelagic and mesopelagic species (NINA and IMR).

Photo-identification of killer whales in waters around the Lofoten and Vesterålen islands in northern Norway was continued both during summer and in October-November. All the groups encountered were resightings from previous years and 25 individuals were added to the catalogue which now consists of 405 whales. As in previous years most of the encounters were made in October-November in the wintering area of herring (*Clupea harengus*). Studies on feeding behaviour were continued in November with a high-frequency sonar. In addition to observations of killer

whales feeding close to the surface, groups of killer whales were observed chasing or feeding on herring schools at 60–90m depth (IMR/NCFS-UITØ).

**SPAIN. PROGRESS REPORT ON CETACEAN RESEARCH, MAY 1993 TO APRIL 1994**

This report refers to cetacean research carried out by the following organisations: Spanish Institute of Oceanography (IEO) of the Ministry of Agriculture, Fisheries and Food; Maritime Museum of the Cantabrian Sea (MMC); Department of Animal Biology of the University of Barcelona (UB); Department of Biology of the University of Oviedo (UD); Department of Animal Biology and Parasitology of the University of Valencia (UV); Faculty of Sea Sciences of the University of Las Palmas (ULP); Study Group on Cetaceans in the Canary Archipelago (GECAC).

**Species and stocks studied**

The following species/stocks were studied: long-finned pilot whales (*Globicephala melas*); short-finned pilot whales (*G. macrorhynchus*) and bottlenose dolphins (*Tursiops truncatus*) of the Canary Islands; striped dolphins (*Stenella coeruleoalba*) of the Mediterranean Sea; sperm whales (* Physeter macrocephalus*) of the Canary Islands and several other cetacean species which were stranded or incidentally caught.

**Field observations and collections**

The patterns of distribution and the density of the Iberian Mediterranean cetaceans are being studied (UB).

Aerial and acoustic surveys between the central Canary Islands (Gran Canaria — Tenerife and Gran Canaria — Fuerteventura) were undertaken to study the distribution and the density of cetaceans, in order to prevent accidents with local ferry lines (ULP).

Research on the biology and ecology of the short-finned pilot whale and the bottlenose dolphin in SW Tenerife was carried out (GECAC); these animals are the subject of while watching activities.

The scheme to collect information on the incidental catches of marine mammals and other marine fauna through an observer’s scheme in distant fisheries was continued (IEO).

During 1993, a proposal to study the bycatch of marine mammals, marine reptiles and sea birds, using onboard observers, was presented and partially funded by the Commission of the European Communities (Directorate General for Fisheries). Spanish fishing fleets operating with purse seines, gillnets, longlines and trawls in the waters of the EU will be sampled during a one year period, starting January 1994. An observer’s manual and forms to collect the information were prepared and training in the recognition of species was given to the observers (IEO).

A study of the incidental catches of marine mammals in the Spanish Mediterranean fisheries is in progress (UB), funded by the EU.

**Laboratory work**

Work continued on the parasitological fauna of long-finned pilot whales from the Faroe Islands and Tierra del Fuego (UV). Investigations on the ecology and taxonomy of marine mammal parasites were carried out by the same department.

The biological characteristics of the segment of the Mediterranean striped dolphin population affected by the epizootic event and the possible role that pollution could have in it are being investigated (UB).

**Research results**

Studies on the mass mortality of the Mediterranean striped dolphin population have recently been published (UB and UV).

**Strandings**

A detailed account of the observations on marine mammals stranded or accidentally caught on the northern Spanish coast during 1992 was presented to the Marine Mammals Committee of ICES (Document CM 1993/N/14).

Strandings of marine mammals are recorded by several institutions and organisations along the Atlantic and Mediterranean coasts as well as the Canary and Balearic Archipelagos. Samples of stomach contents, parasites and different tissues and organs for studies of contaminants are regularly taken.

**Publications (excluding IWC volumes)**

UNITED KINGDOM. PROGRESS REPORT ON CETACEAN RESEARCH, APRIL 1993 TO MAY 1994

This report includes details of the activities of the following: Sea Mammal Research Unit (SMRU), Cambridge; Cetacean Research Group of the Research Group in Mammalian Ecology and Reproduction at University of Cambridge; University of Cambridge, Department of Genetics; Bio-acoustic Research Group, Loughborough University; Ministry of Agriculture, Fisheries and Food (MAFF), Burnham on Crouch; Ministry of Agriculture, Fisheries and Food (MAFF), London; Sea Watch Foundation (SWF) – The Cetacean Monitoring Unit. Oxford; Wildlife Conservation Research Unit (WCRU), Oxford; Natural History Museum, (NHM), London; Institute of Zoology (IOZ) London; Joint Nature Conservation Committee (JNCC), at Aberdeen, University of Aberdeen; Royal Museum of Scotland, Edinburgh (National Museums of Scotland); Scottish Natural Heritage, Edinburgh; Scottish Agricultural College (SAC), Veterinary Services, Inverness; Scottish Office, Agriculture and Fisheries Department (SOAFD); Cornwall Trust for Nature Conservation.

Species and stocks studied
As in previous years, bottlenose dolphins (Tursiops truncatus) continued to be monitored in the Moray Firth, Scotland and in Cardigan Bay, Wales.

During 1993–94, species that have been routinely investigated when carcasses are available, either through stranding or incidental capture around the British Isles, include harbour porpoises (Phocoena phocoena), common dolphin (Delphinus delphis), bottlenose dolphin, long-finned pilot whale (Globicephala melas), white beaked dolphin (Lagenorhynchus albirostris), whitesided dolphin (L. acuta), striped dolphin (Stenella coeruleoalba), northern bottlenose whale (Hyperoodon ampullatus), Blainville’s beaked whale (Mesoplodon densirostris) – the first authentic record in British waters. sperm whale (Physeter macrocephalus), pygmy sperm whale (Kogia breviceps) – the first record since 1980. Cuvier’s beaked whale (Ziphius cavirostris) – the first record since 1985. Risso’s dolphin (Grampus griseus) and minke whale (Balaenoptera acutorostrata) 15 stranded during 1993, mostly off Scotland.

Exotic species studied include the boto (Inia geoffrensis) and tucuxi (Sotalia fluvialis) from Brazil, and white whales (Delphinapterus leucas) in the Canadian high Arctic.

Field observations and collections – British Isles
Bottlenose dolphins
Studies of bottlenose dolphins in the Moray Firth continued throughout 1993, in a collaborative project between SMRU and Aberdeen University. Boat-based photo-identification surveys throughout the year are used to assess seasonal and between-year changes in distribution and school structure. The data will also be used to determine whether capture-recapture techniques can be used to estimate population size and parameters. Long-term plans aim to monitor trends in population size and calving rates. The project has received funds, pledged for the period July 1993–1995, from the Whale and Dolphin Conservation Society. Greenpeace have funded a similar population study of bottlenose dolphins in Cardigan Bay.

In addition to studies of ecology, behaviour and population biology, photographic documentation of skin lesions on the Moray Firth dolphins has continued. Regular photographic surveys are monitoring the prevalence and development of these conditions. Collaborative studies to investigate prevalence of skin lesions in populations in other areas are planned.

The bottlenose dolphins in the Moray Firth continue to be studied as part of a programme to develop acoustically detectable attachments to fishing nets in order to discourage entanglement of cetaceans. This is a collaborative study between the Cetacean Research Group in Cambridge and Loughborough University. (See also under later section. ‘Development of techniques – net entanglement.’)

Scottish Natural Heritage are promoting a sustainable and integrated management scheme for the Moray Firth, which takes account of all issues and activities including marine mammals. They have developed a dolphin awareness scheme that includes a code of practice for all boat operators, particularly those running dolphin-watching trips.

Field observations and collections – outside British waters
White whales
Studies of the distribution, migrations, seasonal movements and diving behaviour of white whales using satellite linked radio-telemetry were carried out by SMRU in the Canadian high Arctic and Hudson’s Bay in collaboration with the Department of Fisheries and Oceans, Canada (DFO). Five animals were equipped with transmitters in Cresswell Bay, Somerset Island. These animals demonstrated that the whales occurring in Prince Regent Inlet merge with and can be considered part of, the same stock as those which spend the summer in Barrow
Strait and Peel Sound. One of the whales crossed Baffin Bay into Greenlandic waters in October, providing the first real evidence that the Canadian high Arctic summering stock may be the same as that which winters off northwest Greenland. Four white whales were tagged at Churchill, western Hudson’s Bay and were resident in the area throughout the summer, rarely moving far offshore.

In the first field season of a 3-year joint project between SMRU, DFO and the local communities of Inuvik and Tuktoyaktuk, four white whales were equipped with transmitters in the Mackenzie Delta, Beaufort Sea. These units were programmed to provide information with which to correct aerial survey data for whales missed below the surface and to target such surveys more effectively. Results from the four white whales were completely unexpected and demonstrated that this stock of animals disperses far more widely than had been thought. One male penetrated more than 1,000km of multi-year ice to reach 106°W, within 350km of the eastern Canadian high Arctic stock and another went northwest through Alaskan waters to 79°N before turning back towards Wrangel Island in Russian territory. One animal travelled over 5,300km in 92 days and spent a month of that time diving to feed on the seabed in one small area where the depth was 420m. Dives of over 20min. duration and to depths greater than 550m, were recorded for this species in the wild for the first time.

Boto and tucuxi
The Instituto Nacional de Pesquisas da Amazonia (INPA), Brazil, in collaboration with SMRU, Cambridge, has started a study of the status, population biology, behaviour and movements of the boto and tucuxi in the Mamiraua Ecological Reserve, Brazilian Amazon.

Marking and tracking
No active marking study is currently underway in the British waters. However, photo-identification of individual bottlenose dolphins in the Moray Firth using natural markings continues.

Studies of the distribution, migration, seasonal movement and diving behaviour of white whales using satellite-linked radio telemetry continued in the Canadian high Arctic and Hudson’s Bay in collaboration with the Department of Fisheries and Oceans, Canada (DFO). (See above under ‘Field observations’.)

The INPA, Brazil and SMRU, Cambridge have commenced a tracking and marking programme in Mamiraua Ecological Reserve in the Amazon. An initial sample of eight botos were equipped with VHF radio transmitters and a network of automatic receiving stations has been set up to track these animals. Observational work on individually recognisable freeze-branded and plastic-tagged animals has been initiated. Regular boat-based visual surveys have been carried out to monitor seasonal changes in the density and distribution of botos and tucuxis in varzea (flooded forest) habitat.

Laboratory work
Life history
A study by Vera da Silva at the University of Cambridge on the biology and population structure of boto and tucuxi from the Amazon River basin, has been concluded as part of a doctoral thesis. The study concluded that, based on discriminant tests on morphometric and meristic characters, there were two species of boto — *Inia geoffrensis* and *I. boliviensis* with two sub-species of *I. geoffrensis* — *I. g. geoffrensis* and *I. g. humboldtiana*. The species and sub-species are geographically isolated in different river systems.

Studies of the biology of harbour porpoise around the coast of the British Isles have continued at SMRU, using samples from bycaught and stranded individuals. The annual harbour porpoise workshop held at SMRU took place in December 1993, with a one-day conference and two days of carcass autopsy in the laboratory. The programme investigating life history and various population parameters of harbour porpoise is nearing completion, with a total analysis of 295 animals including 142 males and 121 females, since 1985. A preliminary report was presented to the IWC Scientific Committee. The porpoise programme operates in close collaboration with the IOZ in London, the NHM in London, the University of Liverpool and parasitologists from the University of Valencia, Spain. There are also close links with the following organisations, and exchange of material and data: Cetacean Research Group of the Research Group in Mammalian Ecology and Reproduction at University of Cambridge; University of Cambridge, Department of Genetics; Bio-aoustic Research Group, Loughborough University; Ministry of Agriculture Fisheries and Food (MAFF), Burnham-on-Crouch; Royal Museum of Scotland, Edinburgh; Scottish Agricultural College (SAC), Veterinary Services, Inverness. Special studies at SMRU focus on life history, age and reproduction, diet and energetics.

Dissection of porpoise heads at SMRU during the December workshop revealed nasal and vertibular sac structures, were valuable in explaining the generation of narrow band acoustic signals. This helped researchers from Loughborough University develop a model for sonar pulse generating mechanisms in this species. Tooth imprints from jaws were also made at this time to help in further investigations of the tooth array echo-receptor hypothesis.

Studies on known-age captive dolphins
Studies of age determination of captive known-age dolphins, using tetracycline time-marks in teeth and correlation of mineralisation patterns and anomalies in the teeth with known life history events continues at SMRU. The purpose is to develop an understanding of the influences on mineralisation processes in teeth and apply findings to teeth from wild populations for investigations of life history and age. Collaboration between various dolphinaria throughout Europe and veterinarians continue to facilitate the project. Species recently investigated include the bottlenose dolphin and Commerson’s dolphin (*Cephalorhynchus commersonii*).

Energetics
A study of porpoise body fat condition in relation to age, sex and reproductive status is being undertaken at SMRU. Future plans include the collection of metabolic rate data, as well as respiratory gas analysis under varying conditions of exercise and diet.

Contaminants
A small number of contaminant analyses of cetacean tissues were carried out in 1993/94 at MAFF in Burnham-on-Crouch. Future plans include a detailed analysis of fish from Cardigan Bay as part of an investigation of the contaminant levels in cetacean prey.
In Aberdeen, Scotland, SOAFD report that in their investigations of organochlorine burden in different species, multi-variate analysis reveals that there are significant differences between species. They are currently investigating models of possible correlations between contaminant burden, metabolic patterns and diet. Additionally, they are also examining the effect of blubber and tissue decay on the outcome of contaminant analysis.

**Population structure**

*Studies on mineralisation patterns in teeth*

Studies initiated by SMRU on mineralisation patterns in teeth of porpoises have shown that certain anomalies of mineralisation and deposition pattern vary with sex and geographical region. In addition, the presence of such anomalies have, in some instances, been linked to biological events in an individual’s life. From initial analysis of tooth samples from other populations in different geographical regions including Denmark, Norway, Newfoundland and California, this study appears promising for investigating population identity. Additional samples from the Netherlands and Sweden are now available and a study will now be planned to examine firstly, potential differences in population structure around the British Isles and secondly, differences or links between progressively more distant populations. It is hoped that these studies will complement current genetic studies on porpoises also being undertaken at SMRU.

**Skull morphometrics**

The Royal Museum of Scotland has recently commenced a study of the skull collection from British stranded cetaceans. The skulls from harbour porpoises and common dolphins will be measured accurately for morphometric analysis to investigate possible geographical variation and differences in growth rate and sexual dimorphism. Most specimens have nearly complete biological data, including age. This study is being undertaken in collaboration with Edinburgh University.

**DNA studies**

SMRU recently started investigating the genetic composition of porpoises from different geographical locations by means of molecular genetic techniques. The main procedure is the amplification of the D-loop region of mitochondrial DNA (mtDNA) via the polymerase chain reaction (PCR), followed by direct sequencing of the amplified product. Through comparison of the nucleotide sequences the variability in animals within and between geographical areas can be compared. Preliminary analyses of a sample of 50 animals including 18 from the Shetlands, 14 from the eastern part of England (North Sea), 4 from the English Channel and 14 from the Irish Sea indicate that 19 genotypes can be identified from comparisons of 380 base sequences. Results showed that significant differences were apparent between Shetland and the Irish Sea, but that there were no significant differences between other areas. Shetland represents the northerly part of the North Sea. Work is now planned for augmenting sample sizes and also collaborating with other researchers to investigate genotypes from other geographical regions.

The University of Cambridge Genetics Department continues to examine the social organisation, breeding systems and population structure of marine mammal species using molecular techniques. The species studied include the long-finned pilot whale from the Faroe Islands and Hawaiian humpback whales (*Megaptera novaeangliae*). Focus is on micro-satellite analysis and, in humpback whales, sloughed skin has been used for DNA extraction. A particular focus is on the development of general molecular probes suitable for analysing a wide range of cetacean species – universal cetacean genetic markers.

**Development of techniques**

*Acoustics and tracking*

As part of an EC-funded project, researchers at Loughborough University have completed the development of a computer-based 20-tracking system for small cetaceans using sparse hydrophone arrays to resolve the position of echolocating animals by their own emissions.

Bottlenose dolphin whistles, recorded in the field in the Moray Firth in 1991/92, have now been analysed and several characteristic whistles have been identified. These whistles, available as spectrogram printouts, were available for reference during field recording trials in the Moray Firth in 1993 and many of the signals picked up were recognisable from previous years. Work is now in hand on developing a cluster-type analysis technique for generating ‘classifiers’ to form the basis of an automatic recognition system.

Software has been further developed for analysing dolphin click-rate in interpreting behaviour patterns and echolocation click sequences. The system can now extract dolphin sonar clicks timing relationships in conditions of extremely high signal noise and reverberation.

The technical development and construction of an improved soundbuoy circuitry with hydrophone preamplification and data capture systems suited to acoustic data capture from small cetaceans continued throughout 1993 and into 1994.

Theodolite measurements made when tracking dolphin movements at sea have now been successfully linked through computer analysis, to display co-ordinates on video recordings in the field.

Planning for the development of a marine acoustic database as part of a proposed EC ‘Acoustic Risk Assessment’ project is now under way. This would include a comprehensive library of cetacean vocalisations suitable for taxonomic identification.

Work on the development of equipment and techniques for assessing harbour porpoise using passive acoustics has continued at the Wildlife Conservation Research Unit (WCRU), Oxford. Successful trials were carried out with the Dyfed Wildlife Trust in Wales and also in Shetland with Sea Watch. WCRU plan to place versions of this computerised equipment on vessels participating in the SCANS survey this year in the North Sea (see section on ‘Sightings data and Surveys’). This will provide a calibration of the acoustic equipment against rigorously collected visual data.

WCRU also collaborated with the University of Gran Canaria during 1993, using the International Fund for Animal Welfare’s research boat, ‘Song of the Whale’, investigating the problem of collisions between jetfoil ferries and sperm whales.

**Net-entanglement of cetaceans**

Methods for reducing entanglement of small cetaceans in fishing gear using target-enhancing passive acoustic devices, now being developed with Government funding by Loughborough University, continue in trials using captive and free-ranging animals. Net testing and
observations of net dynamics underwater were tried out at Sea Fish Industry Authority (SFIA) in their flume tank in Hull during 1993. Net trials were also conducted at sea using passive deterrent devices attached to a 100m segment of single netting. This was at the joint invitation of SFIA and IFREMER. Sea trials in September 1993, using a double barrier of net deterrent reflectors (2 x 2m grid and 2 x 6m grid), were undertaken in the Moray Firth, tracking bottlenose dolphin behaviour when the nets were set one to each side of the dolphins' preferred travel path. Results confirmed previous trials in 1991 and 1992; that echolocating dolphins react to and change course around such nets at ranges in excess of 50m and even as great as 170m. Some animals chose to pass through the 250m gap between the two nets. However, the 'straggling' individual was seen to be at greatest risk of entanglement, unless it was actively echolocating and not just following the herd. This has prompted research into the development of a 'wake-up' device to supplement the passive approach to making nets acoustically detectable. Trials using an inactive semi-submersible oil rig moored in Cromarty Firth, to track porpoise with a theodolite, proved satisfactory. Trials using net barriers in the Firth and focusing on porpoise avoidance behaviour are planned for 1994.

Sightings data and surveys
Land-based monitoring of coastal cetaceans in British waters continues with co-operation of the national sightings network coordinated by Sea Watch Foundation (SWF) at Oxford University. Work has focused on establishing a network of regional groups to help train observers in the standardisation of data collection, including the recording of observer effort, to improve the use of data as indicators of the relative abundance of cetaceans in the region. There are now more than 1,000 observers in SWF, dispersed throughout the British Isles. Funding for this work has been chiefly through the UK Department of the Environment.

Land-based and vessel-based watches for harbour porpoise in the Shetland area have continued from 1992 by SWF in collaboration with Scottish Natural Heritage, Shetland Amenity Trust and Worldwide Fund for Nature. The main objective has been to determine the distribution of this species in the coastal waters of Shetland. Seasonal changes in relative abundance of porpoise have been detected with a low in June and peaks in August and September. Colour echo-sounder surveys were conducted in 1993 to compare porpoise distribution and presence of potential fish prey species, but clear correlations were only obtained for two sub-areas. Similar research is planned for 1994.

SWF conducted a number of line transect surveys aboard the ‘Maguerite Explorer’, a 64ft gaff-rigged ketch, in the Inner Hebrides and Minches area off Scotland during 1993. These surveys, partly funded by Earthwatch, were first conducted in 1992 and it is planned to co-ordinate these with the SCANS survey effort in the North Sea in 1994.

Concern over the potential effect of seismic testing and exploration resulted in Marathon Oil UK Ltd contracting the services of SWF during a seismic reflection survey in the St. George's Channel, southern Irish Sea in May and June 1993. Observers aboard a guard vessel accompanying the seismic vessel, whose course could not be modified during testing and a smaller boat surveying adjacent areas of Cardigan Bay maintained a watch for cetaceans during the period of the tests. Bottlenose dolphins and porpoise were observed but overall cetacean occurrence was low in all areas. In future seismic testing programmes, it is anticipated that observers will be invited to maintain a watch and monitor proceedings for assessing the likely effect of seismic activity on cetacean behaviour. However, a vessel dedicated to more extensive coverage before, during and after seismic tests would be desirable.

The JNCC Seabirds at Sea project, based in Aberdeen, surveyed waters around the British Isles throughout 1993–4, focusing particularly on the Celtic Sea area. Sightings of cetaceans using standard effort-quantified methods have permitted species distributions to be drawn up. In addition to standard surveys, JNCC made two surveys from vessels engaged in seismic exploration, the objective being to determine the potential impact of seismic activity on cetaceans. Advice has been given throughout 1993 on ways in which oil companies might minimise the impact of their activities on cetaceans. During 1994, JNCC plan to cooperate with SCANS during the June-July surveys. There will be an attempt to calibrate the SCANS methods of counting against those used by JNCC Seabirds at Sea. JNCC plan to put effort into surveys off Ireland, the south coast of Dorset and in waters around Scotland and Faroes.

The long-term effort-related database which JNCC have been working on now includes some 14,600 cetacean records. It is hoped that an electronic volume of distribution maps for each species will be published using the UKDMAP map display system.

Small cetacean abundance in the North Sea (SCANS)
The SMRU has been co-ordinating a major European project to investigate the distribution and abundance of harbour porpoises and other small cetaceans in the North Sea and adjacent waters. The 1.4-Mecu project is a collaborative effort between the governments and scientists of eight European countries (Denmark, France, Germany, Ireland, Netherlands, Norway, Sweden and UK). It is 50% funded by the European Commission. The work centres on a sightings survey during the summer 1994 in the North Sea, Skagerrak, Kattegat, western Baltic Sea, the Channel and Celtic Shelf. A total of nine ships and two aircraft provided intensive coverage of the area resulting in estimates of abundance for harbour porpoises and other small cetaceans and forming a baseline for future monitoring. Work on the project to date has comprised preparations for the survey in June/July 1994 including an experimental ship survey to help develop data collection and analysis protocols. The results will be presented at next year’s meeting of the Scientific Committee. Collaboration with particular organisations and research groups, e.g. JNCC, SWF, WCRU, is noted throughout this report.

MAFF has also provided additional funding to allow the SCANS study to be extended to the west of the ASCOBANS area. This enabled the collection of small cetacean population data in the area worked by off-shore gillnetters which participated in an observer scheme – see later under section ‘Bycatch’: Cornwall Trust for Nature Conservation.

Strandings and bycatches
General and strandings
The IOZ, funded by the Department of the Environment, are now into their fourth year acting as a national centre for co-operating research on strandings and bycaught cetaceans. This centre continues to co-operate with other UK-based organisations and also several universities and institutions within Europe (notably SMRU, NHM,
Liverpool University, Veterinary Investigations Centre in Polwhele, Truro, Cornwall, and Veterinary Research Laboratories in Stormont, and Universities of Barcelona and Valencia, Spain). Detailed post-mortem dissections are undertaken by, or on behalf of IOZ, on many carcasses recovered in England and Wales, for the study of disease and epidemiology. In collaboration with other organisations, IOZ undertakes other analyses including histopathology microbiology, serology, parasitology, toxicology (organochlorines, heavy metals, algal toxins and radionuclides), analysis of food remains, age determination and DNA-studies.

During 1993–94, there were 10 live strandings in England and Wales, of which 2 died, 2 were euthanased and 6 died during rehabilitation. Assistance at strandings is facilitated by a network of veterinary surgeons throughout the country, who are willing to attend live strandings and also a group connected with the Royal Society for the Prevention of Cruelty to Animals (RSPCA) and the British Divers Marine Life Rescue. Details of strandings and autopsied animals are listed in Table 1 and cover the period April 1993–March 1994 inclusive. A total of 86 cetaceans were autopsied or examined. From autopsy examination, IOZ estimated that 23% of porpoises and 41% of common dolphins recovered as strandings resulted from bycatch. The greatest number of strandings were porpoises and overall, 26% of all strandings appear to result from bycatches.

Note: Autopsies in England and Wales indicate approximately 26% of all strandings are the result of bycatch. A similar study in Scotland estimated that of 130 autopsies undertaken in 1992 and 1993, 34 or approximately 26% of the strandings originated from bycatch. It is clear that the main casualty species of bycatch is Phocoena phocoena throughout British waters.

The strandings scheme in Scotland, based at the Scottish Agricultural College (SAC), Veterinary Services, has been active throughout 1993–4—the second year of the scheme’s existence. The record of their strandings is shown in Table 1. During 1992 and 1993 a total of 270 strandings were recorded and 34 of 130 autopsies of all species were determined to be the result of interactions with fishing gear representing 26% of strandings investigated. The major casualty of strandings is the harbour porpoise and of those animals ascertained to result from bycatches, most are neonates or very young. A total of 148 cetaceans were recorded stranded throughout 1993, of which 127 were identified to species. During 1993 there were several live strandings, including a northern bottlenose whale and a Cuvier’s beaked whale, both of which were photographed before refloatation and swimming away. Two sperm whales died soon after beaching on the west of Scotland. Other live strandings included a white-beaked dolphin, a minke whale, two unidentified dolphins and a common dolphin, all of which survived. However, attempts to rehabilitate a minke whale, striped dolphin and a common dolphin failed and the animals were euthanased.

All strandings records in Scotland are now ultimately transferred to the NHM in London for the inclusion in records of the British Isles. Since 1992, the Scottish records have greatly increased the UK total strandings records annually. Observer effort in Scotland is now stabilising and it is hoped that meaningful inter-year comparisons can be made in the future.

Analysis of fatal trauma injuries sustained by porpoise found stranded, but otherwise in general good health, supports a growing theory of aggressive encounters and interaction between bottlenose dolphins and porpoise in the area of the Moray and Cromarty Firths. A preliminary presentation of these findings was given in Inverness in February 1993 at the European Cetacean Society meeting. Publication of the findings is planned soon.

The NHM continues to collect and sample all species of stranded cetaceans not otherwise examined and to maintain records of every cetacean stranded in England and Wales. During 1993, a total of 315 strandings were recorded throughout the British Isles. Basic data are given in Table 1, but individual species data have not been made available here. Research into age determination, diet and parasite burden of stranded specimens, other than porpoise, is also undertaken.

The Royal Museum of Scotland collates strandings reports between the Scottish Stranding Scheme and the Natural History Museum, London. They maintain the Scottish strandings archive.

The Scottish Natural Heritage have established a live-strandings scheme in the Hebrides, designed to respond rapidly to such occurrences.

### Pathology

The SAC in Inverness have, as part of their strandings programme, made bacteriological and histopathological investigations of the tissues of carcasses. Bacterial cultures are now being identified and recorded. The most important finding to date is the isolation of a form of Brucella, a notifiable pathogen in the UK, normally causing sterility and abortions in cattle. It is not known if the isolated form is infective to terrestrial mammals (see publications list – Ross, 1994). It is hoped that bacterial investigations can be continued as a routine part of the strandings programme in the future, with the necessary funding.

Virological studies have also been in progress, with the discovery of herpes virus lesions in the reproductive tracts of harbour porpoises. The disease appears to be venereally transmitted and could be significant with regard to the reproductive health and stability of the porpoise population. Details of this were presented at the March 1994 European Cetacean Society meeting in Montpellier.
With the co-operation of Scottish Natural Heritage, a frozen serum and tissue bank has been established in Inverness. It is anticipated that this will be invaluable in studies of disease and epidemiology in cetaceans. This bank has already proved useful in the identification of brucellosis.

**Bycatch**

A programme of volunteer observers on offshore gillnetters, fishing primarily for hake (*Merluccius merluccius*), organised by the Cornwall Trust for Nature Conservation in co-operation with the Cornish Fish Producers Organisation, ended in March 1994. The programme completed 44 trips amounting to about 200 days at sea widely distributed over the Celtic Shelf west of Cornwall and mainly 100–300km offshore. Harbour porpoise bycatches occurred widely over the shelf at about 1 per 1.25km²/hr of net immersion. Common dolphin bycatches were much rarer. Sightings clearly indicate that many common dolphins were present in the area of the fishery and often interacted with the boats during fishery operations. Numbers were highest in winter. Data analysis has not yet been completed.

Two observers were placed on pelagic trawlers fishing for pilchard (*Sardina pilchardus*) and mackerel (*Scomber scombrus*) south of southwest England in the winter of 1993–94 as part of collaborative research project on fishery discards in association with IFREMER, RIVO-DLO, University of Cork and the Cornwall Trust for Nature Conservation. Few cetaceans were detected in the area of these fisheries and no bycatches were observed. Practical experience suggests that it may be impossible to accurately count, or even to detect, small cetacean bycatches by mackerel boats if they are using fish pumping techniques at night. A modification to the trawl to prevent objects as large as a small cetacean from being flushed out of the cod and well astern of the boat when non-target species (mainly pilchard) are discarded would improve this but would require a higher level of co-operation from the fishermen.

At present MAFF and SOAID ask fishermen to report bycatches of marine mammals found around the British Isles. However, reports have been negligible and the scheme has been unsuccessful. MAFF held a number of meetings with specialists to design and discuss the implementation of a new scheme for reporting bycatches. The working group completed their task in late 1993 and made several recommendations including: the need for observers on fishing vessels; means of fostering goodwill and co-operation with the fishermen; education and publicising the importance of reporting bycatches; possible rewards for encouraging factual reporting of bycatches; outlining the actual data required and how to record these; and ways of setting up regional networks for dealing with bycatch associated problems around the country. A final decision regarding the relaunch of the bycatch reporting scheme is awaited.

**Environmental modelling**

The effects of environmental change on whale populations

SMRU has begun a project, initially for three years, to develop a framework for investigating the effects of environmental change on whale populations. A major aim of the project is to help the Scientific Committee develop practical means to address questions raised by a detailed examination of the available data on whale populations and on environmental change. The core of the work involves the development of methods to relate data on marine mammals to extensive oceanographic and environmental data sets and to the results from predictive models. It is envisaged that the work will fall into two broad categories. The first will be based on the correlation of oceanographic and environmental data with whale distributions and the development of models which can describe the apparent relationships. The second will be based on the investigation of the rules which govern how marine mammals respond to variability in the environment, including the development of models which describe the movements and behaviour of individual animals as functions of oceanographic variables, among other factors. Work so far has concentrated on the development of a simple model framework for relating the abundance of Southern Hemisphere minke whales to physical parameters.

**Statistics and data for small cetaceans**

Data on stranded and bycaught small cetaceans continue to be collated by the NHM which maintains an accurate historical record on UK strandings spanning 80 years. Since 1990, the NHM has been commissioned to maintain a computerised database on all strandings around the British Isles. Trends in strandings are also investigated and apart from the unusually high incidence of common dolphins stranded in the southwest of England in early 1992, numbers have been similar in 1993 to previous years. A report of this incident has now been published (see Kuiken et al., 1994b).

**Miscellaneous**

**Sinking of the M.V. Braer, Shetland**

The supertanker *M.V. Braer* was wrecked off Shetland on 4 January 1993. This necessitated action by many organisations, including SAC, Inverness and SMRU, Cambridge. Facilities for autopsy were set up, but during the period immediately after the oil spill, only two porpoises were recovered dead and neither death was attributable to oil contamination. The unusual storm conditions prevailing at this time resulted in the rapid dispersal of the oil and whilst immediate concerns for wildlife were allayed, the long-term effects have been monitored in the following 12 months.

**ASCOBANS**

On 29 March 1994, the Agreement on the Conservation of Small Cetaceans of the Baltic and North Seas (ASCOBANS), came into force with six Parties – Belgium, Denmark, Germany, Netherlands, Sweden and the United Kingdom. This is a regional Agreement concluded under the auspices of the 1979 Bonn Convention on the Conservation of Migratory Species of Wild Animals (CMS). The Interim Secretariat for this Agreement is based at SMRU in Cambridge. In October 1993, a preliminary meeting of Range States to this Agreement was held in Cambridge. At this time, it was agreed that the first full-meeting of Parties would be hosted by Sweden and the meeting would be held in Stockholm from 26–28 September 1994.

**Publications (excluding IWC publications)**

This report briefly summarizes cetacean research conducted or supported from May 1993 to April 1994 by the US National Marine Fisheries Service (NMFS HQ) at Silver Spring, Maryland and at the five NMFS Science Centers: Alaska Fisheries Science Center (AFSC), Northwest Fisheries Science Center (NWFSF), Seattle, Washington; Southwest Fisheries Science Center (SWFSC), La Jolla, California; Northeast Fisheries Science Center (NEFSC), Woods Hole, Massachusetts; Southeast Fisheries Science Center (SEFSC), Miami, Florida. Information was also contributed by the NMFS Northwest Regional Office (NWR), Seattle, Washington and Alaska Regional Office (ARO), Juneau, Alaska, the Alaska Department of Fish and Game (ADF&G), Anchorage, Alaska, the Alaska Inviability Beluga Whale Committee (AIBWC), the North Slope Borough (NSB), Barrow, Alaska and the Marine Mammal Events Program (MMEP), Smithsonian Institution, Washington, D.C.

The following report was compiled, in consultation with the above agencies, by Janec Quintal, Northeast Fisheries Science Center, Woods Hole, MA, 02543.

Species and stocks studied

During the past year studies were conducted on the following species in the following areas:

- Atlantic white-sided dolphin (Lagenorhynchus acutus) – western North Atlantic;
- Beaked whale (Mesoplodon sp.) – eastern tropical Pacific, western North Atlantic, Gulf of Mexico;
- White whale (Delphinapterus leucas) – Alaska, North Pacific;
- Blue whale (Balaenoptera musculus) – California;
- Bottlenose dolphin (Tursiops truncatus) – western North Atlantic, Gulf of Mexico, California, eastern tropical Pacific;
- Bowhead whale (B. mysticetus) – western US Arctic;
- Clymene dolphin (S. clymene) – Gulf of Mexico;
- Common dolphin (Delphinus delphis) – western North Atlantic, California, eastern tropical Pacific, North Pacific; Dall’s porpoise (Phocoenoides dalli) – California, Washington, North Pacific;
- False killer whale (Pseudorca crassidens) – eastern tropical Pacific;
- Fin whale (B. physalus) – western North Atlantic, California;
- Goose-beaked whale (Ziphius cavirostris) – eastern tropical Pacific, western North Atlantic;
- Gray whale (Eschrichtius robustus) – California, Harbors porpoise (Phocoena phocoena) – Alaska, eastern North Pacific, western North Atlantic;
- Humpback whale (Megaptera novaeangliae) – western North Atlantic, California;
- Killer whale (Orcinus Orca) – Alaska, British Columbia, California, eastern tropical Pacific, Gulf of Mexico;
- Minke whale (B. acutorostrata) – western North Atlantic, California;
- Northern right whale dolphin (Lissodelphis borealis) – California, North Pacific;
- Pacific white-sided dolphin (L. obliquidens) – California, eastern tropical Pacific, North Pacific;
- Pantropical spotted dolphin (Stenella attenuata) – western North Atlantic, eastern tropical Pacific, Gulf of Mexico; Pilot whale (Globicephala sp.) – western North Atlantic, California, eastern tropical Pacific, Gulf of Mexico;
- Pygmy killer whale (Feresa attenuata) – eastern tropical Pacific;
- Clymene dolphin (S. clymene) – Gulf of Mexico;
- Common dolphin (Delphinus delphis) – western North Atlantic, California, eastern tropical Pacific, North Pacific; Dall’s porpoise (Phocoenoides dalli) – California, Washington, North Pacific; False killer whale (Pseudorca crassidens) – eastern tropical Pacific; Fin whale (B. physalus) – western North Atlantic, California; Goose-beaked whale (Ziphius cavirostris) – eastern tropical Pacific, western North Atlantic; Gray whale (Eschrichtius robustus) – California, Harbors porpoise (Phocoena phocoena) – Alaska, eastern North Pacific, western North Atlantic; Humpback whale (Megaptera novaeangliae) – western North Atlantic, California; Killer whale (Orcinus Orca) – Alaska, British Columbia, California, eastern tropical Pacific, Gulf of Mexico; Minke whale (B. acutorostrata) – western North Atlantic, California; Northern right whale dolphin (Lissodelphis borealis) – California, North Pacific; Pacific white-sided dolphin (L. obliquidens) – California, eastern tropical Pacific, North Pacific; Pantropical spotted dolphin (Stenella attenuata) – western North Atlantic, eastern tropical Pacific, Gulf of Mexico; Pilot whale (Globicephala sp.) – western North Atlantic, California, eastern tropical Pacific, Gulf of Mexico; Pygmy killer whale (Feresa attenuata) – eastern tropical Pacific;
Right whale (*Balaena glacialis*) – western North Atlantic, California;  
Risso’s dolphin (*Grampus griseus*) – western North Atlantic, California, eastern tropical Pacific, Gulf of Mexico;  
Rough-toothed dolphin (*Steno bredanensis*) – eastern tropical Pacific;  
Sperm whale (*Physeter macrocephalus*) – California, eastern tropical Pacific, western North Atlantic, Gulf of Mexico;  
Spinner dolphin (*Stenella longirostris*) – eastern tropical Pacific;  
Striped dolphin (*Stenella coeruleoalba*) – western North Atlantic, eastern tropical Pacific, California, Gulf of Mexico;  
Vaquita (*Phocoena sinus*) – Gulf of California, Mexico.

Field observations and collections (not sighting data)  
**NEFSC**  
**HARBOR PORPOISE**  
The habitat use and migratory patterns of harbor porpoise was studied from September 7 to 21, 1993 in and about Penobscot Bay, Maine. Four observers worked from a 17’ rigid hull inflatable and surveyed the area for porpoise. Physical oceanographic measurements were taken at the same time and the distribution of fish in the water column monitored with an acoustic fishfinder (Contact: David Potter).

An aerial survey (15 November – 15 December 1993) to study seasonal movements of harbor porpoise was conducted in the area from the southern Bay of Fundy and Gulf of Maine and in coastal waters south to Virginia and east to Sable Island, Nova Scotia. (Palka, 1993a).

An experiment to test the efficiency of acoustic devices for detecting harbor porpoise bycatch in demersal gillnets was conducted in cooperation with Memorial University, Newfoundland and the New England Gillnetters Association. The experiment involved four fishing vessels using 2.8MHz acoustic devices attached to the gillnets every 100m. A total of 138 one day fishing trips were completed with 33 harbor porpoises observed killed, 4 animals taken in 1,302 net sections with acoustic devices and 26 taken in 6,555 net sections without devices (Contact: David Potter).

Researchers from the New England Aquarium and the University of New Hampshire were contracted to test the reaction of harbor porpoise to an acoustic sound-source. The sound-source, operating at 38kHz at 170db, was activated for one half hour every hour and the location and distance that porpoises were sighted from the source was recorded (Contact: Scott Kraus, New England Aquarium).

**SEFSC**  
**RIGHT WHALES**  
The New England Aquarium was contracted to conduct daily aerial surveys of the calving ground of the North Atlantic right whale from 1 December 1993 through 31 March 1994. The primary purpose of the surveys was to locate right whales in order to notify shipping when right whales were near shipping lanes. Transects were flown from shore out to approximately 30km and were spaced approximately 5.6km apart to afford virtually complete visual coverage of the area (Contact: Ben Blaylock). In addition, NEFSC conducted 53 hours of observations from airships (blimps) flying 1,085 nautical miles of overwater surveys in coastal waters of the southeastern United States were made from 5 January to 12 February 1993 to acquire information on right whales in their calving grounds and to mitigate ship strikes (Hain, 1992b).

**SWFSC**  
**SPOTTED DOLPHIN**  
A research cruise was conducted in the eastern tropical Pacific during 6 November – 5 December 1993 in cooperation with the Inter-American Tropical Tuna Commission, the Mexican National Program for the Utilization of Tuna and the Protection of Dolphins, and the University of Hawaii. The primary objective was to study the tuna-dolphin relationship by simultaneously radio-tracking spotted dolphins and sonic tracking yellowfin tuna from the same aggregation. The study of tuna and dolphin movements and interaction in conjunction with food-habit studies will help establish the longevity and dynamics of the tuna-dolphin bond and the degree that it is food-based. This could determine whether the bond loosens or breaks at particular times or under certain conditions and, if so, whether the tuna would be vulnerable to fishing at such times (Contact: Elizabeth Edwards).

**MARKING**  
**NEFSC**  
**NORTH ATLANTIC HUMPBACK WHALES**  
Since 1976 College of the Atlantic (COA) has curated the North Atlantic Humpback Whale Catalog, the central collection of photographs of the flukes of humpback whales obtained from the North Atlantic region. The collection now contains over 4,500 cataloged humpback whales from the years 1952 to 1992. Photographs taken from 1992 to 1994 as part of the Years of the North Atlantic Humpback (YONAH) Project are also being cataloged at COA. During YONAH’s two year field project 4,000 humpback whales were photographed and about 2,600 were biopsied (Allen et al., 1993). The sampling extended from the feeding grounds in the West Indies, including Silver and Navidad Banks, Samana Bay and Puerto Rico and the breeding grounds in the Gulf of Maine, Eastern Canada, West Greenland, Iceland and Norway (Contact: Steve Katona and Peter Stevick).

**RIGHT WHALES**  
New England Aquarium, Boston, MA, maintains the North Atlantic Right Whale Photograph-Identification Catalog. Presently, the catalog contains 6,795 photographed records of 340 right whales taken between 1935 and 1994. One component of this catalog documents scars and wounds resulting from human impacts, principally ship strikes and net entanglement (Contact: Scott Kraus and Amy Knowlton).

**FIN WHALES**  
The North Atlantic Finback Whale Catalog contains over 8,000 photographed records of 706 individual finback whales taken between 1984 and 1990. Geographic distribution of sampling extends from New York to Greenland, with greatest intensity of sampling within the Gulf of Maine and the Gulf of St. Lawrence. The catalog is located at the College of the Atlantic in Bar Harbor, Maine (Contact: Daniel DenDanto).

**SEFSC**  
**BOTTLENOSE DOLPHINS**  
Photo-identification studies of the coastal bottlenose dolphin using natural marks on dorsal fins were continued near Beaufort, North Carolina and initiated near Charleston, South Carolina to provide information on individual residency patterns. A photo-identification field
study using natural markings to identify individuals and estimate population size, vital rate parameters and examine annual variation of bottlenose dolphin population dynamics in Sarasota and Tampa Bay was completed in 1993. Population monitoring studies using photo-identification of bottlenose dolphins along the Texas coast and in Charlotte Harbor, Florida, continued in 1993 (Contact: Larry Hansen).

**SPIRIT WHALES**
Two sperm whales in the northern Gulf of Mexico were tagged with satellite transmitters in June 1993, but one tag became unattached and the transmitter on the other tag failed. (Contact: Larry Hansen).

**AFSC**

**KILLER WHALES**
A second year of photo-identification studies on killer whales was completed to obtain a minimum population estimate in Alaska. Vessel surveys were conducted around Kodiak Island, south of the Alaska Peninsula and in the Bering Sea along the eastern Aleutian Islands from 13 July to 24 August 1993. Killer whale photo-identification studies were also conducted in southeastern Alaska in conjunction with harbor porpoise ship surveys from 30 April to 13 May, 7 to 20 June, and 22 September to 3 October 1993. To obtain a minimum population count for Alaska, each animal identified from 1993 will be compared to the photographs collected from 1989 to 1993 in Prince William Sound and since 1986 in the Bering Sea and southeastern Alaska (Contact: M. Dahlheim).

**SWFSC**

**BLUE AND HUMPBACK WHALES**
Photographs of blue and humpback whales were collected for individual identification during surveys for common dolphins in the eastern tropical Pacific in 1993 (Contact: Jay Barlow).

**Laboratory work**

**NEFSC**
An extensive harbor porpoise tissue collection has been obtained from a series of three necropsy sessions conducted annually since 1992 in collaboration with researchers from the Smithsonian, James Madison University, Woods Hole Oceanographic and NMFS Headquarters. A total of 44 porpoises have been necropsied and a total of 790 soft tissue samples and 132 hard tissue samples were taken. The goal of these sessions is to collect sufficient biological samples to support research for a better understanding of this species. (Nicholas, 1993; In review).

Researchers from the Woods Hole Oceanographic Institution performed a study of the life history of harbor porpoise and pilot whales taken in commercial fishing operations off the northeastern United States. The study concentrated on aspects of the life history of harbor porpoise and pilot whales obtained from samples collected during the sea-sampling program, including the age, growth and reproductive biology of harbor porpoise in the Gulf of Maine, seasonal variation in the diet of harbor porpoises and the diet of pilot whales (Read et al., 1994).

**SEFSC**

**BOTTLENOSE DOLPHINS**
A US Armed Forces Institute of Pathology examination of tissues from Gulf of Mexico bottlenose dolphins stranded along the Florida panhandle in the summer of 1993 indicated that some of these dolphins had apparently died from a morbillivirus infection. Subsequent testing of tissues collected from stranded dolphins in several locations has confirmed the presence of this distemper-like virus in stranded dolphins from a widespread area in the northern Gulf of Mexico (Contact: Larry Hansen).

In cooperation with the SWFSC, a study is being conducted of bottlenose dolphin population stock structure using direct sequencing of the control region of mitochondrial DNA (mtDNA), analysis of randomly amplified polymorphic DNA (RAPD), and analysis of polymorphic microsatellites. DNA samples from inshore and offshore forms and different coastal populations from the Atlantic and Gulf of Mexico are being analyzed (Contact: Sylvia Galloway).

**SWFSC**

**The efficiency of molecular techniques of determining relative genetic relatedness for discriminating local populations are being tested. Three methodologies being tested are (1) direct sequencing of mitochondrial DNA; (2) genotyping of microsatellite loci; and (3) the RAPD-PCR technique. This technique involves the amplification of DNA using the PCR technique and is based on the enzymatic production of copies of portions of sample DNA. The reaction is primed by single oligomers (10 base pair long segments of DNA) of some fixed but arbitrary nucleotide sequence.**

**AFSC**

Age, reproductive status and stomach contents were determined for approximately 150 common dolphins collected during 1990 and 1991 in high seas driftnets. Analyses of growth and reproductive rates were published for the northern right whale dolphin and the Pacific white-sided dolphin (Ferrero and Walker, 1993; Ferrero et al., 1993). Abundance estimates were published for these species and Dall’s porpoise (Buckland et al., 1993), and an analysis of the driftnet fishery impacts in the North Pacific was completed (Hobbs and Jones, 1993).

**GRAY WHALES**

Lengths of 74 gray whales were measured in aerial photogrammetric images collected near Monterey, California, in January 1993. These lengths were taken from 181 whale images measured at AFSC and 177 at SWFSC (Contact: David Withrow).

**Development of techniques**

**NEFSC**

A hand-held pen-based computer system for at-sea data entry of line transect data is being developed (Garrett-Logan et al., 1993). Two Geographic Information System programs are being developed. One is designed to link at-sea observer and fisheries port sampling data to estimate the proportion of harbor porpoise bycatch that may be associated with different seasons and areas in demersal gillnet fishing in the Gulf of Maine (Smith et al., 1993a). The second is designed to link line transect sightings and effort data with contemporaneously collected data on habitat and environment. The goal is to provide a graphic analysis of spatial data for determining habitat requirements (Northridge, 1993).

Behavior observations of cetaceans from airships (blimps) were made in August 1993 using video and high-resolution photography (Hain, 1993a). Extended
behavioral observations were made on right whales and on 42 fin whales to develop improved dive-time correction factors for abundance estimation from line transect surveys (Ellis et al., 1993).

A workshop was held 20-23 September 1993 to identify possible direct changes to sink gillnet fishing gear to reduce the harbor porpoise bycatch rate. Participants included representatives from the gillnet fishing industry, research scientists and statisticians from Japan, New Zealand, Great Britain, Canada and NMFS. The workshop considered modifications which might make nets more acoustically detectable and also those that might make the netting less likely to entangle animals (Frady et al., 1994).

SEFSC
A workshop was held in September 1993 to evaluate a bottlenose dolphin health parameter database collected at Sarasota, Florida, since 1987 to develop a method for evaluating the health of dolphin populations. An age stratified health score was developed and calculated for each year. These scores were examined for correlations with population parameters such as mortality, natality, fecundity and recruitment, and compared with those from a 1992 dolphin health assessment study conducted in Matagorda Bay, Texas (Contact: Larry Hansen).

NWFSC
A rapid screening method was developed for assessing exposure of marine mammals to PCBs, including the highly toxic planar PCB congeners. This method will be very useful in responding to mass mortality events and as a cost-effective means for selection of samples for the more detailed analyses of planar PCBs by high resolution gas chromatography/mass spectrometry (Krah et al., In press).

Research results

NEFSC
The status and habitat requirements of harbor porpoise impacted by the Gulf of Maine and Bay of Fundy gillnet fisheries was reviewed in a workshop held 23-25 February 1994. Differences of a factor of two in estimates of abundance from the successive surveys and new information on animal movements suggested that additional information on population structure is needed before a definitive evaluation of status is possible (Bisack, 1993; Smith et al., 1983; Palka, 1994).

The analysis of experimental survey data suggest that although harbor porpoise do appear to avoid survey ships, this does not occur at distances before observers searching with the unaided eye detect them (Palka, 1993b).

Differences in levels of stable isotopes of nitrogen and carbon in several tissues of pilot whales from the eastern and western Atlantic suggest that the animals do not feed at the same trophic levels. Differences between levels in two western Atlantic prey species, squid and mackerel, suggest that pilot whales taken incidentally in mackeral trawl fishing operations were feeding on a mixture of both species (Abend, 1993).

SEFSC
Average bottlenose dolphin herd size in the Mississippi Sound was estimated to be the same during both spring and summer at 4.9 dolphins/ herd. Estimated dolphin density, 0.56 dolphins/km² (CV = 0.31) in the spring and 0.62 dolphins/km² (CV = 0.26) in the summer, did not vary significantly between seasons in 1993, but were about one-half of the average bottlenose dolphin density estimate for July-September 1992 (1.1 dolphins/km², CV=0.25) (Contact: Keith Mullin).

AFSC
WHITE WHALES
Minimum abundance of white whales in Cook Inlet, Alaska was estimated at 330 animals (Withrow et al., 1994). A genetic stock assessment study was begun and preliminary results were inconclusive (Contact: G. O’Corry-Crowe).

HARBOR PORPOISE
Fifteen days of line-transect aerial and vessel survey effort were dedicated to determining harbor porpoise abundance in Southern Puget Sound (south of latitude 47°55' N) from January-March 1993. No harbor porpoise were observed during these winter surveys, raising concerns because harbor porpoise were once common in this area (Scheffer and Slipp, 1948). Preliminary results from a winter 1994 vessel survey indicate that there may be fewer than 40 harbor porpoise present in Puget Sound. Aerial and shore-based sighting data, collected to correct for the number of harbor porpoise missed on the aerial survey trackline, were reanalyzed and the correction factor is being modified (Calambokidis et al., In press).

In cooperation with SWFSC, a cooperative genetic study with the University of New Hampshire, Scripps Institution of Oceanography and Stanford University is using maternally-linked mitochondrial DNA recovered from skin cells, to determine stock structure differences along the Pacific west coast. Two genetically distinct matrilines were identified. Significant genetic differences exist between some animals from AK and those from CA and WA. However, these and other differences do not show a consistent geographic pattern, suggesting that the matrilines are not geographically distinct (Rosel, 1992).

BOWHEAD WHALES
Lengths of bowhead whales have been calculated through aerial photogrammetry for years 1985-92 with examination of inherent biases and errors (Angliss et al., 1995b). Tests of ratios in lengths between visible body portions are described in Withrow et al. (1995). Projections of distributions of length frequencies developed from photogrammetry are being used to detect differences in population growth rates (Angliss et al., 1995a). Aerial observations of the distribution of bowheads and white whales in the spring near Pt. Barrow are summarized in Rug et al. (1994). Timings of harvests of bowheads by Alaskan subsistence hunters were reviewed by Withrow and Angliss (1994). An analysis of the Alaskan Eskimo subsistence harvest since 1973 is being completed based on a revision of SC/39/PS22 (Braham, In prep; Suydam et al., 1994).

SWFSC
VAQUITA
In cooperation with Mexico’s Ministry of Fisheries, a line transect survey for vaquita was conducted in the upper Gulf of California, Mexico, during which 35 vaquitas were sighted. These sightings have been combined with the sightings reported by other researchers in previous years to obtain a preliminary distribution for vaquitas within and outside the Upper Gulf of California and Colorado River
Delta. A preliminary line transect estimate is approximately 400 animals within the study area. A plan for monitoring the abundance of vaquita has been developed, but will require intensive and directed surveys carried out for at least 10 years to detect a decline of 50% or more (Contact: Robert Brownell).

Sighting data

**NEFSC**

An experimental sighting survey for harbor porpoise was conducted 3–23 August 1993 to test for vessel avoidance. The cruise covered waters from Booth Bay Harbor, ME to Grand Manan Island. New Brunswick to Yarmouth, Nova Scotia. The survey covered approximately 1,213 n.miles of track line in 120 hrs of survey time. There were 1,285 sightings of harbor porpoise groups (4,146 individuals) (Anonymous. 1993b).

A shipboard survey was conducted 1 June – 2 July 1993 to determine beaked whale and pelagic delphinid fine scale distribution in shelf edge and Gulf Stream warm core features. The study was designed to determine if distribution is continuous along Georges Bank shelf edge to Scotian Shelf and if beaked whale distribution is associated with a warm core ring feature. Line transect survey data were collected for 76 transects covering 1,874-km. A total of 494 sightings were recorded during the survey, sperm whales (52 sightings), beaked whales (24 sightings), pilot whales (55 sightings), white-sided dolphins (47 sightings) and common dolphins (39 sightings) were the most frequently sighted cetaceans (Anonymous, 1993a).

**SEFSC**

Aerial and shipboard cetacean sighting surveys were conducted in a cooperative study with Texas A&M University in the continental slope waters of the US Gulf of Mexico. Aerial surveys were conducted each season between May 1993 and April 1994, over depths of 100–2,000m for a seasonal effort of 6,300km. School encounter rates ranged from 0.44 schools/100km (full) to 0.30 schools/100km (spring). During four seasonal Gulf of Mexico aerial surveys, 165 cetacean schools were sighted and 17 species identified. Five species comprised 75% of the 143 identified schools: bottlenose dolphins (30%); pygmy sperm whales (13%); sperm whales (12%); pantropical spotted dolphins (10%); and Risso’s dolphin (10%). Ship surveys were conducted in continental slope waters in 100–2,000m and greater depths during April–June in 1993 and January–February in 1994. Transects covered 6,160km. Eighteen cetacean species were identified in the 291 schools which were encountered. Five species made up 71% of the identified schools: pantropical spotted dolphins (29%); bottlenose dolphins (16%); pygmy sperm whales (10%); sperm whales (9%); and Risso’s dolphins (7%) (Contact: Larry Hansen).

**BOTTLENOSE DOLPHINS**

Aerial surveys of bottlenose dolphins in the Gulf of Mexico continental shelf waters were conducted during September–October 1993, from Louisiana to the northwest Florida coast to estimate the abundance of bottlenose dolphins. Small boat surveys to estimate abundance in the Mississippi Sound, a 1,600km embayment along the northern Gulf of Mexico, were conducted during the spring and summer of 1993 (Contact: Larry Hansen).

**AFSC**

**BOWHEAD WHALES**

Bowhead whale sighting data collected during aerial surveys conducted in cooperation with Atlantic Richfield Co. in the vicinity of drilling platforms and support icebreakers in the western Beaufort Sea were analyzed. These surveys were part of an effort to monitor the impact of noise on bowhead whales migrating past drilling operations (Contact: Doug DeMaster).

**GRAY WHALES**

A systematic count of gray whales was conducted from 10 December 1993 to 18 February 1994 at Granite Canyon, 15km south of Carmel, California, the same site used intermittently since 1975 (Laake et al., 1995). Methods were similar to those used in preceding years (Rugh et al., 1993). Aerial transects (20–40km offshore) were flown 5–18 January 1994 (30 hrs) (Withrow et al., 1995). A total of 269 gray whale groups (483 individuals) were seen on transect, ranging from 0.1 to 33.8km offshore, with 95% of the sightings within 3.9km of the shore. Shore and aerial teams made independent pod size estimates on 48 whale groups. A population estimate for the 1992–1993 and 1993–1994 south bound migration is reported in Laake et al. (1995). The status of this population is reported in Wade (1994) and Breiwick (1994). Finally, a thermal sensor provided 92 hrs of videotape to compare day and night sighting rates (Perryman and Laake, 1994).

**WHITE WHALES**

Aerial surveys of white whales in Cook Inlet, Alaska were conducted during 2–5 June, 25–29 July and 3, 18–19 September (DeMaster, 1993).

**HARBOR PORPOISE**

A three-year study was completed to determine a minimum population estimate for harbor porpoise in Alaska using line-transect surveys. Surveys in 1993 included vessel surveys of inside waters in southeastern Alaska and aerial surveys in offshore waters from Dixon Entrance to Prince William Sound. Vessel surveys were completed in southeastern Alaska from 30 April to 13 May, 7 to 20 June and 22 September to 3 October 1993. Aerial surveys were completed from 1–26 June 1993 (Dahlheim et al., 1994).

**SWFSC**

A series of aerial surveys are being conducted in cooperation with the US Navy to determine the density and distribution of marine mammals in the vicinity of San Nicolas Island, California. The goal is to determine seasons and areas with lowest abundance of marine mammals so that acoustic ship shock trials can be conducted with minimal impact (Contact: Jay Barlow).

**COMMON DOLPHIN**

Ship surveys, with participation of observers from the Mexican National Program for the Utilization of Tuna and the Protection of Dolphins, were conducted in the eastern Pacific Ocean to estimate the absolute abundance of the northern stock of common dolphin. More than 1,200 sightings were made during nearly 10,000 n.miles of survey effort. Physical, biological, and oceanographic data regarding the habitat of marine mammals inhabiting the eastern Pacific Ocean were also collected. Aerial photographs were taken from a helicopter to calibrate observer estimates as well as for species identification. Vessel based photographic identification of dolphins and
whales were also conducted. Biopsy tissue samples were collected from bow riding dolphins for genetic studies. A number of projects were designed to collect data on the distribution, movements and general ecology of sea turtles and sea birds (Contact: Tim Gerrodette).

**BOTTLENOSE DOLPHIN**

An aerial survey of bottle nose dolphins was conducted along the California coast from the US/Mexican border north to Point Conception using two fixed wing airplanes simultaneously, surveying approximately 100 n.miles apart. The use of the two aircraft will aid in determining if separate surveys flown over a short time period yield similar data on the number of dolphins present (Contact: Karen Forney).

**NSB**

**BOWHEAD WHALES**

A combined acoustic and visual sighting survey was conducted jointly with Cornell University near Barrow, AK to estimate total abundance. Extremely favorable weather conditions resulted in a larger sample size than in any previous survey (Contact: Tom Albert).

**Strandings**

A list of strandings can be obtained upon request from the Marine Mammal Events Program (MMEP). Smithsonian Institution, Washington, DC.

**SEFSC**

Marine mammal strandings continued to be monitored on a near real-time basis through a representative sampling plan first implemented in 1991. A newsletter, Strandings, produced to foster information exchange and enhance the quantity and quality of data collected from stranded marine mammals, provided feedback to volunteer participants, university researchers, and federal, state and local wildlife officials (Blaylock et al., 1994).

**Pollution studies**

**SEFSC**

Approximately 130 water samples were collected from a series of stations adjacent to agricultural fields and in bays along the Texas coast between Galveston and Corpus Christi during February-October, 1993. Samples are being screened for selected pesticide residues to quantify the input of non-point source agricultural runoff into estuaries in Texas. Certain of these pesticides were implicated as possibly contributing to an unusually high mortality of bottlenose dolphins in 1992 (Contact: Sylvia Galloway).

**AFSC**

Photographs of individual killer whales occurring in southwest Prince William Sound collected from 7 July to 3 September 1993 were compared to previous photographs to determine the current status of a pod affected by the Exxon Valdez oil spill (Dahlheim et al., 1993).

Organochlorine contaminant concentrations and ratios from 42 blubber samples are being analyzed by six collection areas to determine if geographic ‘fingerprints’ are detectable and if stock structure inferences can be made. Total chlordane and hexachlorocyclohexane (HCH) results, in addition to PCBs, total DDE, and HCB are being compared to the results of Calambokidis and Barlow (1991). Preliminary results indicate that insecticides DDE and chlordane may be the most useful (Contact: Steve Osmek).

**NWFC**

Blubber and liver samples from stranded Atlantic white-sided dolphin, bowhead whales taken in an Alaskan subsistence hunt and harbor porpoise from fishery interactions were analyzed for chlorinated hydrocarbons (blubber and liver) and selected toxic and essential elements (liver only) to determine baseline levels of these substances in archived samples. Over 100 samples of liver, kidney and brain from stranded bottlenose dolphins in the Gulf of Mexico were analyzed for methyl mercury and other toxic and essential metals to provide a more comprehensive understanding of the relationships among levels of these substances among tissues. Similar studies with stranded pilot whales were completed (Meador et al., 1993). Assistance was also provided to the National Institute of Standards and Technology in the development and certification of a Standard Reference Material for chlorinated hydrocarbons (Contact: Usha Varanasi).

Levels of contaminants in tissues and in stomach contents of stranded gray whales were compared, revealing little relationship and suggesting that contaminant levels in tissues are relatively low compared to cetaceans feeding at higher trophic levels (Varanasi et al., 1993).

**Statistics and data for cetaceans**

**NEFSC**

Significant bycatch of several species of marine mammals occurred during 1993 in waters between Cape Hatteras and the Bay of Fundy. In the swordfish drift gillnet fishery from Georges Bank south to No. Carolina, 134 of the 151 days fished were observed. Bycatch included 5 beaked whales, 6 bottlenose dolphins, 2 Risso’s dolphin, 10 pilot whales, 113 common dolphins, 13 striped dolphins, 2 white-sided dolphin, 1 harbor porpoise and 1 humpback whale. In the groundfish gillnet fishery operating in the Gulf of Maine, 729 of the 15,735 days fished were observed. Bycatch included 57 harbor porpoises, 22 harbor seals, 2 gray seals, 2 unidentified seals, 7 white-sided dolphins, 1 bottlenose dolphin and 1 unidentified dolphin (Contact: Pat Gerriar).

**SEFSC**

Fishery observers recorded bycatch of marine mammals in 1993 by the US pelagic longline fishing fleet generally fishing south of 35° latitude. Two Risso’s dolphins and one unidentified pilot whale were observed caught and released alive between May 1993-April 1994. No incidental catch of marine mammals was observed from the Gulf of Mexico shrimp fishery (Contact: Larry Hansen).

Mortalities potentially due to fishery interactions were identified from beach-stranded marine mammals using the presence of fishing nets, cuts and markings attributable to nets, and mutilation of the carcasses as evidence. In 1993, 4.8% of the 763 cetacean strandings were suspected fishery interactions. Reported bottlenose dolphin strandings totaled 630 in 1993 and 34 (5.4%) were suspected fishery interactions. North Carolina had the highest incidence of suspected fishery-related mortalities with over 15% of the bottlenose dolphin strandings suspected to involve fisheries (Contact: Larry Hansen).

**NWR**

No cetacean bycatch was observed in 1993 in the Pacific whiting trawl fishery off the west coast of WA, OR, and CA, the Columbia River salmon gillnet fishery, the Willapa Bay salmon gillnet fishery, and the Grays Harbor salmonod drift and set gillnet fisheries, and the northern Washington marine salmon set-net fishery in 1993. The Ability of IDCRCruises to Detect Changes in Blue Whale Population Size

Tim Gerrodette

US National Marine Fisheries Service, Southwest Fisheries Science Center, PO Box 271, La Jolla, California, USA

ABSTRACT

IDCR circumpolar surveys have indicated no change in non-minke whale abundance during the 6-year period between the first and second sets of cruises, leading to the perception that the 'true' blue whale population is not increasing in size. However, the probability that such cruises would show a statistically significant result, even if the population were increasing (or decreasing), and even if a series of population estimates extended back to the late 1960s, is low. Therefore, while there is no evidence for an increase (or decrease) in blue whale abundance, neither is there evidence for concluding that the blue whale population has not been changing in abundance within a range of ±6%/year.

KEYWORDS: BLUE WHALE; SIGHTINGS-VESSEL; SOUTHERN HEMISPHERE; ASSESSMENT; TRENDS

INTRODUCTION

During the Antarctic summer of 1978/79, the IWC began a series of circumpolar cruises to estimate the abundance of minke whales (Best and Butterworth, 1980). Two sets of IDCRCircumpolar cruises have been completed and a third set is half completed. Estimates of blue, fin, sei and humpback whale abundance based on these surveys showed no statistically significant change in abundance for any of these species during the 6-year period between the first and second set (Butterworth et al., in press). The lack of change during the 6-year period of the IDCRCruises has led to the perception that the 'true' blue whale population, in particular, is not increasing. Hatanaka and Komatsu (1993) noted the apparent lack of growth of the blue whale population and proposed a research programme based on that premise. The purpose of this paper is to examine briefly the power of the IDCRCruise survey data to say whether there have or have not been changes in whale population sizes.

METHODS

Because of the large coefficients of variation (CV) associated with IDCRCircumpolar whale abundance estimates (other than minke whales), it was obvious that any statistical comparison of the estimates from the two sets of surveys would not be significant, and Butterworth et al. (in press) did not attempt any test. If one were to make such a comparison, however, a reasonable statistic would be

\[ T = \frac{N_2 - N_1}{s_{N2-N1}} = \frac{\Delta N}{\hat{s}_\Delta N} \]

where \(N_1\) and \(N_2\) are the estimates of abundance, \(s_{\Delta N}\) is the standard deviation (SD) of their difference and \(T\) follows Student's t-distribution with 1 degree of freedom (df).

If the population grows at an annual rate \(r\) for a 6-year period,

\[ N_2 = N_1 (1 + r)^6 \]

and if we assume there is a common CV for both cruises, we can approximate the SD of the difference of the two estimates by

\[ s_{\Delta N} = \sqrt{s_{N1}^2 + s_{N2}^2} \approx \sqrt{2} (\text{CV}) N_1 \]

With these simplifications, we can express \(T\) as a function of population growth rate and precision of estimation, independent of any particular population estimate:

\[ T = \frac{(1 + r)^6 - 1}{\sqrt{2} CV} \]

If there are more than two points in the series (as when future sets of IDCRCruises are completed), or if we consider hypothetical population estimates made in 1969 and 1975—that is, at 6-year intervals prior to the two sets of IDCRCruises), a linear regression or some similar fitting would be appropriate. It is assumed that a linear regression is used, with the usual test statistic

\[ T = \frac{b}{s_b} \]

where \(b\) is the estimated slope of the regression line and \(s_b\) its estimated standard deviation.

The detection of a change in whale abundance is the rejection of the null hypothesis of no change. The power of the test is the probability, when in fact there has been a change, that \(T\) will exceed the critical value \(t_{\alpha, df}\) for a given significance level \(\alpha\). For a 2-tailed test, this may be written

\[ 1 - \beta = \Phi(t_{\alpha/2, df} - T) + \Phi(T - t_{1-\alpha/2, df}) \]

where \(\Phi\) is the distribution function for the noncentral t-distribution. \(T\) is a function of the \(N_1\) and \(s\), and hence of \(r\) and CV. For the case of more than two estimates, the estimation of power follows the approach described in Gerrodette (1987; 1991; 1993). We consider a 2-tailed test at \(\alpha = 0.05\), for values of \(r\) from 1% to 6%, and of CV from 0.2 to 0.8.

RESULTS

The power of the two IDCRCircumpolar surveys to detect changes in population size for annual rates of change from 1% to 6% and CVs from 0.2 to 0.8 is shown in Table 1(a). For comparison, the probability of rejecting the (true) null hypothesis is also shown in Table 1 under the column of 0% growth rate, or no change in abundance. In all cases, power is low, at or near the minimum possible value, the Type I error level \(\alpha = 0.05\). Power to detect changes in whale abundance increases little when three estimates of
abundance are available over 6-year intervals [Table 1(b)]. Power to detect change in abundance becomes appreciable only with four circumpolar surveys with low CV (0.2) and high growth rates (5-6% yr) [upper right part of Table 1(c)], but even then only reaches about 0.5.

DISCUSSION

Butterworth et al. (In press) estimated the CVs associated with the ‘true’ blue whale abundance estimate to be 0.28 and 0.54 for the two circumpolar surveys. The CVs of the two surveys were therefore not equal, as assumed here, but the power achieved by the two surveys will lie between estimates of power assuming both CVs equal to the smaller (0.28) or the larger (0.54). Because of low sighting rates and consequently high CVs, Butterworth et al. (In press) stated that no conclusion could be drawn about the current rates of increase (or decrease) for blue, fin, sei and humpback whales near the Antarctic continent. However, as those authors clearly recognised, this is not the same as concluding that there has been no increase (or decrease) in abundance.

Research plans and management decisions should not be based on the conclusion that there has been no increase in blue whale abundance. Given present data, there is a high probability of Type 2 error, which can have negative consequences (Peterman, 1990; Taylor and Gerrodette, 1993). The issue is the low statistical power to detect changes in abundance based on CPUE or survey data, an issue well recognised in the IWC, beginning with the paper by de la Mare (1984). The brief analysis presented here is sufficient to show that data now available do not allow conclusions about rates of change to be made. For blue whales, even though abundance estimates for the two circumpolar surveys are identical (Butterworth et al., In press), the precision of the estimates is such that, even if blue whales had been increasing at their maximum rate, there would be little chance of detecting that change. In other words, there is no evidence for either an increase or decrease in blue whale abundance, but neither is there evidence for concluding that the blue whale population has not been changing in abundance within a range of 6%/yr.

It is of some interest to estimate how much more survey effort would be required to detect changes with high probability. To detect a rate of change of 6%/yr with at least 90% probability would require four surveys with a CV of 0.1. The amount of survey effort required to achieve such a CV depends on the abundance and patchiness of whales, the variance in the size of groups of whales and the particular vessel and survey methods used. Other things remaining equal, CV is inversely proportional to the square root of the number of sightings in a line-transect survey (see Taylor and Gerrodette, 1993, for an example). Therefore, to reduce the CV of the present surveys from 0.28 to 0.1 would require increasing effort by a factor of (0.28/0.1)², or approximately eight times. To detect rates of change of less than 6%/yr, or with fewer than four circumpolar surveys, would require even more effort.

ACKNOWLEDGMENTS

The examination of the power of the IDCR survey was suggested by Robert Brownell. The paper benefited from comments by Robert Brownell, Stephen Reilly and two anonymous reviewers.

Segregation of the Two Sub-species of the Blue Whale in the Southern Hemisphere

Hidechiro Kato, Tomio Miyashita and Hiroyuki Shimada
National Research Institute of Far Seas Fisheries, 5-7-1 Orido, Shimizu, Shizuoka 424, Japan

ABSTRACT
This paper examines segregation of the two sub-species of blue whales in the Southern Hemisphere by reviewing sightings data (the JSV, IWC/IDCR and Japanese sightings surveys) collected up to 1992. Blue whales were seen often in the Indian Ocean and they occur over a wide latitudinal range even in mid-summer when they are normally thought to be feeding in the Antarctic. From the available catch information, it seems clear that the blue whales seen in lower latitudes are pygmy blue whales and that in mid-summer they are segregated from the true blue whales (being found in more northerly waters) although the sub-species cannot be distinguished at sea due to difficulties in identification. The present analysis also suggests pygmy blue whales are found in the western region of the South Pacific and the eastern region of the South Atlantic. An identification key needs to be developed further in order to distinguish the two sub-species during sighting surveys.

KEYWORDS: SOUTHERN HEMISPHERE; SOUTH ATLANTIC; SOUTH PACIFIC; INDIAN OCEAN; BLUE WHALE; PYGMY BLUE WHALE; DISTRIBUTION; STOCK IDENTITY; WHALING-MODERN

INTRODUCTION
Three sub-species of blue whale (Balaenoptera musculus) are generally recognised (Rice, 1977; Yochem and Leatherwood, 1985): B.m. musculus in the North Atlantic and the North Pacific; B.m. intermedia in the Southern Hemisphere; and B.m. brevicauda also in the Southern Hemisphere and perhaps elsewhere (Fig. 1). B.m. brevicauda, the pygmy blue whale has been identified since 1961 on the basis of a number of characters including its shorter tail, broader baleen plates and smaller body length at sexual and physical maturity, when compared to the southern blue whale, B.m. intermedia (Ichihara, 1961; 1963; 1966; Zemsky and Boronin, 1964; Omura et al., 1970).

Ichihara (1966; 1981) believed that pygmy blue whales lived mainly in the sub-Antarctic region adjacent to the Kerguelen Islands in summer. Aguayo (1974) reported some pygmy blue whales in catches off Chile during whaling operations there.

The main problem in examining the distribution of the sub-species of the blue whale is that identification is extremely difficult at sea, although some experienced whalers believe that pygmy blue whales can be identified from the ordinary blue whales (e.g. see discussion in Donovan, 1984). Thus for almost all dedicated sighting surveys, both sub-species have been recorded as simply ‘blue whale’ except in certain rare cases.

Despite identification problems however, it is feasible to examine the population status of blue whale sub-species if certain, semi-arbitrary assumptions about geographical boundaries are made (e.g. Butterworth et al., in press).

The International Whaling Commission’s Scientific Committee has stressed that in order to complete the comprehensive assessment of the southern baleen whales, as well as in considering research related to the conservation of large baleen whales (IWC, 1995), the separation of the two sub-species must be clarified. The present paper attempts to examine geographical segregation between the sub-species by reviewing the sightings data collected after the cessation of blue whale catching in the Southern Hemisphere in the light of the available catch data.

MATERIALS AND METHODS
Sightings data
The following sightings data are reviewed: data collected by scouting vessels attached to the Japanese whaling expeditions ('JSV data') from 1965/66 to 1987/88; IWC/IDCR Southern Hemisphere minke whale assessment cruise data from 1978/79 to 1992/93; and data collected by the Japanese national whale sighting projects in the Southern Hemisphere since 1978/79 (before and after the IWC/IDCR cruises). With rare exceptions, the data do not distinguish between the two sub-species of blue whales in the Southern Hemisphere. The JSV operations have been described by Ohsumi and Yamamura (1982) and more recently by Miyashita et al. (1994). The searching distances and numbers of blue whales sighted for the JSV data were summed by 5° squares and months for the 1965/66 to 1987/88 seasons based on the noon positions of the vessels. ‘Primary’ and ‘secondary’ sightings were not separately recorded and only the total number of sightings per day was given for each species, along with noon position and total searching distance per day (Miyashita et al., 1994). A density index has been obtained (the encounter rate) by calculating the number of animals sighted per 10,000 n.miles distance steamed in each 5° square using both data sets of the JSV and the national sighting projects. This follows the approach of Kasuya and Wada (1991) who examined available data for the Indian Ocean from 1965/66–1984/85.

A total of 101 blue whale sightings have been made during the IDCR cruises from 1978/79 – 1991/92 seasons and the relevant data have been extracted. However, it should be remembered that most effort occurred in waters south of 60°S.

[Text continues on p. 280]

1 Primary sightings are those seen when the vessel is in full searching mode whereas secondary sightings are those made when the ship is mainly engaged in other activities such as closing with a sighting to confirm species identity, school size, etc.
Fig. 1. Blue whales in the Southern Hemisphere, which were photographed in mid-summer. A and B are true blue whales in high latitudes, 65°03’S-11°54’E (photo by H. Shimada), whereas C must be a pygmy blue whale photographed off the southern coast of Australia (photo courtesy of Mr S. Nishiwaki).
Table 1

Sighting information of Southern Hemisphere blue whales by 5° square based on the JSV sighting data collected from 1965/66 to 1978/88. Upper figures: searching distance in nautical miles; middle: number of blue whale sightings (individual base); bottom: the index of whale density (number of individuals /10,000 n.miles).

</table>
Fig. 2. Distribution and density variation of blue whales in the Southern Hemisphere, by 5° square in each month through November to April, which are based on sighting data from the Japanese scouting vessels (1965/66 – 1987/88) and the IWC/IDCR cruises (1978/79 – 1991/92).
Catch data
The most accurate identification to sub-species can be made from carcasses and thus the catch distribution of pygmy blue whales by Japanese whaling expeditions in 1959/60 to 1962/63 seasons is also examined in this paper.

RESULTS

Sightings distribution
Numbers of blue whale sightings from the JSV data, searching distances and density indices are given in Table 1 by 5° square. Despite the small number of blue whale sightings, a number of concentrations of sightings are apparent: 40–45°S – 30–55°E; 35–40°S – 115–140°E; 65°S – 135–165°E; and 70–75°S – 180–175°W.

Clearly, any analysis of sightings data must take into account the seasonal movements of whales and in particular the southerly migration to the feeding grounds. Monthly sightings (November to April) are thus shown in Fig. 2, expressed as density by 5° square. Fig. 3 shows the monthly positions of blue whale sightings during the IWC/IDCR cruises.

The changes in distribution by month are summarised below.

November-December
This probably represents the beginning of the southerly migration for the true blue whales. Sightings are relatively rare throughout the area but small high density areas can be seen in low and middle latitudes such as waters off Peru (0°–10°S), the southern coasts of Madagascar (25–35°S) and Australia (30–45°S) and the western coast of New Zealand (35–45°S). It should be noted that some blue whales were also seen in high latitudes during these months.

January-February
These months probably represent the peak of southerly migration. Sightings are relatively more frequent and particularly high density areas can be seen in mid-latitudeal waters (35–50°S), as well as in waters off the west coast of New Zealand (35–40°S). In the Antarctic, blue whales are also seen near ice edge zones although not as often as they are in circumpolar waters north of 60°S.

March
This probably represents the end of the southerly migration. Almost no blue whales were seen in the higher latitudes, but relatively large numbers were recorded in mid-latitudeal waters (40–50°S) in the Indian Ocean and around New Zealand.
Catch distribution

As discussed by Ichihara (1966), Japanese whaling expeditions had captured pygmy blue whales in the waters around Marion Island (47°S-38°E), the Crozet Islands (46°S-51°E) and the Kerguelen Islands (49°S-70°E) between 1959/60 and 1962/63. Fig. 4 shows the catch distribution for these whales. Although the longitudinal coverage of the catching operations was from 0° to 80°E, pygmy blue whale catches were mainly between 25°E and 75°E. A catch hiatus is apparent between 55°E and 65°E but this seems to be an artifact of several factors including the operational strategy of the fleets. The latitudinal range of the pygmy blue whale catch is from 40°S-54°S with no local variation within the operational range of 25°E-80°E, although Gambell (1964) reported that a female pygmy blue whale was taken at Durban (30°30′S, 31°28′E) in September 1963.

The catch distribution of true blue whales is also shown for comparison in Fig. 4 based on Ichihara (1966), who provided catch distributions for the Japanese fleet from 1946/47 to 1962/63. Horwood (1986) also reviewed catch distributions of blue whales but included data for Soviet fleets which have subsequently been found to have been falsified (e.g. Yablokov, 1994). It is clear that true blue whales were caught largely in waters south of 55°S or the Antarctic convergence.

DISCUSSION

Catch data

The catch data, which allow full identification by subspecies, reveal that pygmy blue whales were mainly caught in the mid-latitudinal waters (40°-54°S) of the Indian Ocean while true blue whales were taken in waters south of 55°S.
This suggests that in mid-summer, pygmy blue whales are found to the north of the convergence whereas true blue whales are found to the south. This view is not contradicted by recent examination (e.g. Brownell and Donaghue, 1994) of corrected catch data for pygmy blue whales taken by the Soviet whaling fleet in the Indian and other oceans. These data had been published by Zemsky and Sazhinov (1982) but largely ignored as the paper had been written in Russian and published in the USSR.

**Sightings data**

**Indian Ocean**

The sightings data collected from 1965/66 onward reveal relatively high densities of blue whales in mid-latitudinal waters of the Indian Ocean even in January and February, when one might expect the southerly migration of blue whales to the Antarctic to have reached its peak. The segregation revealed by the catch data suggests that the high densities seen in middle latitudes were pygmy blue whales to the Antarctic to have reached its peak. The segregation revealed by the catch data suggests that the high densities seen in middle latitudes were pygmy blue whales while the sightings in the high latitudes were true blue whales (Fig. 5). This is in accord with Kasuya and Wada’s (1991) analysis. Bannister and Nishiwaki (pers. comm.) reported an immature true blue whale within an area of sightings of pygmy blue whales off the south coast of Australia in March. Their findings were based on identification by experienced crew members who referred to the different behaviour of the two sub-species; however it is still not clear exactly how true and pygmy blue whales were distinguished.

**South Atlantic**

Catches of the pygmy blue whales, as well as sightings of blue whales in the middle latitudes in the eastern South Atlantic, reveal the existence of the sub-species and suggest similar summer segregation for these waters to those in the Indian Ocean (Fig. 5).

**South Pacific**

The sightings of blue whales in the mid-latitudinal waters of the western region of the South Pacific also suggest that pygmy blue whales are found there and that similar segregation occurs.

Aguayo (1974) reported blue whale sightings off Chile in December and 10 pygmy blue whales were identified out of 168 blue whales caught in waters off Chile. He also (pers. comm., cited in Ichihara, 1981) suggested that the two sub-species co-exist (but in separate schools) in Chilean waters. Donovan (1984) discussed sightings of blue whales made...
off Peru in December 1982. He noted the difficulties in differentiating between sub-species but concluded that the animals seen were probably pygmy blue whales. He also noted that true blue whales had been recorded for the area and briefly discussed the question of stock identity.

Of the morphological differences identified by Ichihara (1966), probably only the shorter tail is useful in the context of field surveys. This character and its applicability in field studies requires further examination.

ACKNOWLEDGMENTS

During the early stages of the present study, S.B. Reilly, Southwest Fisheries Science Center, USA gave valuable suggestions for the analyses. T. Kasuya, National Research Institute of Far Seas Fisheries (NRIFS), Japan and S. Ohsumi, Institute of Cetacean Research (ICR) also made helpful suggestions. T. Ichih of the NRIFS, K. Sakuramoto of Tokyo University of Fisheries, G.P. Donovan (IWC) and an anonymous reviewer kindly reviewed the manuscript. R. Shige assisted with the artwork.

North Atlantic Whales
Fin Whale Abundance in the Eastern Temperate North Atlantic for 1993

ABSTRACT

A sightings survey was conducted in the temperate waters of the eastern North Atlantic during the summer of 1993, to estimate the density and absolute abundance of cetacean species in the area. The analysis of line transect data for the fin whale population produced an abundance estimate of 7,507 animals (CV=1,150, 95% CI: 5,600-10,100 whales).

KEYWORDS: FIN WHALE; NORTH ATLANTIC; SURVEY-SHIP; ASSESSMENT

INTRODUCTION

A line transect survey to assess cetacean abundance was conducted in the temperate waters of the eastern North Atlantic during the summer of 1993 by the French Institute IFREMER. The survey was part of a programme to assess the impact of the French Albacore tuna drift gillnet fishery on small cetaceans at the population level (Goujon et al., 1993). It was carried out over three different cruises between 3 July and 22 August 1993 by a team of observers from France, Spain, Belgium and Italy.

The area covered during the survey (Fig. 1) is a polygon located between the continental slope of the Gulf of Biscay in the east, the 21°W meridian in the west, the 51°30’N and the 43°N parallels in the north and the south respectively. It was chosen to reflect the area of the albacore fishery rather than any known or presumed cetacean stock boundaries. The area spans 204,929 n.miles² and is mostly included in the IWC ‘Spain-Portugal-British Isles’ management stock of fin whales, the boundaries of which are described in Donovan (1991). Parts of this stock have been surveyed on several occasions in the past (e.g. Sanpera and Jover, 1986; Sanpera and Jover, 1989; Buckland et al., 1992b) but the whole management area has never been covered in a single survey. The area covered in the present survey coincides with the areas covered as part of NASS-87 and NASS-89 (North Atlantic Sightings Surveys).

In this paper, the data have been analysed to estimate the density and abundance of fin whales (Balaenoptera physalus) in the surveyed area. The results of the analysis are compared to those of previous surveys conducted in similar areas of the eastern North Atlantic. It should be noted that this estimate refers merely to a geographical area; the biological stock structure of fin whales in the eastern North Atlantic remains unclear (e.g. IWC, 1992).

METHODS

Data collection

The area surveyed was divided into six sub-areas for logistical reasons and these had no known relationship to fin whale distribution and/or abundance. A zig-zag cruise track with a random starting point (IWC, 1994) was determined for each sub-area (Fig. 1).

The survey was conducted from the 38m trawler Croix Morand from Dhelemmes, in Concarneau, France. The cruising speed was set between 10.5-11.5 knots and the observation platform was situated at a height of 6.2m. Sighting angles and distances were collected for all cetaceans encountered, following standard line transect sampling methods (Buckland et al., 1993). As the major target species of the project, only small cetaceans were approached when sighted, in order to estimate school size and identify the species. Observers were told to adopt conservative criteria for the identification of whale species (large orca versus minke whale) and many whale sightings remained unidentified.

Data were stratified according to area, sea state (classified according to the Beaufort Scale) and visibility (with classes 1 for visibility <2,000m, 2 for visibility between 2,000-4,000m and 3 for visibility >4,000m).

Data analysis

Within a stratum, whale abundance \( \hat{N} \) was estimated as follows (Burnham et al., 1980)

\[
\hat{N} = (n \cdot f(0) \cdot 8 \cdot A) / (2 \cdot L)
\]

where

\( n \) = number of sightings used for the analysis;

\( f(0) \) = estimated probability density of perpendicular distances evaluated at zero;
\( s \) = mean group size;

\( L \) = distance covered on effort;

\( A \) = size of the area sampled;

with the variance obtained by

\[
\text{var}(N) = \bar{N}^2 \cdot \left[ \text{var}(n)/n^2 + \text{var}(f(0))/f^2 + \text{var}(s)/s^2 \right]
\]

Accordingly, whale density is defined as \( N/A \) and encounter rate is \( n/L \). The probability, \( g(0) \), of detecting animals on the trackline was not estimated, because of the lack of a second platform on the vessel (e.g. see discussion in IWC, 1994). Hence, as has been the case in most fin whale surveys, \( g(0) \) was assumed to be equal to one and the effective strip width (esw) was defined as \( 1/f(0) \).

For the estimation of \( f(0) \), several models were fitted to the perpendicular distance data after truncation and the best model was chosen according to the Akaike Information Criterion (Akaike, 1973). Data were analysed using the computer program DISTANCE V.2.03 (Laake et al., 1993).

School size (or group size) was estimated in all analyses as the average of school size estimates for each sighting.

When estimating abundance, only primary sightings (i.e. those made during normal searching effort along the trackline) forward of abeam were used and perpendicular distances were truncated at 2,000m. Stratification of effort was attempted and, following Buckland et al. (1992b), three potential stratification factors were considered: sea state, geographic area and school size. The effect of sea state on the estimate was assessed by comparing for different sea state categories the three main components of the abundance estimator: the effective strip width; the encounter rate; and the average school size. Differences in the estimates of the three parameters were assessed using...
z-tests. A similar methodology was used to examine the effect of different geographic blocks and school size, where sample size permitted. Based on experience from this and previous surveys, conditions corresponding to sea states ≤4 and visibility greater than 2,000m were considered optimal and are referred to hereafter as ‘observations under optimal conditions’. Only such data were included in the analyses. No significant differences were found in the esw and encounter rate by different sea state or school size categories, therefore perpendicular distance data were pooled across all the stratification factors.

The lack of closure with sightings other than small cetaceans resulted in a large number of ‘large rorqual sightings’. Rather than discard potentially valuable data, two analyses were carried out: one for identified fin whales and one for fin whales and unidentified large rorquals pooled (e.g. see Buckland et al., 1992a; b).

For the analysis of fin whale data, several models were fitted to the perpendicular distance distribution of 43 (of the 58) primary sightings; i.e. those made at perpendicular distances < 2,000m, under ‘optimal conditions’.

For the pooled data, models were fitted to the perpendicular distance distribution of 158 (of the 196) primary sightings; i.e. those made at a perpendicular distance < 2,000m under ‘optimal conditions’.

RESULTS

Of the 230 sightings of large rorquals made during the survey, 196 were primary sightings (see Table 1).

Fin whale sightings only

The best model fit was for the two term Fourier series (Fig. 2). With this model, abundance was estimated as 3.589 fin whales (SE: 866), encounter rate as 1.57 schools per 100 n.miles (SE: 2.8 10^{-3}), esw as 955m (SE: 143) with a mean school size of 1.32 individuals (SE: 0.08).

Large rorqual (including fin whale) sightings

The best model fit was for the one term Fourier series (Fig. 3). Abundance was estimated as 7.307 whales (SE: 1.127), encounter rate as 4.56 schools per 100 n.miles (SE: 6.10^{-3}), esw as 1.294m (SE: 0.83) with a mean school size of 1.29 individuals (SE: 0.05).

Comparison of the ‘fin whale’ and ‘pooled’ estimates

In order to investigate the differences between the two estimates, perpendicular distances of identified fin whales and unidentified large rorqual sightings made at perpendicular distances < 2,000m and under ‘optimal’ conditions, were compared in frequency groups (Table 2). Only 2 out of 14 sightings of large rorquals were unidentified at distances closer than 100m, whereas 10 out of 16 were unidentified at distances between 100 and 200m.

In view of these results, a further estimate, using only fin whale sightings and perpendicular distances truncated at 100m was attempted. This new analysis, although ‘wasteful’ of data (compared with what is recommended by Buckland et al., 1993) yields an estimate (6,017 fin whales; SE 1.913) that is not significantly different from that obtained for the pooled large rorqual sightings.

For reasons discussed below, we believe the most appropriate analysis is for the pooled sightings, giving an estimate of 7.307 fin whales (CV=0.150 and 95% CI 5.600-10.100) for the area surveyed.

DISCUSSION

The variation in abundance estimates for the ‘identified fin whales’ versus ‘pooled’ data sets seems largely due to the number of unidentified animals relatively close to the transect line (>100m). Discarding these animals (about 66% of sightings) will result in a negatively biased estimate due to the non-representative and small number of identified fin whales further away from the trackline. In order to examine this further, we carried out the analysis with the truncation set at 100m, where most of the animals (86%) were identified. The resultant point estimate was closer to the ‘pooled’ estimate and the two estimates were not significantly different. It is clear that the estimate using only identified fin whales is negatively biased.

The main additional assumption involved in the ‘pooled’ analysis is that all the unidentified large rorquals were fin whales. As shown in Table 1, the only identified large rorquals seen during the survey were fin whales. This is in accord with observations of previous sighting cruises carried out in the North Atlantic off Spain. During the
Table 2

three cruises *Ballena* 2, 3 and 4 (Sanpera et al., 1984; 1985; Sanpera and Jover, 1986). 132 large rorquals were observed; 103 were identified as fin whales and only three as other species (the remaining 26 were unidentified). Lens (1991) reported 166 observations of large rorquals in the Bay of Biscay (42° - 52°N and 2°- 25°W), of which 76 were identified as fin whales. The remaining animals were all unidentified except one blue whale. Thus it seems that the assumption that all of the unidentified large rorquals were fin whales is not unreasonable and thus that the ‘pooledd’ estimate represents the best estimate of the number of fin whales in the surveyed area in summer 1993.

For the present survey, the density was estimated as 0.037 (SE: 5.5 10⁻³) whales per n.mile². This value is slightly lower than the density found in 1989 by Buckland et al. (1992b) in the Bay of Biscay area (0.047 whales per n.mile²) but higher than that found by Sanpera and Jover (1989) in 1987 (0.023 whales per n.mile²). An important factor to recall is that the 1993 cruise was targeting small cetaceans and not whales, unlike the other cruises. The estimated encounter rate and cens from the 1993 survey are greater than the estimates made for 1989 (by 6% and 39% respectively). This is probably partially due to the fact that unidentified sightings of large rorquals were included: they were not included in the analysis of Buckland et al. (1992b). Finally, the 1993 mean school size estimate (1.29 whales per cluster) was 24% smaller than the one estimated for the 1989 survey and very similar to the one estimated from the NASS-87 cruises (1.30). The area surveyed during 1989 included part of the southern Iberian fin whale stock (south of 45°N), which was not covered during 1993. This southernmost region is known to be an important area of summer distribution for northeast Atlantic fin whales (Aguiol et al., 1983; Mizroch and Sanpera, 1984).

ACKNOWLEDGEMENTS

Thanks are due to all the observers who participated in the cruises, to the crew of the Croix Morand, and also to Loïc Antoine, Phil Hammond and Anne Collet who participated in the preparation of the project. Very special thanks are due to Steve Buckland and David Borechers (University of St Andrews, Mathematical Institute, North Haugh, St Andrews, Fife KY16 9SS, Scotland) who provided valuable suggestions for the analysis and the manuscript, as did G.P. Donovan and two anonymous reviewers.

ABSTRACT

A method based on Hardy Weinberg equilibrium predictions for genotype frequencies is developed to estimate the relative proportions of the minke whales in a subarea of the western North Pacific which belong to two different stocks. Bootstrap methods are applied to estimate the precision of the results. The estimates obtained from existing genetic data for subareas 7 and 11 indicate J stock: O stock ratios at various times of the year which are consistent with those inferred from conception data, and more precisely determined. It is suggested that this information could be included with that being used at present to condition the Revised Management Procedure trials for North Pacific minke whales. Calculations are made of the power of the method to determine the O stock: W stock ratio in a subarea, as a function of sample size. This power is an increasing function of the difference between the allele proportions for the O stock and the (hypothesised) W stock, but generally decreases for higher values of the actual O stock: W stock ratio.

KEYWORDS: GENETICS; STOCK IDENTITY; MINKE WHALES; NORTH PACIFIC; MANAGEMENT

INTRODUCTION

In the Revised Management Procedure (RMP) trials for minke whales in the North Pacific (IWC, 1994, Appendix 3), partial mixing of three stocks is envisaged in the various subareas of the western North Pacific considered (see Fig. 1). These three stocks are the J (Sea of Japan, Yellow Sea, East China Sea) stock, the O (Okhotsk Sea) stock and an hypothesised W (West Pacific) stock.

The process of conditioning these trials requires information on the breakdown by stock of the abundance of minke whales in these subareas during various periods of the year. At present, conception date data is used for this purpose (see table 4b of Appendix 3 of IWC, 1994). Genetic information is also utilised (see section F, paragraph (e) of that Appendix), but the value of 0.2 assumed for the CV of the associated estimate was a somewhat arbitrary choice. The primary purpose of this paper is to place the incorporation of such results in the conditioning process on a sounder quantitative basis.

First, we develop a method to analyse available data on Adh-1* frequencies for minke whales in subareas 7 and 11, to estimate the ratios of the J stock: O stock animals present in these subareas at various times of the year. A bootstrap approach is applied to provide estimates of precision.

There are as yet no similar data from subareas further to the north and east of Japan, which might allow a similar attempt to estimate ratios for the O stock: W stock animals in those subareas. This means that the present RMP trials need to consider a wide range of possibilities in this regard. Collection of such data could provide a basis to narrow this range, but it is important to investigate the relationship between sample size and the expected precision of the resultant estimates, if such an exercise is to be planned. The method developed is therefore applied to determine this precision, which is a function also of certain other parameters of the hypothesised W stock whose values are not yet known.

MATERIALS AND METHODS

Data

Wada (1991) reports on the genetic analysis of liver samples collected by whalers from minke whales caught in Japanese small-type whaling during 1980-87. Allozyme variation was examined by ordinary horizontal starch gel electrophoresis, as described in Wada and Numachi (1991). Three loci were genotyped, and of these the results for Adh-1 (Alcohol dehydrogenase-1) are listed in Table 1 and considered in the analyses that follow.

Estimation of the J-stock: O-stock ratio of minke whales in subareas 7 and 11

Under the assumption of Hardy Weinberg equilibrium, the fractions of the three major genotypes: hh, dh, and dd in a single homogeneous stock are: $f_{hh} = p^2$, $f_{dh} = 2p(1-p)$ and $f_{dd} = (1-p)^2$, where in this case $p$ is the Adh-1* proportion. We denote this proportion for the J stock by $p_j$ and that for the O stock by $p_o$. If the J and O stocks mix in a particular area, and the proportion of the total number in this area which are J whales is $\alpha$, then the fractions of genotypes hh, dh, and dd in the area are:
\[ f_{hh} = \alpha(p_J)^2 + (1-\alpha)(p_O)^2 \]
\[ f_{dh} = 2(\alpha p_J(1-p_J) + (1-\alpha)p_O(1-p_O)) \]
\[ f_{dd} = \alpha(1-p_J)^2 + (1-\alpha)(1-p_O)^2. \]

The data that are available to estimate \( p_J, p_O \) and the relative stock proportions in each subarea are the number of samples with each genotype by whaling ground, year and month (Table 1). For this analysis, the available data for North Pacific minke whaling grounds B and C (see Fig. 2) are pooled to provide data for subarea 7 of the operating model developed for RMP trials for the North Pacific minke whale population (IWC, 1994, Appendix 3). Data for ground A provides information for subarea 11. The data are also pooled into two-month strata (April – May, June – July, and August – September) to conform to the structure of the operating model for these trials. Finally, the data are pooled across years to provide data by subarea and two-month period (see Table 2).

The estimates of \( p_J \) and \( p_O \) and the \( \alpha \)'s for each two-month/subarea stratum are obtained by a maximum likelihood approach. For each such stratum, the contribution to the log-likelihood function is (up to a constant):

\[ \ln L = n_{hh} \ln f_{hh} (p_J, p_O, \alpha) + n_{dh} \ln f_{dh} (p_J, p_O, \alpha) + n_{dd} \ln f_{dd} (p_J, p_O, \alpha) \]  

where

- \( n_{hh} \) is the number of samples in the stratum with genotype \( hh \),
- \( n_{dh} \) is the number of samples in the stratum with genotype \( dh \),
- \( n_{dd} \) is the number of samples in the stratum with genotype \( dd \), and
- \( \alpha \) is the proportion of the minke whales in the stratum which belong to the J stock.

The overall log likelihood maximised is then the sum of these contributions over the strata.

Thus, the number of estimable parameters is eight: \( p_J, p_O, \) and an \( \alpha \) for each of the six two-month/subarea strata. However, an estimate of \( p_J \), which is independent of the data from whaling grounds A, B and C, can be obtained from the samples collected from grounds H and J (these grounds are to the east and west of Korea – see Fig. 2 – where it seems reasonable to assume that J stock animals only are present, as is the case for almost all of the scenarios envisaged in the RMP trials (IWC, 1994)). Of the 45 animals sampled on these grounds during 1982, one had genotype \( hh \) and four had genotype \( dh \) (Table 1), which provides an estimate of \( p_J \) of \( 6/49 = 0.067 \). Treating \( p_J \) as fixed and equal to this value in equation (2), means that the number of parameters estimated in the likelihood maximisation process is seven.
This approach is similar to that developed by Millar (1987), the differences being that here the value of \( p_D \) is estimated along with the mixing proportions instead of being determined from background data, and that this analysis is based on a single isozyme polymorphism only.

A bootstrap procedure is used to estimate standard errors (SEs) and coefficients of variation (CVs) for the parameter estimates. This involves generating 1,000 pseudo data sets based on the available data, and then repeating the procedure described above for each set to provide distributions for the estimated parameters. The empirical 5% and 95%-tiles of these distributions are used to provide estimates of 90% confidence intervals (CIs). The pseudo data sets are generated as follows:

(i) a value for \( p_D \) is generated from the binomial distribution \( B(p = 690; n = 90) \); and

(ii) genotype frequencies are generated for each stratum by selecting, at random and with replacement, from the frequencies by year (see Table 1), until the total number of samples exceeds the number in the actual sample for that stratum (listed in Table 2).

The reason that this resampling approach is used, rather than generation from a multinomial distribution, is that the samples were collected opportunistically rather than randomly. This could introduce ‘clumping’ effects, because if several samples are collected at the same time and from the same location, there is a high likelihood that they all come from the same stock rather than reflect the overall mix of stocks in the subarea. Basing an analysis on the assumption of multinomiality in such a situation would lead to negatively biased estimates of precision. By choosing a year as the sampling unit in this bootstrap approach, estimates of precision (CVs) are obtained which are not subject to this bias. However, these CVs then reflect not only the estimation error for the average value of \( \alpha \), but also the inter-annual variability in this proportion.

Adding yearly data to the pseudo data set until the total in the set exceeds the number actually sampled, means that the sample sizes for the pseudo data sets will be the same, or larger, than those for the original data set, which introduces negative bias in the estimates of CVs. In order to quantify the extent of such a bias, a sensitivity analysis is conducted in which yearly data sets are selected at random and with replacement until the total number of samples for the stratum would, had the next set been added, have exceeded the number in the actual sample. This procedure

| Year | Month | Whaling ground | Genotype | | Year | Month | Whaling ground | Genotype |

</tbody>
</table>
of these two stocks present in the subarea from which the samples might be taken, on the ability to estimate this ratio from such data. This exercise involves generating 500 artificial genotype frequency data sets for a range of sample sizes (n), applying the estimator described in the preceding sub-section (except, of course, that only a single stratum is now involved), and then summarizing the distributions of the differences between the actual and model-predicted values for \(p_W\) and the proportion of the whales in the subarea which belong to the O stock (\(\beta\)). For each result reported, the actual Adh-1^4 gene frequencies for the two stocks (denoted \(p_O\) and \(p_W\)) and the proportion (\(\beta\)) of minke whales in the area which belong to the O stock, are fixed. Each genotype frequency pseudo data set is generated as follows:

(i) the number of animals sampled which are from the O stock, \(n_O\), is generated from a binomial distribution \(B(\beta, n)\); and

(ii) for both the O and the W stocks, the frequencies of the three genotypes for the animals in this set from that stock are generated from multinomial distributions.

The underlying assumption here is that the data under analysis are obtained from a scientifically planned random sampling exercise, thus justifying use of the binomial distribution for (i), and in contrast to the analysis in the preceding sub-section of historic data which were collected opportunistically.

The value of \(p_O\) is well-determined from the data already available (refer to discussion below in regard to the results given in Table 3), so that its actual value has been fixed at 0.68 for all these simulations. The estimator described above [see equation (2) and surrounding text] is used to estimate the value of \(p_W\) and \(\beta\) for each pseudo data set, under the assumption that \(p_O\) is known exactly. The value assumed for \(p_O\) is not the true value, but is drawn from the normal distribution \(N(\mu=0.68; \sigma^2=0.01^2)\) to allow for the estimation error for \(p_O\) indicated in Table 3.

The implications of alternative choices for sample size (for different sets of fixed \(p_W\) and \(\beta\)) are summarized by four statistics:

(a) the RMSE of the estimate of \(\beta\): \(E([\hat{\beta} - \beta]^2)\).
(b) the RMSE of the estimate of \(p_W\): \(E((\hat{p}_W - p_W)^2)\).
(c) the bias of the estimate of \(\beta\): \(E(\hat{\beta} - \beta)\), and
(d) the bias of the estimate of \(p_W\): \(E(\hat{p}_W - p_W)\).

RESULTS AND DISCUSSION

Table 2 compares the results for frequencies of genotypes by subarea and period, as predicted by the model of equation (2) and its associated text, to the data. This comparison reflects a value of \(\chi^2 = 9.3\) for 4 degrees of freedom, which is not statistically significant at the 5% level. Only for subarea 7 in the August-September period is there some suggestion of lack of fit.

The estimates of the allele proportions for the two stocks (\(p_O\) and \(p_W\)), together with estimates of the fraction of whales belonging to the J stock in subareas 7 and 11, by two-month period, are given in Table 3. Bootstrap estimates of precision are also given in this Table; the results for both the negatively and the positively biased method differ only slightly.
There is a clear indication of stock mixing in subarea 11 in the April-May period (α = 0.29 with 90% CI [0.23; 0.37]). This estimate is quite compatible with those from conception data of 0.33 and 0.16 (IWC, 1994, Appendix 3, table 4b) given their associated variances, but has the advantage of slightly greater precision. For the other subarea-period combinations, the estimates of α are very close to zero and precisely determined, with the exception of subarea 7 in August-September for which the upper 90% CI for α is 0.14 – information which represents a considerable increase in precision compared to that provided by the conception data for which the SE is 0.51.

These conclusions must, however, be seen in the context that the estimates of precision in Table 3 are likely to be negatively biased to some extent. Such bias could arise from ‘clumping’ effects in the opportunistic sampling of grounds H and J (this having led, perhaps, to the sampling of relatives), and to violation of the assumption of perfect Hardy-Weinberg equilibrium.

Tables 4–7 give results for the power of this method to determine the O stock : W stock ratio in a subarea, as a function of sample size. These four Tables provide values of RMSE(β), RMSE(ρ_w), bias(β) and bias(ρ_w) respectively for ranges of the actual (and currently unknown) values of β and ρ_w (recall that β is the fraction of the whales in the subarea that belong to the O stock). Fig. 3 shows the results of Table 4 for RMSE(β) graphically.

One would not expect this method to be able to estimate β well when there is little difference in the allele proportions in the two stocks. Given that ρ_w = 0.68, it is

therefore not surprising that the worst estimation performance, in terms of RMSE(\( \hat{\beta} \)), is manifest for an actual value of \( p_W = 0.6 \) (this being the closest of the four values considered to \( p_O \)). For the other three values of \( p_W \) investigated, performance for \( p_W = 0.4 \) and \( p_W = 0.9 \) is similar, with that \( p_W = 0.1 \) best. In terms of the actual value of \( \beta \), performance is generally better the smaller \( \beta \), i.e., the method will be better able to estimate the fraction of the whales in a subarea that belong to the W stock if this fraction is large. Bias in the estimate of \( \hat{\beta} \) (Table 6) decreases with sample size, and is generally small unless \( p_W \) is close to \( p_O \), or \( \beta \) is near to 0 or 1.

**CONCLUSIONS**

The method developed has provided an estimate of 0.29 for the fraction of whales in subarea 11 in April-May which belong to the J stock, and an accompanying probability
distribution, which could be included with the information used to condition the RMP trials for North Pacific minke whales. The results obtained suggest that J whales could be considered to be absent from subareas 7 and 11 at other times, except perhaps for subarea 7 in August-September (for which the precision of the associated estimate is also a great improvement on that available from conception data).

The power of the method to determine the ratio of O stock : W stock whales in a subarea depends on the true value of this ratio and the difference in the allele proportions in the two stocks, as indicated by the results tabulated.

On the Bayesian Approach Suggested for the Assessment of the Bering-Chukchi-Beaufort Seas Stock of Bowhead Whales

D. S. Butterworth

Fisheries Research Institute WH-10, University of Washington, Seattle, WA 98195, USA

ABSTRACT
A simplified version of the Bayesian approach suggested by Givens et al. (1993b) for the assessment of the bowhead population is found to be particularly sensitive to alternative choices for input prior distributions for MSYR and the pre-exploitation population size K. It is argued that the method suggested by Givens et al. (1993b) to develop a prior for K is questionable in the context of their overall procedure because, inter alia, it makes the implicit assumption that MSYR=0. A reworking (termed a 'Backwards' method) of their Bayesian approach is suggested, which avoids the need for the explicit specification of a prior for K by treating a recent absolute abundance estimate as a model input rather than a model output. This 'Backwards' method is applied to the data and prior choices agreed at the 1994 Scientific Committee meeting, and gives results which show some notable differences from those provided by the Givens et al. method. A particular advantage of the Bayesian approach is that it allows population age structure information to be taken into account, and ensures that the constraints imposed by a maximum possible pregnancy rate are respected; however, both these factors are shown to have little influence on the results of current Bayesian assessment, and the 'Backwards' method indicates that this is also the case for CPUE data from the first two decades of commercial exploitation. The 'Backwards' Bayesian results, though less discrepant than those of the Givens et al. method from estimates provided by the maximum likelihood methodology of the Hitter-Fitter package, differ from the latter to an important extent. The relative influences on this difference of the upper bound on pregnancy rate imposed by the Bayesian approach, and the particular prior for MSYR chosen by the 1994 Scientific Committee meeting, are merit examination.

KEYWORDS: BOWHEAD WHALE; ARCTIC; NORTH PACIFIC; ASSESSMENT; BIOLOGICAL PARAMETERS; WHALING-HISTORICAL; CPUE; TRENDS

INTRODUCTION
At the 1993 Annual Meeting of the Scientific Committee, the Working Group on MSY rates considered two different assessments of the Bering-Chukchi-Beaufort Seas stock of bowhead whales (IWC, 1994). One (Butterworth and Punt, 1992) was based on a standard application (except for one minor adjustment) of the Hitter-Fitter package (de la Mare, 1989; Punt and Butterworth, 1991), and provided maximum likelihood estimates. The other (Givens et al., 1993b), although based on the same population dynamics model as the Hitter-Fitter package, used a Bayesian estimation technique. The two approaches yielded rather different results: for example, the former provided an MSYR(1+) estimate of 3.1% with a 95% confidence interval of [1.2; 8.6%], while the posterior mode and corresponding interval for this quantity for the latter procedure were only 1.3% and [0.5; 2.5%] respectively.

A particular aim of this paper is to investigate the reasons for such differences, which have important implications for estimates of quantities such as the replacement yield (RY), upon which the Scientific Committee has previously and continues to base its management advice for this stock (e.g. IWC, 1992, p.63; IWC, 1995). The analysis presented not only includes data available at the time of the 1993 meeting but also data that have subsequently become available, and were taken into account in deliberations at the Scientific Committee’s 1994 meeting (IWC, 1995).

The paper addresses a number of issues related to the application of the Bayesian approach: the sensitivity of results to different choices for input priors for MSYR and the initial population size (K); the implications of the approach used by Givens et al. (1993b) to develop an input prior for K; an alternative formulation which obviates the need to specify an input prior for K; the constraint imposed by an upper bound on pregnancy rate; the manner in which choices for priors for biological parameters influence results; and the incorporation of age-structure and other information.

SENSITIVITY TO CHOICES FOR PRIORS FOR MSYR AND K
To facilitate an initial comparison between the Hitter-Fitter maximum likelihood and Bayesian approaches, the first set of analyses conducted take no account of age and pregnancy rate data in the Bayesian estimation process, and the priors for many of the biological/operational parameters required for that approach are taken to be delta functions, at values corresponding to those assumed in Butterworth and Punt (1992), viz:

- Natural mortality ages 1 to 5 ($M_1$): 0.04 yr⁻¹
- Natural mortality ages 6 to 35+ ($M_2$): 0.01 yr⁻¹
- Age at recruitment (knife-edge) ($t_r$): 1 yr
- Age at first parturition (knife-edge) ($t_m$): 13 yr
- Maximum sustainable yield level (MSYL): 0.6 K

Givens et al. (1993a) have criticised the Hitter-Fitter approach because of its requirement for fixed inputs for biological/operational parameters, so that uncertainties associated with the values chosen are not incorporated in the statistics output by the associated package. However, the sensitivity of Hitter-Fitter results to values of biological/operational parameters has been investigated for many applications of this assessment method in the past (and specifically for this stock for the 'Hitting-with-fixed-
MSYR' option by Allison (1989), as directed by the Scientific Committee IWC (1989b). This sensitivity has regularly been found to be slight. Accordingly, the choices made here seem unlikely to prejudice the comparison in question, except perhaps insofar as the ability of the Bayesian approach to incorporate information on an upper bound for the pregnancy rate is not taken into account. The associated implications are addressed in a later section of this paper.

Apart, of course, from the historic catch data, the only other input information used for both procedures is that related to the estimate of 1+ population size in 1988 ($P_{1988}$) and the 1978–1993 annual rate of increase of the population ('Slope'. expressed hereafter as a percentage). This information is, however, used in slightly different forms by the two procedures. The maximum likelihood approach assumes $P_{1988}$ to be log-normally distributed about a median of 7,500 with a CV of 0.093, while the Bayesian procedure takes this as an output prior derived by a Bayes empirical Bayes analysis with a mode of 7,500 and 95% confidence interval of [6400, 9200] (IWC, 1995, table 4). Further, while the former approach takes direct account of the individual estimates of relative abundance (see Table 1) which contribute to 'Slope', the latter uses only the summary statistic, which is compared to the gradient of a linear regression of the logarithm of the 1+ population values produced by the model for the 1978–1993 period. The output prior for this summary statistic is:

$$\exp(0.0302 + 0.0069 t_k) - 1$$

where $t_k$ is a random variable with a t-distribution for 8 degrees of freedom (IWC, 1995, Appendix 6). Both approaches ignore the covariance arising from the fact $P_{1988}$ and the relative abundance index for that same year are based on the same data, and treat these as independent sources of information.

### Table 1

Estimates of relative abundance for the bowhead population (IWC, 1995, Appendix 6), as used for input to Hitter-Fitter maximum likelihood estimation.

In Butterworth and Punt (1992), the version of the Hitter-Fitter population model used assumed that MSYR = 0.6K for the 1+ component of the population, and that density dependence also acted on this component. Further investigation has shown that this prescription has arguably undesirable properties in the region of parameter space under investigation here. Specifically, as MSYR is increased, the parameter z which sets the degree of compensation in the density dependent term in recruitment (Punt and Butterworth, 1991) decreases, and can become negative for the range of MSYR values considered here. In these circumstances, the resilience parameter $\gamma$ also becomes negative. Such a model implies an infinite degree of compensation as the population level approaches zero, and so may not be appropriate in circumstances where the actual population may have been reduced to very low levels in the past.

Accordingly, the calculations of this paper all assume that MSYL is expressed in terms of the mature component of the population, and that the density dependence is related to this same component. Brief investigations indicated that the $\gamma$ parameter is much less influenced by the value of MSYR in these circumstances.

The information above is sufficient to define the Hitter-Fitter maximum likelihood estimates, but the application of the Bayesian approach as implemented by Givens et al. (1993b) requires priors for the initial 1+ population ($K$) and MSYR(1+) in addition. Four sets of such priors have been investigated:

(I) the gamma functions distributions put forward by Givens et al. (1993b);

(II) MSYR from U[0.25%; 8%] and $K$ from U[5000; 40000];

(III) MSYR from U[0.25%; 8%] and $K$ from U[5000; 20000]; and

(IV) MSYR from U[0.25%; 4%] and $K$ from U[5000; 20000];

where U indicates a uniform distribution over the range specified.

### Results and Discussion

Table 2 compares the medians of the Bayesian posteriors for MSYR(1+) and $K$ for the four choices considered for priors for these quantities. Results are shown both before and after the Bayesian procedure takes information about the 'Slope' of the population trajectory (the median of this prior is about 3%) and the estimate of the absolute abundance in 1988 (a prior mode of 7500) into account. These 'before' medians for MSYR(1+) and $K$ are NOT identical to the medians of the corresponding priors. This is because of the constraints imposed by the population model — essentially, combinations of low $K$ and low MSYR are excluded, because it would not have been possible to take the recorded historic catches from the resource were those the values of these parameters, without rendering it extinct.

### Table 2

A comparison of posterior medians for MSYR(1+) (in %) and $K$ for different prior choices for these quantities. The results are shown for the Bayesian procedure's updated estimates both 'Before' and 'After' the available information on 'Slope' and $P_{1988}$ is taken into account.

PROBLEMS ASSOCIATED WITH INPUT PRIORS FOR K

This last result prompts a closer look at the basis for the prior for K put forward by Givens et al. (1993b). This is
based on the application for a de Lury assessment method, in which CPUE is regressed against cumulative catch:

\[ CPUE_t = \frac{1}{q} \left( K - \sum_{r}^t C_r \right) \]  

where \( C_r \) is the catch taken in year \( t \) and \( q \) is the catchability coefficient. Givens et al. (1993b) develop their prior for K
from an application of this method, using CPUE data from Bockstoece and Botkin (1983) for the years 1849 to 1870.

There are several problems with this approach. The application of a dynamic production model to data of the
nature considered here is a classic example of the 'one way trip' (Hilborn, 1979; Hilborn and Walters, 1992, p.312),
for which the parameters of such models cannot be successfully estimated. The particular de Lury technique
applied by Givens et al. (1993b) is a special case of such models, which gets around this problem of the confounding
of the estimates of the model parameters by fixing one externally – in this instance, by effectively setting
MSYR=0. But this means that prior information about MSYR additional to that contained in the MSYR prior
alone is being imposed upon the Bayesian assessment procedure, which could influence ('bias') the results
substantially.

This might not be an important problem if the age-at-
recruitment in the fishery in those early years was high, so
that the recruited component of the population (indexed
by the CPUE) was hardly affected by the density
dependent response to exploitation during the 1849–1870
period considered. But making allowance for such
considerations already necessitates more complex
population models – for example, equation (1) could be
retained only if K is taken to refer to the recruited
component of the initial pre-exploitation size. K(rec),
rather than to the total population as assumed in Givens
et al. (1993b). Furthermore, the general acceptance of
CPUE as an index of abundance has proved problematic
in the past in the Scientific Committee (IJC, 1988, p.35;
IWC, 1989a), and even in instances of fisheries where such
relationships are accepted for assessment purposes,
production model analyses are frequently suggestive of
marked changes in the catchability coefficient \( q \) in the first
few years of harvesting (e.g. Butterworth and Andrew,
1987; Prager and Scott, 1993) – behaviour for which plausible
mechanisms (such as the effects of learning, or
the fishing down of some easily found concentrations of
high density but low abundance compared to the whole
population) are readily suggested. Indeed, conventional
fisheries assessment practice is often either to down-weight
or omit such data from analyses.

In essence, our concern about a population model-based
assessment procedure which requires a prior for K (as does
the Givens et al. (1993b) method), is that usually (and
indeed in this case) an informative prior can be obtained
only by means of the application of a population model. In
other words, the method as applied seems to involve a contradiction. It requires the combination of a population model with a prior for \( K \) independent of that model, but the prior for \( K \) can be obtained only from an application of just such a model.

An alternative approach (given these difficulties in attempting to make use of CPUE data) is to ignore them and instead seek a noninformative prior for \( K \). A uniform prior for \( K \) would not, however, be a satisfactory candidate. As is evident from Table 3, results depend on the end-points of the range of such a prior. The fundamental reason for this behaviour becomes clear from inspection of Fig. 1, which shows the relationship between \( P_{1988} \) and \( K \) for various values of MSYR(\(+\)) for the population model and biological/operational parameter values specified above. Note that the slopes of the graphs for the different MSYR values considered are not the same over the range of \( P_{1988} \) values corresponding to the 95% CI for the survey estimate of this quantity. A uniform prior on \( K \) would effectively give greater weight to an MSYR value for which this slope is lower. Thus a uniform prior on \( K \) is not noninformative, as it would incorporate an implicit informative prior on MSYR. The situation is further complicated by the fact that these slopes will depend also on the values of \( M, M_f \) and \( m_m \), for which the full Bayesian procedure involves priors too.

**AVOIDING THE NEED TO SPECIFY AN INPUT PRIOR FOR \( K \)**

The previous section drew attention to the circular reasoning inherent in the attempt by Givens et al. (1993b) to develop an informative prior for \( K \). There is though a way around this problem, which in principle is easily applied if one or more estimates of absolute abundance are available (Givens et al. (1993b) make use of only one such estimate, \( P_{1988} \), in this context). This is, in the terminology of Givens et al. (1993b), to treat one of these estimates – e.g. \( P_{1988} \) in this case – as a model input rather than as a model output. If there is more than one such estimate, the remainder can continue to be treated as model outputs. In the context of a particular Monte Carlo realisation of all the prior distributions then, the value of \( K \) which corresponds to those specific values of the biological/operational parameters (including MSYR), as well as the chosen (e.g. \( P_{1988} \)) population estimate, can be uniquely2 determined from the application of the population model (‘Hitting-with-fixed-MSYR’, in Hitter-Fitter terminology). Thus, these other priors implicitly determine the prior for \( K \). A Bayesian approach in these circumstances neither needs an ‘independent’ prior for \( K \) to be input, nor even the explicit computation of the prior for \( K \) implicit in the combination of the population model and the other priors. We refer to this approach as a ‘Backwards’ method (projecting the population backwards from \( P_{1988} \) to \( K \)), in contrast to the Givens et al. (1993b) technique of projecting the population ‘Forwards’ from the input prior for \( K \).

Such a ‘Backwards’ approach does not exclude utilisation of the Boeksteeg and Botkin (1983) CPUE data, which can be related to model outputs, rather than remain essential as an implicit model input. Nor, in principle, would any temporal censoring of these data be required, as was needed for Givens et al. (1993b) analysis. More importantly, though, given the questionable acceptability of such CPUE data, they need no longer constitute an essential input; instead the sensitivity of results to their inclusion or exclusion becomes readily testable.

Table 4 contrasts the results obtained from the ‘Forwards’ and ‘Backwards’ Bayesian methods in circumstances where priors are imposed for all the biological parameter values, and for the information on the age structure of the population, in the forms agreed by the 1994 Scientific Committee meeting (IWC, 1995, table 4). Table 4a relates to the results reported earlier in this paper, in that it ignores the prior on the ‘Maximum historic ratio Calves/Mature Females’ (i.e. no upper bounds imposed on the pregnancy rate).

These results show important differences between the outputs from the two methods – for example, medians and lower 95% confidence bounds for MSYR(m) and the

---

2 This is not always the case. Fig. 1 shows that for higher values of MSYR, a particular value of \( P_{1988} \) can correspond to more than one value of \( K \). The reason for this is that a model with time-lag(s) (here to the age-at-first-parturition) can manifest oscillatory behaviour for high MSYR. This leads to a potential problem with the suggestion that \( P_{1988} \) be used as an input prior: a further decision then becomes required on how to weight alternative possible \( K \) values for \( P_{1988} \) MSYR combinations that admit multiple solutions for \( K \). Fortunately in this case, values of \( P_{1988} \) for which such multiple solutions exist lie well above the upper confidence bound for the corresponding survey estimate, so that this feature does not lead to a problem here. In general, such difficulties could be avoided by modifying the Hitter-Fitter model to a form less likely to give rise to oscillatory solutions, e.g. by having density dependence act on natural mortality rather than fecundity (Punt and Butterworth, 1993).
Comparison of results from the ‘Forwards’ and ‘Backwards’ methods (see text) of applying the Bayesian approach. The notation is as in Table 3, though note that MSYR here refers to the mature component of the population. Unlike Tables 2 and 3, for which delta function priors were used for biological parameters, the results below use the prior distributions agreed by the 1994 meeting of the Scientific Committee, and (except where otherwise indicated) information on population age-structure as detailed in table 4 of IWC (1995). The age at recruitment is knife-edge at $t_r = 1$yr throughout.

1 Biological parameters set at central values of priors in table 4 of IWC (1995), viz. $M_f$ = 0.06 (ages 1 to 5), $M$ = 0.01, $t_m = 21$, MSYL_{est} = 0.6.
2 This corresponds to the ‘base case assessment methodology’ adopted by the 1994 IWC Scientific Committee (see IWC, 1995, Appendix 7). The slight differences between the results quoted in that Appendix and those above are to be expected as a result of Monte Carlo variation in the computational procedure.

1993 replacement yield are notably higher for the ‘Backwards’ method. The primary reason for this may well be the removal of the influence of the implicit prior for MSYR inherent in the Givens et al. (1993b) approach for specifying an input prior for $K$ for the ‘Forwards’ method.

A possible counter-argument to this conclusion is that these differences could instead reflect the influence of the early Bockstoe and Botkin (1983) CPUE data, which are taken into account in the ‘Forwards’ method (through the prior for $K$), but ignored for the ‘Backwards’ results quoted. A fully Bayesian approach to incorporate these data in all their detail in the ‘Backwards’ method is beyond the scope of this paper; however, a simpler approach has been investigated which attempts reasonable comparability with the use made of these data by Givens et al. (1993b) (which in essence involves only their trend).

This is to evaluate the slope of a linear regression fit to the particular index considered by Givens et al. (1993b) for the period 1849-1865. (Givens et al. (1993b) integrate their de Lury results over end-points from 1859 to 1870 for this range; choosing a central value of 1865 should reasonably approximate their approach.) To express this slope in relative terms, it is divided by the regression estimate for 1857 (the mid-point of the 1849-1865 period considered), which provides an output prior for this single statistic derived from the early CPUE data of:

$$-0.0536 + 0.0353 t_{15} \text{ yr}^{-1}$$

where $t_{15}$ is a random variable with a t-distribution for 15 degrees of freedom. In the process of reweighting output population trajectories which the Bayesian approach involves, this output prior is related to the slope of a linear regression through the 1+ population abundances for 1949 to 1865, divided by the regression estimate for 1+ numbers in 1857, for the trajectory under consideration.

Table 4(a) includes results for the ‘Backwards’ method which incorporate the Bockstoe and Botkin (1983) CPUE data in this manner. They scarcely differ from the ‘Backwards’ results without such data, which lends support to our thesis that these data provide little discriminatory power, and that the de Lury method used by Givens et al. (1993b) to attempt to take them into account involves an assumption which introduces a non-negligible bias in final outputs.
THE CONSTRAINT IMPOSED BY A MAXIMUM POSSIBLE PREGNANCY RATE

The calculations reported above have taken no account of the fact that there must be biological constraints on the pregnancy rate for bowhead whales. Givens et al. (1993b) impose such constraints through the mechanism of an output prior on the historical maximum productivity, where productivity is the calves/mature female ratio.

We find it more easily interpretable (in the sense of the need to agree upon a prior based on data) to deal with this constraint in terms of the maximum pregnancy rate permitted by the model used, which in Hitter-Fitter terms is:

$$ p = \text{FEC}(1 + A) $$

where FEC reflects fecundity (the annual number of births per mature female) at pre-exploitation equilibrium and A is the resilience parameter.

We also find it simpler to conceptualise this prior in the mathematically equivalent form of an input constraint rather than as an output prior. Thus, given a delta function prior for the maximum pregnancy rate ($\rho$), any combination of the other model parameters that generates a value of $\text{FEC}(1 + A)$ which exceeds this value of $\rho$, is discarded in the process of Monte Carlo integration over the priors. This approach is readily extended to more general forms of priors for $\rho$ than delta functions, but calculations have been restricted to delta functions for the moment for ease of illustration.

The results for estimation procedures ‘0’ and ‘1’ in each of Tables 5(a) and 5(b) show output from the (‘Forwards’) Bayesian approach both without and with this additional constraint, for the cases where $\rho=1/2$ and $\rho=1/3$ (i.e. maximum calving intervals of 2 and 3 years respectively). The constraint has some effect on these results. It must also be remembered that these results are for the case where $M = 0.005 \text{yr}^{-1}$ for all ages and $t_{m} = 15 \text{yr}$, which are both probably the lowest values which could now plausibly be argued (see IWC, 1995, table 4). Clearly for higher values of $M$ and/or $t_{m}$, and for lower values of $\rho$, this constraint will have even greater influence.

However, a comparison of the results of Table 4(b), which incorporates the ‘Maximum historic ration Calves/ Mature Females’ prior from table 4 of IWC (1995), with those of Table 4(a) which does not, shows that the maximum possible pregnancy rate constraint in fact has scarcely any influence on estimates given the input data and priors most recently agreed by the Scientific Committee. (Naturally, a different conclusion might result should these inputs be changed.)

Other entries in Table 4(b) show also that the ‘Backwards’ results are hardly affected by the inclusion of either the early period CPUE data or the population age structure data. However, they do still differ from the corresponding Hitter-Fitter maximum likelihood results, which are included in Table 4(a) because that approach does not incorporate any upper bound on pregnancy rate. For example, the Hitter-Fitter point estimate for MSYR$_{(mat)}$ is notably higher than the median for the corresponding ‘Backwards’ posterior, and the 95% confidence interval wider (at both ends). This difference is not simply a consequence of the pregnancy rate constraint for the latter approach, however, but also of the choice for the prior for MSYR$_{(mat)}$ (IWC, 1995, table 4) which imposes an upper bound of 7% in circumstances where the upper confidence bounds in Table 4(b) are suggestive that higher values are not incompatible with the data available. The relative importance of these two factors in producing the difference between the maximum likelihood and ‘Backwards’ Bayesian results merits further investigation.

THE SPECIFICATION OF PRIORS FOR BIOLOGICAL PARAMETERS

The preceding section indicates that the choices for prior distributions for biological parameters in the Bayesian procedure do have the potential to influence the results obtained.

To illustrate this, Fig. 2 plots the isolines of maximum population growth rate possible (given a stable population age-structure) for different values of $\rho$, $t_{m}$ and (age-independent) $M$. Clearly the higher the value of $t_{m}$ of $M$ (or the lower the value of $\rho$), the lower is the upper bound placed on the population’s growth rate, and hence its MSY rate.

Tables 5(a) and 5(b) demonstrate this by showing a progression of results as uniform priors for $M$ and $t_{m}$ are gradually extended from their initial delta function values of 0.005 yr$^{-1}$ and 15 yrs respectively. As this extension progresses, the upper 95% confidence interval estimates for MSYR (for example) are reduced, because the increased phase-space made available by this process corresponds to regions with successively tighter constraints on growth rate and MSYR, as shown in Fig. 2.

The effects of this extension are not substantial for the results reported in Table 5. Indeed, no trend at all would have been evident had they been computed using the actual value of the standard error of ‘Slope’ – this was doubled for the Table 5 calculations. This absence of sensitivity is essentially another way of reflecting the absence of influence of the upper bound on pregnancy rate given the present input data and prior choices, as evident from a comparison of the results in Tables 4(a) and 4(b).

In general, however, the effects of this extension may be substantial in certain regions of parameter space. This draws attention to the care which needs to be taken in specifying priors for biological parameters, and to possible difficulties such as co-variance considerations in this regard, as discussed by Butterworth (1995).

THE INCORPORATION OF POPULATION AGE-STRUCTURE AND OTHER INFORMATION IN THE BAYESIAN APPROACH

In their method, Givens et al. (1993b) include data on the observed proportions for calves, immatures and matures in the population in the form of output priors. However, this raises potential difficulties in two fronts. The first is the need to take account of possible biases in the observational data (a matter of substantial debate in the past in relation to estimates of the gross annual recruitment rate for the bowhead population). The second is more fundamental, and relates to the vexed debate in the Scientific Committee (IWC, 1998; 1990; 1991; 1992) about whether or not age-structure information from a population is capable of (sufficiently) unambiguous interpretation (given, for example, the possibility of age-dependence in natural mortality) to be of value in a management context.

Givens et al. (1993b) are able to make use of such information only because they have assumed a specific functional form for the age-dependence of natural mortality, which for convenience is reflected here in terms of the annual survival rate ($5$). They assume that this is
Results for the ("Forwards") Bayesian procedure as they are affected by the introduction of a constraint on the maximum pregnancy rate ($\rho$) possible, and successive extension of prior distributions on the age-at-first-parturition ($t_{ma}$) and (age independent) natural mortality rate ($M$) from delta functions at 15 years and 0.005 yr$^{-1}$ respectively (see text for details).

(1) The biological parameter 'priors' are as follows for the various estimation procedures.

0; $t_{ma} = 15; M = 0.005$; no constraint imposed by maximum pregnancy rate
1; $t_{ma} = 15; M = 0.005$; constraint on pregnancy rate imposed now and hereafter
2; $t_{ma} = 15; M = 0.005$; constraint on pregnancy rate imposed now and hereafter
3; $t_{ma} = 15; M = 0.005$; constraint on pregnancy rate imposed now and hereafter
4; $t_{ma} = 15; M = 0.005$; constraint on pregnancy rate imposed now and hereafter

(2) The quantity RY* is defined by:

$$
\begin{cases}
\text{RY} & P < \text{MSYL} \\
\text{MSYL} & P < \text{MSYL}
\end{cases}
$$

This statistic may be more appropriate than RY, which can give the misleading impression of a necessarily low result as $P$ approaches $K$. 

| Brandon | Page 319 of 478 | Ex. M-0521 |
Robustness of results to such alternative prescriptions needs to be checked if age-structure information is to be taken into account in the Bayesian procedure (although the results in Table 4 suggest that it has relatively little influence in this instance, except as regards narrowing confidence intervals for the ‘Forwards’ approach when the upper bound on pregnancy rate is not imposed).

Further information which could be accommodated in the Bayesian procedure is that which was previously raised in ‘anecdotal’ form in the Scientific Committee, i.e. that the bowhead population now is considerably greater than it was near the turn of the century when commercial whaling ceased (primarily as a result, presumably, of the low population size at that time). Prior to the bowhead census estimates becoming available over a sufficiently long period to allow the direct estimation of the population’s increase rate, such comments were advanced to argue the recovery of the population over recent decades under aboriginal harvest levels.

CONCLUSIONS

The major concern about the particular ‘Forwards’ methodology proposed by Givens et al. (1993b) for the application of a Bayesian estimation approach to the Bering-Chukchi-Beaufort Seas stock of bowhead whales to which the analyses of this paper gives rise, involves their approach for specifying a prior for the initial population size $K$. Both their approach, based on the application of a de Lury estimator to CPUE data, and that of specifying a uniform prior for $K$, are problematic because they involve the implicit addition of information about MSYR to that already specified in the MSYR prior. The alternative ‘Backwards’ method proposed in this paper to solve this problem by avoiding the need to specify an input prior for $K$, provides estimates which differ from those from the ‘Forwards’ method in important respects.

In principle, a particular advantage of the Bayesian approach of Givens et al. (1993b) is that it imposes the constraints on quantities such as population growth rate which are implied by information on demographic parameters (specifically mortality rates, maximum pregnancy rates and the age-at-first-parturition). However, the calculations reported in Table 4 of this paper indicate that these constraints (and also population age-structure information) have minimal influence on the estimates provided by the Bayesian approach, given the input data and priors for biological parameters for this stock most recently agreed by the Scientific Committee.

ACKNOWLEDGEMENTS

The authors are appreciative of the comments of Geof Givens and Bill de la Mare on an earlier version of this paper.

Evaluations of Aerial Photogrammetric Length Measurements of the Bering-Chukchi-Beaufort Seas Stock of Bowhead Whales

(Balaena mysticetus)

Robyn P. Angliss, David J. Rugh, David E. Withrow, and Roderick C. Hobbs

National Marine Mammal Laboratory, Alaska Fisheries Science Center, NOAA/NMFS, 7600 Sand Point Way NE, Seattle, WA 98115-8070, USA

ABSTRACT

Aerial photogrammetric techniques were used in 1985, 1986 and 1989 through 1992 to establish the length structure of the Bering-Chukchi-Beaufort Seas stock of the bowhead whale population, producing a sample size of 1,896 measured individuals. The success rate, defined as the ratio of the measured individuals to the total number of animals photographed, averaged 75% and ranged from 65% to 86% per year. Biases and errors inherent in camera systems result in imprecision in the estimated length of less than 0.77% and the error introduced by the radar altimeter of the aircraft is less than 3.1% of lengths measured from a single photograph. Sampling biases discussed are differences in ability to measure each of the maturity classes, preferential removal of duplicates of large, well-marked animals from the sample, behaviors exhibited by different maturity classes that may affect their inclusion in the sample of measured individuals and the temporal distribution of aerial survey effort. The percent of adults, juveniles and calves using revised length frequency data are 41.1%, 53.7% and 5.2%, respectively. Proportions of animals in these maturity classes corrected for periods of missing effort are 41.1%, 53.7% and 5.2% respectively.

INTRODUCTION

Studies of the age-structure of a population have proven to be valuable in both terrestrial and marine wildlife management (e.g., Loxodonta africana, Jachmann, 1986; Arctocephalus gazella, Boyd et al., 1990) and in fisheries management (e.g., Quinn, 1981; Vaughan, 1981). There are many marine vertebrate species that cannot be aged (tropical fish are a notorious example; see Pauly and Morgan, 1987); however, length is correlated with age in most species. Therefore, analyses of the length structure of a population can provide estimates for many of the same parameters estimated by analysis of age structures (e.g., Beverton and Holt, 1956; Gulland, 1965; Jones, 1984).

Aerial photogrammetric techniques have been employed in cetacean research to estimate the lengths of animals since Heyland (1974) used vertical photographs to census white whales (Delphinapterus leucas). Research on the Bering-Chukchi-Beaufort Seas stock of bowhead whales (Balaena mysticetus) using aerial photogrammetry to determine the length frequency of the population began with the surveys conducted by Davis et al. (1982; 1983) and Cubbage et al. (1984) in the summer feeding grounds in the eastern Beaufort Sea. Aerial photogrammetric analysis of the bowhead whale population in conjunction with aerial photo-identification has yielded estimates of: (1) the length at first reproduction (Koski et al., 1992; 1993; Withrow and Angliss, 1992); (2) the gross annual reproductive rate (Davis et al., 1983; Withrow and Angliss, 1992; Koski et al., 1993); and (3) calving intervals (Miller et al., 1992; Rugh et al., 1992; Withrow and Angliss, 1992).

Biases and errors inherent in aerial photogrammetric analyses of cetacean populations fall into two main categories: technical and biological. Technical biases and errors have been reviewed in aerial photogrammetric texts (e.g., Wolf, 1983) and many have been examined in detail in earlier papers on aerial photogrammetry of cetaceans (Whitehead and Payne, 1981; Davis et al., 1982; 1983; 1986a; b; Ratnaswamy, 1982; Cubbage and Calambokidis, 1984; Nerini et al., 1987). Image quality affects the precision of length measurements (Davis et al., 1986b). Biological factors such as size segregation of the bowhead whale population on the summer feeding grounds (Cubbage and Calambokidis, 1987; Koski et al., 1988) or behavioral aspects that might cause under-sampling of a size class (Davis et al., 1983; Nerini et al., 1987; this paper) may also affect the length frequency of the sampled population.

The Bering-Chukchi-Beaufort Seas stock of the bowhead whale migrates annually from winter grounds in the Bering Sea to summering areas in the Beaufort Sea between mid-April and early June. We assume the majority of the stock passes Point Barrow, Alaska, (Fig. 1) during this migration. This assumption is based on a historic paucity of sightings in the western Chukchi Sea during the spring (Braham et al., 1980) and summer (Miller et al., 1986) and is an assumption required by both this analysis and by the ice-based census of bowhead whales conducted near Point Barrow (Zeh et al., 1993). Some data sources suggest a small portion of the population may migrate to the southwestern Chukchi Sea in the summer (see Moore and Reeves, 1993, for a review). This portion is considered to be too small to significantly bias data collected near Point Barrow. Therefore, the bowhead population migrating past Point Barrow provides the most representative sampling opportunity for the Bering-Chukchi-Beaufort Seas stock. The narrowed corridor of the migration as the whales pass between Point Barrow and the polar ice pack (Braham et al., 1980) and the convenience of operating out of Barrow have made this a favored research location. Census efforts by the National Marine Mammal Laboratory (NMML) and the North Slope Borough (Krogman et al., 1989; Zeh et al., 1993),
have resulted in the collection of considerable data on the timing and size of the bowhead population migrating past Point Barrow. This report presents a summary and refinement of photogrammetric lengths of bowhead whales obtained by the NMML during 1985, 1986 and 1989 through 1992 (Withrow and Angliss, 1992; 1994). In addition, biases and errors, both technical and biological, are summarized and examined.

METHODS

Field procedures and photogrammetric data processing
The aerial survey platform used by the NMML during all years examined in this paper was a de Havilland Twin Otter\footnote{Reference to trade names does not necessarily indicate endorsement by the National Marine Fisheries Service.}, a high-wing, dual engine aircraft. Descriptions of the aircraft and camera systems used in aerial photogrammetric studies from 1985 through 1992 are provided by Withrow and Goebel-Diaz (1989) and Withrow and Angliss (1992; 1994). Aerial photographs were collected at altitudes between 137m and 152m to ensure operations were conducted in the altitude range where the radar altimeter was the most accurate. Some departures from typical altitudes were necessary due to weather.

Precision and accuracy of the aircraft’s radar altimeter were calculated from measurements of photographic images of known-sized targets. Photographs of targets were taken at altitudes between 30m and 260m, bracketing the altitudes used to photograph whales. Photographs of an aquatic target (a 21.4m x 21.4m fish pen) in Puget Sound, Washington, were taken at the beginning of each field season and at the end of some seasons. Correct altitudes were calculated from measurements of this target in the photographic images. An equation was developed to compute accurate altitudes based on the ratio between measured image sizes and the known sizes of calibration targets. The resulting formula was used to determine relative altimeter accuracy and to adjust altimeter measurements. The calibrated altitudes (along with the focal length of the camera lens and the length of the whale in the photographic image) were used to compute whale lengths.

Each season, a target array was constructed on the sea ice near Point Barrow. This array was photographed frequently to provide assurance that the photogrammetric system and the altimeter were functional throughout the field study. However, we chose to use the aquatic target rather than the target constructed on the sea ice because radar signals over water were thought to be more representative of the signals obtained when a whale was photographed. Typically, 13 targets were set on the shorefast ice <1km southwest of Point Barrow in an 80m x 80m array, which provided 30 measurements of differing lengths between targets. The size of the target array was determined by the surface area that one photographic image covered at an altitude of approximately 152m. The targets were 60cm x 60cm horizontal plywood boards supported by four legs. The boards had black backgrounds with a 15cm diameter black dot centered in a 30cm white square. Each target had a coded individual identification.

Three standard morphometric measurements were made on each whale (total length, fluke width and rostral length); however, because the focus of the photogrammetric research has been to obtain a length frequency of the population, only length measurements taken from the tip of the upper rostrum along the backbone to the notch in the flukes (Norris, 1961) were used in this paper (Fig. 2). No features other than the total lengths of bowhead whales were consistently distinct enough to make repeatable measurements for the intent of this project. The clarity of each morphometric characteristic for each bowhead whale image was quality rated on a scale from 1 (highest) to 5 (lowest) for the standard measurements (Table 1). The flatness, or relative degree of bend or torsion, of the whale and the width measurements were rated on a scale from 1 (flat) to 3 (bent). Animals assigned

![Map of Alaska showing the locations of the Eskimo whaling villages.](image-url)
a rating of 5 were discarded because missing endpoints prevented accurate length measurements. Because the approximate location of one missing endpoint could often be estimated accurately, animals assigned a total length quality of 4 were retained in the sample. In addition, comparisons between 3-dimensional and 2-dimensional measurements carried out by Nerini et al. (1987) indicated that there was no difference in length between the same individual whale when severely bent (flatness quality of 3) or flat (flatness quality of 1). Thus, whales assigned all flatness qualities were retained in the sample of measured whales. However, when two or more photographs were taken of the same individual whale, measurements from the image with the best overall quality ratings were used in the analysis.

Fig. 2. Length measurements taken on bowhead whale images. (A) total length, (B) fluke width, (C) length from the center of the blowhole to the tip of the upper rostrum, (D) maximum width and (E) width at the blowhole.

In 1985 and 1986, bowhead whale images were measured using a Wild analytic stereo comparator or a Nikon dissection microscope in conjunction with a digitizing pad (Nerini et al., 1987). In 1989, computer image analysis software and hardware were used to take standard morphometric measurements (Withrow and Angliss, 1992). For all years, independent measurements of morphometric characters were collected by at least two readers. The total length of an animal was remeasured by both observers if their original measurements differed by greater than 3.0% calculated by (|length_{Obs#1} - length_{Obs#2}|)/mean length. If measurements did not converge after three independent measurements, measurements from that animal were determined to be unreliable and were discarded. Bowhead whale lengths were segregated into three size classes based on published definitions of calf, juvenile and adult animals (Withrow and Angliss, 1992; Koski et al., 1993; Zett et al., 1993). Calves were identified as those animals less than 6m in length, juvenile non-calf animals were 6-12.99m in length and adults were determined to be at least 13m in length. Because all calves photographed near Barrow during the spring were very young animals, there was relatively little overlap between the sizes of calf and non-calf (>6m) animals compared to the sizes of whales photographed in late summer and fall in the eastern Canadian Beaufort Sea (Davis et al., 1983). The paucity of records of lengths near 6m allows identification of calves in the spring based on size alone; other physical characteristics (as described in Miller et al., 1992; Rugh et al., 1992b) can be used to substantiate the identification of a calf.

Aerial survey protocol after the 1985 field season consisted of a search within an area extending 170km to the east and 50km to the north of Point Barrow. This approximated the main axis of the migration route (Withrow and Angliss, 1992). The emphasis was not on a systematic trackline but on increasing the opportunities for photographing whales in available open water. After following open leads and holes to the east, surveys progressed northward then southwestward on a course approximately parallel to the outboard course. This survey protocol minimized duplicate sightings, as the same general area was surveyed only once each day with roughly the same amount of effort on each survey. Aerial surveys conducted in 1985 covered the same general area as surveys in subsequent years, but the focus was on collecting the maximum number of photographs possible, regardless of whether photographs contained possible duplicate animals.

Occasionally, significant departures from the typical survey protocol have occurred. For example, some surveys extended as much as 270km southwest of Barrow (to Icy Cape) in 1985 and 1990. In 1985 and 1992, the same lead was sometimes searched multiple times for photographic opportunities. These departures from the protocol potentially resulted in re-sampling portions of the population. Daily notes in the field logs were examined for each year and data were removed from the length frequency analysis when there was potential resampling.

In 1991 and 1992, a problem between the hardware and software affected calculations of photogrammetric lengths. The data for these years, as presented in Withrow and Angliss (1994), were generated using a linear instead of exponential relationship between true altitude and radar altimeter readings for altitudes over 152m. This error resulted in slightly underestimated whale lengths when photographs were taken at altitudes over 152m. Individual whale lengths and subsequent length frequency distributions were recalculated for 1991 and 1992 based on the correct relationship.

In past studies (Nerini et al., 1987; Withrow and Angliss, 1992; 1994) known duplicate animals were removed from the sample of measured individuals using group designations recognized by location in the field and later by photo-identification techniques (Rugh, 1990; Rugh et al., 1992a). For this analysis, we have taken a more conservative approach by removing both known duplicates and animals photographed during periods of resampling, as determined by an examination of field logbooks.
Examination of biases and errors

Technical errors, such as those caused by lens distortion, film flatness or image distortion caused by the forward motion of the aircraft, are caused by equipment. These errors are an inherent part of any photogrammetric project. Literature on aerial photogrammetry, both related and unrelated to cetacean research, was examined to compile a table of technical biases and errors that have been addressed by various sources (Table 2a).

Some biases and errors in aerial photogrammetry are specific to a particular species and, as such, aerial photogrammetric data cannot be examined accurately without an understanding of the species' biology. Searches for biases in the bowhead whale aerial photogrammetry data focused on suspected 'problem areas' described in the literature.

To examine the precision of our measurement system and test for repeatability among readers and different measurement systems, we used the t-test to compare multiple measurements of a known-sized aquatic target photographed from altitudes between 121m and 167m. Results from a floating calibration target (21m x 21m) were used instead of from land targets because radar altimeters may behave differently over water and land. Because

</tbody>
</table>
precision is related to aircraft altitude, our analysis was restricted to altitudes at which most bowhead whale photographs were collected (106m to 152m).

Ten multiple measurements from each of eight different whales were taken to determine the error involved in the measurement procedure. Ten multiple measurements by different observers of single photographs of different whales were compared to determine the relative magnitude of inter-observer differences. A summary of available studies examining the question of precision is given in Table 2b.

The possibility that some portion of the bowhead whale population was not included in our sample of measured individuals was examined by scrutinizing the trends in the quality of each measurement. In addition, this study incorporated quality ratings developed for photo-identification studies of bowhead whales (Rugh, 1990). The dorsal surfaces of photographed bowhead whales were rated as either highly marked, moderately marked or unmarked. These ratings were incorporated with length information for 1991 and 1992 to compare size classes as a function of quality ratings.

The bowhead whale population segregates temporally by maturity class during the spring migration (Nerini et al., 1987; Rugh, 1990; Zeh et al., 1993). Inadequate sampling during any portion of the migration does, therefore, have the potential of affecting the reported length frequency distribution of the population. To address this problem, the numbers of measured adult, juvenile and calf bowhead whales were tallied by date for 1985 through 1992. Daily search effort was calculated as the number of kilometers flown over areas where bowhead whales could potentially be seen. Kilometers flown over land or solid ice were not included; nor was effort expended in periods considered to be resamplings of a portion of the migration. Whales-per-unit-effort by day was calculated for each maturity class using a tapered 9-day moving average. Proportions of maturity classes were then calculated from these time series corrected for inconsistent effort between seasons. A summary of available studies on biases and errors in photogrammetric studies associated with the biology of the bowhead whale is given in Table 2c (overleaf).

RESULTS

Aerial photogrammetric surveys for bowhead whales during the springs of 1985, 1986 and 1989 through 1992 have resulted in the collection of photographs of 2,479 bowhead whales of which 1,898 were measured. The success rate, defined as the ratio of the number of measurable individuals to the estimated number of individuals photographed was 0.77 for all years, and ranged from 0.65 in 1991 to 0.86 in 1985.

The errant hardware-software relationship in 1991 and 1992 resulted in a maximum of 0.57m bias in any one whale length (representing an inaccuracy of 3.7% to a whale approximately 14.5m in length). This was based on: (1) an inaccurate mathematical relationship between voltage and computed altitude; and (2) calibration of the altimeter using incorrect altitudes in the regression equation in 1991. The magnitude of the error was larger in 1991 than in 1992 ($\overline{x}_{1991} = 0.09m, s = 0.0043$; $\overline{x}_{1992} = 0.001m, s = 0.0005$) because efforts were made in 1992 to fly just below 152m in altitude, which avoided a reduction of accuracy in radar altimeter readings at higher altitudes. After adjustments in lengths were calculated, the net result was the transfer of only one measured individual from the juvenile to the adult maturity class in the 1991 sample.

In our examination of the field logbooks, we found three probable cases of resampling. In 1985, when the sea ice near Point Barrow prevented effective photogrammetric surveys, the field team conducted photographic forays to the southwest. In this analysis, we retained photographs from four of the five surveys that took place southwest of Barrow because no photographs were collected near Point Barrow on succeeding days. However, all whales photographed during the 5th survey (14 May) were deleted because these animals were probably in the Point Barrow area during flights on 16, 17 or 18 May. Additional support for the removal of these data is provided by the re-identification of an animal photographed at Icy Cape on 14 May and again near Point Barrow on 17 May. A total of 61 measured images was removed from the 1985 sample.

On 5 May 1990, heavy sea ice cover near Point Barrow again compelled the aerial survey team to conduct a photographic flight to the southwest. The photographed segment of the population probably arrived near Point Barrow on 8 or 9 May; therefore, the 26 whales photographed and measured on 5 May were removed from the sample.

On 23 April 1992, the aerial survey team made several photographic passes over the same lead. Since this departure from typical survey protocol occurred early in the season, the majority (82%) of the animals photographed were poorly marked juvenile animals, which made re-identifications between passes improbable. Accordingly, only photographs taken during the first pass were used. A total of 30 lengths was removed from the 1992 sample.

1Davis et al. (1983) found that the length frequency distributions for the different quality ratings were significantly different. Most of the difference was attributed to a high proportion of large animals in the quality 1 category. When those animals in the quality 1 category were removed, there was no difference in the length frequency distributions between quality categories 2-4.

2Cubbage et al. (1984) credit Whitehead and Payne (1981) for realizing that the % measurement error due to refraction is a function of the angle from the camera to the water surface, the altitude and the depth of the animal below the water surface.

3In a few cases in this study (<10 measured whales from 1985-92), refraction caused ghost endpoints in the wake of the whale. If the observers could not agree which was a 'ghost' and which was a true endpoint, that whale was not included in the data set.

1 Indicates corrected frequencies from Zeh et al. (1993).

After the removal of all definite and possible duplicates, animals in each size class (calf, juvenile and adult) were tallied (Tables 3 and 4; Fig. 3). Because the survey in 1986 did not adequately represent the whole season (Zeh et al., 1993), results from this season were not included in all of the following analyses. The proportions of adults sampled during the spring migration in 1985 through 1992 were significantly different between years (χ² = 31.02; 1994).

1 Indicates corrected frequencies.
Examination of biases and errors

We determined the precision of our techniques by comparing multiple measurements of an object of known size (21 m) in different photographs as made by only one reader. The mean CVs for multiple measurements of the target ranged from 0.92% to 1.27%.

Multiple measurements of the target were made by two individuals using the digitizer and the image measuring system. There was no significant difference in measurements between individuals using the digitizer (t-test for all p ≥ 0.25) or using the image measuring system (t-test for all p ≥ 0.22), so measurements for both individuals were pooled. The pooled CV for measurements from the digitizer and the image measuring system were 1.05% and 1.08%, respectively. There was no significant difference between measurements taken by one individual using the digitizer and the image measuring system (t-test for all p ≥ 0.21).

To indicate the magnitude of human measurement error involved in the measurement technique, 10 multiple measurements of individual bowhead whales in the same photograph were made by an experienced observer (who had measured >500 whales) and an inexperienced observer (who had measured <10 whales). This resulted in mean CV of 0.60% and 1.0%, respectively. Multiple measurements of bowhead whales by two readers yielded a mean CV of 1.0%.

The possibility that either juveniles (6 m-13 m) or adults (>13 m) were preferentially discarded from the sample was examined by testing for differences in the proportions of the size classes assigned different quality ratings for length measurements and for whether they were highly, moderately, or unmarked. Using measured whales from 1991 and 1992 (Table 5), adults were found to comprise 60% of the animals in the highly marked category, 45% of the animals in the moderately marked category and 4% of the unmarked animals. The difference in the proportion of size classes for all categories of dorsal marks was significant (t-test; p<0.01). This shows empirically what is evident intuitively: as whales increase in length, and presumably age, the number of dorsal marks increases. Therefore, larger whales are more likely to be reidentified and removed from the sample. Nearly all (0.96) of the unmarked whales were juveniles and nearly all (0.97) of the adults were marked only moderately marked.

Measurements were compared as a function of five different quality ratings (Table 5). Comparing adults to juveniles in a sample of 260 whales photographed in 1991 and 1992 showed no statistically significant patterns in the proportions of animals assigned qualities 1–4 (Table 5; t-test for all p≥0.07, 0.33, 0.34, 0.09, respectively) when all marked categories were considered. A trend was apparent only for highly marked bowhead whales in quality categories 1–4, where the proportion of adults to juveniles decreased from 0.91 to 0.23, respectively. The proportions of moderately marked juvenile and adult whales was similar for all qualities of length measurements and for the intermediate quality categories (2 and 3) there was no difference in the proportions of adults and juveniles.

The bowhead whale spring migration past Point Barrow is segregated by maturity class (Fig. 4). Approximately 80% of the animals passing the survey area in late April were juvenile animals, but the proportion decreased to under 20% by early June. In contrast, under 20% of the
animals photographed in late April were single mature whales, increasing to 70% by early June. Female bowhead whales accompanied by calves began to arrive in mid May but typically did not comprise more than 5% of the sampled animals until late May.

The temporal distribution of relative search effort in kilometers surveyed is illustrated in Fig. 5. With the exception of 1986, aerial survey effort occurs throughout the duration of the bowhead whale spring migration in all years. There are, however, multiple gaps of five or more days in most years.

### DISCUSSION

The reliability of the length frequency distribution of bowhead whales depends on the magnitude and direction of both technical and biological biases. Many technical biases, such as lens distortion and image smear, are universal, and the magnitude and direction of biases in our study can be inferred from other studies. Biases caused by biological factors, such as spatial or temporal distribution of whales, however, must be considered specifically for this study. Environmental conditions and animal behavior in other areas are not directly comparable to the situations encountered north and east of Point Barrow during the bowhead whale’s spring migration. Examination of the technical errors allows an apparent ‘confidence interval’ to be constructed around each length measurement. Examination of biases resulting from biological factors involves the issue of whether the length distribution of our sample is representative of the distribution of the population.

#### Technical errors

Most technical errors, such as elongation caused by motion, distortion due to vibration and error due to the orientation of an object on the film, result in errors under 0.1m at the altitudes typically used in this study. Many published and unpublished accounts report errors in terms of CVs and do not report the mean or standard deviation; thus the absolute magnitude of an error (e.g. in meters or percents) cannot be determined. The CV for the radar altimeter ranges from 0.8 to 4.1%, representing the largest technical error in our system. No estimates of the error that occurs as a result of the camera not being perpendicular with the ground were available in the literature, but this is not believed to be a problem unless deviations from perpendicular greater than 3.0° are experienced (Wolf, 1983). Methods have been developed to eliminate this problem by minimizing changes in altitude and not turning the aircraft until approximately 2 seconds before or 3 seconds after a photograph was taken. The CV for measurements of a known-sized target provide an assessment of the relative precision of a photogrammetric system and range from 1.1% (Davis et al., 1983) to 3.9% (Ratnaswamy, 1982). Mean CVs computed by Perryman and Lynn (1993) for measurements of inanimate dolphin-shaped targets and actual dolphins ranged from 0.08 to 2.6%. Further, the accuracy was estimated to have an average error under 1.0%, and the overall CV was approximately 1.0% (Perryman and Lynn, 1993). We estimated the CV to be between 0.92 and 1.27%. The difference between the CVs reported here and those reported by Nerini et al. (1987) is likely due to the nature of the targets used in that study. Nerini et al. (1987) used a log and a boat as calibration targets; the log may have had less distinct endpoints than the aquatic target used for this study and measurements of a boat are complicated by its three-dimensionality relative to the two-dimensional fishpen.

Because measurement techniques used in this study have changed since its inception in 1985, it is important that the techniques be compared. Although our sample size is small (t-tests performed on six sets of paired measurements), we found no significant differences between calibration target lengths calculated with the computerized image-measuring and the digitizing techniques.

Errors in whale lengths caused by the position, orientation and behavior of whales are categorized as ‘biological’ biases. However, most biological biases and errors will have a technical component. Cubbage et al. (1984) found that six repeated measurements of the same individual whale by the same observer resulted in a mean difference of 0.01m. Our study determined that the CV for 10 repeated measurements of eight individual bowhead whales using the same photograph was 0.6% for an experienced observer and 1.0% for an inexperienced observer. Although the units of comparison differ (mean difference vs CV), it is apparent by inspection that any errors due to measurement precision are smaller than the error in the aircraft altimeter (0.8-4.1%).

Inaccurate measurements due to whale position, as recorded by flatness quality, can be partially eliminated by using three-dimensional stereomagery which allows measurements along a three-dimensional curve. When aerial photogrammetry was first conducted on bowhead whales, the potential error caused by measuring animals in two rather than three-dimensions was examined by Cubbage et al. (1984). Measurements of severely bent
whales in two-dimensions were shorter than those measured in three-dimensions. The average difference from the mean was determined to be 1.71% for two-dimensional measurements and 1.15% for three-dimensional measurements. Although the precision of the measurements increased when three-dimensional imagery was used, the increased cost of the three-dimensional procedure, in terms of money and time, outweighed the slight improvement in precision, and only two-dimensional measurements were used after 1985.

**Sampling biases**

The length frequency distribution of the bowhead whale population obtained during any study needs to be examined in the context of the whales' spatial and temporal distribution. For example, the large-scale spatial segregation of size classes in the eastern Canadian Beaufort Sea (Cubbage and Calambokidis, 1987) effectively prevents the acquisition of a representative sample of the population. Although there is some evidence of relatively small-scale spatial (north-south) segregation during the spring migration (Withrow and Goebel-Díaz, 1989), this would have little affect on the portions sampled during aerial photogrammetric surveys near Point Barrow. Temporal segregation does, however, remain a concern.

The spring migration of bowhead whales is temporally segregated by maturity class (Fig. 4; Nerini et al., 1984; 1987; Rugh, 1990; Zeh et al., 1993). Due to this segregation, a significant lack of aerial survey effort in any one portion of the spring field season could result in an inadequate sample of a portion of the population. An extreme case occurred in 1986 when the NWMMF aerial survey team did not arrive in Barrow until 1 May. In addition, there were fewer days surveyed late in the season in 1989–1992 than in 1985 and 1986. The magnitude of the effects of changes in the temporal distribution of effort on the resulting size class frequency of bowhead whales is unknown, but merits additional examination.

Previous research has documented that as a bowhead whale's length (and presumably age) increases, the amount of white on the flukes and caudal peduncle and the number of white scars on the dorsal surface of the animal increases (Davis et al., 1983; Rugh, 1990). Because animals with more markings are more likely to be reidentified between photographs, larger animals are more likely than smaller animals to be recognized as duplicate sightings and removed from the sample of measured individuals. Removal of a disproportionate number of adult animals artificially inflates the number of juvenile animals in the population by an unknown amount.

There are numerous behaviors that could potentially result in one maturity class being sampled more often than another. As an example, the approach of an aircraft might make juveniles startle more than adults, affecting measurement quality when they dive or splash. An opposing bias would result from adults being more often engaged in mating activities than juveniles, which can make whale lengths difficult to measure (Nerini et al., 1987). Also, because there is an increasing trend in the amount of white on bowhead flukes as they age (Rugh, 1990), contrasting with the surrounding water, larger whales may be easier to measure. If size-specific behaviors or coloration affected the relative measurability of a particular maturity class, this should be apparent in the proportions of the maturity classes assigned different total length quality ratings. Our results indicate a detectable but not statistically significant trend in the proportion of juvenile and adult animals assigned different quality ratings.

**Size class frequency**

In previous reports (Withrow and Angliss, 1992; 1994), known duplicate measurements were removed from the sample of whale lengths used to construct length frequency histograms and to compute the proportions of animals in different maturity classes. In an effort to increase the representative nature of our sample, in this work we also removed measurements of those animals photographed under circumstances that potentially resulted in a resampling of a particular portion of the migration. Because most departures from the typical survey protocol occurred early in the bowhead whale migration, immature animals were removed disproportionately from the sample of measured individuals.

The average percent of mature bowhead whales calculated in this report is 41.1%, slightly higher than the 38.2% reported in Withrow and Angliss (1994). The difference is primarily due to two factors: the disproportionate removal of immature animals photographed during flights in which the population was probably sampled more than once and the inclusion of the corrected 1986 data. The inclusion of the 1986 data (a year with a high frequency of calves) also increases the average percent of calves to 5.2%.

Biases caused by the ease of re-identifying large animals relative to small animals, temporal distribution of effort, and differential measurability of adult and juvenile animals are included in the proportions of the maturity classes. Although the absolute magnitude of these biases cannot be determined, some conclusions regarding the relative magnitude and the direction of the biases are warranted. The most important bias is probably due to preferential removal of duplicates of large, well-marked animals from the sample which will decrease the proportion of adults in the sample. A competing bias, but one that is likely smaller in magnitude, is differential measurability by maturity class; this bias is suggested in the data (Table 5), indicating an overrepresentation of juveniles in unmeasureable images. Additional effort spent photographing cow/calf pairs may increase the proportion of adults and calves in the sampled population and the likelihood that cow/calf pairs are near the surface more frequently than other whales increases the likelihood of seeing and photographing cow/calf pairs. A significant competing bias is the unknown number of whales that are pregnant and have not yet calved before passing Point Barrow (Nerini et al., 1984). If the differential removal of large, well-marked animals from the sample is the most important bias, it is possible our analysis underrepresents the percent of adults in the population (41.1%), but by an unknown amount.

Interpretation of the length frequency histograms and the proportions of animals in each size class is not straightforward. By inspection, there seems to be a general downward trend in the percent mature from 1985 to 1992, but this trend cannot be confirmed without a thorough analysis of confounding factors such as variable sighting and photographic effort for all years. The relatively high proportion of immature animals is consistent with the characteristics expected of a population increasing in size, but further interpretation may be unwarranted. Because only a small proportion of the bowhead whale population is sampled in any one year, there is also considerable
potential for error due to annual variations in survey effort or migration timing. Whether the length frequency distribution of the bowhead whale population will be useful as an indicator of population status relative to carrying capacity and whether a sufficient number of animals can be sampled in order to make conclusions about the population status is yet to be determined.

ACKNOWLEDGEMENTS

We are grateful for the helpful reviews and support of Howard Brahm and Doug DeMaster. Mary Nerini was instrumental in the inception of the aerial photogrammetric project. Bowhead whale lengths were measured by Camille Goebel-Diaz, Bryan Herzegov, Kathy Strickland and Larry Tsunoda. Kim Shelden assisted with fieldwork, whale measurements and reviewed the manuscript. We are grateful to the members of the North Slope Borough for their support. Reviews of this manuscript were provided by Merrill Gosho and Chuck Fowler (National Marine Mammal Laboratory, 7600 Sand Point Way NE, Seattle, WA 98115), Jim Sumich (8800 Grossmont College Drive, El Cajon, CA 92020), Wayne Perryman (Southwest Fisheries Science Center, 8604 La Jolla Shores Drive, La Jolla, CA 92038) and William Koski (LGL, Ltd., 22 Fisher St., King City, Ontario, Canada L7B 1A6). Perryman also assisted in the field and provided the reconnaissance camera. The National Marine Mammal Laboratory operated under Permit Number 580 issued under the provisions of the Marine Mammal Protection Act and the Endangered Species Act.

Response to Comments by Butterworth and Punt in SC/46/AS2 on the Bayesian Synthesis Approach

Geoff H. Givens, Adrian E. Raftery and Judith E. Zeh

ABSTRACT

In this paper we address some of the concerns raised by Butterworth and Punt (1995) regarding the Bayesian synthesis method. We use the sensitivity of the Bayesian synthesis approach is similar to that of alternative methods, and that the case with which sensitivity can be detected is one of the advantages of the method. We also note that some of the examples given in Butterworth and Punt (1995) use applications of the Bayesian synthesis framework which are potentially misleading. Specifically, they examine a simplified version of the Bayesian synthesis method. The sensitivity displayed in their results is partially an artifact of this simplification, which removes the very features from the Bayesian synthesis method which help it avoid problems involving sensitivity, estimation bias and precision. We also address concerns raised by Butterworth and Punt (1995) regarding the use of information about various biological parameters.

KEYWORDS: BOWHEAD WHALE; ARCTIC; NORTH PACIFIC; ASSESSMENT

INTRODUCTION

Butterworth and Punt (1995) raise concerns about the Bayesian synthesis approach (Givens et al., 1993b; 1995; Givens, 1993; Raftery et al., 1995) used for the assessment of the Bering-Chukchi-Beaufort Seas stock of bowhead whales.

The comments of Butterworth and Punt (1995) were constructive, and Givens et al. (1994) investigate some of these concerns in their assessment paper where they describe a lengthy sensitivity analysis using a variety of methods. This analysis was motivated by and modelled after the Butterworth and Punt (1995) trial, and shows that when the conditional sensitivity analysis of Butterworth and Punt (1995) is replaced by a fuller and more exact analysis, the results are insensitive: in particular, see table 2 of Givens et al. (1995). The apparent sensitivity in the results of Butterworth and Punt (1995) turns out to be due partially to the simplifications they use.

The subsequent sections of this paper discuss several issues raised by Butterworth and Punt (1995): sensitivity, the choice of prior for initial stock size, the use of maximum pregnancy rate information, the choice of priors for survival rate and age of sexual maturity, and the use of age structure data.

The benefits of the Bayesian synthesis approach, compared to past methodologies, are described in detail by Givens et al. (1993a).

SENSITIVITY

The Bayesian synthesis approach and the conditional maximum likelihood approach (e.g. Butterworth and Punt, 1995) exhibit similar sensitivities in applications to the bowhead problem. In some cases, the sensitivity of the conditional maximum likelihood approach may even be greater than with the Bayesian synthesis method since the former approach conditions on many parameters, potentially exaggerating the influence of the others.

Whether this occurs depends on the model relationships between variables and on the values of parameters which receive high probability from the pre-model distribution.

Value of sensitivity

That a method is sensitive does not imply that it is a poor one, merely that one must be careful to express the evidence and uncertainty about model parameters and predictions as precisely as possible. Sensitivity concerns also exist with conditional approaches such as the conditional maximum likelihood method used by Butterworth and Punt (1995). This is particularly true since that approach fixes parameters at single values, although studies have shown (de la Mare, 1986; 1990; Lankester and Cooke, 1987) that the parameters typically chosen for conditioning are less influential than yield-related parameters. With the Bayesian synthesis approach, a much wider range (i.e. a probability distribution) is considered for each parameter. Thus the Bayesian synthesis approach resembles a sensitivity analysis of the results from a conditional analysis.

Givens et al. (1993b; 1995) have shown that the post-model distributions of replacement yield (RY), maximum sustainable yield rate (MSYR), carrying capacity (K), and recent rate of population increase (ROI) are highly related, implying that conclusions about each are sensitive to assumptions about each. To the extent that such sensitivity exists, we believe that it shows a strength of the Bayesian synthesis methodology: the method allows for fast, explicit and quantitative assessment of the sensitivities and relationships between variables. Givens et al. (1994) have provided the IWC Secretariat with computer software for implementing such sensitivity analysis, and have shown how useful information can be obtained through such investigations which may not be available using other methods. In principle, the likelihood surface can also be used to investigate the relationships between variables, as has been done by de la Mare (1986; 1990) and Lankester and Cooke (1987) for some choices of models and parameterisations.

Conditional design of sensitivity analyses

The tabulated results of Butterworth and Punt (1995) are based on some simplifications of a complex, multidimensional problem. Their examinations of
sensitivity begin with an important modification of the Bayesian synthesis method: they condition on single values of many of the model inputs and outputs, and ignore evidence about many others. An examination of such conditional results can be misleading. Butterworth and Punt (1995) note that the sensitivity of conditional maximum likelihood results to values of the biological parameters has been investigated and found to be small. In particular, Lankester and Cooke (1987) and de la Mare (1986) show that the results should be fairly insensitive to choices of biological parameters as long as at least one yield-determining parameter is allowed to vary. They show that depletion is particularly robust, while MSY is more sensitive. The evidence about yield-determining parameters such as MSYR used by Givens et al. (1993b) implies that these parameters are not wholly unconstrained, and, further, Givens et al. (1993b: 1995) have examined the correlation structure of the post-model distribution and identified several strong nonlinear relationships between variables. To the extent that such relationships exist, conditioning on fixed parameter values is potentially influential and the difficulties discussed in this section may occur.

Examining sensitivity of conditional distributions from a simplified problem is not the same as examining sensitivity of the marginal distributions derived from a full joint post-model density. This oversimplification may lead to conditional distributions which misrepresent the existence, degree and direction of sensitivity, and the inherent uncertainty about parameters.

To demonstrate the potential difficulties which may occur, we consider the hypothetical situation shown in Fig. 1. This figure shows a relationship between three variables: A, B and RY. We can imagine that the post-model distribution for these three variables is distributed uniformly on the two-dimensional manifold shown in Fig. 1.

![Graph showing hypothetical relationship between three variables](image)

Fig. 1. Hypothetical relationship between three variables.

We begin by considering what would happen if we investigated sensitivity of RY to variable B while variable A is also allowed to vary. In this case, the marginal relationship between RY and B is jointly uniform. In other words, RY is not sensitive to B when we integrate over the range of plausible values of A. Further, in this case, we would conclude that the plausible range of RY was 50 to 150. We believe that these conclusions, reflecting marginalisation over the range of plausible values of A, are the most reasonable Bayesian ones, and this approach is the basis for our sensitivity results.

Suppose that we are interested in assessing the sensitivity of RY to variable B, and we decide to simplify the sensitivity analysis by first conditioning on variable A. This simplification, as is done by Butterworth and Punt (1995), can strongly influence the results of a sensitivity analysis. We begin by considering what would happen if we conditioned on a central value of A=2.5. In this case, the same value of RY (100) would be associated with any value of B, given A=2.5, so we would again conclude that RY is not sensitive to B. However, in this case, our assessment of uncertainty about RY has completely changed. On the basis of this alternative approach, we would conclude that RY is extremely close to 100. Thus the conditioning step has created greater apparent certainty about RY. In fact, the effect can go in the opposite direction, for example when distributions are not uniform and/or the relationships between variables are different from the hypothetical ones shown in Fig. 1. For example, the conditional maximum likelihood approach of Butterworth and Punt (1995: table 4) produces a confidence interval for MSYR of (2.3, 42.3), whereas the full Bayesian synthesis application yields the more precise confidence interval of (2.0, 6.8). In this case, the Butterworth and Punt (1995) simplification leads to increased uncertainty because they conditioned on parameter values which were, in fact, sub-optimal. The (MSYR, K) profile of the full joint post-model distribution upon which their analysis was based is apparently one which is extremely diffuse in the MSYR direction.

Next consider what happens if we condition on an extreme value of A, say A=0. In this case, a conditional sensitivity analysis would indicate a strong positive dependency between RY and B. However, if we instead conditioned on A=5, a conditional sensitivity analysis would indicate a strong negative dependency. The range of uncertainty about RY would be similar to that from the unconditional analysis in either case. This example has shown that it is possible for the dependencies between variables to differ for alternative values of the conditioning variables. This situation does occur in the bowhead analysis. For example, the slope of the relationship between age of sexual maturity and current percent calves is about 70% greater for low values of adult survival rate than for high values. Figs 17 and 18 of Givens et al. (1995) indicate other strong relationships between variables.

Reduction of parameter space

Butterworth and Punt (1995) have removed (through conditioning or omission) nearly all the evidence used by the Bayesian synthesis method. What remains in their comparisons is a simplified approach which depends on only two inputs: MSYR and K. It is no surprise, therefore, that the results are sensitive to these two remaining inputs! This is especially true since they effectively define 'results' as the post-model estimates of MSYR and K. If they had conditioned on MSYR and K and allowed only any other two inputs to vary, the results would vary directly as these inputs varied, although perhaps not over as great a range. Thus the sensitivity they find is partially an artifact of their modification of the Bayesian synthesis method. Nevertheless, they have demonstrated the important point that estimates of RY can change noticeably when one simultaneously permits extremely large values for K and extremely small values for MSYR. Table 2 of Givens et al. (1995) displays a sensitivity analysis of the full Bayesian synthesis method.
When evidence and uncertainty are incorporated for all inputs and outputs, as in the full Bayesian synthesis approach, sensitivity can be reduced because each source of information implies constraints on the other parameters. In this sense, the full Bayesian synthesis approach includes a system of ‘checks and balances’. The ‘check’ occurs because, for each parameter, the method checks to see whether the information about all other parameters is sensible and consistent with what is known about the current parameter. The ‘balance’ occurs because evidence about each parameter is balanced against evidence about each other parameter in proportion to the uncertainty regarding each parameter. The effectiveness of this system of checks and balances depends on the region of the parameter space considered. The simplified conditional approach employed by Butterworth and Punt (1995) eliminates this system of checks and balances, permitting exaggerated sensitivity.

**Parameter values chosen for conditioning**

The examples used by Butterworth and Punt (1995) are quite extreme for bowhead whales, and therefore do not represent the best basis for judgment or comparison between methods. The pre-model distributions and conditioned values of input parameters they use do not result in bowhead trajectories which are likely to reflect reality. For example, consider the trial labelled ‘MSYR U(0.25, 8), K U(5000, 20000)’ in table 3 of Butterworth and Punt (1995), hereafter called the BP1 trial. If we use the priors of the BP1 trial and the BP1 post-model medians for K and MSYR, we obtain the trajectory shown in Fig. 2. In this trajectory, the 1988 population size is 11% above K and estimated to number 11,906 whales, compared to the Raftery and Zeh (1991; 1993) estimate of 7,500. The current percentage of mature whales from the BP1 trajectory is 67%, compared to the Angliss et al. (1995) estimated 1985–1992 average of 41%. The 1993 population is 21% above K, and the trajectory exhibits the unusual behaviour shown in Fig. 2. This trajectory shows a population which increased dramatically from 50% below K to 40% above K in the first 35 years of this century, then decreased under the small aboriginal harvest from 1.4K to 0.9K before rebounding to 1.2K in the last 20 years. The results produced from the BP1 run of Butterworth and Punt (1995) conflict with diverse scientific evidence for bowheads, and therefore are inappropriate as a basis for sensitivity analysis.

The point is not that the Butterworth and Punt (1995) estimates are poor, but that by choosing pre-model distributions which favour high MSYR values and low values for K, they have set the Bayesian synthesis procedure at an unrealistic and exaggerated operating point. Using their results to examine sensitivity for the Bayesian synthesis approach investigates an irrelevant region of the parameter space. Many of the trajectories which appear to cause sensitivity in their trials would have been ruled out during a realistic application of the Bayesian synthesis framework because these trajectories would have been inconsistent with other available evidence. In a more realistic application, sensitivity would have been reduced.

We conclude that the conditioning simplification employed by Butterworth and Punt (1995) for reason of comparison is a potentially misleading approach because it may exhibit any or all of the problems listed above.

**USE OF EVIDENCE ABOUT INITIAL STOCK SIZE**

Butterworth and Punt (1995) claim that the choice of the prior for the initial stock size, K, used by Givens et al. (1993b), based on an application of the DeLury (1947) method, involves an a priori assumption that MSYR = 0 and that this has a strong influence on the results. The assumption of the DeLury method to which they refer is that the exploitable population is closed except for the catch, so that the effects of emigration, immigration, natural mortality and births are negligible.

The closed population assumption can lead to underestimation of the uncertainty of the estimate of K. Whether the estimate of K is biased upwards or downwards depends on the spatial location and aggregation of whales and whaling vessels. Givens et al. (1993b) are careful to apply the DeLury method to only a small number of years at the beginning of the harvest when the annual catch was very large, so that the impact of population dynamics, including births and deaths, was negligible compared to the hunt. Thus, we believe that the effect of the closed population assumption is relatively small compared to the breadth of the probability interval for K. (8.263, 30.374). Further, the Bayesian synthesis approach uses a full prior distribution for K, not merely a point estimate, so some bias in the location of this prior is not important as long as the prior is sufficiently diffuse. The pre-model distribution for K obtained by Givens et al. (1993b) assigns 95% of its probability between 8.263 and 30.374. This distribution is not in disagreement with priors or with bootstrap confidence interval results of Butterworth and Punt (1992; 1995). In table 5 of their paper, Butterworth and Punt (1995) show that uniform distributions with different upper limits (20,000 or 40,000) give different estimates of important population parameters. While this shows that a bias in the prior for K can change the results, any bias in our prior is not likely to be so influential for the two reasons: (i) it is not likely to be as big as the difference investigated by Butterworth and Punt (1995); and (ii) our gamma distribution prior has much lighter tails than a uniform distribution, thus lessening the impact of such bias.

Butterworth and Punt (1995) suggest an alternative application of the Bayesian synthesis framework which solves for K conditional on the current abundance, age distribution and life history parameters. This ‘hitting with fixed MSYR’ method involves an implicit pre-model distribution for K, determined by the equations which relate K to other model parameters. Because of this implicit pre-model distribution, the results of this method are different from those that would be obtained using a
broad uniform pre-model distribution for $K$ in the forward projection of the model used by Givens et al. (1993b). Because the hitting method does not require an explicit pre-model distribution for $K$, it may be a useful technique. The successful application of this method would sidestep the debate over how to obtain an estimate of $K$ from CPUE data. The IWC Scientific Committee noted that this approach (discussed in IWC, 1995b) should be investigated further (IWC, 1995a). If it is to be used, it is important to understand the precise nature of the implicit pre-model distribution for $K$. The hitting method forces every trajectory to originate from some starting population, so trajectories which would go extinct on the basis of their biological parameters if projected forward are instead forced to avoid extinction and begin from some $K$ when the hitting method is employed. This constraint must have important consequences for the implicit pre-model distribution of $K$.

Butterworth and Punt (1995) also argue that the prior for $K$ used by Givens et al. (1993b) amounts to using the same information (a population dynamics model) twice. An estimate of $K$ which relied on the BALEEN II model or another population dynamics model would indeed be using the population dynamics information twice. This is why Givens et al. (1995) use the minimal ‘model’ with negligible population dynamics occurring during the short initial period of heavy hunting mortality.

**USE OF MAXIMUM PREGNANCY RATE INFORMATION**

Butterworth and Punt (1995) present data in their table 4 which supports their argument that a constraint on maximum pregnancy rate has virtually no influence on estimates for the assessment of Givens et al. (1993b). However, in their table 5, Butterworth and Punt (1995) show two sets of assessment results: one based on an analysis which did not use a prior on maximum pregnancy rate, and the other based on an analysis which did use this information (scenarios 0 and 1, respectively, in their notation). Comparison of these two tables shows that the upper confidence limit for $MSYR$ and the lower limit for $RY$ are sensitive to inclusion of the maximum pregnancy rate evidence. For example, in one case the upper limit for $MSYR$ is 7.9% and the lower limit for $RY$ is −43 when maximum pregnancy rate evidence is ignored, but when the evidence is used these limits change to 5.7% and 72, respectively. This comparison shows that the evidence on maximum pregnancy rate can be useful because it eliminates population trajectories corresponding to extraordinarily fertile populations (high $MSYR$) which would have recovered to pre-exploitation levels quickly so that current $RY$ would be low. The effect of the maximum pregnancy rate evidence depends on the other components of the pre-model distribution. It is for this reason that results differ in Butterworth and Punt (1995) table 4 and table 5.

Butterworth and Punt (1995) state that they have chosen a very high survival rate so as to minimise the influence of the maximum pregnancy rate evidence. Our examination of their table 5 shows that the maximum pregnancy rate information is still influential, and according to their reasoning, it would be even more important if lower survival rates had been used. Indeed, we believe lower survival rates are more reasonable than the rate chosen by Butterworth and Punt (1995). With their rate, the expected lifespan of the whales is 200 years, and nearly half the population would live to age 150, at which point these whales would be expected to live to age 350.

**USE OF AGE STRUCTURE DATA**

Butterworth and Punt (1995) note that Givens et al. (1993b) assume a specific functional form for the age dependence of natural mortality. Each different functional form may imply different equilibrium proportions of calves, juveniles and adults, so Butterworth and Punt (1995) argue that the use of age data is problematic because it is unclear how such data would correspond to the age structure implied by a particular functional form for age dependent mortality or survival.

Butterworth and Punt (1995) examine three potential schedules of survival rate for whales aged 1,...,a. They are:

(a) $S_a = S_2 = ... = S_a = 1$
(b) $S_a = S_2 = ... = S_a = S_2$
(c) $S_a = S_2 = ... = S_a = 1 : S_a = S_2$

where whales of age $i$ have survival rate $S_i$ for $i = 1,...,a$ and $S_2$ represents the juvenile survival rate for scenario (b). In all three scenarios, whales older than $a$ are assumed to have survival rate $S_A$. Scenarios (a) and (c) are extreme cases which bracket scenario (b), which was used by Givens et al. (1993b).

Butterworth and Punt (1995) note that these three scenarios imply different equilibrium proportions of juveniles (aged 1,...,a). The expressions for juveniles given in Butterworth and Punt (1995) are not proportional to each other; the equilibrium proportions of juveniles relative to the equilibrium 1+ populations for the three scenarios are:

(a) $(1 + (a - 1) S_a^2) / (A + 1 + (a - 1) S_a^2)$
(b) $((1 - S_a^2) / (1 - S_a)) / (A + ((1 - S_a^2) / (1 - S_a)))$
(c) $a / (A + a)$

where $A = S_a^2 / (1 - S_a)$. Although these three expressions appear very different algebraically, they are in fact very close for the range of parameter values reasonable for bowhead whales. For example, using the values $a = 5$, $S_a = 0.94$ and $S_A = 0.99$ adopted by Butterworth and Punt (1995) in their analyses, these three proportions of juveniles are 5.0%, 5.4% and 5.8% for scenarios (a), (b) and (c), respectively. Thus, the variation due to misspecification of the functional form of age dependent survival is quite small compared to the dispersion of the age structure prior distributions used by Givens et al. (1993b), so the sensitivity of the results to the choice of functional form of age dependent survival should be small.

**PRIORS FOR SURVIVAL RATE AND AGE OF SEXUAL MATURITY**

Butterworth and Punt (1995) also used their table 5 to support their argument that results for $MSYR$ depend critically on the width of the prior distributions for survival rate and age of sexual maturity. The experiment described in their table 5 is not properly controlled to support such a conclusion. They begin with delta function priors at very low values of mortality rate and age of sexual maturity. Then, rather than widen each prior equally on each side, they widen each prior entirely on one side, so that the previous central value of each parameter becomes the new extreme value. For each widening, they repeat this one-sided expansion of the parameter ranges. This approach
means that the increase in interval width is confounded with the change in the central location of each interval. Therefore, it is not possible to conclude whether the observed changes for MSYR are due to the change in prior width or the change in prior location, or both.

CONCLUSION

We have argued that the sensitivities found by Butterworth and Punt (1995) were partially due to their choice of study design, including effects of conditioning and confounding, and to the region of the parameter space they chose to explore, which does not entirely correspond to the region supported by diverse scientific data. Butterworth and Punt (1995) have provided some useful topics for consideration, particularly an alternative Bayesian synthesis approach employing a hitting method which eliminates the need for a prior on \( K \) and which merits further investigation.

Determination of the Sample Size Necessary to Detect Changes in Length Frequency Distributions from a Recovering Population of Bowhead Whales

Robyn P. Angliss¹, Roderick C. Hobbs and Douglas P. DeMaster
National Marine Mammal Laboratory, Alaska Fisheries Science Center, NOAA/NMFS, 7600 Sand Point Way N.E., Seattle, WA 98115-0070, USA

ABSTRACT
The Lotka model was used to determine the stable age distributions of the female portion of hypothetical bowhead whale (Balaena mysticetus) populations increasing at population growth rates thought to be representative of populations at high, medium and low density (r=0.001, 0.017 and 0.03, respectively). The age distributions were transformed into estimated length distributions using published information on age-at-length. The modelled populations of 10,000 females were sampled (n=500, 1,000 and 1,500) 100 times each and the length distributions of these samples were compared (Kolmogorov-Smirnov) to test for significant differences between the populations at different relative densities. Length distributions from random samples of 1,000 females from populations exhibiting rates of increase of 0.001, 0.017 and 0.03 were significantly different (p<0.1) in more than 95% of the comparisons.

KEYWORDS: BOWHEAD WHALE; ARCTIC; NORTH PACIFIC; PHOTOGRAMMETRY; LENGTH DISTRIBUTION; TREND

INTRODUCTION
The length structure of the western Arctic stock of the bowhead whale (Balaena mysticetus) population has been studied extensively using aerial photogrammetry (Davis et al., 1982; Cubbage and Calambokidis, 1984; Withrow and Angliss, 1992; 1994; Angliss et al., 1995). To determine whether length structure data are appropriate for population assessment, length data must be evaluated using a simulation modelling approach. If length structure information can be used to assess the population size relative to carrying capacity, aerial photogrammetry would become more valuable for the management of the bowhead whale population. This paper calculates the number of individual length measurements (sample size) necessary to detect significant differences between the length distributions of hypothetical populations exhibiting population rates of increase typical of a population at a high, medium, or low density (population rates of increase 0.001, 0.017 and 0.03, respectively).

METHODS
Determining the age structure of the population
The Lotka equation (Lotka, 1907; simplified by Cole, 1954) was solved for the stable age structure of the female segment of the bowhead whale population. Estimates of age at sexual maturity and age-specific survival rates were taken from Givens et al. (1995). Age-specific survivorship was fitted to the five-parameter Siler function (Siler, 1979; Eberhardt, 1985) and was constrained to yield an average adult survival rate of approximately 0.98 (as per Givens et al., 1995).

The reproductive interval of mature females may decrease with increasing population density, as density-dependent changes in calf mortality increase the number of mature females available to breed (Perrin and Donovan, 1984). This situation was modelled as a binomial process that allows a shortening of the reproductive interval of mature females as a function of calf mortality (c.f., DeMaster and Stirling, 1983). The harmonic mean was used to calculate the birth rate (female births per female per year): 

$$ BR = 0.5 \sum_{x=1}^{3} \left( \frac{1}{x} \right) f(x), $$

where x is the calving interval given a particular calf survival scenario and f(x) is the probability of occurrence of a particular reproductive interval:

<table>
<thead>
<tr>
<th>x</th>
<th>f(x)</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1-P₀</td>
<td>A female will have a 1-year calving interval if the calf dies in the first year.</td>
</tr>
<tr>
<td>2</td>
<td>P₀(1-P₀)</td>
<td>A female will have a 2-year calving interval if the calf lives in the first year and dies in the second year.</td>
</tr>
<tr>
<td>3</td>
<td>P₀ P₀</td>
<td>A female will have a 3-year calving interval if the calf lives in the first and second years.</td>
</tr>
</tbody>
</table>

In this model, P₀ is the probability that the calf will survive 1 year and 1-P₀ is the probability that the calf will die. This approach assumes: (1) no interannual variation in calf survivorship; (2) equal survival rates of young of the year and yearlings; (3) mature females available to breed will reproduce successfully; (4) the calving interval conditional on calf survival is 3 years (Rugh et al., 1992); and (5) the gestation period is approximately 1 year. Birth rates were calculated based on calf survival for each modelled population.

The parameters for the Siler model of age-specific survivorship were chosen using an iterative process such that the average juvenile and adult survival rates, weighted by the proportion of animals in each age group (except age groups 72 through 76), were within 0.01 of the modal values (0.937 and 0.982, respectively) presented by Givens

¹ Present address: Office of Protected Resources, NOAA/NMFS, 1335 East-West Highway, Silver Spring, MD 20910, USA
et al. (1995). The survivorship of age groups 72 through 76 declined linearly from 0.96 to 0.00 to incorporate a senescent effect. The survivorship and fecundity schedules corresponding to the modal values for the juvenile and adult survival rate resulted in a modelled population with a growth rate ($r$) of 0.017. The parameters in the Siler equation which primarily affect juvenile survivorship were then decreased and increased iteratively to solve the Lotka equation for the target rates of increase of 0.001 and 0.03 (Table 1). The age at which 50% of the females were sexually mature was set at 20 years (Givens et al., 1995). Sexual maturity was phased in over 5 years in recognition of the fact that not all females would become sexually mature at the same age and that the females that give birth at ages 18, 19 and 20 may not be available for breeding at age 21 (after Taylor et al., 1987). To accomplish this, the fecundity rate for age class 22 was multiplied by 0.4, 0.4, 0.8, and 0.6 for age groups 18–21, respectively. The age at sexual maturity remained constant for all three cases. The birth rate was recalculated for each case based on the calf survival rate. The age distributions resulting from the schedules of survivorship (Fig. 1A) and birth rates (Fig. 1B) for all three cases were calculated with the modelled populations of 10,000 individual females.

Constructing a length frequency distribution from the age distribution

Analysis of stable carbon isotope oscillations in bowhead whale baleen currently best the estimate of age at length (Schell et al., 1989; Schell, 1992; Schell and Sauge, 1993). Due to baleen wear, the stable carbon isotope technique cannot be used to age animals over 12m in length or approximately 13 years in age. Growth rates for animals under 12m in length have been used to project an age at sexual maturity of 15 to 17 years (Schell, 1992). Estimates from other sources range from 17 to 31 years (Koski et al., 1992; Schell and Sauge, 1993; Zeh et al., 1993).

The Laird model (Laird, 1969), parametrised as in Ferrero and Walker (1993) was used to determine the expected length in months for each individual in the populations of 10,000 animals. The model was fitted to length-at-age data for seven age groups of female bowhead whales presented in Schell (1992). Average lengths were used when there was more than one aged animal per age group. The age and length at sexual maturity (20 years and 13m) was included in the fit to provide a better growth curve. The growth curve was forced to achieve an asymptote at approximately 16m, which allowed a small proportion of animals to be over 17m in length. The equation used to translate ages into mean lengths was

$$\lambda = 6.9457e^{0.8611(1 - e^{-(0.0696 \times \text{age})})}. $$

Calves were unavailable for ageing in the stable carbon isotope study, therefore the mean calf length (4.68m, CV=10.7%) measured from aerial photographs (NMFS unpublished data) was used. To allow for individual variation in growth, lengths in meters for non-calves were assigned to each animal based on a normal distribution using the mean length from the Laird model and a CV of 0.07 (based on Schell, 1992).

![Survivorship and Birth Rate Curves](https://example.com/fig1.png)

**Fig. 1.** Survivorship (A) and birth rate (B) curves for the modelled populations of 10,000 females. The decrease in the birth rate for age group 21 occurs as a result of females in age groups 19 and 20 being burdened with calves and thus unavailable for breeding.

Statistical procedure

The age-length key constructed during this study was used to convert age distributions to hypothetical populations of 10,000 individual lengths. Random samples of 500, 1,000 or 1,500 individual lengths were drawn without replacement from the population of lengths at each population growth rate. Lengths were grouped into 0.25m categories, which was the smallest reasonable category given the resolution of the photogrammetry. The Kolmogorov-Smirnov (K-S) two-sample statistic (Beyer, 1991) was used to compare the cumulative percent frequencies of the samples. This was repeated 100 times for

each comparison by sample size and population growth rate. The 95% confidence interval for each frequency was determined by transforming the frequency via the empirical logistic transform (Cox and Snell, 1989), calculating confidence limits for the transformed frequency and applying the inverse transform to these limits. Because the length frequency data were grouped and thus compared as discrete rather than continuous distributions, the results from the K-S test are conservative.

**RESULTS**

Sample length frequencies for populations exhibiting a growth rate of 0.001, 0.017 and 0.03 can be distinguished visually by noting the high proportion of adults in the high density case relative to the medium and low density cases. Representative length frequency histograms for a sample of 1,500 animals from populations at a high, medium and low density relative to carrying capacity are illustrated in Fig. 2. Defining mature animals as those with lengths greater than 13m (Withrow and Angliss, 1992), the percent mature of the bowhead whale population at a high \((r=0.001)\), medium \((r=0.017)\) and low density \((r=0.03)\) was 54%, 44% and 37%, respectively (Table 2).

![Fig. 2. Length frequency histogram for representative samples of 1,500 animals drawn from hypothetical populations with growth rates typical of high \((r=0.001)\), medium \((r=0.017)\) and low \((r=0.03)\) densities.](image)

In order to have a reasonable chance (>75%) of differentiating length frequency distribution from populations increasing at a high, medium and low density, a sample size of approximately 1,000 animals is required at both the 0.1 and 0.05 levels of significance (Table 3). As expected, the sample size required to obtain a significant difference between a population at a high versus a low density is lower than the sample size required to obtain a significant difference between a population at a low versus a medium density, or a medium density versus a high density.

**DISCUSSION**

Several assumptions were made in the course of this exercise that could affect the sample size calculations. Our approach considered only the female portion of the population, while the aerial photogrammetric approach samples both male and female animals. Because the age-at-length relationship is slightly different for males and females, some error is expected in the computation of the percent mature using 13m as the lower limit of the mature size class. We use a deterministic model and have not incorporated dynamics such as variable recruitment or mortality. Finally, the specific density-dependent changes in life history parameters used in this model are only one set of many possible combinations of changes in parameters.

For our model, we also assumed that the growth rate of the individuals was not density dependent. This pattern has been documented for fin whales (Balaenoptera physalus) in the Antarctic: although the mean age at sexual maturity
changed in response to population density, the mean length at sexual maturity remained constant (Lockyer, 1984). Other marine mammals, however, have exhibited a decline in growth rates as the population size increases relative to the carrying capacity (e.g. Steller sea lion, Eumetopias jubatus; Calkins and Goodwin, 1988). If the growth rate for bowhead whales is proven to be density dependent, the length structure for a high density population would be skewed toward smaller animals, which would reduce the contrast between the length frequency distributions for the population at differing densities.

Although the recommended sample size of 1,000 lengths of individual animals is larger than the sample obtained through aerial photogrammetry in any 1 year (sample sizes range from 195 to 623; Angliss et al., 1995), combining the survey results from six consecutive years provides a sample size of over 1,800 animals, which should be adequate. Because a stable age distribution was sampled and because density dependent effects on population parameters were not modelled, the true sample size necessary to detect shifts in the length frequency distribution would probably be higher than that calculated here. The sample size of 1,000 animals may, therefore, be considered a lower bound on necessary sampling directed at detecting shifts in the length frequency distribution of bowhead whales over time. Future modelling of changes in the length frequency distribution of the bowhead whale population should include the effects of density dependent population parameters and the subsistence harvest on the length frequency distribution.

ACKNOWLEDGMENTS

We appreciate the support and review provided by Howard Braham, Peter Boveng, Jeff Breiwick, Cyndy Tynan (National Marine Mammal Laboratory), Chris Grue and Glenn VanBlaricom (University of Washington, Washington Cooperative Fish and Wildlife Research Unit), Judy Zeh (University of Washington, Department of Statistics) and two anonymous reviewers provided helpful reviews of this document. Dave Rugh, Kim Sheldon and Dave Withrow (NMML) provided comments on an earlier version of the manuscript. The manuscript was also improved by comments received from the 1994 Scientific Committee Meeting of the IWC and by comments received from Gary Duker and James Lee (National Marine Fisheries Service, Publications). This manuscript was completed in partial fulfillment of the senior author’s Master’s degree in the School of Fisheries, University of Washington. This research was conducted in association with the Washington Cooperative Fish and Wildlife Research Unit. Revised Data on the Subsistence Harvest of Bowhead Whales (Balaena mysticetus) by Alaska Eskimos, 1973–1993

Robert S. Suydam¹, Robyn P. Angliess², John C. George¹, Stephen R. Braund³ and Douglas P. DeMaster⁴

ABSTRACT

The subsistence harvest of bowhead whales in Alaska is managed within the IWC catch limits via a quota system through an agreement between the Alaska Eskimo Whaling Commission and the US National Oceanic and Atmospheric Administration. The quota is based on the subsistence and cultural need of Alaska Eskimo whaling communities and the size and growth rate of the bowhead whale population. Aspects of the harvest data from 1973 to 1993 have been reported by several authors; however, there are many discrepancies in the data among these sources. We have revised the harvest data to reflect the best available information, addressed inconsistencies in how whales that were killed and lost have been reported and re-evaluated how mortality has been assigned to struck and lost whales.

KEYWORDS: ARCTIC; BOWHEAD WHALE; NORTH PACIFIC; WHALING-ABORIGINAL

INTRODUCTION

Alaska Eskimos have harvested bowhead whales for thousands of years (Bockstoce, 1977). Bowhead whales provide a vital subsistence and cultural foundation for many Eskimo communities. By the early 1900s, the Bering-Chukchi-Beaufort Seas stock of bowhead whales was severely depleted by an excessive commercial harvest (Marquette and Bockstoce, 1980). Commercial whaling was no longer profitable and eventually ceased by 1915 but subsistence whaling by Alaska Natives continued (Tillman, 1980).

In June 1977, the International Whaling Commission (IWC) banned the subsistence harvest of bowhead whales for the 1978 season (IWC, 1978a; Tillman, 1980) due to the suspected small population size and the considerable increase in the number of whales harvested by Alaska Eskimos (IWC, 1978b). The ban was rescinded however, due to the cultural and subsistence dependence on bowhead whales by Alaska Natives and a quota system was initiated in December 1977 (IWC, 1980; Gambell, 1982). Transition from federal to local management of the harvest occurred in 1981 when the Alaska Eskimo Whaling Commission (AEWC) and the National Marine Fisheries Service (NMFS) of the US National Oceanic and Atmospheric Administration agreed that the harvest should be locally managed (IWC, 1983). The current harvest quota is based on the subsistence and cultural need of bowhead whales by Alaska Eskimos and estimates of the size and growth rate of the bowhead whale population (Donovan, 1982; Braund, 1992).

The determination of the subsistence and cultural need for bowhead whales by Alaska Eskimos was based on the number of whales landed per capita and the population size of each Alaska Eskimo community (Braund, 1992). The bowhead whale population currently numbers approximately 7,500 animals (Zeh et al., 1993) and has increased since at least 1978 and probably since 1910 (Zeh et al., 1991). An accurate assessment of the number of whales landed and struck and lost was important to establish a quota that provides for the subsistence and cultural need of Alaska Eskimos, while at the same time allowing for the bowhead whale population to continue to recover. An accurate assessment of the historical catch is also important for modeling bowhead whale population dynamics.

An initial summary of the commercial and subsistence harvest was compiled by Marquette and Bockstoce (1980) and revised and updated by Braund et al. (1988). Beginning in 1973, the NMFS initiated a harvest documentation program (Marquette, 1977) and the North Slope Borough has continued that work since 1981 (Dronenburg et al., 1983). These recent harvest data, from 1973 to present, have been reported by several authors, including Marquette and Bockstoce (1980), Braund et al. (1988), the IWC (1992), the Marine Mammal Commission (1993) and Philo et al. (1993). For various reasons, there are numerous discrepancies in the harvest data among these sources. Therefore, the objectives of this paper are to: (1) revise and update the subsistence harvest data of bowhead whales from 1973 to 1993 using the best available data; (2) address inconsistencies in how killed and lost whales have been reported (IWC, 1992); and (3) re-evaluate how mortality has been assigned to whales that were struck and lost (Brenchick et al., 1984). We have used the data reported by the IWC (1992) as the starting point for this revision.

REVISED HARVEST DATA

The data in IWC (1992) for the harvest of bowhead whales from the Bering-Chukchi-Beaufort Seas stock were divided into seven categories: (1) total pelagic kill; (2) Alaska shore kill; (3) Canadian shore kill; (4) Soviet shore kill; (5) total shore kill; (6) shore struck and lost; and (7) total kill. This paper only addresses the subsistence harvest by Alaska Eskimos, i.e. (2) Alaska shore kill; (6) shore struck and lost, and (7) total kill.

Table 1 shows revised data on the subsistence harvest of bowhead whales by Alaska Eskimos from 1973 to 1993. We have added four categories to those used by the IWC (1992): landed; killed and lost; total strikes; efficiency. Below is a summary by year of updated subsistence harvest statistics. For the years that are not listed, we believe that the data in IWC (1992) are accurate.

</table>

\(^1\)Assessment as made by the hunters.

\(^2\)Sum of the Alaska shore kill and a fraction of the struck and lost. The assignment of whales struck and lost to the total kill is based on an assumption of a 50% mortality rate for 1973-1980 (Breivik et al. 1984) and a poor chance of survival or probably died for 1981-1993 (see Table 2).

\(^3\)Sum of the shore kill and the struck and lost.

\(^4\)Calculated by dividing the number landed by the total strikes.

George et al. (1992) reported 4 whales killed and lost and 4 struck and lost. One of the struck and lost whales was incorrectly reported by George et al. (1992) to have a poor chance of survival but hunters had estimated it to have died (Philo et al., 1993).

1973
In IWC (1992), 40 whales were reported killed and 15 whales struck and lost. Marquette (1977) reported 37 whales killed and landed and Braund et al. (1988) accounted for an additional two whales killed and landed in Wainwright. The 40th whale killed (IWC, 1992) might be one reported as killed and lost at Kivalina by Harry (1973; in Braund et al., 1988). Braund et al. (1988) chose to categorize this whale as struck and lost based on information from Burch (1988) who was present at Kivalina in 1973 soon after this event occurred. The total of 39 whales killed in 1973 (2 at Gambell, 4 at Savoonga, 7 at Point Hope, 5 at Wainwright, 17 at Barrow, 1 at Nuiqsut and 3 at Kaktovik) reported by Braund et al. (1988) is thus to be preferred.

The reported 15 whales struck and lost in IWC (1992) is probably based on Marquette and Bockstoce (1980); however, Braund et al. (1988) tallied 20 whales struck and lost, including the 1 struck and lost at Kivalina. The total of 20 whales struck and lost (3 at Gambell, 2 at Savoonga, 1 at Kivalina, 7 at Wainwright and 7 at Barrow) reported by Braund et al. (1988) is thus to be preferred.

1974
In IWC (1992), 23 whales were reported killed and 28 whales struck and lost. These numbers probably come from Marquette (1977). Braund et al. (1988) also tallied 23 bowhead whales killed but accounted for 32 whales struck and lost; the difference with Marquette is due to strikes at Gambell and Wales. Unlike Marquette (1977), Braund et al. (1988) reported two whales struck and lost at each of these villages. The additional 28 whales that were struck and lost were at Savoonga (2), Kivalina (1), Point Hope (5) and Barrow (20). The total of 32 whales struck and lost (Braund et al., 1988) is thus to be preferred.

1976
In IWC (1992), 57 whales were reported killed and 35 whales struck and lost, but the report of 57 whales killed is inconsistent with original sources. Marquette (1977; 1978) recorded only 56 whales killed and 35 whales struck and lost. Marquette and Bockstoce (1980) and Braund et al. (1988) also reported 56 whales killed and 35 whales struck and lost. The correct numbers should thus be 56 whales killed and 35 struck and lost.

1978
In IWC (1992), 12 whales were reported killed and 5 whales struck and lost, but the report of 5 whales struck and lost is inconsistent with original sources. Braham et al. (1979; 1980) and Braund et al. (1988) reported 12 whales killed and 6 whales struck and lost. The correct numbers should thus be 12 whales killed and 6 struck and lost.

1980
In IWC (1992), 16 whales were reported killed and 18 whales struck and lost. Johnson et al. (1981) and Marquette et al. (1982) reported 16 whales killed and landed, 3 whales killed and lost, and 15 whales struck and lost. Braund et al. (1988) reported conflicting harvest reports from Johnson et al. (1981), Marquette et al. (1982) and the AEWC (1980) but did not select one source as being the most accurate. We have combined the three sources and selected the largest value for the number of whales landed and the number struck and lost at each village with the exception of the St. Lawrence Island villages of Gambell and Savoonga. The harvest reports for St. Lawrence Island are consistent with three whales landed but are inconsistent in how many whales were landed at each village. Therefore, we report
the number of whales landed on St. Lawrence Island and do not distinguish between Gambell and Savoonga for the number of whales landed in 1980.

A total of 16 whales was landed (3 on St. Lawrence Island, 1 at Wales, 1 at Shaktookil, 1 at Wainwright, 9 at Barrow, and 1 at Kaktovik). 3 whales were killed and lost (2 at Barrow and 1 at Kaktovik) and 25 whales were struck and lost (3 at Gambell, 1 at Point Hope, 1 at Wainwright, 18 at Barrow, 1 at Kaktovik, and 1 at Little Diomede) (Johnson et al., 1981; Marquette et al., 1982; Braund et al., 1988). The struck and lost whale at Little Diomede was reported by Braund (1991) as struck and lost in 1979. We have included this whale in the 1980 summary based on Johnson et al. (1981). The total for 1980 should be 19 whales killed (including 3 killed and lost) and 25 whales struck and lost.

1981

In IWC (1992), 17 whales were reported as killed and 9 whales were struck and lost. Marquette et al. (1982) reported 14 whales landed and 11 struck and lost (2 of these as killed and lost) during the spring hunt. Drenenberg et al. (1983) reported only 2 of 3 whales that were killed and landed in the fall hunt (L.M. Philo, North Slope Borough, Barrow, AK, pers. comm.). The total for 1981 should be 19 whales killed (1 at Gambell, 2 at Savoonga, 4 at Point Hope, 3 at Wainwright, 6 at Barrow [includes 2 killed and lost] and 3 at Kaktovik) and 9 whales struck and lost (2 at Gambell, 1 at Savoonga, 2 at Kivalina, 1 at Point Hope and 3 at Barrow).

1984–1990

Beginning in 1984, the harvest data published by the IWC (1992) reflect an undescended change; whales that were reported as killed and lost were not included in the 'Alaska shore kill' category as had been done in years prior to 1984 but were instead included as struck and lost. We have distinguished between killed and lost and struck and lost for all years to help eliminate some of the inconsistencies that have occurred in the presentation of past subsistence harvest data (Table 1).

For 1984, the IWC (1992) reported 12 whales killed and 13 whales struck and lost. The revised numbers should be 13 whales killed (includes 1 whale killed and lost) and 12 whales struck and lost (George and Tarpley, 1986).

For 1985, the IWC (1992) reported 11 whales killed and 6 whales struck and lost. The revised numbers should be 12 whales killed (includes 1 whale killed and lost) and 5 whales struck and lost (George and Tarpley, 1986).

For 1987, the IWC (1992) reported 22 whales killed and 9 whales struck and lost. The revised numbers should be 23 whales killed (includes 1 whale killed and lost) and 8 whales struck and lost (George et al., 1988).

For 1989, the IWC (1992) reported 18 whales killed and 8 whales struck and lost. The revised numbers should be 23 whales killed (includes 5 whales killed and lost) and 3 whales struck and lost (Philo et al., 1993).

For 1990, the IWC (1992) reported 30 whales killed and 14 whales struck and lost. The revised numbers should be 32 whales killed (includes 2 whales killed and lost) and 12 whales struck and lost (George et al., 1992).

MORTALITY OF STRUCK AND LOST WHALES

Johnson et al. (1981) report on a bowhead whale that was struck and lost that was known to have survived and other bowheads have also been suspected of surviving a strike (Albert et al., 1980); however, the fraction of struck and lost whales that survive is unknown (Marquette et al., 1982). The IWC (1992) assigned a proportion of the struck and lost to the total kill following the methodology of Breiwick et al. (1984). In the absence of data on the rate of struck and lost whales, Breiwick et al. (1984) assumed a 50% mortality rate for the whales that were struck and lost from 1970 to 1977 and a 75% mortality rate for the struck and lost whales from 1978 to 1982.

The 50% and 75% mortality rates are reflected in the total kill as published by the IWC (1992); however, the footnote associated with this harvest data is erroneous. The footnote ascribes a 50% mortality rate to the whales that were struck and lost for the years 1970–1981 and a 75% mortality rate to the whales that were struck and lost for the years 1982–1990. As shown above, the ranges should instead be 1970–1977 for the 50% mortality rate and 1978–1990 for the 75% mortality rate. Although the footnote is inaccurate, the 'Total kill' category is correct.

</table>

1 Does not include whales that were struck and lost and reported as having died.
2 Whales with a reported fate of probably died or with a poor chance of survival.
3 Whales with a reported fate of probably lived or with a fair, good or excellent chance of survival.
4 George et al. (1992) reported the chance of survival for struck and lost whales as 3 poor and 1 excellent. One of the struck and lost whales was incorrectly reported with a poor chance of survival by George et al. (1992). Hunters estimated that it had died. The correct numbers should be 2 poor and 1 excellent (Philo et al., 1993).

Since 1981, the chance of survival for whales that were struck and lost has been estimated by the hunters (Table 2). The hunters reported the chance of survival of struck and lost whales as either: 'excellent' or 'lived', 'good', 'fair' or 'probably lived', 'poor' or 'probably died', 'died', or 'unknown' (Philo et al., 1993). Instead of assuming a constant mortality rate for struck and lost whales since 1981, we have used the hunters' assessment of the probability of survival of struck and lost whales to determine the total kill as described by Braham (1989). Whales that were reported as having died have been added to the kill under the category 'killed and lost' (Table 1). Whales that were reported as probably having died or with a poor chance of survival were added to the total kill. Whales that were reported as probably having lived or
having a fair, good, or excellent chance of survival, were assumed to have lived. When the fate was reported as unknown, we assumed a mortality rate similar to other struck and lost whales from that same year. For example, in 1990, 12 whales were struck and lost. The fate was reported for 8 of these whales, 6 (75%) of which were reported to have probably died. Thus, we added 3 (75%) of the 4 whales with an unknown fate to the total kill (Tables 1 and 2).

Due to the absence of data on the estimated fate of struck and lost whales prior to 1981, we have used a 50% mortality rate. Support for using this rate comes from two sources: (1) this is the same rate used by Breiwick et al. (1984) for 1970–1977; and (2) the chance of survival for whales that were struck and lost from 1981 to 1986 was estimated at 49%. In the more recent years, 1987–1993, 80% of the whales that were struck and lost were reported to have probably died. The larger percentage of whales estimated by the hunters as having probably died from 1987 to 1993 is most likely due to continuing efforts by Alaska Eskimos to increase hunting efficiency (George et al., 1992).

ACKNOWLEDGEMENTS
We thank the Alaska Eskimo Whaling Commission for providing harvest data. Tom Albert (North Slope Borough Department of Wildlife Management, Barrow, AK), Howard Braham, Dave Withrow (National Marine Fisheries Service, National Marine Mammal Laboratory, Seattle, WA) and an anonymous reviewer provided helpful comments on earlier versions of the manuscript.

ABSTRACT

The number of bowhead whales, *Balaena mysticetus*, passing within viewing range of the ice-based census at Point Barrow, Alaska, during spring migrations from 1978 to 1993 is estimated from the visual census data as described by Zeh et al. (1991). The trend in these annual numbers yields an estimated annual rate of increase of 4.9% (95% CI 1.4%-8.8%). It is estimated that 7,249 whales (95% CI 5,294–9,204 based on the most conservative of two alternative variance estimates) passed Point Barrow within viewing range in 1993. Since this estimate is considerably higher than past estimates, we examined factors unique to the 1993 season that could have affected the estimate. Porpoise location may have had a positive influence and the use of 'plotting sheets' by observers a negative influence on the estimate. The dominant factor was found to be the distribution of the whales offshore from the observation site. In previous years, up to half of the whales were outside viewing range. Acoustic data indicate that 90.7% of the population passed within viewing range in 1993. A 1993 population estimate that accounts for the whales that passed beyond viewing range is 8,000 (95% CI 6,900-9,200). An estimate of 1978–1993 rate of increase that takes into account whales that passed beyond viewing range was derived by Raftery et al. (1995). Their estimate is 3.1% per year (95% CI 1.4%-4.7%). When this estimate is combined with data on bowhead pregnancy rates and other life history parameters, population size, population age structure and historic catches via a population dynamics model, the post-model distribution of 1978–1993 rate of increase has a median of 2.3% and a 95% probability interval from 0.9%-3.4% (IWC, 1995). This probability interval provides the most precise estimate of annual rate of increase available at this time.

KEYWORDS: ARCTIC; NORTH PACIFIC; BOWHEAD WHALE; ASSESSMENT; TREND; SURVEY-LAND BASED; ACOUSTICS

INTRODUCTION

An ice-based census of the Bering-Chukchi-Beaufort Seas stock (sometimes called the Bering Sea stock or western Arctic stock) of bowhead whales, *Balaena mysticetus*, was conducted annually between 1978 and 1988 off Point Barrow, Alaska, during the whales’ spring migration from the Bering Sea to the Beaufort Sea. The census was typically conducted from 15 April to 1 June. Census methodology and population estimates for 1978–1983 were presented by Krogman et al. (1989). Zeh et al. (1991) revised the method of estimating the number of whales passing within viewing range of the observation sites to accommodate the lack of data from two observation sites operating simultaneously in the years since 1985. They used the revised methodology to estimate whale numbers for 1978–1988. The trend in the estimated numbers led to an estimated annual rate of increase of 3.1% (95% CI 0.1%-6.2%) for the stock during that period.

Censuses were not conducted from 1989 to 1991. A census was carried out in 1992. However, visibility conditions were the poorest of any year in the history of the ice-based census. The nearshore leads through which whales must pass if they are to be seen by the counters were closed by ice throughout most of the census period and only 291 whales were counted (Philo et al., 1994). This is the smallest number recorded in any year of the census at Point Barrow. Many days of watch were missed when moving pack ice buried the observation site or severe storms and dangerous ice conditions prevented watch. As in 1979 and 1984, the data in 1992 were inadequate to support a meaningful estimate of the number of whales that passed within viewing range.

The 1993 census was conducted from 10 April to 4 June under unusually good environmental conditions and counters tallied 3,383 whales (George et al., 1995); this is the highest number since the census began. Thus, for the first time in five years, data were available to estimate the number of whales passing within viewing range and to update the estimate of the annual rate of increase.

METHODS

Estimates of the rate of increase have been based on visual data because acoustic data were not collected regularly before 1984 or in 1987 (Zeh et al., 1991). However, the acoustic data collected since 1984 aid the interpretation of the estimated rate of increase and allow a more precise estimate to be computed (Raftery et al., 1995). Visual census and estimation methods were described by Krogman et al. (1989) and Zeh et al. (1991). Acoustic methods were described in detail by Clark et al. (1986a; b; c). Both visual and acoustic methods were summarised by Zeh et al. (1993). The 1993 census is described in detail by George et al. (1995). Clark et al. (1994) describe methods used in computing the 1993 acoustic locations, i.e. the positions of whales whose calls were recorded. We therefore summarise census and estimation methods only briefly in this paper.

Data collection and processing

Visual counts were made from observation sites, called perches, on top of high ice ridges as near the lead edge as possible. There were at least three observers on the perch, 24 hours a day, for most of the season. Observers used a binocular-compass device to obtain an initial bearing to a whale. After the position of the whale was obtained by an observer using a theodolite, a second observer recorded the information on a data sheet. The recorder also plotted
each sighting on a ‘plotting sheet’ and attempted to link
together sightings based on a whale’s position in the lead,
whether it was paired with another whale or calf, its swim
speed and swim direction and, rarely, its physical
appearance. Each whale sighting was subsequently
recorded as new (if the whale was seen for the first time),
conditional (if not certain whether it was seen before), or
duplicate (if seen before). The whale’s behaviour and
direction of travel were also noted. Visibility and other
environmental data were recorded at regular intervals.

Acoustic data (bowhead whale calls) were gathered
using a three- to five-element hydrophone array positioned
along the lead edge. The array was also monitored on a 24-
hour basis. Sounds (including whale calls) received by
the hydrophones were broadcast to a receiving hut and
recorded on a DAT recorder. A whale’s location was
determined from the times of arrival of its call at the
different hydrophones. The along-shore direction was
defined by the line between the first and last hydrophone in
the array, and the offshore direction was assumed to be
perpendicular to that line. Acoustic locations directly
offshore from that line were used to estimate whale
distribution relative to the lead edge.

Estimating the proportion of the population within viewing
range

The proportion of the population that passed within
viewing range (4km) of the perch was estimated by the
percentage proportion of the acoustic locations directly
offshore from the hydrophone array. We will refer to the
estimated proportion as \( P_a \). \( P_a \) is actually computed as an
average over blocks representing different parts of the
season, each containing around 100 locations. The
standard error (SE) used for \( P_a \) is the SE of this average.
An SE estimated from the observed proportion under a
binomial sampling assumption could be unrealistically
small, failing to reflect uncertainty related to within-year
variability in the whales’ offshore distribution.

Examination of experimental factors affecting counts

Two experiments were carried out to examine factors that
might have led to the unusually high count of whales in 1993.
To test for effects of perch location on the number of
whales counted, observers conducted 22 hours of
simultaneous counts at two perches. Carolyn Perch, west of Point Barrow, was the one used for most of
the 1993 census whereas Spasmolot Perch, north of Point
Barrow, was in a location more typical of those used in
previous censuses. Methods used for collecting and
analysing data from this experiment are described by
George et al. (1995). To test for possible bias associated
with using plotting sheets in 1993, George et al. (1995)
plotted sightings made during the 1988 census as would
have been done in the field had plotting sheets been in use
in 1988 and scored them as new, conditional or duplicate
using the same procedures used during the 1993 census.

Estimating the number of whales within viewing range

To estimate the number of whales that passed within
viewing range from the visual counts, we must correct the
counts for whales missed by observers both during watch
and during periods with no watch. Counts from the
primary census perch are corrected for whales missed
during watch by dividing them by the probability \( p \)
of seeing a whale.

The probability \( q = 1 - p \) of missing a whale during watch is
estimated as a function of visibility, number of observers
and distance of the whale offshore using a generalised
linear model (McCullagh and Nelder, 1983). The model is
based on the removal method, reviewed by Seber (1982).
The data for fitting the model are counts \( n_1 \) of whales seen
at the primary census perch and \( n_2 \) of whales missed by
the primary observers but counted by observers at a second
perch operating simultaneously. Under the assumptions of
the removal method, the maximum likelihood estimate of
\( q \) is \( n_2/n_1 \).

Each census year with simultaneous watch at two
perches under a particular visibility condition, with a
particular number of observers and with whales seen in a
particular range of distances offshore, provides a data
point \( (n_1, \, n_2) \) for that combination of factors. A
complementary log-log link function is used in fitting the
generalised linear model \( \log (1 - q) = \beta X \) where \( \beta \) is
the natural logarithm, \( X \) is a row vector giving the values of
the explanatory variables, and \( \beta \) is a column vector with
the coefficients in the linear combination. We estimate \( \beta \)
and the resulting \( q \) from the data points \( (n_1, \, n_2) \) and
the corresponding \( X \). We estimate a scale parameter from
the data to represent over-dispersion relative to the
binomial distribution assumed by the model fitting program
(McCullagh and Nelder, 1983). Since \( q \) is estimated more
accurately when \( n_1 \) is large than when it is small, we assign
to each data point a weight that reflects the estimated
accuracy.

Once \( q \) has been estimated for given conditions
(visibility, number of observers and offshore distance),
counts made under those conditions on a given day are
corrected by dividing by \( 1 - q \). The estimate of the number
of whales that passed within viewing range on that day is a
linear combination of the corrected counts under the
conditions that occurred, adjusted for any time during the
day when there was no watch under acceptable visibility
conditions. A time series interpolator (Zeh et al., 1986b) is
used to obtain estimates for missed days, defined as those
with less than an hour of watch under acceptable visibility
conditions. We sum the resulting estimates over the days in
the census season to obtain an estimate of the total number of
whales that passed within viewing range (4km) during
the season. We will refer to the estimated number of
whales that passed within viewing range as \( N_a \). We use the
jackknife as described by Zeh et al. (1986b) or an
expression derived by Zeh et al. (1986a) to estimate the
variance of \( N_a \).

Estimating rate of increase

The model we fit to test for a trend is the exponential
growth model \( p_{t+1} = (1 + R) p_t \), where \( p_t \) and \( p_{t+1} \) are values
of \( N_a \) (or \( N_a/P_a \) ) in year \( t \) and the following
year, respectively, and \( R \) is the annual net recruitment rate (rate of increase or decrease) during the time period. Then

\[
\log (p_{t+1}/p_t) = x \log (1 + R) + \log (p_{1978.5})
\]

and \( R \) can be estimated from the slope in a simple linear
regression of \( \log (p_{t+1}/p_t) \) on \( x \), \( x = 0.2, 3, 4, 5, 7, 8, 9, 10, 15 \).

The years omitted from \( x \) are those in which a successful
census was not conducted. Zeh et al. (1991) give details
about how the regression analysis was carried out and a
confidence interval for \( R \) was computed. In addition to the
weighted regression they describe, we carried out an
unweighted regression to give each year’s data more equal
influence on the result. Influence was measured by Cook’s
distance (Weisberg, 1985).

Ex. M-0521
RESULTS AND DISCUSSION

Census results

The 1993 count of 3,383 whales was the largest ever. By comparison, 2,089 whales were counted in 1988. Despite this difference, the environmental conditions and whale migratory behaviour were similar in 1988 and 1993. In both 1988 and 1993, the first whale was seen on 17 April and whales were counted on 46 days between 15 April and 1 June. In 1988 one day of watch was missed; in 1993 no days were missed. Peaks in the number of whales seen per day occurred in early May in both seasons and most whales had passed by 20 May.

In the following sections, we discuss estimates of whale numbers and rate of increase based on the census results and computed exactly as in Zeh et al. (1991). We then discuss improved estimates that take into account whales that passed beyond viewing range and other data.

Estimated number of whales within viewing range

Estimates of $q$ and values of $N_t$ for the successful censuses between 1978 and 1988 were reported by Zeh et al. (1991). The value of $N_t$ for 1993 was 7,249. The jackknife SE of Zeh et al. (1986b) was 505, while the SE based on the alternative variance expression of Zeh et al. (1986a) was 998. The values of $N_t$ for all the years are shown in Fig. 1, with 95% confidence intervals (95% CI) based on the jackknife SE. The alternative SE was not used because it can only be computed in years in which no days of watch were missed; the only such years were 1980, 1987 and 1993. A 95% CI for the number of whales that passed within viewing range in 1993 based on the alternative SE and computed as in Zeh et al. (1986a) is 5,294 to 9,204.

Since the 1993 count was the largest ever, it is not surprising that the 1993 estimate of whale numbers is also the largest. The 1988 estimate (4,862) is the next largest, and its confidence interval (Fig. 1) does not overlap that of the 1993 estimate. The 1993 value of $N_t$ is comparable to the estimate of total whale numbers (those that passed both within and beyond viewing range) obtained by Raftery and Zeh (1993) from the combined visual and acoustic data collected in 1988. The posterior distribution for the number of whales presented by Raftery and Zeh (1993) had its mode (most probable value) at 7,900 and 95% of its probability between 6,400 and 9,200.

Rate of increase based on whales within viewing range

Because the 1993 census occurred five years after the previous series of annual censuses, the 1993 data legitimately have considerable influence on the estimate of the rate of increase $R$. However, because the 1993 value of $N_t$ is the highest ever and is estimated to be very precise, it may have undue influence.

The estimate of $R$ computed as in Zeh et al. (1991), expressed as a percentage annual rate of increase, was 5.2% (95% CI 2.5%-8.3%) and is shown as a dotted line in Fig. 1. Cook’s distance, which measures the influence of each year’s data on the estimate of $R$, was 2.6 for 1993, 0.9 for 1978 and 0.1 or less for all other years. If Cook’s distance is greater than 1.0 for a particular year, that year’s data may have had undue influence on the estimate. Recall that before the 1993 data were included, $R$ was estimated to be 3.1% (95% CI 0.1%-6.2%). The 1988 data had the most influence on that estimate, with a Cook’s distance of 1.4.

The fact that the alternative SE estimate was considerably larger than the jackknife SE estimate for 1993 suggests that the weighted regression used by Zeh et al. (1991) gives the 1993 value of $N_t$ too much weight. The jackknife estimate was generally larger than the alternative estimate during the early years of the census and was adopted by Zeh et al. (1986b), Krugman et al. (1989) and Zeh et al. (1991) because it was thought to be more realistic. However, this estimate primarily reflects variability due to missed days of watch and may underestimate variability in years like 1993 in which few days or none were missed in a migration that lasted more than a month. Further research on how best to estimate the variance of $N_t$ is warranted.

This is not to suggest that there is anything ‘wrong’ with the 1993 value of $N_t$ but rather that, for the reasons just discussed, it may have had too much influence on the estimate of $R$. To reduce this influence, we used an unweighted regression in which each year was given the same weight. The estimated annual rate of increase obtained from this regression was (see the dashed line in Fig. 1) 4.9% (95% CI 1.4%-8.5%). Cook’s distance for 1993 in this regression was 1.1 and for all other years less than 0.2. Thus 1993 still had considerable influence, but not as much as in the weighted regression.

It is important to focus on the confidence interval rather than the point estimate of $R$ since a rate of increase as high as 4.9% does not accord well with other data. Angliss et al. (1995) give 5.2% as the average percentage of calves in the population. Pregnancy and photo-identification data summarized by Miller et al. (1992), Rugh et al. (1992), George et al. (1995) and Koski et al. (1993) suggest an average calving interval of 3 to 4 years. The data of Angliss et al. (1995) indicate that only around 40% of the Bering-Chukchi-Beaufort Seas bowheads are sexually mature. If
half of these are cows who calve once every 3–4 years, the percentage of calves would be around 6%. Even though natural mortality in this population is believed to be low, and annual mortality due to the subsistence hunt conducted by native Alaskans is well under 1%, an annual rate of increase of 4.9% or more is too high to allow for likely mortality. When a population dynamics model is used to synthesise biological data, catch data since 1848, and the data on current population size, rate of increase, and age composition (Givens et al., 1995), a current annual rate of increase exceeding 3.4% is found to be unlikely (IWC, 1995).

Role of experimental factors
The experiments detailed in George et al. (1995) were designed to investigate two factors that might have contributed to the high count of whales and consequent high estimates of both the number of whales that passed within viewing range in 1993 and the rate of increase. George et al. (1995) discuss reasons for suspecting that the location of Carolyn Perch, from which most of the whales were counted, may have contributed to the high count. They also present and discuss the results of the simultaneous counts at Carolyn and Spamatula. Although more whales were seen at Carolyn, the difference was not statistically significant. However, the experiment involving plotting sheets indicated that a significantly lower percentage of 1988 sightings were scored as new when plotting sheets were used than when they were not. Thus the use of plotting sheets in 1993 is likely to have lowered rather than raised the 1993 count of whales relative to other recent counts. Plotting sheets were used during the 1978 census, so the 1978 and 1993 points, which are influential for estimating rate of increase, should be comparable in terms of plotting sheet effects.

Proportion of the population within viewing range
Acoustic location data collected in 1985, 1986, 1988, and 1993 provide an explanation for the difference between the 1993 value of N4 and the other recent values. In all those years, viewing range can be taken to be 4km. Fewer than 1% of the locations of whales counted by the visual census were more than 4km offshore from the perches. Table 4 of Raftery and Zeh (1993) shows values of P4 for 1985, 1986, and 1988 ranging from 0.518 to 0.739. The 1993 value of P4 is 0.907. A much higher proportion of the population passed within viewing range in 1993 than in other recent years, accounting for the higher estimate of the number that passed within viewing range.

Data on the proportion of the population that passed within viewing range during the censuses prior to 1985 is much more limited. Zeh et al. (1993) summarise results of aerial transect surveys conducted during the Point Barrow censuses of 1979, 1981 and 1984 to assess the offshore distribution of the migrating whales. A total of 106 bowheads were seen on transect during those surveys, leading to estimates of 0.85, 0.75 and 1.00 for the proportion of the population that passed within 4km. Zeh et al. (1993) discuss the limitations of these data. Only the 1981 survey was done in a year that also produced an estimated N4. None of the surveys included enough different days over the census season or saw a large enough number of whales to provide an accurate and precise estimate of the proportion that passed within 4km. Nevertheless, they suggest the possibility that most of the population may have passed within viewing range in at least some of the early years of the census.

Braham et al. (1979) reported on aerial surveys during the 1978 census. They did not present data from which the proportion of bowheads that passed within 4km could be computed. However, they stated that

‘narrowing of the lead near Pt. Barrow and the apparent absence of whales in offshore leads appears to have brought essentially all migrating bowhead whales within viewing range of the Pt. Barrow ice camp census teams.’

Thus the 1993 offshore distribution of the whales may not be as unusual as it appears to be when it is compared with only the most recent years.

Population size
Raftery and Zeh (1993) described an alternative estimate of bowhead population size (N4/P4) which they compared with the Bayes empirical Bayes population estimate. Table 1 shows the N4/P4 estimates given by Raftery and Zeh (1993) for 1985, 1986 and 1988 and the corresponding value for 1993. The 1993 estimate of 7,992 (SE 587) does not differ significantly from the others.

Table 1 gives 95% confidence intervals for bowhead population size, computed as recommended by Buckland (1992) from the estimates N4/P4. Finally, the table gives the modes of the Bayes empirical Bayes posterior distributions of population size for the years for which they have been computed (Raftery and Zeh, 1993; 1994), along with intervals which represent the range in which 95% of the posterior probability is concentrated. The Scientific Committee (IWC, 1992) agreed that the Bayes empirical Bayes approach was the most appropriate for estimating current bowhead population size. The Scientific Committee also agreed that the 1988 Bayes empirical Bayes posterior distribution provided the best information on population size to use for assessment purposes (IWC, 1992; 1995).

There are qualitative similarities between the two types of estimates. Both indicate that bowhead population size was estimated least precisely in 1986 and most precisely in 1993. The Bayes empirical Bayes estimate and the alternative estimate agree very well for 1988, somewhat less well for the other two years. Raftery and Zeh (1993; 1994) discuss possible sources of bias in each estimate and reasons for differences between them. But when the estimates differ, there is no certain way to determine which better reflects reality. It seems prudent to continue to compute both types of estimates.

Raftery and Zeh (1993) proposed the \( N/P_4 \) estimates as a simple alternative to the Bayes empirical Bayes estimate that does not depend on the tracking algorithm used in the latter estimation procedure to link visual and acoustic locations. Much of the complicated data analysis required in computing the Bayes empirical Bayes estimates is related to choosing appropriate tracking algorithm parameters and estimating tracking algorithm error probabilities. These analyses require more acoustic data than the computation of \( P_4 \); in particular, repeated locations from acoustically identified whales. When there are few such locations, as in the 1993 data set, it becomes difficult to determine correct values for the tracking algorithm parameters and error probabilities. The need to estimate so many auxiliary parameters in order to compute the Bayes empirical Bayes estimates may contribute to the year-to-year variability in these estimates. In fact, Raftery and Zeh (1993) suggested that further analyses of the 1986 data, not done because of limitations on time and computing power, were needed to make the 1986 estimate fully comparable with the 1988 estimate. The same statement can be made regarding the 1993 Bayes empirical Bayes estimates.

The estimate of \( N/P_4 \) does not require the estimation of any parameters other than \( N_4 \) and \( P_4 \), which are computed directly from the current census data as described above. This is both a strength and a weakness. The probabilities \( q \) of missing whales under particular conditions were estimated from data collected between 1978 and 1985 and are assumed to be applicable to the more recent censuses. Independent observer experiments or other experiments to verify that these probabilities have not changed in recent years would help to resolve whether \( N/P_4 \) provides an unbiased estimate of current population size. The fact that it is sometimes lower and sometimes higher than the Bayes empirical Bayes estimate provides reassurance that neither population estimation technique is producing estimates with large and systematic biases.

The \( N/P_4 \) estimates in Table 1 are more consistent than the Bayes empirical Bayes estimates with the scenario of an increasing population. The Bayes empirical Bayes estimates cannot be used to estimate trend. As already noted, they are not strictly comparable because of differences in the way the analyses were carried out. In addition, the concentration of the whales close to shore in 1993 caused the tracking algorithm on which the Bayes empirical Bayes estimates are based to count many fewer whales than were seen by observers. Although the Bayes empirical Bayes procedure makes some adjustments for under counting by the tracking algorithm, it is likely that those adjustments were not adequate in this case, leading to a downwardly biased 1993 estimate (Raftery and Zeh, 1994). The Scientific Committee (IWC, 1995) therefore concluded that the best available estimate of the current size of the Bering-Chukchi-Beaufort Seas stock of bowheads is the 1993 \( N/P_4 \) estimate of approximately 8,000 animals (95% CI 6,900–9,200).

Rate of increase accounting for whales beyond viewing range

The estimates \( N/P_4 \) in Table 1 can be used in a weighted regression as in Zeh et al. (1991) to obtain an estimate of the rate of population increase. The estimated rate, since it is based on actual population estimates instead of estimated numbers of whales that passed within viewing range, is not affected by year-to-year variability in the proportion of whales that passed within viewing range. The result is an estimated annual rate of increase of 2.5% with an approximate SE of 1.5% for the years 1985–1993. Since the estimate is based on only four data points, it has a wide 95% CI (-3.5% to 9.0%), i.e. it is not significantly different from zero. However, it suggests that continued population increase is more likely to have occurred than a decrease under the higher subsistence harvest quotas of recent years. In the eight years since 1985, an average of 36 bowheads were killed per year, compared to an average of 19 in the previous eight years (Suydam et al., 1995). Nevertheless, the analysis of the four available data points provides 89% confidence that the population was increasing between 1985 and 1993.

The lack of precision of the estimate of rate of increase just discussed is a consequence of the omission of 60% of the visual census data. However, the Scientific Committee (IWC, 1995) considered it important to base the estimate of rate of increase on the population estimates \( N/P_4 \) rather than on the values \( N_4 \) which are not corrected for whales that passed beyond viewing range. Raftery et al. (1995) developed an estimate of rate of increase that used the acoustic data on offshore distribution from 1985, 1986, 1988 and 1993 together with all of the visual census data. \( P_4 \) for the years without acoustic data was estimated as the geometric mean of the values for the years with acoustic data. The resulting estimate of 1978–1993 rate of increase was 3.1% with a 95% confidence interval from 1.4% to 4.7%. This estimate was more precise than the estimates based on \( N_4 \) because much of the variability due to between-year differences in offshore distribution was eliminated.

It was agreed that the estimate of Raftery et al. (1995) was the best one to use in the bowhead assessment. However, the Scientific Committee recommended further analyses of the census data that would incorporate information on wind and ice conditions and aerial survey data on offshore distributions of the whales for years before acoustic data were available. Such analyses could improve the estimates of \( P_4 \) for the years without acoustic data and could lead to better estimates of rate of increase. These analyses will be carried out before the 1995 Scientific Committee meeting.

CONCLUSIONS

Both census counts and population models support our conclusion that the bowhead population is increasing, but a longer time series of estimates is required to determine the rate of increase precisely without the aid of population models and other types of data. IWC (1995) used the Bayesian synthesis approach of Givens et al. (1995) to combine the empirical data on rate of increase with data on pregnancy rates and other bowhead life history parameters, population size, population age structure and historic catches via a population dynamics model. The post-model distribution of 1978–1993 rate of increase, with a median of 2.3% and 95% of its probability between 0.9% and 3.4%, provides the most precise estimate of annual rate of increase available at this time.
Practical considerations favour the continued use of $N_1$ to provide the primary empirical data for assessing population rate of increase. It can be computed from the visual census data immediately after the census without waiting for acoustic location data or carrying out the complicated data analyses required to set parameters for the Bayes empirical Bayes procedure. It can be computed in years like 1987 when full-scale acoustic monitoring is not carried out. The combined visual and acoustic census is considerably more expensive and logistically difficult to conduct than the visual census, so the acoustic component may not be included in every future census. However, the data on whales that pass beyond viewing range provided by the acoustic component improves the precision of the estimate of rate of increase, so it should be collected when possible.

ACKNOWLEDGEMENTS

We acknowledge the cooperation of the Alaska Eskimo Whaling Commission and the whale hunters of Barrow who have supported our studies. We appreciate the efforts of numerous people who participated in this difficult and sometimes dangerous census. They include: Susie Ahcoottook, William Agvuluk, Barbie Anderton, Perry Anashugak, Peggy Barnes, Charles D.N. Brower, Harry Brower, Jr., Joe Burgeson, Tom Calupec, Todd Chandler, Chris Clark, Geoff Carroll, Lance Craighead, Andy Deering, Beaver Deering, Adam Frankel, Christine Gabriele, Christie Giessinger, Mia Grifalconi, Matt Iriaga, Michelle Johnson, K.C. Miller, Peter Montesano, Flip Ninklin, Taqilik Opie, Melvin Panik, Sam Payne and Mia Wesselman. We appreciate the support of Benjamin Nageak, the former Director of the Department of Wildlife Management. We gratefully acknowledge funding provided by the North Slope Borough, the Alaska Department of Community and Regional Affairs, National Oceanic and Atmospheric Administration (through the AEWG), and British Petroleum Exploration (Alaska). We dedicate the 1993 work to two women, Dr Carolyn Glass and Ms. Carolyn Craighead, deeply committed to preserving wilderness and wildlife, who passed away at the time of the census. Finally, we thank Ms Robyn Angliss, Office of Protected Resources, 1335 East-West Highway, Silver Spring, MD 20910, USA; Dr Barbara Taylor, NMFS/Southwest Fisheries Science Center, La Jolla, CA 92038; USA; and two anonymous reviewers for their helpful comments on the manuscript.

Assessment of the Bering-Chukchi-Beaufort Seas Stock of Bowhead Whales Using the BALEEN II Model in a Bayesian Synthesis Framework

Geof H. Givens¹, Judith E. Zeh² and Adrian E. Raftery²

ABSTRACT

We apply the Bayesian synthesis framework (Givens, 1993; Raftery et al., 1995a) to the BALEEN II population dynamics model (de la Mare and Cooke, 1992) to assess the Bering-Chukchi-Beaufort Seas stock of bowhead whales, using the best and most recent evidence about the species. Unlike methods used in previous bowhead assessments, the Bayesian synthesis method takes full account of the evidence and uncertainty about bowhead life history, abundance and age distribution. This paper describes the scientific evidence about model inputs and outputs which, when combined with the evidence inherent in the model, provides the basis for inference.

The application of the Bayesian synthesis framework was successful in reducing uncertainty about quantities of interest, for example, the variance of the estimated annual rate of population increase was reduced by 86%. The recent annual rate of population increase is likely to be in the lower half of the confidence interval computed by Zeh et al. (1995), but it is almost certainly positive. The analysis described in detail in this paper produced a post-model distribution of replacement yield with its 5% point at 54; two replicate runs obtained values of 50 and 60, respectively, for this percentile. Alternative distributions for model inputs and outputs that we considered gave 5% points ranging from 45 to 68.

At its 1994 meeting, the IWC Scientific Committee agreed on modifications to some of our distributions of model inputs and outputs, believing them to provide a better summary of available evidence about bowhead whales. The results of the analysis using the agreed distributions are given in Appendix 3. The 5% point of the post-model distribution of replacement yield from this analysis is 104, the same as the value 104 obtained by a shortcut method during the meeting. The largest contributor to the difference between this result and the results described above is the more precise pre-model distribution of rate of increase derived by Raftery et al. (1995b) during the meeting.

1. INTRODUCTION

Givens (1993) and Raftery et al. (1995b) have presented a framework for making statistical inference from multiple sources of evidence and uncertainty which are linked by complex models. This is a Bayesian approach which synthesizes information about model inputs and outputs to identify model simulations which are compatible with all available evidence. The 'Bayesian synthesis' approach is not a new model, but a better way to obtain estimates and make inferences from existing models. Indeed, the Scientific Committee of the International Whaling Commission (IWC) has agreed that this approach provided a substantial improvement in assessment methodology and recommends its use for the planned bowhead whale assessment' (IWC, 1994).

In this paper, we apply the Bayesian synthesis framework to the BALEEN II population dynamics model (PDM) described in de la Mare and Cooke (1992), BALEEN II is a standardized version of older versions of the underlying population model of the Hitter-Fitter package (de la Mare, 1989; Pun and Butterworth, 1991). It is the PDM currently favored by the IWC Scientific Committee, and has been validated by the IWC Secretariat (IWC, 1995a). The software used to obtain the results in this paper is scheduled for IWC validation.

Previous assessment approaches assumed fixed values for most model inputs, and were not capable of accounting for many available types of evidence about model outputs. The use of mostly fixed input parameters was based on studies (de la Mare, 1986; 1990; Lankester and Cooke, 1987) which demonstrated that estimation of quantities important for assessment (replacement yield, RY; maximum sustainable yield, MSY; and depletion level) from population modeling and abundance data was not particularly sensitive to misspecification of model structure or input parameters, as long as one yield-determining parameter was free to vary. The Bayesian synthesis framework does not assume fixed values for model parameters. It permits evidence about model inputs to be incorporated directly in the analysis, and produces a richer and more realistic set of results using an approach which is conceptually simple and practically feasible. A comparison of the Bayesian synthesis and previous approaches and a discussion of the benefits of the Bayesian synthesis method is given by Givens et al. (1993).

2. REVIEW OF THE BAYESIAN SYNTHESIS APPROACH

Consider a complex deterministic model which uses input parameter vector \( \theta \). The model may incorporate data (e.g. the historic kill record) in its mechanism. Its outputs are \( M(\theta) \). For BALEEN II, the inputs and outputs listed in Table 1 would be elements of \( \theta \) and \( M(\theta) \), respectively.

Let \( \phi \subseteq M(\theta) \) be model outputs about which we have additional evidence independent of the model. For example, the 1993 stock size would be an element of \( \phi \) since an independent estimate of this quantity is available (Raftery and Zeh, 1994). Let \( \psi \) denote the set of quantities of interest, which may be model inputs or model outputs or functions of both, and which may or may not include elements of \( \phi \) or \( \theta \). Note that both \( \phi \) and \( \psi \) are functions of \( \theta \). It is not unusual for \( \psi \) to include all inputs and outputs.
Evidence about \((\theta, \phi)\) from all sources except the model itself may be summarized by a pre-model distribution, \(p(\theta, \phi)\). This evidence may consist of priors, or posteriors or likelihoods from other analyses. The model defines a mapping \(\Phi\) from the inputs \(\theta\) to the outputs \(\phi\). This mapping embodies the evidence provided by the model itself, since \(A = \{(\theta, \phi) : \Phi(\theta) = \phi\}\) is a subspace of the pre-model parameter space. Thus the evidence about \((\theta, \phi)\) conditional on the model is simply \(p(\theta, \phi)\) constrained to \(A\). Denote this post-model distribution by:

\[
\pi(\theta, \phi) = \begin{cases} 
p(\theta, \Phi(\theta)) & \text{if } \Phi(\theta) = \phi \\
0 & \text{otherwise}
\end{cases}
\]

where \(\propto\) denotes proportionality. Thus the marginal post-model distribution of \(\theta\) is \(\pi(\theta) \propto p(\theta, \Phi(\theta))\), and the post-model distribution of quantities of interest \(\psi\), denoted \(\pi(\psi)\), can be estimated directly from \(\pi(\theta)\) since \(\psi\) is a known function of \(\theta\).

Typically, post-model distributions are impossible to evaluate analytically. However, a sample from the post-model distribution \(\pi(\theta)\) is sufficient for the estimation of \(\pi(\psi)\). The simplest way to obtain such a sample is via the Sampling Importance Resampling (SIR) algorithm (Rubin, 1987: 1988).

For the BALEEN II application, we consider a very simple version of the SIR algorithm where the pre-model distribution is specified as \(p(\theta, \phi) = p(\theta)p(\phi)\). In this situation, the Bayesian synthesis approach can be implemented with the following importance resampling scheme:

1. Begin with an initial guess for \(\pi(\theta)\), here simply \(p(\theta)\).
2. Draw \(\theta_1, \ldots, \theta_m\) from the initial guess \(p(\theta)\).
3. Form importance weights \(w(\theta_1), \ldots, w(\theta_m)\) with \(w(\theta) \propto \pi(\theta)/p(\theta)\). Since \(\theta_1, \ldots, \theta_m\) generate \(\Phi(\theta_1), \ldots, \Phi(\theta_m)\) via the model, \(w(\theta) = p(\theta)p(\Phi(\theta))/p(\phi) = p(\Phi(\theta))\).
4. Sample \(\phi^* \sim \cdots \sim \phi_m^*\) from \(\theta_1, \ldots, \theta_m\) with replacement with probabilities proportional to \(w(\phi_1), \ldots, w(\phi_m)\).
5. Use \(\phi_1^*, \ldots, \phi_m^*\) for inference and/or to estimate \(\pi(\psi)\).

This method becomes exact as \(n \to \infty\) for any fixed \(m\) and easily generalizes to the case of arbitrary \(p(\theta, \phi)\). This method will require \(n\) runs of the model. We have found \(n = 200,000\) and \(m = 5,000\) to be satisfactory.

### 3. THE BALEEN II MODEL FOR BOWHEAD WHALES

The details of the BALEEN II PDM and its predecessors are beyond the scope of this paper but are well described in de la Mare (1989), Punt and Butterworth (1991) and de la Mare and Cooke (1992).

The BALEEN II PDM is an age- and sex-stratified model which projects a population trajectory through time, reflecting changes in the population due to natural mortality, age-dependent recruitment, sex-selective hunting mortality and density-dependent fertility. The PDM was structured for the Bayesian synthesis analysis of bowheads in the following ways.

#### 3.1 Parameterization

One of the strengths of the BALEEN II PDM is its generality. For example, it allows mortality rates to be age- and sex-specific. Such flexibility is often unnecessary, as PDMs for whales are rarely more than a rough approximation to reality. In order to establish a pre-model distribution on mortality rates, it is helpful to reduce the dimensionality of the mortality rate parameter space. We therefore assume that mortality rates do not differ by sex. Further, we assume that mortality is a piecewise constant function of age. These assumptions are common when using BALEEN II, its predecessors or other PDMs (e.g. Breivik et al. (1984), who tailored the model to bowheads). We assign annual mortality rate \(1-s_a\) to juvenile whales aged 1 through \(a\) and \(1-s_a\) to whales aged at least \(a+1\). Newborn calves are assumed to have mortality rate \((1-s_a)(1-s_b)\).

For simplicity, we refer to \(a\) as the age of transition to adulthood. It is important to note that 'adulthood' in this context means neither physical nor sexual maturity. 'Juveniles' are simply those animals with annual survival rate \(s_a\) and 'adults' those with survival rate \(s\). These 'adults' include physically and sexually immature animals.

BALEEN II allows the transition to sexual maturity to spread over a range of ages, by specifying a function which fixes the proportions of each age class that are counted as being sexually mature. However, for simplicity, we assume all whales become mature at age \(m\), and that first parturition occurs at age \(m+1\). We set BALEEN II to group all whales 35 years or older into a single age class, since all operational and biological parameters are unchanged with age above 35. This is not an assumption that whales die or stop reproducing at 35; it is merely a book-keeping convenience. Although we assume a model parameterization which specifies abrupt developmental transitions, the ages at which such transitions occur are unknown quantities which we do not predetermine – the uncertainty about these ages is incorporated in the pre-model distribution, and the results of Lankester and Cooke (1987) suggest that these simplifications are unlikely to affect assessment results.
This parameterization of bowhead survival and reproduction is shown in Fig. 1. We have made the graph for the situation where $a=6, s_0=0.92, s=0.98$ and $m=20$, although these parameters are treated as uncertain in the Bayesian synthesis analysis. In addition to these four parameters, the BALEEN II PDM takes as inputs maximum sustainable yield level (MSYL), maximum sustainable yield rate (MSYR) and initial population size, the size of the stock in 1848 before commercial whaling began. These seven parameters constitute \( \theta \).

### 3.2 Model structure

The BALEEN II PDM allows the user to customize the PDM structure for its intended use. These customizations specify the model in a more fundamental way than do the input parameters about which we express uncertainty via the pre-model distribution. In the following paragraphs, we list the specifications chosen to customize the BALEEN II PDM for bowheads.

BALEEN II allows the general concept of a recruited population, namely the population that is susceptible to hunting. Whales are recruited gradually or instantaneously as they reach some minimum age at recruitment. We set the model so that the recruited population consists of all whales aged 1 year or more, i.e. the ‘1+ population’. This age at recruitment is clearly correct for the present subsistence harvest. Since 1981, the Scientific Committee has recommended that the catch be restricted to small, immature animals because they ‘have proportionally less reproductive potential than sexually mature adults’ (IWC, 1987, p.50). Of the 15 whales harvested since 1981 whose baleen was examined by Schell et al. (1989), four were estimated to be less than 2 years old. Breidvik et al. (1984) summarized evidence that even before 1981, around 80% of whales taken in the subsistence harvest were immature. Boekstock and Botkin (1983) presented data on barrels of oil per whale suggesting that in the first 5-15 years of the commercial hunt of bowheads, whales have reached larger, hence older, animals. However, throughout the remaining years of the commercial hunt, they appear to have taken any whales they found, regardless of size.

BALEEN II assumes unselective harvesting from recruited age classes. As noted above, age-selective hunting has occurred and has varied over time. The PDM of Breidvik et al. (1984) assumed that 80% of the whales taken in the commercial hunt were mature and that 80% of those taken in the subsequent subsistence harvest were immature. Outputs from their model are similar to those from the BALEEN II model, thus uncertainty about hunting age selectivity does not appear to be critical.

The BALEEN II PDM allows density dependence to depend on either the total (1+), the exploitable, or the mature depletion. For bowheads, we take the exploitable population to equal the 1+ population, so the density dependence choices are limited to mature versus 1+. Butterworth and Punt (1992b) argue that depletion is more naturally expressed in terms of the mature female population component, and they indicate that there has been IWC precedent for this choice (IWC, 1992a). Cooke and de la Mare (1992, p.3) investigated the choice of population component for density dependence and stated that ‘changing the component on which density dependence acts has no appreciable effect on the results’ from their work. These authors concur with Butterworth and Punt (1992b) that it is appropriate to use the mature female population component when considering stock reduction and density dependence.

There has been considerable confusion about how to express MSYL and MSYR (Allen, 1976; Cooke and Lankester, 1987; Butterworth and Best, 1990; Butterworth and Punt, 1992b; Cooke and de la Mare, 1992). Holt (1992) has questioned whether it is even reasonable to consider MSYL and MSYR as fixed intrinsic properties of a population. Butterworth and Punt (1992b) argue that discussions of reasonable values for these parameters by the IWC Scientific Committee have frequently used reasoning corresponding to the 1+ component, while the IWC Scientific Committee typically uses values in trials and estimation procedures which are relative to the mature component. For example, MSYL and MSYR were expressed in terms of the mature component for simulation trials of the revised management procedure for commercial whaling (IWC, 1992a, b). As this example illustrates, the ‘conventional wisdom’ of the IWC Scientific Committee is usually expressed in terms of the mature component, and we will consider MSYL and MSYR to be relative to this component. Cooke and de la Mare (1992) note that this choice would be consistent with our choice for density dependence. (See Sections 4.1.5 and 4.1.6 for further details).

We consider the carrying capacity to be unchanged from 1848 to the present, so we assume a constant carrying capacity profile.

### 3.3 The historic catch record

BALEEN II requires the historic kill record to be broken down by year and by sex within each year. We use the annual total kill data for 1848-1972 as given on p.140 of IWC (1992c), and for 1973-1993 as given by Suydam et al. (1995), which are revised data that differ from the IWC (1992c) counts by a few whales. These data are shown in Fig. 2. We assume that equal numbers of males and females were killed each year. George et al. (1992) reported that 51.7% of the 180 whales of known sex landed in the subsistence harvest between 1980 and 1990 were females. This percentage does not differ significantly from 50%. Nor have we found any evidence to suggest differential kills by sex in earlier subsistence or commercial catches. Although the annual kills are not in fact known exactly, the data are the product of careful historical research beginning with the work documented by Boekstock and Botkin (1983), and we treat the historic kill record as part of the deterministic PDM, i.e. as known without error. It is straightforward to investigate sensitivity to this assumption.
4. THE PRE-MODEL DISTRIBUTION

To apply the Bayesian synthesis framework to the BALEEN II PDM, we must first specify a pre-model distribution of the inputs and outputs. Some of these quantities (e.g., 1993 population size) have been estimated from substantial data. Many others (e.g., mortality and fertility rates) are not at all well known. Natural births and deaths are rarely observed in the bowhead population, and it is difficult to estimate bowhead ages. Most of the available research on the bowhead is summarized in The Bowhead Whale (Burns et al., 1993).

It is critical that the information in \( p(\theta, \phi) \) not include any evidence from runs of BALEEN II itself. In fact, no evidence obtained from any PDM should be used since the BALEEN II PDM was not designed independently or in ignorance of competing PDMs. To use model-based evidence in the pre-model distribution would be to count the information twice since it is used later in the weighting stage of our approach.

Information that can be used to specify \( p(\theta, \phi) \) includes the following: effort data from the historic commercial hunt; biological studies of bowhead fertility, mortality, growth and other life history parameters; interspecific comparisons of the same; aerial, land-based visual and acoustic studies of bowhead abundance, population trend and age distribution; the 1991 assessment carried out by the IWC (1992d) and anecdotal evidence from the Eskimo community.

In the following sections we summarize the available data and the reasoning used to establish the pre-model distribution of model inputs and outputs. The IWC Scientific Committee has agreed that the approaches used below for setting pre-model distributions are acceptable (IWC, 1994), although the specific choices are our own; of course other reasonable choices exist (see Section 6). In every case, our choices reflect the priority that no plausible values of any parameter should be ignored (i.e., given prior probability zero). Except where otherwise noted, the marginal pre-model distributions of each of the inputs and outputs are treated as independent when calculating \( p(\theta, \phi) \).

During its 1994 meeting, the Scientific Committee agreed upon a different pre-model distribution (IWC, 1995a); results for this choice are shown in Appendix 3.

4.1 Model inputs

The marginal pre-model distributions of the inputs to BALEEN II are shown in Fig. 3. We give some extracts from IWC (1992d), which help to explain our choices for the pre-model distributions of inputs.

![Fig. 3. Marginal pre-model distributions of model inputs.](image)

4.1.1 Adult and juvenile survival rates, \( s \) and \( s_0 \)

Bowhead survival is specified by rates \( s \) and \( s_0 \) for whales aged at least \( a+1 \) and for whales aged \( 1 \) through \( a \), respectively. Considering annual natural mortality, \( 1-s \) and \( 1-s_0 \), IWC (1992d) reports:

**Adult mortality:** Eberhardt and Breiwick (1992) used values of 0.01 and 0.02. No direct data on mortality rates are available for bowheads, but..., similar low values had been estimated for the killer whale (Olesiuk et al., 1990). The sub-committee noted that although estimates for other baleen whales are higher than this, those for right whales are similar to those used in Eberhardt and Breiwick (1992). Consequently, values of 0.01 and 0.02 were chosen for the HITTER/FITTER runs.

**Juvenile mortality:** No direct evidence is available. Eberhardt and Breiwick (1992) used a range of 0.04 to 0.06 under the assumption that juvenile mortality would be higher than adult mortality; the sub-committee adopted that range for use in this assessment. Sensitivity analyses run by the Secretariat in 1988 (Allison, 1989) indicate that Hitter-Fitter results for depletion level are relatively insensitive to mortality values used, so the sub-committee did not consider these parameters in further depth.

We therefore adopted distributions with much, but not all, of their probability in the range 0.92 to 0.96 for \( s_0 \) and 0.98 to 0.99 for \( s \), such that \( s_0 \leq s \). For the juvenile survival rate we adopted a \( N(0.94,0.03^2) \) distribution truncated at 0 and 1. For the adult survival rate conditional on the juvenile rate, we adopted a \( N(0.98,0.03^2) \) distribution.
truncated at the juvenile rate and 1. The resulting pre-model joint distribution of \((s_0, s)\) is shown in Fig. 4, and the marginal pre-model distributions are shown in Fig. 5.

![Fig. 4. Joint pre-model distributions of \(s_0\) and \(s\).](image)

4.1.2 Age of transition to adulthood, \(a\)

Although there is little evidence on this parameter, IWC (1992d) adopted a value of 5 years. However, we believe it is more appropriate to take account of the uncertainty by using a fairly flat pre-model distribution. We wanted to constrain \(a\) to be less than the age of sexual maturity, \(m\), and since we adopted a lower limit of 10 for \(m\) (see Section 4.1.3), we used a discrete uniform distribution for \(a\) on the integers 1, 2, ..., 9.

4.1.3 Age at sexual maturity, \(m\)

Breiwick \textit{et al.} (1984) used a range of 5 to 9 years for their PDM, corresponding to prevailing beliefs at that time based on knowledge of other whale species. More recent research suggests much higher values, but these have been greeted with skepticism by some scientists because they are high relative to most other whales and large mammals. IWC (1992d) summarizes the evidence as follows:

Aerial photometric measurements indicate that the average length at maturity for both sexes is approximately 13m (Withrow and Angliss, 1992). Evidence from the landed catch suggests a female length at sexual maturity of about 14m (Withrow and Angliss, 1992). Precursors to Eberhardt and Breiwick (1992) (e.g., Breiwick and Braham, 1990) assumed that whales reach this length at ages of 9 years or earlier. However, Eberhardt and Breiwick (1992) increased this age to 13-17 years, citing recent evidence from carbon isotope aging of baleen plates (Schell \textit{et al.}, 1989) that bowheads grow very slowly, and reach 13m at ages between 18 and 20 years. The sub-committee had before it more recent results for baleen aging and photometry (Koski \textit{et al.}, 1992; Withrow \textit{et al.}, 1992), suggesting that bowheads grow very slowly, and that an upper limit exceeding 17 years could also be considered.

The sub-committee concluded that even given the tentative nature of results from these lines of study, sufficient evidence exists to warrant consideration of 19 years as an upper limit on age at first parturition ... it was agreed to use values of 13, 15 and 19 years.

Since first parturition is assumed to occur at age \(m+1\), this suggests a pre-model distribution for \(m\) which has most of its mass in the range 12-18. However, some Scientific Committee members, after considering the evidence further, concluded that higher values of \(m\) were at least equally likely. Koski \textit{et al.} (1992) examined 69 pairs of length measurements of identified whales photographed in different years. They concluded from the slow growth indicated by these measurements that bowheads may be in their late teens to perhaps 31 years old by the time they become sexually mature, with females probably reaching sexual maturity before males. Other Scientific Committee members suggested that ages at sexual maturity exceeding 30 years were not plausible and that ages as low as 10 were more consistent with data on other baleen whales. We therefore used a discrete uniform pre-model distribution on the integers 10, 11, ..., 30 for \(m\).

4.1.4 Initial population size, \(P_0\)

Intuitively, the historic kill record (Fig. 2) provides information about the initial (pre-exploitation) population level, \(P_0\). However, the appropriate extraction of this evidence is difficult.

Estimates of \(P_0\) cited by Breiwick \textit{et al.} (1984) have ranged from 9,000 to 40,000. They have been based on catch and effort data and have, at least implicitly, involved population dynamics models. We chose the approach of Leslie and Davis (1939) and DeLury (1947). In this approach, \(P_0\) is estimated from a linear regression of catch per unit effort (CPUE) on cumulative catch. The estimate of \(P_0\) is the intercept of the line on the cumulative catch axis. The effort data provide information about \(P_0\) independent of any other information used in our analyses, and the cumulative catch data are assumed to be known without error, as elsewhere in our analyses.

DeLury (1947) outlines the assumptions on which his approach is based. They can be summarized as follows:

1. the population is closed except for the catch; i.e. the effects of emigration, immigration, natural mortality and births are negligible;
2. the units of effort are independent and do not compete with one another;
3. the catchability, the proportion of the population captured in a particular time period by a single unit of effort, is constant – catchability \(k\) does not differ for different individuals or change over time.

It follows from these assumptions that the relationship between CPUE and cumulative catch is linear:

\[
U_t = kP_0 - kK_t
\]

where \(U_t\) is the CPUE in year \(t\) and \(K_t\) is the total kill up to but not including year \(t\).

Bockstoce and Botkin (1983) compiled CPUE time series for the years 1849-1914 using whalers’ log books and journals and other historical records. They presented several different measures of catch and CPUE to which they applied the DeLury method, obtaining estimates of around 30,000 for \(P_0\). In most of their analyses, they used kill per unit effort (KPUE), which includes both whales caught and whales struck and lost dying, as the measure of catch per unit effort \(U_t\). This measure was also used in the analyses discussed below.

Units of effort are ‘Type 1 Days’ (Bockstoce and Botkin, 1983). A Type 1 Day is a day of whaling effort by a single ship under weather conditions during which whales were caught during the 66-year period of commercial harvests. Days with a combination of ice, wind and visibility conditions under which whales were never caught are excluded from the effort measure. Not all voyages were documented in every year.

\(U_t\) was estimated from data on the \(n_t\) documented voyages in year \(t\). We assume the total population of (actual and potential) voyages for each year is \(N = 224\), the
maximum number of voyages in any one year. Bockstoce and Botkin (1983) use a ratio estimate (Whales Killed)/(Type 1 Days) for $U$. If we assume that the between-voyage variability in kill, given $U$, and effort, is the same each year, and include a finite population correction, then the estimated variance of $U$ is proportional to $(N-n)/n\bar{E}$, where $\bar{E}$ is the average number of Type 1 Days per documented voyage in year $t$ (Cochran, 1977). Inverting this expression, we obtain weights proportional to the inverse of the estimated variance. We use these weights in the regression based on equation (2).

Tillman et al. (1983) criticized the application of the DeLury method by Bockstoce and Botkin (1983). They argued that the assumption of a closed population was violated when the analysis was based on the entire 66-year history of the commercial fishery and that, as a consequence, the estimates of $P_0$ given by Bockstoce and Botkin were biased upwards. The closed population assumption of the DeLury method requires that births do not add to the catchable population during the time period considered. If this time period is the entire history of the fishery, an unreasonable PDM with $\text{MSYR} = 0$ is implied. Tillman et al. obtained lower estimates of $P_0$ using reasonable PDMs that allowed births to add to the catchable population.

Because we agreed with the criticisms of Tillman et al. (1983) but wanted a prior distribution for $P_0$ which did not depend on particular assumptions about population dynamics, we chose to apply the DeLury method to a small number of years at the beginning of the commercial fishery when the kill was high. If this is done, the effects of population dynamics should be slight compared to the effects of the commercial kill.

It does not appear reasonable to consider the years from 1880 on. The addition of steamships to the whaling fleet starting in 1880 and other changes in the nature of the whaling effort guaranteed that the assumption of constant catchability over time would be violated if these later years were included. In addition, falling prices for whale oil and the loss of many ships in the treacherous ice conditions of the northeast Chukchi Sea permanently reduced the size of the whaling fleet and the annual kills from 1871 on (Bockstoce, 1986). However, an even shorter period must be considered to avoid violation of the closed population assumption. A nonparametric smooth of the data (Fig. 5) indicates that the relationship between KPUE and cumulative kill is linear until cumulative kill reaches about 8,000 (i.e. until about 1860), but that a nonlinear relationship or a different linear relationship holds thereafter.

The decrease in KPUE with cumulative kill may be less rapid in the later years because births are adding to the population available to be killed. However, as argued by Bockstoce and Botkin (1983), effects of population dynamics are confounded with effects of changes in the geographic distribution of the whaling effort. In the early years of the fishery, whales were taken only in the Bering and southern Chukchi Seas. Whales that migrated into the Beaufort Sea only began to be killed in great numbers in the 1860s, as ships ventured into the northeast Chukchi Sea and stayed later in the fall to catch whales returning from the Beaufort Sea. Thus the migrating whales were not 'equally catchable' in the early years of the fishery, and a distribution for $P_0$ based on the early years is biased downward because it does not adequately represent these whales.

Fig. 5. Kill per unit effort vs cumulative kill during the first 31 years of the fishery. Cumulative kill is computed from the total kill values tabulated in Annex E of IWC (1992e). The area of the circle shown for each year is proportional to the weight that year has in the regression based on (2). The line through the data is produced by locally weighted scatterplot smoothing (Cleveland, 1979).

An additional source of downward bias in such a distribution noted by Butterworth and Punt (1995) would be present if a high age at recruitment in the early years of the fishery made the closed population assumption valid during those years. In this case, the DeLury estimate of $P_0$ would represent only the older catchable population, not the total population.

The heavy line in Fig. 6 shows a prior distribution for $P_0$ based on 1849 to 1860 data only. The minimum estimated mean squared error of the estimate of $P_0$ was obtained with this choice of years. The distribution is a 'fiducial distribution' obtained using a method described by Fieller (1954). See Appendix 1 for details. The distribution is highly skewed, with 95% of the probability between 7.700 and 26.000 but half the probability below 10.600. Since the cumulative kill through 1860 was 8,354 and the assumptions of the DeLury method imply that $P_0$ must exceed this cumulative kill, the distribution appears to put too much weight on low values. On the other hand, a distribution based on data to 1866 or later puts no weight at all on values of $P_0$ below 10.600.

Fig. 6. Fiducial distributions for initial population size $P_0$ based on applications of the DeLury method to cumulative kill and kill per unit effort data from 1849 through multiple choices (1859–1870) of ending year. The heavy line corresponds to an ending year of 1860.

Fig. 6 shows fiducial distributions for initial population size $P_0$, based on different choices of ending year, from 1859 through 1870. The distributions shown turn out to be
located sequentially from left to right with increasing choice of ending year. Since we had no additional pre-model information to help us choose among these fiducial distributions, we treated them as conditional on ending year, with each of these ending years assumed equally likely to be the 'correct' one, i.e. the one producing an unbiased distribution for \( P_b \). Integrating out the 'ending year' nuisance parameter, we obtained a pre-model distribution for \( P_b \). This distribution is extremely well approximated by the distribution of \( X + 6.400 \) where \( X \) has a Gamma \((2.8085, \ 0.0002886)\) distribution. We therefore use this offset gamma distribution (which has mean 16.132 and mode 12.667, with 95% of the probability between 8.263 and 30.374) as our pre-model distribution for \( P_b \). It is shown in Fig. 3.

### 4.1.5 MSYL\(_{\text{(new)}}\)
We chose to define MSYL relative to the mature population component (see Section 3.2).

In simulation trials of the revised management procedure for commercial whaling, the Scientific Committee has used values of 0.4–0.8, with 0.6 considered as the ‘base case’, for MSYL\(_{\text{(new)}}\) (IWC, 1992a; b). IWC (1992d) adopted 0.6–0.7 for MSYL, but it was not clear what definition of MSYL was used. Holt (1992) suggested that implications of values of MSYL being much higher than 0.6, particularly when modelling large changes in the size of a stock as with bowheads, have been ‘insufficiently explored’.

To accommodate this range of views, we choose a broad uniform prior from 0.4 to 0.8 on MSYL\(_{\text{(new)}}\).

### 4.1.6 MSYR\(_{\text{(new)}}\)
We express MSYR in terms of the mature component (see Section 3.2).

The Scientific Committee (IWC, 1993) chose MSYR\(_{\text{(new)}}\) values of 1%, 2.5%, 4%, and 7% for management trials. The irregular spacing of these values suggests that perhaps values in the range 1% to 4% were considered more likely than those greater than 4%. A ‘random parameters’ trial (IWC, 1993) used MSYR\(_{\text{(new)}}\) values down to 0.1%. Some recent papers (Best, 1992; Butterworth and Punt, 1992a; b) argue that even 1% is an unreasonably low value, given observed rates of increase of depleted stocks. Others (Cooke and de la Mare, 1992; Holt, 1992), although they are reasonably satisfied with the 1% to 7% range used in the management trials, argue that the available evidence allows us to say only that the lower bound is positive and that the upper bound could exceed 7%.

In order to give most weight to the 1% to 4% range, but to allow smaller values down to 0% and larger up to 7% or more, we chose a Gamma \((3.7, 110)\) pre-model distribution for MSYR\(_{\text{(new)}}\)/100. This distribution for MSYR\(_{\text{(new)}}\) has an approximate mode of 2.45% and mean of 3.36%; 95% of its probability lies between 0.86% and 7.56%.

### 4.2 Model outputs
The raw model outputs are counts of whales of each age in each year. There is considerable pre-model information from the 1978–1993 studies about recent values of quantities that can be calculated from the model outputs. We choose to establish pre-model distributions on the following model outputs: 1993 population size, average 1985–1992 population age structure, 1978–1993 annual rate of population increase and the historical maximum ratio of calves to mature females. We do not put a pre-model distribution on \( R_Y \); thus \( R_Y \) is an element of \( \psi \) but not of \( \phi \). Our marginal pre-model distributions for the model outputs are shown in Fig. 7.

#### 4.2.1 1993 population, \( P_{1993} \)
The pre-model distribution for \( P_{1993} \) is the Bayes empirical Bayes posterior distribution from Raftery and Zeh (1994). This distribution is provisional in that not all the acoustic data collected in the 1993 census have yet been analyzed, and it may be downwardly biased. We nevertheless use it because it is based on the most recent available census data and the population estimation method endorsed by IWC (1992c).

#### 4.2.2 Average 1985–1992 age distribution: % calves, % immature, % mature
Since percent calves, immature and mature sum to one, we have specified the pre-model distribution in terms of percent calves and percent mature only. The length data of Angliss et al. (1995) provide information about the age distribution. They present counts of calves, immatures and matures for 1985, 1986, 1989, 1990, 1991 and 1992, based on photogrammetric aerial surveys during the spring migration. The observed percentages of calves and mature whales varied substantially during these years, and we assume that it varied about some average for this period. Although there may be an age distribution trend during these years, it should be negligible compared to the variability of the observations.
Assume the 1985–1992 average proportion of mature whales was $\pi$, to be estimated by
\[
\hat{\pi} = \frac{1}{n} \sum_{i=1}^{n} \hat{\pi}(y_i)
\]
where $\hat{\pi}(y_i)$ is the observed proportion in the $i^{th}$ year, and $n=6$. The estimate $\hat{\pi}(y_i)$ depends on the data, $y_i$, for the $i^{th}$ year, and may be quite a biased estimate of $\pi$. There are many sources of bias, including missed days, survey timing and ice conditions, and the bias in each set of data may be very different. We will denote the sampling scheme for the $i^{th}$ year, with all its inherent biases, as $S_i$.

With this notation, and assuming independence between years,
\[
\text{var} \hat{\pi} = \frac{1}{n^2} \sum_{i=1}^{n} \text{var} \hat{\pi}(y_i)
\]
\[
= \frac{1}{n^2} \sum_{i=1}^{n} [\text{var}_{i} (E\hat{\pi}(y_i) \mid S_i) + E_{S_i} (\text{var} \hat{\pi}(y_i) \mid S_i)]
\]
\[
= \frac{1}{n^2} \sum_{i=1}^{n} \text{var} \hat{\pi}(y_i) + \frac{1}{n} \sum_{i=1}^{n} \hat{\pi}(y_i)(1 - \hat{\pi}(y_i))
\]
\[
= \frac{1}{n} \text{var} \hat{\pi}(y_i) + \frac{n-1}{n^2} \text{var} \hat{\pi}(y_i)
\]
\[
= \frac{1}{n} \left[ \frac{\hat{\pi} + \sum_{i=1}^{n} \hat{B}_i}{n} \right] = \hat{\pi} + \hat{\pi}
\]
where $\text{var}$ is the sample variance and $h_i$ is the total number of whales measured in the $i^{th}$ year. The notation in equation (7) suggests an overdispersed binomial model for the variance of $\hat{\pi}$, where $\hat{\pi}$ estimates the year-to-year variability (i.e. the overdispersion or extra-binomial variation) due to the sampling schemes $S_i$ ($i=1, \ldots, 6$), and $\hat{B}_i$, estimates the binomial sampling variability within each year (i.e. conditional upon each $S_i$). There may be a systematic, cyclic variation in calf production, in which case one might imagine the $S_i$ to include this pattern.

Note that $\pi \left( \frac{1}{n} \hat{\pi} \right)$ should approximately follow a $t$ distribution. Replacing $\left( \frac{1}{n} \hat{\pi} \right)$ by $\hat{\pi}$ inflates the total variance by about 10% (and only 5% for calves). It is reasonable, therefore, to choose a scaled $t$ distribution for the proportion of mature, where the scale factor is $\hat{\pi}$. The same method was used for the proportion of calves. Thus we assume that (% mature / $100 - 0.41$) / 0.0286 and (% calves / 100 - 0.052) / 0.0164 each have a $t$ distribution truncated at 0 and 1.

Anghiss et al. (1995) did not observe precisely the proportion of calves defined in the BALEEN II PDM because not all calves had been born at the time of data collection and some observed calves were certain to die before the end of the year. This imprecision is negligible compared to the dispersion of the pre-model distribution for this variable.

4.2.3 1978–1993 annual rate of increase, ROI
The pre-model distribution for ROI is that of $e^{0.0477 \pm 1.14 R_{0.8}} - 1$, where $t_i$ is a random variable that has a $t$ distribution with 8 degrees of freedom. This is based on the results of Zeh et al. (1995). We assume that the degree of dependence between ROI and $R_{0.05}$ is small, and hence treat them as independent.

4.2.4 Maximum historic ratio of calves to mature females, MCM
We have found that the BALEEN II model sometimes produces unrealistic trajectories from seemingly reasonable sets of inputs. An example of such a trajectory is Fig. 8. This trajectory is clearly unreasonable since, for example, it requires 321 mature females to produce 1809 calves immediately following the slaughter of 2,709 whales in 1852. (For this trajectory, only 13.8% of the 4,657 whales were sexually mature after this catch.) These rapidly oscillating trajectories suggest establishing a pre-model distribution on the maximum possible ratio of calves to mature females, which we denote by MCM.

![Fig. 8. Example of a rapidly oscillating trajectory produced by the BALEEN II PDM. This trajectory has a completely unreasonable MCM value of 5.64, which implies that in some year between 1848 and 1988, the average mature female produced 5 or 6 calves.](image-url)

There is no direct evidence on maximum productivity since it represents a maximum realized in a single year over a period of 140 years. However, there is information about bowhead calving interval which is relevant. IWC (1992d) cited two studies (Miller et al., 1992; Rugh et al., 1992) which concluded from photographic re-identification methods that bowheads may calve at intervals of 4 to 7 years. Miller et al. (1992) report five pairs of photographs of the same cow with a calf in two different years. Two of these were at 4-year intervals and the remaining three at 7-year intervals. Since the latter cows were not seen in the intervening years, we cannot determine whether the 7-year intervals are true calving intervals or whether these cows had calves at a three or four year interval but were not photographed at that time. The fact that the photographs were taken indicates that these calves survived at least part of their first year; calves who died at or very soon after birth would be unlikely to be photographed. In fact, one of the 4-year intervals involved a yearling in the first year and a calf three years later. These photographs prove that some bowhead females are capable of calving at 4-year intervals at the present time. One might therefore expect MCM to be at least 0.25, and most likely higher, since it is a maximum throughout history. But we could also take the median 7-year interval as representing the population as a whole, and assume no calf who lived through its first year was born in the intervening years. These are both conservative assumptions, and a would suggest a conservative lower bound of 0.14 for MCM.
Of 72 harvested females greater than 13m in length assumed to be mature from 1973 through 1993, 16 were pregnant (George et al., 1995), giving a pregnancy rate of 0.22 with a binomial 5% lower bound of 0.14. This bound may be biased downwards since small foetuses were likely to be missed, particularly before 1976, and since we are taking the extremely conservative step of bounding a historic maximum with a minimum bound for the current rate. There are also several potential sources of upward bias. We have made no correction for the fact that hunters do not kill cows with calves, so that the mature females in the harvest data may represent only pregnant and resting mature females instead of all mature females. We do not believe we could make such a correction without more data on the frequency with which hunters encounter females with calves and choose not to kill them. Upward bias may also be introduced since we make no allowance for miscarriage or calf mortality. Also, bowhead pregnancies could be more than a year (12–16 months) long (Koski et al., 1993), which would mean that females seen in one year’s harvest could potentially represent pregnancies from two different years. Another source of bias in either direction is that all females at least 13m in length were assumed to be mature. Koski et al. (1993) presents evidence that some whales between 12 and 13m may be mature, and some whales between 13 and 14m may be immature. Since our sample includes 15 females in the 12 to 14m range, with eight of these longer than 13m and therefore assumed mature by us, it is not likely that this source of bias is important. These data also support 0.14 as a conservative lower bound for MCM.

We chose to put a very broad prior on maximum productivity to reflect our uncertainty and our desire to eliminate only productivity values that are unrealistically large or small. The pre-model distribution of maximum productivity is uniform between 0.14 and 0.5, and linearly decreasing to 0 from 0.5 to 1.

5. RESULTS

The final resample of 5,000 values of \( \theta \) yielded 898 unique points. The most likely single value was sampled 55 times, and 300 points were sampled only once.

The output of most interest is 1993 replacement yield (RY). The IWC defines the replacement yield as the catch from the recruited stock which, if taken, would leave the recruited population at the same level at the beginning of the next season (IWC, 1988). The post-model distribution for 1993 RY is shown in Fig. 9, with mode 116 and 95% probability interval (45, 207). Fig. 9 shows a histogram of the post-model sample with an estimate of the post-model density superimposed. The latter was calculated with a non-parametric Gaussian kernel estimator using the maximal smoothing span of Terrell (1990). The 5% point of this post-model distribution is 54. Two replicate runs of the same analysis (see Section 6) yielded values of 56 and 60. The mean of these replicate estimates is 57, which would be a reasonable estimate of the 5th percentile of 1993 RY to use when making management decisions.

Figs 10, 11, 12 and 13 show the marginal post-model distributions of other model inputs and outputs with appropriate summary statistics. The marginal pre-model distributions (dotted line) and histograms of the post-model sample are drawn in these figures. These graphs also show density estimates of the marginal post-model distribution (solid line). The relevant summary statistics shown in these figures describe the post-model distribution.

The most interesting results occur when the post-model distribution represents important new evidence not present in the pre-model specifications. For example, Fig. 12 shows the marginal post-model distribution of the 1978–1993 annual rate of increase. The post-model distribution here does not conflict with the results of Zeh et al. (1995) because the post-model 95% probability interval (0.3%, 2.8%) overlaps with the 95% confidence interval (1.4%, 8.5%) obtained by Zeh et al. However, there is strong evidence that the true rate of increase is in the lower half of their confidence interval.

In another three cases, the Bayesian synthesis approach leads to a substantial narrowing of the probability intervals for unknown quantities. Firstly, Fig. 11 shows that there is no evidence for higher values of MSYRF(\text{1993}) because the right tail of the post-model distribution diminishes well short of the likely range specified by the pre-model distribution. The combined evidence indicates that MSYRF(\text{1993}) values greater than about 5.4% are unlikely for bowheads.
Secondly, Fig. 11 also shows that 95% of the post-model distribution of $P_0$ is concentrated between 11,660 and 20,886. This range is only 42% as wide as the corresponding pre-model range of 8,263 to 30,374. The post-model 95% probability interval also agrees well with the range of 10,400–23,000 given by Woodby and Botkin (1993) based on their review of the historic data and previous attempts to estimate $P_0$, but our interval is more precise. Their range could not be used to define the pre-model distribution for $P_0$ since it depended on a PDM.

Finally, Fig. 13 shows that the post-model distribution for MCM is concentrated between 0.16 and 0.47. This interval is consistent with the discussion in Section 4.2.4, even though the pre-model distribution chosen for this parameter allowed a much wider range of possibilities.

Fig. 10 and 12 demonstrate that the results also provide narrower confidence intervals for $s$ and the 1985–1992 average percent of calves.

The post-model distribution is partially successful at settling the controversy over age of sexual maturity. Fig. 10 shows that values of $m$ as low as 12 are very unlikely. Values of $m$ in the high teens or low twenties are preferred, but there is not sufficient evidence to rule out higher values.

The results also indicate that the stock is still depleted (Fig. 13). The post-model mode of the depletion level of the mature component is 0.27 with a confidence interval of (0.22, 0.35), and depletion of the total stock ($P_{\text{pre}}/P_0$) is estimated to be between 0.31 and 0.55. The probability that the stock is above MSY$_{\text{(mat)}}$ is only 0.0002. Fig. 12 indicates that MSY is estimated as 134 with a 95% confidence interval of (55, 358). The historic minimum population size was probably about 2,200.

The model was not able to shed much light on some parameters, and in these cases the results must be interpreted carefully. Fig. 11 shows that no clear range of values dominated the post-model distribution of MSY$_{\text{(mat)}}$. BALEEN II is capable of producing reasonable trajectories with reasonable values of all other inputs and outputs while still allowing freedom for MSY$_{\text{(mat)}}$ to vary. We conclude that the analysis provides
no additional information about MSYR\textsubscript{(mat)}. Investigations of de la Marc (1990) have previously demonstrated very flat marginal likelihoods for MSYL given diverse modeling assumptions. Our analysis is also unable to provide a precise estimate of a.

The pre- and post-model distributions of \( P\textsubscript{1993} \) also do not differ. This means that the combined information does not refine our knowledge of \( P\textsubscript{1993} \). However, \( P\textsubscript{1993} \) itself is quite informative about other parameters; see Section 6.

Fig. 14 shows the ratio of the post-model variance to the pre-model variance for model inputs and outputs. This shows about which quantities the model is most informative. A value close to 1 means that the model does not provide much additional information, while a value much smaller than 1 indicates the model is substantially reducing uncertainty. Fig. 14 shows that the model is most informative about \( s \), \( P\textsubscript{0} \), MSYR\textsubscript{(mat)}, \% calves, ROI and MCM, as is also evident from Figs 10–13.

Figs 10–13 allow us to perform an informal sensitivity analysis to the pre-model specifications; see Section 6 and Givens \textit{et al.} (1994) for a more thorough discussion. These figures suggest no incompatibilities between the pre-model and post-model distributions; hence the BALEEN II PDM is capable of accommodating all the available evidence without conflict. Further, changing the pre-model distribution of any input or output so as to assign less weight to values with weight in the pre-model distribution but virtually no weight in the post-model distribution would have little effect on the results. For example, changing the pre-model distribution so as to exclude values of \( P\textsubscript{0} \) between 25,000 and 35,000 would have virtually no effect on the results given above and the conclusions drawn from them concerning quantities of interest.

Fig. 15 shows the post-model pointwise median trajectory for the total population size with a pointwise 95% confidence band. The limits of this band at each time point indicate a 95% post-model probability interval for the population size at that time point. The 15 most likely trajectories are shown in Fig. 16. Notice that these trajectories are qualitatively similar and they all agree with existing beliefs and with the pre-model evidence.

Fig. 16. The fifteen most likely total population trajectories drawn from the post-model distribution. These 15 trajectories (1.7% of the unique ones in the final sample) account for 13.3% of the probability.

Fig. 17 shows the results of a cluster analysis on the quantities of interest using the connected hierarchical clustering method (Everitt, 1980), where the distance measure is chosen to be one minus the absolute post-model
Fig. 18. Pairwise scatterplots of the post-model sample of RY, MSYRMAT, ROI and $P_0$.

correlation. It shows that the quantity of primary interest, RY, is far more highly correlated with $P_0$, MSYRMAT and ROI, than with other variables. The plot also shows another looser cluster of variables, $m$, $s$, % calves and MCM, which are strongly interrelated but not as strongly related to the RY cluster. In this plot, if $h$ is the height of the branch connecting two variables, then the magnitude of the post-model correlation between these variables is at most $1-h$. Fig. 18 shows pairwise scatterplots of the post-model sample of RY, MSYRMAT, ROI and $P_0$. These four quantities are highly inter-correlated and only moderately correlated with other variables.
6. SENSITIVITY ANALYSIS

No Bayesian approach is complete without investigating the sensitivity of the results to the choice of priors. With our methodology, this means determining how sensitive the post-model distribution is to the choice of the pre-model distribution. We noted in Section 5 that Figs 10, 11, 12 and 13 allow us to identify which parts of the pre-model distribution are not important determinants of the post-model results. In this section, we consider sensitivity more thoroughly.

6.1 Influence of evidence on inputs and outputs

6.1.1 Description of graphical methods

The pre-model distribution of the inputs, $p(\theta)$, defines an implicit probability distribution for the outputs, $\phi$, since evidence about inputs can be transformed into evidence about outputs through applying the model. In Sections 6.1.3 and 6.1.2, we use graphical methods to examine whether the pre-model distribution of inputs, the model structure, or the pre-model distribution and data on outputs has the greatest impact on the final results.

We do this by comparing three distributions: the pre-weighted distribution defined as $p(\theta)$ constrained to eliminate extinct trajectories (and, for outputs, transformed to the output space), the actual pre-model distribution determined by the available data and evidence, and the resulting post-model distribution.

For inputs, the pre-weighted distribution isolates the evidence about inputs due to the pre-model distribution of inputs and the model structure. For outputs, the pre-weighted distribution describes what evidence the pre-model distribution of inputs alone provides about the outputs.

One way to estimate the pre-weighted distribution of an input is to sample from the pre-model distribution of the inputs, retain the value of the input for each trajectory which did not go extinct, then use this sample to estimate the density. Similarly, the pre-weighted distribution of an output can be obtained by sampling from the pre-model distribution of the inputs, retaining the value of the output for each trajectory which did not go extinct, then using this sample to estimate the density.

To analyze an influence graph for an input, begin with the pre-model distribution. This shows the marginal evidence assumed about the input. Next, the pre-weighted distribution shows what happens to this evidence when we eliminate sets of inputs which lead to extinct trajectories. Finally, the post-model distribution shows what happens when we also add the evidence about outputs.

To analyze an influence graph for an output, begin with the pre-weighted distribution. This shows how the evidence about inputs gets translated by the model into the output space (eliminating extinct trajectories). Next, the pre-model distribution of the output shows the evidence about the output, most of which is based on data from the visual and acoustic censuses and the aerial surveys. Finally, the post-model distribution shows what we get when we combine these two sources of evidence.

In either case, the three distributions can be plotted on a single influence graph to investigate which source of information is most important. In these graphs, the region of support is very important, so that the choice of limits for the horizontal axis should be determined by the limits of probability, even if the probability is small. For this reason, some of the graphs in the following sections show unusually wide axis limits.

6.1.2 Inputs

Fig. 19 shows an influence graph for MSYR$_{max}$. This graph indicates that the pre-model distribution of MSYR$_{max}$ limits high values which might otherwise be permitted by the model structure itself. The post-model distribution indicates that pre-model distribution of the outputs is the predominant influence in the final curve. In fact, $p(\theta)$ limits large values of MSYR$_{max}$ more severely than the pre-model distribution, indicating that giving more probability to large values of MSYR$_{max}$ in $p(\theta)$ would not change the results.

![Fig. 19. Pre-model (dotted), pre-weighted (dashed) and post-model (solid) distributions for MSYR$_{max}$](image)

The influence graph for $P_0$ is shown in Fig. 20. The graph is conceptually similar to the one for MSYR$_{max}$, but even more pronounced. The pre-model distribution appears to have little influence on the results. The model tends to eliminate many low values of $P_0$ which lead to extinction, while tolerating quite high values. The results appear to be influenced mainly by the pre-model distribution of the outputs.

![Fig. 20. Pre-model (dotted), pre-weighted (dashed) and post-model (solid) distributions for $P_0$.](image)

6.1.3 Outputs

Fig. 21 shows the influence graph for $P_{1993}$. This graph shows that the pre-weighted distribution was extremely diffuse, with a lot of probability in the short, heavy tail to
the left. The data favor this heavy tail region, and pre-model distribution of $P_{1993}$ is very precise. The post-model distribution of $P_{1993}$ is very close to the pre-model distribution. This graph indicates that the data-driven pre-model distribution of $P_{1993}$ dominates any possible influence by the pre-model distribution of the inputs, which represents evidence about the model inputs. Indeed, we believe that the data about $P_{1993}$ is a very important component of the overall analysis.

Fig. 21. Pre-model (dotted), pre-weighted (dashed) and post-model (solid) distributions for 1993 population size.

Fig. 22 shows the influence graph for 1985–1992 average percent calves. This graph shows that the pre-weighted distribution has little influence over inference regarding this parameter, but that the data-driven pre-model distribution for percent calves does help shape the post-model distribution. This indicates that the data regarding bowhead age structure play a role in the final inference, but there are other data on outputs which also influence the results, since the post-model distribution is narrower than the pre-model distribution.

Fig. 22. Pre-model (dotted), pre-weighted (dashed) and post-model (solid) distributions for 1985–1992 average percent calves.

The influence graph for 1985–1992 average percent mature shown in Fig. 23 is conceptually similar to that for $P_{1993}$. It shows that the pre-weighted distribution had no influence on the results, which appear to be driven by the data. This graph suggests that percent mature may be a very important variable.

Fig. 23. Pre-model (dotted), pre-weighted (dashed) and post-model (solid) distributions for 1985–1992 average percent mature.

Fig. 24 is the influence graph for MCM. This graph shows that the pre-weighted distribution for MCM is more restrictive, except for low probability outliers, than the actual pre-model distribution on the upper end, while the latter is more restrictive on the lower end. The outliers in the pre-weighted distribution show that some input parameters which are reasonable according to $p(\theta)$ produce MCM's much larger than 1. Other outputs must also be influencing the results, since the post-model distribution goes to zero more quickly in the upper tail than either the pre-model or the pre-weighted distribution.

Fig. 24. Pre-model (dotted), pre-weighted (dashed) and post-model (solid) distributions for MCM.

The influence graph for ROI shown in Fig. 25 tells an interesting story. The pre-weighted distribution shows that it is virtually impossible to find any plausible combinations of input parameters which produce ROI greater than about 3%. We believe this indicates that the catch data is playing a major role in the analysis. Because there is a period of over 80 years with low catches since the end of commercial whaling, moderate to high MSYR values produce trajectories indicating that the present population has fully recovered, so current ROI is near zero in the pre-weighted distribution. Low MSYR values also produce low ROI values in the pre-weighted distribution since MSYR and ROI are correlated. The Bayesian synthesis method must place the post-model distribution on the common ground shared by the pre-weighted and actual pre-model
distributions, so the solid line is the post-model distribution. Data regarding other outputs may play a role in its shape.

Finally, we consider the influence graph for 1993 RY shown in Fig. 26. The pre-weighted distribution of the inputs gives probability to RY's as extreme as ±2,000, and is concentrated on a range from about -500 to 500. This shows that the pre-model evidence about inputs does not determine the results for RY. In this graph there is no dashed line corresponding to the actual pre-model distribution of RY, since no such distribution was imposed. The post-model distribution, though, is quite precise and clearly positive, indicating that data about other outputs dominates inference regarding this quantity.

![Fig. 25. Pre-model (dotted), pre-weighted (dashed) and post-model (solid) distributions for ROI.](image)

**6.2 Formal sensitivity analysis**

In this section we consider some possible changes to the joint pre-model distribution. The first three consider changing $p(P_a)$ to a uniform distribution on 5,000 to 40,000 and changing $p(MS_{YR_{vern}})$ to a uniform distribution on 1% to 7%, first individually, then simultaneously. Some of these trials resemble trials in the approximate sensitivity analysis described by Butterworth and Punt (1995). We also consider trials which (i) replace the preliminary Bayes empirical Bayes estimate of 1993 population size with the final Bayes empirical Bayes estimate of 1988 population size and (ii) replace the 1978–1993 ROI estimate (Zeh et al., 1995) with the 1978–1988 estimate (Zeh et al., 1991). These changes are also investigated individually and simultaneously. Table 2 shows the results from these trials. We also show the results from the main analysis and from two replicate runs of the main analysis in rows 1–3 of this table.

The results are quite insensitive across these trials. Roughly speaking, these trials all suggest $P_a$ around 15,000, MSYR$_{vern}$ around 3%, ROI around 1.5% and a 5th percentile for RY near 60.

The Bayesian synthesis approach also allows for complete sensitivity analysis to be done with a simple reweighting scheme. If a new choice of pre-model distribution, say $p(\theta, \phi)_{new}$, has no appreciable mass anywhere the old pre-model distribution, $p(\theta, \phi)_{old}$, had none, then the old post-model sample can simply be reweighted by the ratios $p(\theta, \phi)_{new}/p(\theta, \phi)_{old}$ and resampled with replacement to obtain an approximate draw as if $p(\theta, \phi)_{new}$ had been used in the first place. Givens et al. (1994) describe the details of this idea and provide software to perform such sensitivity analysis. Application of this software to the model in this paper requires a database not given by Givens et al. (1994), but which is available from the authors. For details, see Appendix 2.

![Fig. 26. Pre-weighted (dashed) and post-model (solid) distributions for 1993 RY.](image)

**7. DISCUSSION**

Givens et al. (1993) give a broad discussion of the relative benefits of the Bayesian synthesis approach compared to past methodologies. Criticisms of particular aspects of our application of the approach to bowheads are presented by Butterworth and Punt (1995). Givens et al. (1995) respond to these criticisms. Scientific Committee discussions summarized in IWC (1995b) led to modifications of some of our pre-model distributions and different assessment results (Appendix 3). Research in areas highlighted by these dialogues is continuing. In particular, the version of the approach suggested by Butterworth and Punt (1995) that does not require a pre-model distribution for $P_a$ is being investigated further.

Several improvements to this methodology are possible. A PDM which modeled more of the harvest and environmental pressures on the stock could improve our analyses. The space-time harvest pattern and changes in carrying capacity due to environmental factors and reduced range have not yet been fully explored by bowhead PDM’s. The weak evidence found by Givens et al. (1993) in favor of a reduced carrying capacity model invites further research in this area, but limitations of the historic data restrict what may be learned.

Uncertainty about the historic kill record could also be explicitly included in the model mechanism. This would be more realistic than pretending that numbers killed a century ago are known exactly while acknowledging the uncertainty in estimates of such quantities as current population size. We believe that the graphs in Section 6.1 suggest that the kill record plays a very important role in the analysis – for example, it appears to be a factor in prohibiting large values of ROI.

A stochastic PDM would be more realistic than the deterministic one that we are currently using. A deterministic model is much simpler, and its use is based on the assumption that only a small part of the overall uncertainty is due to random variation in the numbers of births and deaths. The IWC has always taken this view. If

THE DELURY (1947) ESTIMATE

In this appendix, we present some of the mathematical details involved in obtaining a 'fiducial distribution' (Fieller, 1954) for initial population size $P_0$, where $P_0$ is estimated from equation (2) using the approach of DeLury (1947). This equation and our assumptions concerning the variance of $U$, the catch per unit effort in year $t$, imply a general linear model:

$$ U = XB + \epsilon \quad \text{Ec} = 0, \quad \text{var}(\epsilon) = \sigma^2 \Sigma $$

where $U$ is the vector of $U_t$'s for all the years $t$ of the catch history. $X$ is a matrix with $1$ as the first column and $-K_t$ in the second column of row $t$. $\beta = (kP_0, k)^T$ and $\Sigma$ is a diagonal matrix with diagonal elements $(N-n_t)/n_t K_t^2$. Recall $K_t$ is the total commercial kill up to but not including year $t$. $N = 224$ is the maximum number of voyages in a single year during the bowhead commercial fishery. $n_t$ is the number of documented voyages in year $t$ and $\bar{x}$ is the average number of Type 1 days per documented voyage in year $t$.

Standard least squares theory tells us that the best linear unbiased estimate of $\beta$ is:

$$ \hat{\beta} = (X' \Sigma^{-1} X)^{-1} X' \Sigma^{-1} U $$

with estimated covariance matrix:

$$ \hat{\sigma}^2 (X' \Sigma^{-1} X)^{-1} = (v_{xy}, v_{yx}) $$

The estimate $\hat{\beta}$ and the estimated covariance matrix of $\hat{\beta}$ can be obtained from most least squares regression programs. However, our interest is not in $\eta$, which estimates $kP_0$, or $x$, which estimates $k$, but rather in the ratio $\eta/x$, which estimates $P_0$.

Fieller (1954) derives the fiducial distribution of such a ratio. In his notation, $P_0$ is called $a$. Our $x, y, v_{xy}, v_{yx}$ and $\epsilon$ correspond to his. Let $p$ denote any probability $0 < p < 1$. If we can determine values $\alpha_1$ and $\alpha_2$ with $Pr(\alpha_1 \leq P_0 \leq \alpha_2) = 1 - p$ in the fiducial distribution, then the entire distribution is determined.

Fieller shows that $\alpha_1$ and $\alpha_2$ are the roots of the quadratic equation:

$$ \alpha^2 (x^2 - \alpha^2 v_{xx}) - 2\alpha (xy - \alpha v_{xy}) + (y^2 - \alpha^2 v_{yy}) = 0 $$

where $t$ is the 1-$p/2$ quantile of a $t$-distribution with $n-2$ degrees of freedom, and $n$ is the number of years included in the regression. We assume that the errors $\epsilon$ are normally distributed. We must also have $x^2 - \alpha^2 v_{xx} > 0$, i.e. the $p$-value of the regression must be less than $p$. For each of the ending years we considered, the $p$-value of the regression was less than 0.02, so we were able to compute a grid of quantiles for $P_0$ corresponding to probabilities from 0.01 to 0.99. Probability densities were computed for the midpoints between the quantiles, and the values of $P_0$ at which the probability density could be assumed to be approximately 0 were computed by a rough extrapolation. A discrete distribution with probabilities assigned to $P_0 = 4,000, 4.100, \ldots, 40,000$ was then computed by approximation from this density.

Appendix 2

SENSITIVITY ANALYSIS VIA REWEIGHTING

The reweighting program BERGS (Givens et al., 1994) can be used for investigating sensitivity of the results in this paper. The necessary software is available from the authors or the IWC Secretariat, who are scheduled to validate the code. However, a new database is necessary for the BALEEN II model. This database is available from the authors. It provides the raw data from a run of the Bayesian synthesis approach with the BALEEN II PDM and the set of maximally diffuse pre-model distributions shown in Table 3.

The maximally diffuse pre-model distributions of $s$, $s_0$, $a$ and $m$ should be noncontroversial and self-explanatory. We also allow the oldest age class, $w$, to vary in the maximally diffuse pre-model distribution, though it has no effect on the results. See the next paragraph for some further discussion of the choices for $P_0$ and MSYR$_{\text{norm}}$. We include a database file for both $P_{\text{norm}}$ and $P_{\text{norm}}$ so that users may experiment with pre-model distributions for either or both. The maximally diffuse pre-model distributions for 1985–1992 average percentages of calves and mature whales are taken to be normal with means and variances equal to the sample means and variances of the yearly data. Generally, the pre-model distributions of the outputs are data-driven and it would not be reasonable to consider major changes without new data or reconsideration of the existing data.

As is discussed by Givens et al. (1994), the region of support for the maximally diffuse pre-model distribution is important, but the shape of the distribution has no impact on the results of a sensitivity run, although it can affect the amount of computer time needed. To maximize efficiency while ensuring that sufficiently broad ranges are chosen, we have chosen piecewise uniform densities for some maximally diffuse pre-model distributions. These permit

Brandon
Page 372 of 478
Ex. M-0521
sensitivity analysis over a very wide range of parameter values, while giving greater efficiency by providing a larger proportion of the sample from areas where non-zero post-model probability exists. For example, if we make the crude assumption that values of $P_0$ greater than 30,000 or less than 10,000 are unlikely to have probability under any post-model distribution investigated, then using $P_0 \sim U(5,000, 40,000)$ wastes about 43% of the sample, whereas using the distribution for $P_0$ given in Table 3 wastes only 16% of the sample. Similarly, the choice of maximally diffuse pre-model distribution for $MSYR_{(max)}$ given in

Table 3 results in at least a threefold reduction in wasted samples compared to a uniform distribution over the same range, if values of $MSYR_{(max)}$ greater than 7% are unlikely to have probability under any post-model distribution investigated. The distributions for $P_0$ and $MSYR_{(max)}$ given in Table 3 have density height four times greater for central values than for peripheral values.

The results in this paper can be replicated with the BERGS program by using the 'bergs.in' file shown in Table 4.

Appendix 3

THE ANALYSIS OF THE SCIENTIFIC COMMITTEE

In 1993, the IWC Scientific Committee agreed to use the Bayesian synthesis method for the 1994 bowhead whale assessment (IWC, 1994, p.55). At their 1994 meeting, after reviewing the analyses described in this paper, the Scientific Committee performed a different Bayesian synthesis analysis using an alternative set of pre-model distributions upon which they could agree (IWC, 1995b, table 7). The IWC Scientific Committee accepted these results (IWC, 1995b).

This alternative Bayesian synthesis assessment was carried out using the reweighting procedure described by Givens et al. (1994) and the maximally diffuse database
described in Appendix 2. The results are described in Appendix 7, Annex F of the Scientific Committee report (IWC, 1995a). The 5th percentile of RY was estimated as 104.

The following paragraphs summarize the results obtained using the pre-model distributions agreed upon by the Scientific Committee and using the full Bayesian synthesis approach instead of the reweighting method. The results are nearly identical to those obtained by the Scientific Committee, as they should be, since the reweighting method is merely a quick way to simulate what would be obtained from the full analysis.

**Pre-model distributions**

Many of the pre-model distributions used in this paper were retained by the Scientific Committee. The following distributions were changed by the Scientific Committee.

The distributions for \( s_0 \) and \( s \) were taken to be proportional to \( s \sim N(0.99, 0.02^2) \) and \( s_0 | s \sim N(0.94, 0.04^2) \) over the joint range \( 0 < s_0 \leq s < 1 \). For the age at sexual maturity, the Scientific Committee used a pre-model distribution proportional to \( m \sim N(20.3^2) \) on the range \( m \in \{14,\ldots,26\} \). The distribution for MSYR\(_{\text{med}}\) was MSYR\(_{\text{med}} \sim U(1\%, 7\%)\). The Scientific Committee used the posterior distribution for 1988 population size obtained by Raftery and Zeh (1991; 1993) as the pre-model information about current abundance. For ROI, the pre-model distribution for ROI employed by the Scientific Committee gives much less probability to low rates of increase than does the choice described in Section 4.2.3. The resulting distribution was MCM \( \sim U(0.25, 0.50) \).

The rationale for these pre-model distribution choices is discussed in the Scientific Committee report (IWC, 1995b).

**Results**

Bayesian synthesis results for the joint pre-model distribution used by the Scientific Committee are given in Table 5. Shown in this table are the posterior medians and 95% probability intervals for key quantities of interest. In addition to these results, we find the post-model lower 5% bound for RY to be 117.

<table>
<thead>

<td>(90, 309)</td>
</tr>
<tr>
<td>ROI</td>
<td>2.20%</td>
<td>(0.84%, 3.21%)</td>
</tr>
</tbody>
</table>

The estimated lower bound for RY is substantially higher with the choice of pre-model distribution used by the Scientific Committee because nearly all their alterations to the pre-model distribution reflect less conservatism than the choice made in the analyses of the main text. One very important change is that the pre-model distribution for ROI employed by the Scientific Committee gives much less probability to low rates of increase than does the choice described in Section 4.2.3. Further sensitivity analysis using the methodology described in Appendix 2 has indicated that this change to the pre-model distribution for ROI is the dominant source of change in the post-model distribution obtained by the Scientific Committee. Also, the pre-model distribution for MSYR\(_{\text{med}}\) chosen by the Scientific Committee eliminates the possibility of MSY rates less than 1%. The Scientific Committee also raised adult survival (\( s \)) and eliminated the possibility of low historic calf/mature female ratios (MCM).
Abundance of Minke and Fin Whales off West Greenland, 1993

F. Larsen
Greenland Fisheries Research Institute, Tagensvej 135, DK-2200 Copenhagen N., Denmark

ABSTRACT
An aerial survey with the purpose of collecting data for estimation of minke and fin whales abundance was conducted off West Greenland in July-August, 1993. Sightings included 36 observations comprising 66 minke whales and eight observations comprising 15 fin whales. Poor weather meant that not all of the planned area was surveyed. This was particularly significant for fin whales where areas of previously high densities were not covered. Cetacean counting data were collected and analysed to obtain estimates of the number of minke and fin whales present at West Greenland in 1993. The estimates arrived at for minke whales are 10,879 (95% CI: 3,923-20,642), alternatively 8,371 (95% CI: 2,414-16,929), depending on the model chosen for the probability function estimation. For fin whales the corresponding estimates are 294 (95% CI: 26-557) and 178 (95% CI: 26-382). These estimates require modification when an agreed method of determining cetacean density and their associated variance is arrived at. The fin whale estimate, in particular, is not considered useful for management purposes as the area to which it applies excludes areas of high density from previous surveys.

KEYWORDS: NORTH ATLANTIC; ASSESSMENT; FIN WHALE; MINKE WHALE; SURVEY-AERIAL; RESPIRATION

INTRODUCTION
In the period 1983-85, several sightings surveys using traditional line transect methodology were conducted off West Greenland, with the aim of collecting data for estimation of stock size primarily for minke and fin whales (Larsen, 1984; 1985; 1986). Although useful distributional data were collected, none of the surveys resulted in reliable estimates of abundance.

In 1987 and 1988 aerial surveys were conducted off West Greenland employing the 'cetacean counting' procedure described by Hiby and Hammond (1989) for counting data on minke and fin whales. This resulted in the first estimates of the number of minke and fin whales occurring off West Greenland during the summer (Hiby et al., 1989; Larsen and Nielsen, 1989; Larsen et al., 1989). Further aerial surveys were attempted in 1989, 1991 and 1992, but due to adverse sighting conditions resulting in very low coverage, no new estimates of abundance could be produced (e.g. Donovan, 1990).

However, in the summer of 1993 sighting conditions were considerably better. The present paper reports on the 1993 survey and presents distributional data as well as estimates of abundance for minke and fin whales off West Greenland.

MATERIALS AND METHODS
Survey design
The area surveyed is shown in Fig. 1. The area is divided into the same number of main blocks as in earlier surveys (blocks 1-5), but the experience from these earlier surveys suggested that the main blocks should be subdivided, to allow more effort to be expended in the nearshore areas, where most observations of minke whales had been made (see e.g. Larsen et al., 1989). Thus the blocks 2A-5 were each divided into a coastal (designated in the following by the letter c) and an offshore (designated by the letter o).

Highest priority was given to southern and coastal blocks, and the intention was to place approximately twice as much effort in the coastal blocks as in the offshore blocks, if weather and time allowed.

Track design followed the procedure recommended by Cooke and Hiby (1987) as described by Donovan and Guanlaugsson (1989). A track is here a zig-zag line covering a particular block from one end to the other. Each zig and zig in a track is considered a line.

The aircraft and data collection procedure were as described by Donovan and Guanlaugsson (1989). In addition, an onboard computer continuously logged information on time, position, speed, heading and altitude from the Global Positioning System.

The target species were minke and fin whales, but observations of all cetaceans were recorded.

Analysis
Data were collected in a manner that allow both standard line transect and cetacean counting procedures to be used. However, the analyses presented here are only those based on the cetacean counting procedure (e.g. see Hiby and Hammond, 1989) as described by Buckland et al. (1993). The data analyses were carried out using the program DISTANCE Ver. 2.1 (Laake et al., 1994). Analyses were based on exact distances. All models for fitting the frequency distributions of distances available in DISTANCE, i.e. the hazard rate, the half-normal, the uniform and the negative exponential, were explored.

Selection of the model to use for calculating abundance was based on Akaikes Information Criterion (AIC) as calculated by DISTANCE.

The detection function was estimated based on all distance data pooled across blocks, whereas whale densities and numbers were calculated separately for each block. A pooled estimate of density and number of whales for the total area was calculated as the area weighted sum of the stratum estimates with appropriate estimates of variance.

Confidence limits were calculated by the bootstrap procedure in DISTANCE. The basic sampling unit is a line. The confidence limits presented here are the 2.5% and 97.5% quantiles of the 1,000 bootstrap estimates.

RESULTS
Survey itinerary
A total of 91.5 hours were spent in survey and transit flights to and from the blocks. The total time 'on effort' with sea states 3 or less was 38 hours. The total surveyed track was approximately 7,030km.
Fig. 1. Map of surveyed area showing blocks and lines covered on effort.
The surveys were conducted from 24 July to 20 August. Surveying in the first two weeks was concentrated on blocks 4 and 5, as these are known from earlier years to have the highest densities of minke whales but also normally the most difficult survey conditions. In the remaining two weeks, surveys were flown primarily in the northern areas. The survey sequence, which was largely determined by weather conditions, was: 4-c, 5-c, 5-o, 4-c, 5-c, 3-c, 3-o, 4-o, 4-c, 5-c, 2B-c, 1B, 1A, 2A-c, 2B-c and 3-c. Fig. 1a shows the survey lines covered on effort in each block.

**Distribution**

The geographical distribution of the sightings of minke whales is shown in Fig. 1b. Most of the sightings were made in blocks 5-c and 4-c, with the remainder in blocks 5-o, 3-c and 2B-c. Most (48) of the sightings were of single animals, six sightings were of pods of two animals and two sightings were of pods of three animals.

The geographical distribution of the sightings of fin whales is shown in Fig. 1c. Fin whales were observed in blocks 2A-c, 4-c, 4-o, 5-c and 5-o only. The sightings were of seven single animals and one pod of eight animals.

**Population estimates**

Table 1 presents data for each block on the total area, the total effort expended and the number of cues recorded for minke and fin whales while on effort.

</table>

Sun glare severely limited efficiency on some survey line sections. The extent of the glare was recorded as an angle sector of V degrees. Glare was then adjusted for in the estimate of total effort by reducing the recorded effort for a particular line section with glare problems by the ratio between V and the total observation sector (180°). This approach requires that any observations recorded within the glare sectors are excluded from the abundance estimation procedures. In fact no minke or fin whales were recorded seen in the glare sectors.

**Minke whales**

For the estimation of abundance, only blocks in which minke whales were recorded on effort, i.e. only blocks 2B-c, 3-c, 4-c, 5-c and 5-o, were considered. The total effort expended in these blocks at sea states of 3 or less was 95,632 seconds, during which a total of 59 cues with an associated distance were recorded.

The initial exploration of the data suggested truncating at 1,200m, leaving 39 cues for the final analyses. Chi-square tests of goodness-of-fit were based on the following intervals (in meters): 0-200, 200-500, 500-700, 700-900 and 900-1,200. The model giving the lowest AIC value was the negative exponential with no adjustment parameters (AIC value: 11.31). This model gave a very good fit (chi-square=0.2447, d.f.=4, p<0.01). The second best model was the half-normal with one adjustment parameter (AIC=12.56, chi-square=1.0241, d.f.=3, p<0.20). The fits of these two models to the distance data are shown in Figs 2-3. As the two models yield different estimates of abundance and the negative exponential model often produces positively biased estimates (see Buckland et al., 1993), results from both models are presented below.

Table 2 presents the estimates, the percent coefficients of variation of these estimates and the associated 95% confidence intervals for the density and the number of whales for each block as well as for a pooled estimate for the total area. The surfacing rate for minke whales used in these analyses is taken from Hily et al. (1989), i.e. 53 surfacings per whale per hour, to enable comparison with their abundance estimate. The question of the most appropriate cue rate and incorporation of the associated variance is considered in the Discussion.

Block 5-c shows by far the highest densities of minke whales and also the largest number of whales. However, confidence intervals are quite wide for all blocks. The pooled estimates of abundance for all blocks with minke whale sightings, i.e. blocks 2B-c, 3-c, 4-c, 5-c and 5-o, are 10,879 (95% CI: 9,293-20,642) and 8,371 (95% CI: 2,414-16,929) for the negative exponential model and the half-normal model, respectively.
**Fin whales**

For the estimation of abundance, only blocks in which fin whales were recorded on effort, i.e., only blocks 4-c, 4-o, 5-c and 5-o, were considered. The total effort expended in these blocks at sea states of 3 or less was 75,139 seconds, during which a total of six cues with an associated distance were recorded.

It is clearly not possible to reliably fit a model to only six observations. The 1993 data were therefore pooled with distance data from 1987 (44 observations) and 1988 (23 observations), for the probability function estimation.

The initial exploration of the data suggested left-truncation at 200m and right-truncation at 4,200m, leaving 70 cues for the final analyses. Chi-square tests of goodness-of-fit were based on the following intervals (in meters): 200–700, 700–1,200, 1,200–1,700, 1,700–2,200, 2,200–2,700, 2,700–3,200 and 3,200–4,200. The model giving the lowest AIC value was the negative exponential with no adjustment parameters (AIC value: 168.03). This model gave a good fit (chi-square=1.1019, d.f.=5, p<0.05). The second best model was the half-normal with one adjustment parameter (AIC=169.12, chi-square=0.4326, d.f.=4, p<0.03). The fits of these two models to the data are shown in Figs 4–5. As the two models yield different estimates of abundance and the negative exponential model can produce positively biased estimates, results from both models are presented.

---

**Table 2**

The table presents the estimates, the percent coefficients of variation of these estimates and the associated 95% confidence intervals for the density (D) and the number of minke whales (N) for each block as well as for a pooled estimate for the all blocks with sightings. Results are presented for both models used to fit the distance data.

**Fig. 4.** Fin whales: half-normal model with no adjustment parameters (see text).

---

**Table 3**

Table 3 presents the estimates, the percent coefficients of variation of these estimates and the associated 95% confidence intervals for the density and the number of whales for each block as well as for a pooled estimate for the total area. The surfacing rate for fin whales used in these analyses is taken from Hiby (1992), i.e., 52.4 surfacings per whale per hour (see Discussion).
DISCUSSION

Distribution

The distribution of minke whale sightings made during the 1993 survey off West Greenland confirms the general pattern from the surveys in the most recent years (Larsen and Nielsen, 1989; Larsen et al., 1989), i.e. that minke whales are primarily found close to shore. Due to unfavourable survey conditions there was, however, no effort expended in the offshore part of blocks 2A and 2B, and very little in the offshore part of blocks 3 and 4. For this reason it cannot be ruled out that minke whales occurred in 1993 along the outer slopes of Store and Lille Hallevitkebanken (in 2A-o, 2B-o and 3-o) where they were abundant before the mid 1980s and where a few sightings were made during the surveys in 1987 and 1988.

In the earlier surveys, fin whales were found in all blocks, inshore as well as offshore (Larsen and Nielsen, 1989; Larsen et al., 1989; Donovan, 1990). The distribution of sightings from the 1993 surveys neither confirms nor contradicts this pattern. The low number of sightings and the low survey coverage in the offshore blocks precludes any meaningful comparisons of distribution.

Population estimates

For both the minke whale and the fin whale distance data analysed in this paper, the AIC values point to the negative exponential model as the model that best represents the data, with the half-normal as a close second choice. The negative exponential model differs most importantly from the half-normal model in that it does not exhibit a shoulder close to the track line in the detection probability distribution, as is clearly seen from Figs 2 and 4. This will in most cases result in a positive bias in the obtained estimates. As one would intuitively expect the true detection probability distribution to exhibit a shoulder close to the track line, especially in aerial surveys, the half-normal model seems to be a more appropriate choice.

In fact the estimates of abundance obtained from the two models have large variances and are not appreciably different, for either species. Most of this variance comes from sampling, i.e. inter-line variability, caused by the uneven distribution of both minke and fin whales. A way around this problem could be to increase the survey effort sufficiently to allow a larger sampling unit to be used, e.g. using tracks instead of lines, although prevailing weather conditions would make this difficult to achieve.

It should be noted, however, that the cue rates used by the Scientific Committee for both minke and fin whales do not include estimates of variance. In this respect, the variance of the abundance estimates for West Greenland minke and fin whales previously accepted (IWC, 1990; 1992) are probably underestimated.

Information from radio-tagged minke whales (Folke and Blix, 1993) has become available since the value of 53 surfacings per hour was used by Hoby et al. (1989) based on visual shipboard observations in 1987 (Gunnlaugsson, 1989; Joyce et al., 1989). An examination of these reveals considerable variation both between animals and over time for the same animals. For example, for the animal recorded for the longest period of time, surfacing rates (based on 2 hour sampling units) varied from as low as 33.5 per hour to as high as 60.5 per hour, whilst daytime (0400–2200 hours) means for each animal vary from 42.91 per hour to 52.97 per hour. Consideration as to the most appropriate mean and variance cue rate values to use when estimating abundance is required urgently.
Minke whales

The previously accepted estimate of the number of minke whales present in the survey area at West Greenland is 3,266 (approximate 95% CI: 1,700–5,710). This estimate was calculated at the meeting of the IWC Scientific Committee in 1989 as a simple mean of the estimates from 1987 and 1988 (IWC, 1990). The reason for averaging the two estimates instead of pooling the data was that the estimated Effective Search Areas for the two years were different.

The estimate for 1993, i.e. 8,371 (95% CI: 2,400–16,900) animals using the half-normal model, is considerably higher than the combined 1987–88 estimate, but the two estimates are not significantly different.

At least one possible source of bias in the 1993 estimate can be identified. This is the lack of survey coverage in blocks 2A-o and 2B-o, and the low coverage in block 3-o and 4-o. Minke whales were observed in these blocks during the surveys in 1987 and 1988, although not in large numbers (Larsen and Nielsen, 1989; Larsen et al., 1989). If minke whales were present here again in 1993, this would lead to a negative bias in the abundance estimates.

Fin whales

The most recent estimate of the number of fin whales present in the survey area at West Greenland is based on surveys conducted in 1987 and 1988 and was first calculated at the meeting of the IWC Scientific Committee in 1989 to be 1,589 animals by combining the data from the two years (IWC, 1990). At the Comprehensive Assessment Special Meeting on North Atlantic Fin Whales it was agreed to revise the 1993 estimate from 36 blow per whale per hour to 52.4 blow. This led to a revised estimate of 1,096 (approximate 95% CI: 520–2,100) for West Greenland fin whales (IWC, 1992).

The estimate for 1993, i.e. 178 (95% CI: 26–382) using the half-normal model, is considerably lower than the previous estimates. However, the lack of survey coverage in blocks 2A-o and 2B-o, and the low coverage in block 3-o and 4-o is probably even more important as a source of downward bias in the abundance estimates for fin whales than it is for minke whales. During the surveys in 1987 and 1988 these blocks had a considerable number of fin whale sightings (Larsen and Nielsen, 1989; Larsen et al., 1989). The present estimate cannot thus be considered a reliable estimate of the number of fin whales summering off West Greenland.

ACKNOWLEDGEMENTS

I am indebted to Greg Donovan and Randy Reeves for defying weather and boredom to lead the West Greenland aerial surveys for so many years, to Jette Jensen, Aqquita Rosing-Asvid and Rene Søder for acting as observers during the 1993 survey, and to Leif Petersen for his always skillful flying. I am also indebted to Preben Bech for assistance with data preparation and for drawing the maps. I am grateful to Steve Buckland and Dave Borchers, University of St. Andrews, for invaluable help and suggestions during the analyses of these data and to Greg and Steve for helpful comments and suggestions for improvement to an earlier draft.

ABSTRACT

In 1993, observers counted a total of 3,383 bowhead whales (including 66 calves) during a total of 1,067 hours of watch. Acoustic technicians field-tailed over 49,000 cells in 951 hours of watch. The raw visual count for 1993 is 1.62 times higher than the previous highest in 1988. Although this partially reflects an estimated increase in the population, acoustic distribution data revealed that over 90% of the whales passed within 4 km of the perch and it is this that probably explains much of the increase in numbers of new whales counted. Studies to determine the effect of perch location and the use of marine plotting sheets on the number of new whales counted suggested that observers scored new whales more conservatively in 1993 relative to 1988. East winds maintained open leads which contributed greatly to the success of the census (and the hunt at Barrow). The number of days during May with east winds was among the highest since 1922. There was a significant positive relationship between the number of calls recorded and number of whales seen. Subsistence hunters landed 41 whales using 52 strikes; the hunting efficiency of 78.9% is the second highest since 1973. The pregnancy rate for the period 1973 to 1993 as determined by the recovery of foetuses from landed whales was 22.2%. This rate is probably negatively biased since many whales were examined during or immediately following the mating season which is a period when pregnancies are difficult or impossible to detect visually. When only autumn-harvested whales are considered (a period when foetuses are much easier to detect) the rate increases to 26–35%. The higher estimate could be biased upward since cows with calves were not included in the sample and the lower estimate could be biased downward because some females that calved in the year of harvest are included. Two stone whale harpoon points were retrieved from a large (16.7 m) whale taken in Wainwright, Alaska.

KEYWORDS: ARCTIC; BOWHEAD WHALES; SURVEY-LAND; ACOUSTICS; WHALING-ABORIGINAL; BIOLOGICAL PARAMETERS; REPRODUCTION; AGEING.

INTRODUCTION

The Bering-Chukchi-Beaufort Seas stock of bowhead whales (*Balaena mysticetus*) has been the focus of considerable study since the mid-1970s, mostly centered on estimating the size of the population. The 1993 census marks the 15th ice-based census conducted near Point Barrow, Alaska since 1976 (Zeh et al., 1993).

The census initially used only visual surveillance; however, acoustic surveillance was added to complement visual detection in 1984. After extensive review, the IWC adopted the use of integrated acoustic and visual location data to estimate the number of whales passing Point Barrow and in 1990 the Bayesian approach for evaluating these data was adopted by the IWC (IWC, 1991).

Alaska Eskimos from nine villages hunt bowhead whales from this stock under a quota system. Modifications to the quota are based on population size and trends and documented need (Braund et al., 1988; Zeh et al., 1988a, b; 1991; IWC, 1989; Raftery and Zeh, 1991). For details and historical background on the subsistence hunt refer to Stoker and Krupnik (1993). Biological information gathered from landed whales has supported numerous studies on morphology, reproduction, food habits and ageing (Haldeman et al., 1985; Tarpley et al., 1987; Albert, 1988; Schell et al., 1989; George et al., 1992; Lowry, 1993; Tarpley and Stott, 1994).

This paper reports details of the 1993 ice-based census. The discussion focuses on the marked increase in the number of new whales seen in comparison with past seasons. Statistics for the subsistence hunt are presented as well as new data on pregnancy rates.

METHODS

Visual and acoustic census

Census methods have been described in detail by Krogman et al. (1989) and George et al. (1990). Visual counts are made from counting stations, called perches, on top of high ice ridges located as near to the lead edge as possible. The census is usually conducted near Point Barrow but ice conditions meant that a more southerly perch position was used in 1993. At least three observers were on the perch, 24 hours a day; one operated a teledolite (used for obtaining whale positions), another recorded the data and a third watched for whales. Observers worked two 4-hour shifts per day. The shifts overlapped by two hours so that there was always at least one rested observer and at least one observer that was acquainted with recent whale positions and lead conditions.

Observers used modified nautical 'plotting sheets' and calculators to help them link whale sightings. Plotting sheets were used in early census years and calculators and portable computers have been used since 1980 (Johnson et al., 1981). The plotting sheets were simple 21×28 cm paper charts with range and bearing graduations in a half-hemisphere designed to display the field of observer vision beyond the landfast ice edge. As in past years, the intention was to conduct visual and acoustic monitoring from 15 April to 1 June. Intermittent watches were started on 10 April and ice conditions necessitated terminating the
monitoring effort on 30 May. Acoustic data were gathered using a three to five element passive array of hydrophones as described in Clark et al. (1986).

Experiments
As the 1993 census progressed, it became apparent that many more whales were being seen by a given date than in previous census years. In order to test for possible effects of field procedures on the number of whales counted, two experiments were conducted. In order to examine effects of perch location, 22 hours of simultaneous monitoring were conducted on 25 and 26 May at two perches (Fig. 1): Carolyn Perch, southwest of Point Barrow, was the perch used for most of the 1993 census whilst Spamatol Perch, north of Point Barrow, was in a location more typical of those used in previous censuses. Methods used for sighting and counting whales were identical at the two locations, except that a theodolite was not used at Spamatol. The number of whales that passed within viewing range of each perch during the two day period was estimated from the comparable hours of watch by the method used in Zeh et al. (1991). The same methods were used to estimate the number of whales that passed within viewing range for the whole season.

The second experiment was designed to test for possible difference in linking sightings that might be associated with using plotting sheets in 1993. A total of 197 sightings was made during 10.2 hours of watch on 7 May 1985 and plotted on those sheets. An observer “blind” to the 1988 scoring of the whales then scored them as new, conditional or duplicate using the 1993 census procedures. McNemar’s test (Zar, 1984) was used to assess differences in proportions of sightings scored as new or conditional with and without plotting sheets.

Examination of subsistence harvest
Whales were examined in the villages other than Barrow by the hunters and at Barrow by biologists. Hunters recorded whale length, sex, date landed and in some instances they examined the stomach for food, collected specimens and took additional morphometric data. They also recorded their estimate of the fate of struck and lost whales. At Barrow, detailed examinations were made of all landed whales which included: over 30 morphometric measurements, examination of stomach contents, collection of tissues for contaminant analysis (NOAA-Alaska Marine Mammal Tissue Archival Project) and DNA analysis.

Pregnancy rates
Pregnancy rates (P) were estimated using data from harvested whales examined from 1973 to 1993 in the following manner.

\[ P = \frac{N_p}{N_{mf}} \]

The 90% confidence interval (CI) was calculated as,

\[ CI = \pm 1.645 \sqrt{\frac{P(1-P)}{N_{mf}}} \]

where \( N_p \) is the number of pregnant females in the catch and \( N_{mf} \) is the number of presumed mature females (≥13m). \( P \) was also estimated using 13.5m as the lower length bound for mature females.

RESULTS AND DISCUSSION

The 1993 ice-based whale census was conducted from 10 April to 30 May (Tables 1 and 2) with most of the effort from Carolyn Perch (Fig. 1). Observers counted a total of 3,383 new (seen for the first time), 804 conditional (observer not certain if whale was seen before) and 2,869 duplicate (these are assumed but not confirmed duplicates, e.g. through photogrammetry) sightings of bowheads in 1,067 hours of watch (Table 1, Fig. 2). Sixty-six calves (2.0% of the new whales) were seen during the season. Acoustic technicians tallied 49,000 bowhead calls in 951 hours of watch (Fig. 2). Both the numbers of new whales and calves are higher than any previous census.

Chronology and field summary
10–30 April
Prior to census field activities, observers undertook an intensive three day training course that emphasised ice-safety, data recording and techniques for spotting and linking whale sightings. The first bowhead was seen at Barrow by hunters on 10 April and the census began on the same day at Carolyn Perch, 3.6km west of the village of Barrow. The perch was situated north ("downstream") of the whaling crews to minimise disturbance to the hunt and had to be considerably further south of the perch location used in previous years near Point Barrow due to a large and unstable ice section of ungrounded ice near Point Barrow.

Visual watch effort was restricted to 16 hours a day for the first week due to darkness. Visibility conditions were generally good with temperatures above normal (often well above -18°C) although the lead was covered with 'young' ice ("siqiyuk"). A three element acoustic array was deployed on 15 April and 24 hour surveillance began. Whales were first heard and seen by census personnel on 17 April. Winds increased to 35km/hr on 19 April and cleared the leads of young ice. Whaling activity became intense quite early in the season (20 April) and many crews were in the vicinity of the perch. The first 'pulse' of whales...
began on 21 April and Barrow hunters landed their first whales of the season on that day. Winds dropped on 21 April and the lead began refreezing with thin young ice: this apron of ice persisted until the end of the month. Most whales sighted confined their surfacing to a few small areas of open water described by observers as ‘puddle jumping’, for the period 25–29 April linking whales was difficult as was assessing sighting probability.

1–14 May
Winds increased to over 40km hr$^{-1}$ and forced the hunt to stop between 4 and 6 May although a ‘stinker’ whale was recovered and landed on 4 May. All crews kept a careful vigil for landfast ice fractures. Counts of new whales were strong and steady (ca 200/day) between 4 and 10 May and observers commented that they did not have time to record all (particularly distant) whale sightings. Over 1,600 whales were counted in seven days. Passage rates reached 40 whales hr$^{-1}$, which had only been matched previously during the 1980 census when an unusual ice blockage compressed the bulk of the migration into roughly ten days or less (Johnston et al., 1981). Improved conditions allowed hunters to reach their quota by 11 May after which they left the area. The large pulse of whales stopped abruptly on 11 May. Some mating activity was noted. Northbound currents predominated through this period increasing the whales’ apparent ground speed, pushing even some ‘resting’ (not actively swimming) whales northward.

15–30 May
Migration rates during this period were relatively low at first: whales passed in small groups with 1–2hrs between sightings. On 17 May, at 0400hr, a crack developed shoreward of the camp in a grounded pressure ridge close to shore (20m bathymetry line). The crack extended from the village north past Point Barrow. At 0600hr, a 2x1.5 km section of landfast ice began calving and the camp was moved to safe ice. The census efforts were moved north and Spamatot Perch was established 4.5km NE of Point Barrow (on grounded ice, water depth 20m: Fig. 1).

After the ungrounded section of ice calved, it left a 2–3m vertical wall of ice along the lead edge north of Point Barrow, which made deployment of a hydrophone array difficult. During the seven day census period at Spamatol Perch, SW currents were strong, at times exceeding 5km hr$^{-1}$ and amongst the strongest currents measured during a census. We occasionally saw bowheads forced southwest (while attempting to travel northeast i.e. ‘tail-first’) during surfacings by currents. Collection of acoustic data was greatly compromised by the water noise and safety problems due to the ice conditions.

A second pulse of whales started on 20 May. The pulse peaked at 100 whales/day and persisted until 28 May. Numbers of cow-calf pairs increased sharply. On 25 May, census operations returned to Corinna Perch (which had not drifted off on 17 May and was now considered safe) and
### Table 2
Numbers of whales counted by visibility condition during the 1993 ice-based census of bowhead whales near Point Barrow, Alaska. New and conditional sightings are shown as a ratio under the 'Daily Total' column. Watch conditions abbreviations are: EX = excellent, VG = very good, GO = good, FA = fair, PO = poor and UN = unacceptable.

remained there until the conclusion of the season. The count of new whales exceeded 3,000, considerably higher than any previous census. Currents abruptly turned northbound on 24 May and many whales were tracked moving in excess of 7km hr\(^{-1}\); observers made two reliable sightings of whales exceeding 10km/h — over twice the mean migratory speed of about 4km hr\(^{-1}\) (Zeh et al., 1993). On 25 and 26 May, 10 and 12 hours of simultaneous watch were conducted at Carolyn and Spansull Perches to gather comparative information on counts from the two locations. Cow-calf sightings totalled 13 pairs on 26 May and 26 pairs on 27 May; the latter is the highest daily count recorded.
Factors affecting the visual census

Two small experiments were conducted to investigate factors that may have influenced the counts or scoring of whales as new, conditional or duplicate. These factors were: (a) the southerly perch location used in 1993; and (b) the use of 'plotting sheets'.

Comparative counts from Carolyn and Spamalot Perch

The objective of this experiment was to see if the typical location of the main perch could explain the greater number of whales seen in 1993. Watch at Spamalot Perch (a more usual location) totalled 12 hours on 25 May and 10 hours on 26 May; watch at Carolyn Perch, 15.9 km away was continuous on those days. The average estimated swimming speed for those days was 4.0 km hr⁻¹ i.e. the whales should have reached Spamalot Perch about four hours after passing Carolyn Perch: this was supported by an examination of the temporal pattern of sightings at the two perches (Fig. 3). Sightings at Carolyn Perch from 6:05 to 18:05 on 25 May were thus compared with those at Spamalot between 10:05 and 22:05 on 25 May, whilst on the following day the times were 8:00 to 18:00 and 12:00 to 22:00, respectively. Shifts of an hour in the time periods considered at Carolyn Perch had little effect on the results.

More whales were seen at Carolyn than at Spamalot over the 22 hour watch period: 54 new and four conditional whales compared to 47 new and six conditional. This is somewhat surprising since the visibility was scored as poor for more of the time at Carolyn than Spamalot. Although the point estimate of the number of whales that passed within viewing range was also higher at Carolyn (276 vs 204) the 95% CI for Spamalot (50–358) is completely contained within the 95% CI for Carolyn (49–503). The estimated variability was higher at Carolyn because of poor visibility. Counts made under poor conditions are not used in the estimation procedure, so the corresponding hours must be accounted for by extrapolation, increasing the variability.

In fact it is most appropriate to compare the counts on 25 May since visibility was similar at both perches. As shown in Table 3, these estimates differed by about nine whales and each had a standard error of nearly 40 whales, so the difference was not significant statistically.

Some temporal and spatial patterns suggested that different whales were being seen at the two perches (Fig. 3). Because cow-calf pairs are infrequent and are highly distinguishable from other sightings they provide an independent means of comparing the counts from the two perches. A similar experiment was conducted in 1986; then and in 1993, more calves were seen at the southern perch (George et al., 1987). An examination of the time of the sightings suggests that many of those seen at the southern perch may not have been seen at the northern perch and vice versa (Fig. 3). The times of sightings of migrating white whales (Delphinapterus leucas) were also examined for both perches to see if they provided any additional information on (swim) lag times but this proved inconclusive (Fig. 3). It is not unexpected that whales were ‘missed’ especially in light of the results from the two-perch counting method used from 1978 to 1985. For instance, even during periods of ‘good’ visibility the probability of missing a whale within 4 km ranged from 0.34 to 0.64 depending on distance from shore (Zeh et al., 1991).

Replot experiment

The purpose of this ‘experiment’ was to determine if the use of plotting sheets somehow inflated the count in 1993. Whales seen in 1988 were ‘rescored’ using the same

---

The previous being 10 on 25 May 1982. Visibility was poor on 28 and 29 May. It was suspected that many more cow-calf pairs passed unseen, since each time the visibility improved observers saw a few cow-calf pairs.

Trail conditions deteriorated rapidly in late May and became close to impassable and it was decided to close the camp on 30 May and begin a “commute” watch with reduced effort. The acoustic array was removed on this date which marks the end of the full census. However some whales, particularly cow-calf pairs, probably passed after this date. The ice behind Carolyn Perch cracked the following day and the perch rolled seaward at a substantial angle and broke free a few days later.

1–15 June

During early June, fog made visibility poor. Although a few short watches were conducted near Carolyn Perch, at Spamalot Perch and from the coastal bluffs in Barrow, few whales were seen.

Two short aerial surveys were carried out on 11 and 17 June and the only sighting was of a dead bowhead whale northeast of Point Barrow (see harvest section) on the 17 June. On 15 June, numerous blows (>50) were seen in about 1 hour of watch from the coastal bluffs near Barrow. The species could not be determined and a local hunter, R. Williams, believed them to be a mix of bowhead and gray whales.
Fig. 3. Chart comparing simultaneous counts of adult (A) and calf (C) bowhead whales as well as beluga whales at Spamalot and Carolyn perches on 25 and 26 May. A lag time of four hours was used to compare counts (stippled areas) to allow for the time needed for whales to swim the distance (15.9km) between the perches. Sightings of beluga whale pods were included as an independent means of determining the time needed to swim between perches.

nautical plotting sheets from the 1993 census. We chose 7 May 1988 since it had periods of both low and high passage rates. In 1988 observers made a total of 193 sightings and scored them as 118 new and 38 conditionals whereas the replot 'observer' scored 82 whales as new and 36 as conditional. The percentage of sightings scored as new in 1988 was significantly higher than those rescored as new (p<0.001, McNemar's test; Zar, 1984).

This experiment suggests that the 1993 count was conservative relative to the 1988 counts. If this was a result of the use of plotting sheets, rather than differences in observer judgement per se, then plotting sheets were also used during the 1978 census which may make that similarly biased. 'Observer aids' such as calculators and computers have been used in every census since 1980. When considering Table 4, it is important to note that sightings, not whales, were re-evaluated. This was because some sightings included two or more whales and it is not possible to determine from the records whether the whales were truly paired or were singletons. The 1988 observers would also have used information no longer available (e.g. size, colour patterns, scars) to identify possible duplicates as new individuals.

Similar percentages were scored as conditional by both methods, but the new and duplicate percentages were reversed; in 1988, 49.2% (95 of 193) sightings were scored as new with the rest conditional or duplicate while in the replot experiment only 35.2% (68 of 193) were scored as new and 49.2% as duplicate.

A regression of differences in counts against the average (of 1988 new and replot new; Table 5) whales per time-bin shows the correlation to be not significant (p=0.19).
although it probably would be with more data. The three largest count differences occurred in periods with more than 10 new whales per bin; atlow passage rates the counts are more similar. This suggests that observers from both years were more likely to link whales as the same at low rates (Table 5).

1 Because of the watch period used, the ten time bins totalled slightly more than 1 hour each or 1.03 hours.

We surmise that much of the difference between the two methods is attributable to the manner in which observers link whales while on the perch. For instance, on 4 May 1993, observers made 51 sightings of 36 whales in one hour (almost one per minute) and not all sightings were recorded because the recorder simply could not write fast enough. Observers would have had to search back through three pages of data to find appropriate links in this situation, an awkward and time-consuming process. Plotting sheets make the earlier sightings more apparent and accessible for linking, although the plotting process is tedious and ties up the observer recording the data, which effectively reduces the watch to two observers. In 1985 and 1986, a laptop computer was used on the perch which listed ‘appropriate’ links based on predetermined swim speeds and directions, but one of the authors (JEZ) strongly recommended against this practice since the Bayesian estimation approach assumes that the observers are providing independent and unbiased data on whale swimming behaviour. The computer has only been used occasionally for training purposes since then. These data are used to assess tracking algorithm performance and set tracking parameters (Raftery and Zeh, 1991). Nevertheless, observers using plotting sheets or a laptop computer are probably more likely to link a whale sighting back to a previous one, which would reduce the number of whales scored as new (giving a more conservative count).

A number of problems are apparent with this ‘experiment’. For example perch conditions could not be ‘reconstructed’ in the laboratory and neither could discussion amongst perch observers with respect to likely links or use of differences in whale size, colour, speed and behaviour to help link sightings. The best experimental approach would be to conduct simultaneous counts from two identical perches using both counting methods but this would require a major research effort. However, at high passage rates there is little time to ‘watch’ whales and thus observers have little time to link whales (or look for linking clues); at such rates reploting whales in the laboratory may not be very different than assessing links on the perch.

From the census viewpoint a more appropriate question is which method produces the most accurate counts of whales and which is the most consistent between years? It is not possible to answer this question with available data and there are arguments to support each side. For inexperienced observers, the plotting sheets provide a more systematic and intuitive means of linking whales, and since more sightings are available for linking, more accurate counts may result. On the other hand there is a real possibility of ‘over linking’ at high rates (as the tracking algorithm sometimes does) using plotting sheets or computers since there are so many possibilities to choose from. Plotting sheets probably provide a more structured framework and would therefore produce more consistent counts between years.

Wind effects on lead width, whale distribution and census and hunting success

George et al. (1990) presented data which indicated a significant correlation between numbers of whales seen and numbers of days with predominately east winds in a particular season. This is mainly because easterly winds hold the leads open and allow better viewing conditions. This relationship was clearly demonstrated during the 1993 season. For 1978 to 1993, numbers of east-wind days in May (when most whales pass) and numbers of whales seen were significantly correlated \( R=0.65; \) \( df=11, n=13 \) (Fig. 4).

![Fig. 4](A) Raw numbers of whales counted by wind direction for the period 1978 to 1993 near Point Barrow, Alaska. (B) Numbers of east-wind days for April and May by year from 1922 to 1993 at Barrow, Alaska (source: US National Weather Service).

The data also suggest that these higher counts may be due, in part, to differences in whale distribution caused by changes in sea-ice density, which is ultimately driven by the
prevailing wind. Moore and Reeves (1993) reported a tendency during the autumn migration for whales to travel closer to shore in light ice years as compared to heavy ice years. Qualitatively this relationship appears to hold for the spring migration at Barrow; that is, whales appear to be distributed further offshore in years with greater ice cover (Table 6). For instance, in years with greater periods of closed leads4 (1984, 1985, 1986) about 26% to 66% of the whales were within 3 to 4 km of the lead edge (Clark et al., 1986). Conversely, in years with very few periods of closed leads (1988 and 1993), 74% and 91% of the whales were within 4 km of the lead edge (Raftery and Zeh, 1991; Givens et al., 1995). Thus, past census seasons with high counts could have reflected both better visibility conditions and a higher proportion of whales within 4 km of the lead edge rather than an increase in the number of whales passing Barrow.

Table 6  
Proportion of whales passing within 4 km (P4) (Zeh et al., 1994) of the perch calculated from acoustic data and the estimated percent of season with leads closed by heavy ice.

</tbody>
</table>

1 Note for 1984, only an estimate of the proportion of whales within 3 km of lead edge is available (as calculated using methodology of Clark et al., 1986).

2 'Closed leads' defined as periods where nearshore lead was closed by heavy multi-year ice, not young ice.

An examination of weather data collected at Barrow since 1922 (Fig. 4) shows the average number of east-wind days for May to be 24.0 (SD = 6.97, N = 68). Assuming that census estimates cannot be obtained if leads are closed for more than 10 days in May and that leads were closed for all days with westerly winds, then censuses in approximately 13 seasons since 1922 (19%) would have failed. This is consistent with the 13 census years since 1978 during which three (23%) failed due to environmental factors. From a management perspective, it should be noted that there were periods, such as in the late 1960s, when a census would probably have failed several years in a row.

Whale calls and numbers of whales seen  
Additional evidence that whales passed closer to the perch in 1993 is implied by the statistically significant correlation (r = 0.56) between numbers of whale seen and numbers of calls counted per day (Fig. 5). This correlation was observed in 1988 but not in 1985 and 1986. A detailed analysis of the 1985 census data found no correlation between numbers seen and heard (Ko et al., 1986). This was probably because most whales passed beyond the view of observers in those years (Table 6).

4 In this analysis, the term closed lead refers to lead systems closed by heavy multi-year sea ice, not young ice, since bowhead whales can easily break through thin ice to breathe.

![Fig. 5. Raw numbers of bowhead whales counted and numbers of whale calls per day for (A) 1985, (B) 1988 and (C) 1993 from ice-based census data near Point Barrow, Alaska.](image)

Cow-calf passage  
The count of 66 calves from 1993 was the highest ever during a census. This provides some support for the view that 3–4 year cycle in recruitment described by Koski et al. (1993) is continuing.

Koski et al. (1993) concluded, from an examination of several years of photogrammetric data, that bowhead whale recruitment was highly variable among years. Census data probably underestimate the number of calves in the population because of the difficulty of seeing calves and because some females give birth after passing Barrow. Although lower, the estimates of percent-calfes from census data confirm the inter-year variations in GARR from photogrammetric data (Koski et al., 1993; Withrow and Angliss, 1994b) (Fig. 6a).

George and Carroll (1987) noted that calves comprised a significantly greater proportion of the migrating whales in the later part of the census season (i.e. after 15 May; Fig. 6b). This was true in 1993 when calves constituted 8.6% of the whale sightings after 15 May but only 0.3% prior to 15 May (Fig. 7). The 1987 and 1988 seasons were very similar to 1993 in terms of visibility, lead character and migration timing in the early part of the season but differed from 1993 in that (1) few calves were seen (refer to Table 1) despite good visibility during the late season and (2) few whales were seen after 20 May (George et al., 1990). In 1993, over 667 whales were counted (19.7%) from 15 May to early June which included most of the calves seen that season. Other protracted migrations such as 1982 and 1986 also tended to have high proportions of calves. Thus, it may be that seasons with high recruitment rates tend to have protracted migrations.
view in 1993 according to the acoustic evidence. However, Givens et al. (1995) suggest that the high count will also reflect the increase in population size that has occurred since at least 1978. A simplistic comparison of 1978 (Braham et al., 1979) and 1993 shows that in both years, visibility, watch effort and whale distribution were almost identical but nearly twice as many whales were seen in 1993 (Table 2), suggesting about 4.5% annual growth in population size.

Migratory behaviour (direction of travel)
In 1993, there were 2,832 resightings of whales for which direction of travel was recorded. Of these 90.7% travelled steadily northward, 1.2% travelled steadily southward and 8.0% 'lingered' within view of the observers. Estimates of percentages of northbound whales for 1987 and 1988 were 85% and 74% respectively, suggesting the 1993 migration was highly directed and uninterrupted compared to previous seasons (Zeh et al., 1993).

1993 SUBSISTENCE HARVEST OF BOWHEAD WHALES
In 1993, Alaskan Eskimo hunters made 52 strikes resulting in 41 whales landed (Tables 7 and 8). The efficiency of landing whales that were struck was 78.9%. In only one year since 1973 has the hunting efficiency exceeded that of 1993 (George et al., 1992). This reflects the fact that hunting conditions in Barrow in 1993 were considerably better than in 1992; clear leads allow better access to migrating whales and probably more efficient recovery of struck whales. For instance, in Spring 1992, westerly winds and closed leads at Barrow precluded hunting until 28 May when two whales were landed before leads again closed. At Wainwright, closed leads prevented any hunting and no strikes were used there in 1992.

The sex ratio of the landed whales was almost unity in 1993: 20 were males and 21 were females (Table 7). Four of the 21 females (19.5%) were greater than 13.0m in length and presumably mature (Koski et al., 1993).

As in the past, a range of specimens was collected, A focus on 93B20 was collected and preserved in formalin for anatomical studies. Samples were also collected for the Alaska Marine Mammal Tissue Archival Project (for monitoring contaminant levels in tissues) and for evaluation of food habits, blood serum constituents and estimation of genetic variation.

Case reports
Four areas (2.0×0.5cm) of white skin, presumed to be scars and in a rectangular pattern approximately 15cm×32cm were seen 365cm behind the blowhole and approximately 25cm to the right of midline of whale 93B21. These are tentatively attributed to satellite transmitter attachment injuries.

Two bowhead whales were found dead in 1993. One (93FD1 at 71°27.8'N, 156°16.7'W), estimated at over 13m in length, was seen during a survey on 17 June and may have been struck but lost during the spring hunt at Barrow. The second whale (93FD2), a 15m female, was found on a beach 15km SW of Barrow. The flukes were tangled with approximately 30m of 2cm thick synthetic line that had cut approximately 30cm into the anterior edge of the right fluke, abraded the base of a flipper and was entangled in
Pregnancy rates
Examination of 72 mature females (≥13.0m) harvested from 1973 through 1993, revealed 16 foetuses, suggesting a pregnancy rate of 22.2% (90% CI = 0.14 – 0.36). This rate would be biased downwards if: (a) foetuses were missed; (b) the mean length at maturity was greater than 13.0m; or (c) hunters avoided pregnant animals. Following Koski et al. (1993) we assumed females ≥13.0m in length are mature. Since there is some indication that harvested animals stretch during the hauling process, Koski (pers. comm.) suggested 13.5m for landed animals as a more appropriate value. Using 13.5m, the pregnancy rate increases to 22.9% (90% CI = 0.14 to 0.31). When only females (30) specifically examined for maturity were used, 13 were pregnant (1980–1992), giving a pregnancy rate of 0.43 (Tarpely and Stott, 1994). This estimate does not accord well with other data (Koski et al., 1993) but Tarpely and Stott (1994) do not suggest reasons for this apparently high rate.

Mating activity has been observed during the hunting season and foetuses in recently conceived females would not be seen. Small (<30cm) foetuses would undoubtedly be missed, even during examination by biologists and whale hunters do not routinely search the uterus for small foetuses. If only data from Barrow (where examinations were more rigorous) are used, eight foetuses have been recovered and 39 females were ≥13m giving an apparent rate of 20.5% (CI 0.10–0.31). If only mature females from the autumn hunt are considered, the problem of detection of small foetuses is minimised since all foetuses examined then have been over 75cm in length with most about 150cm (Tarpely and Stott, 1994); this gives an apparent rate of 34.6% (CI 0.19–0.50). Miller et al. (1992) reported an estimate of 30.3% based on a large multi-year photogrammetric sample (n=1,046). However, autumn estimates may be positively biased since cows with calves are not taken by hunters; the denominator (26) therefore may be too small.

Additional considerations in determining pregnancy rate are given below.

1. Data provided by the Alaska Eskimo Whaling Commission.
2. Estimated fate is the Captian’s estimate of survival: f(fair) and p(poor).

---

These tables provide a summary of the number of landed whales and the estimated fate based on the hunters' observations.
Fig. 8. (A) Stone whale points recovered from a 16.7m male bowhead whale (03WW5) taken at Wainwright, Alaska on 30 May 1993 by Captain Ben Aknaogak, Sr. (B) A reproduction from Murdock (1892) showing two harpoon points collected at Barrow, Alaska ca. 1881-1883.
(1) The rate for spring-harvested females could be biased slightly upwards by the inclusion of near-term foetuses. We have assumed that gestation is one year, although Koski et al. (1993) suggest a gestation period of 13 to 14 months.

(2) We have made no correction for the fact that since the establishment of the quota in 1977, hunters which encounter females with obvious calves do not harvest them. From personal observations at Barrow, the frequency of crews encountering cow-calve pairs depends on how late in the season the hunt extends; hunters at Barrow seldom encounter cow/calve pairs before about 20 May and therefore this bias may be small.

George et al. (1992) reported an increase in the pregnancy rate of the landed catch since 1985. A logistic regression for the years 1973 to 1993 found an upward, but non-significant, trend ($p=0.11$; Fig. 9). One explanation is that more foetuses have been recovered since 1985 due to the increase in the autumn catch (Fig. 9).

Ex. M-0521

Fig. 10. Scatter plot of lengths of harvested bowhead whales by date for (A) the spring hunt and (B) the autumn hunt at Barrow, Alaska. (Both are statistically significant at $p<0.01$).

whales will be relatively small: conversely if the hunt is delayed, then larger whales (including pregnant females) may be taken.

In the autumn hunt, the opposite trend was observed where a decrease in whale size with time occurred. Crews hunting in early September at Barrow tended to harvest larger whales than those hunting later in the season (Fig. 10).

Thus for any year in succession, the number of mature females available for examination will vary depending on the timing of the hunt. Over many years, however, random changes in the timing of the hunt may have produced a representative sample of mature females. This may explain the similarity between estimates of pregnancy rates from harvest data and photogrammetric data. Because of the biases noted above and the relatively small sample size, the photogrammetric data would probably provide more accurate estimates of calf production. However, caution must also be used when interpreting photogrammetric data since sampling timing and location can greatly bias these data as well (Koski et al., 1993; Withrow and Angliss, 1994a).

In summary, the available data from landed whales suggest that the annual pregnancy rate for this stock of bowhead whales ranges from about 20–35%.

ACKNOWLEDGMENTS
We acknowledge the cooperation of the Alaska Eskimo Whaling Commission and the whale hunters of Barrow who supported our studies. We also appreciate help in the field from: William Aguvuk, Suzie Ahkootchook, Perry Anashugak, Barbie Anderton, Kirsten Bagne, Peggy Barnes, Tom Calupca, Joe Burgener, Charles D. N. Brower, Harry Brower, Jr., Todd Chandler, Chris Clark,

Small Cetaceans
Estimates of Incidental Mortality of Dolphins in the Eastern Pacific Ocean Tuna Fishery in 1993

C. Lennert and M.A. Hall

Inter-American Tropical Tuna Commission, 8604 La Jolla Shores Drive, La Jolla, CA 92037-1508, USA

ABSTRACT

Estimates of dolphin mortality incidental to fishing operations of the eastern Pacific Ocean tuna fleet in 1993 are presented. Mortality estimates were computed, using data collected by observers aboard 369 trips of tuna vessels from the international fleet. As a result of complete observer coverage for this fishery in 1993, total dolphin mortality incidental to fishing operations was assumed to be known. However, because detailed by-set data were not always available, mortality by species and stock for 1993 were not known and had to be estimated. Estimates of mortality by stock were computed using a method different than that used in previous years to incorporate the information available on total dolphin mortality into the estimation process. Total dolphin mortality for 1993 was 3,601 animals, a 97% decrease in the level of incidental mortality in this fishery relative to the estimated level in 1986. Most of this decrease is attributable to improvements to dolphin safety gear and in the performance of vessel captains and crew members; between 1986 and 1993, the average mortality of dolphins per set decreased by 96%.

INTRODUCTION

The association of yellowfin tuna (Thunnus albacares) with several species of dolphins (in particular: pantropical spotted dolphins, Stenella attenuata; spinner dolphins, S. longirostris and common dolphins, Delphinus delphis) in the eastern Pacific Ocean (EPO) has long been exploited by the international purse seine fishery to catch the tuna. The incidental take of dolphins associated with this fishery has been monitored by both national and international observer programs: the US National Marine Fisheries Service (NMFS) has been placing observers on US-flag vessels regularly since 1971. The Inter-American Tropical Tuna Commission (IATTC) has been placing observers aboard tuna vessels of the international fleet since 1979 and the government of Mexico began a national observer program, Programa Nacional para el Aprovechamiento del Atún y Protección de los Delfines (PNAAPD), in late 1991. Mortality estimates for previous years can be found in Smith (1983), Lo and Smith (1986), Wahlen (1986), Allen and Goldsmith (1981; 1982), Hammond and Tsai (1983), Hammond (1984), Hammond and Hall (1985), Hall and Boyer (1986; 1987; 1988; 1989; 1990; 1991; 1992), Wade (1993) and Hall and Lennert (1993: 1994). Revised estimates for 1979–1987 can be found in the Annual Report of the IATTC for 1988 (IATTC, 1989). This paper presents estimates of dolphin mortality in the EPO incidental to fishing operations of the international purse seine tuna fishery during 1993.

DATA SOURCES

IATTC observers accompanied vessels of the international fleet fishing for tunas in the EPO on 294 trips during 1993. An additional 53 trips which started in late 1992 and continued into 1993, or started in late 1993 and continued into 1994, were also monitored. All vessels sampled had carrying capacities of 400 short tons or greater. Of these 347 sampled trips, 185 involved sets made on tunas associated with dolphins. (Data from one observed trip were not available for analysis because the data were lost due to the sinking of the vessel.) Twenty-three trips by US vessels were monitored by NMFS observers and 102 trips by Mexican vessels were monitored by PNAAPD observers. Sampling coverage for the international fleet by the IATTC and by national programs of the USA and Mexico was 100%. In the case of the USA and Mexico, national programs complement the IATTC observer program to achieve 100% coverage. IATTC, NMFS and PNAAPD sampling coverage for the international fleet in 1993 is summarized in Table 1.

METHODS

Because the level of observer coverage in 1993 was 100%,
total dolphin mortality incidental to this fishery was
assumed to be known. However, detailed by-set data from
the PNAAPD are not yet available to the IATTC, and
species and stock identification was not possible for the
PNAAPD data. Data available from the PNAAPD were a
tally of observed mortalities of all dolphins, a tally of the
number of trips making sets on tuna associated with
dolphins and a preliminary tally of the number of dolphin
sets. It was therefore necessary to estimate the mortality
for each stock. Mortality was estimated for the same stocks
(and groups of stocks) as have been used in previous years:
northeastern and western-southern stocks of spotted
dolphins; eastern and whitebelly stocks of spinner
dolphins; northern, central and southern stocks of
common dolphins; and striped and other dolphins (see
the footnote to Table 2 for species included in this
category).

a Unidentified spinner dolphins were prorated to their eastern or
whitebelly stocks.

b No mortality observed for this stock.

c ‘Other dolphins’ includes the following species and stocks, whose
observed mortalities are shown in brackets: striped dolphins
(Stenella coerulealba) [17], bottlenose dolphins (Tursiops truncatus)
[24], rough-toothed dolphins (Steno bredanensis) [1], Costa Rican
spinner dolphins (Stenella longirostris centroamericana) [18],
melon-headed whales (Peponocephala electra) [2], whitebelly
dolphins (includes common, striped, Fraser’s, Pacific whitesided and
whitebelly spinner dolphins) [14] and unidentified dolphins [41].

There were not enough data to make separate estimates for these
species.

The estimated proportions of mortality by stock (estimator described below) for Mexican-flag vessels
(IATTC data) differed significantly from that for non-
Mexican-flag vessels for several of these stocks, possibly as a
result of differences in the spatial distribution of fishing
effort between the two fleet categories (Student’s r statistic
with 71 degrees of freedom: northeastern spotted dolphins,
p = 0.013; western-southern spotted dolphins, p = 0.001;
eastern spinner dolphins, p = 0.001; whitebelly spinner
dolphins, p = 0.001; and northern common dolphins, p = 0.002).
For this reason, a stratified estimator of mortality by stock was used, with two strata: Mexican fleet
and non-Mexican fleet.

For the non-Mexican fleet, mortality by stock (m_i) was
assumed to be known because sampling coverage was
100% and detailed by-set data were available (IATTC and
NMFS data). To estimate mortality by stock for the
Mexican fleet, the proportion of mortality by stock (r_i) was
estimated from IATTC data for Mexican-flag vessels and
used to prorate the total mortality observed for the
Mexican fleet (M = the sum of tallies of PNAAPD and
IATTC mortalities) to stocks. That is, Mexican fleet
mortality by stock was estimated using a ratio estimator,
where mortality of all stocks was regarded as the auxiliary
variable. The proportion of mortality by stock for stock i
was estimated as r_i = average mortality-per-trip for stock i
divided by the average mortality-per-trip for all stocks.
Estimated total mortality for stock i was then computed as
the sum of the observed mortalities m_i plus the prorated mortalities r_i M.

An estimate of the standard error (SE) of total mortality
for stock i was obtained as SE(m_i + r_i M) which, because
m_i was assumed to be known, is equal to M SE(r_i). An
approximation to a bootstrap estimate of SE(r_i) was
computed following a resampling method for sample
survey data proposed by Sitter (1992) which generates
‘bootstrap samples’ of trips in a manner that better reflects
the data collection process. A bootstrap sample of Mexican
fleet trips was constructed by drawing n’ Mexican fleet
trips, without replacement, from the n Mexican fleet trips
with sets on tuna associated with dolphins in the IATTC
database (n’ < n) and then repeating this subsampling,
with replacement, k times for an overall sample of n’k
trips. With the restriction that n’ and k be integers,
choosing n’ = fN (f = a/N. N = the sum of PNAAPD and
IATTC tallies of Mexican fleet trips with sets on tuna
associated with dolphins) and k = f/ f would result in the
bootstrap sampling fraction n’k/n equaling the data
sampling fraction f, and the bootstrap sample size n’k
equaling the data sample size n. Because neither n’ nor k
were integers for our sample and population sizes, a two-
stage randomization method (Sitter, 1992) was employed
to select between bracketing integer values of n’ and k. The
above resampling procedure was repeated 1,000 times (the
large number of bootstrap samples of trips was necessary
for estimating confidence intervals of mortality by stock
and of mortality relative to stock size, described below).
’Bootstrap replicates’ of the proportion of mortality by stock
(\bar{r}_{ij} = 1,..., 1,000) were computed for each of the i stocks from the 1,000 bootstrap samples of trips. A
bootstrap estimate of SE(\bar{r}) was approximated by Monte
Carlo as [(1/1,000) \sum(\bar{r}_{ij} – \bar{r})^2]^{1/2}, where \bar{r}_{ij} = (1/1,000)
\sum_r \bar{r}_{ij} (e.g. Sitter, 1992).

Nonparametric approximate 95% confidence intervals for
mortality by stock were estimated by the BCa bootstrap
method (Efron, 1987; Efron and Tibshirani, 1993). The
BCa method, which generalizes the percentile method
(Efron, 1982), has been shown to produce second-order
correct approximate confidence intervals in a number of
infinite population settings in which the percentile method
would fail to do so (Efron, 1987). Although use of the BCa
method in a finite population setting appears to be reasonable (comment on page 1288, Booth et al., 1994),
the second-order correctness of BCa CI estimates has not
been established yet for this case. Bootstrap replicates of
mortality by stock were computed for each of the i stocks as
m_i + M \bar{r}_{ij} (j = 1,..., 1,000). As with the percentile
method, endpoints of the BCa intervals for mortality by
stock are obtained from percentiles of these bootstrap
replicates. However, the percentiles used in the BCa
method differ from the values that would be used for the percentile method as a result of adjustments for 'bias' and 'acceleration'. Bias refers to a difference between the median of the bootstrap replicates \((m_j + ̂r_j, M, j = 1, \ldots, 1,000)\) and the estimate of stock mortality \(m_j + ̂r_j, M\). Acceleration refers to the rate of change of \(SE(m_j + ̂r_j, M)\) with the true but unknown stock mortality. The bias-correction and acceleration constants were estimated as outlined in Efron and Tibshirani (1993).

Mortality relative to stock size has been used in some instances for marine mammal management purposes (Hammond, 1991). A rough estimate of the relative mortality for stock \(i\) was obtained by dividing the estimate of total mortality for stock \(i\) (described above) by the most recent estimate of absolute abundance for stock \(i\) (pooled abundance estimates for 1986-1990 from Wade and Gerrodette (1993)), multiplied by 100. Approximate 95% CIs for relative mortality by stock were estimated from 1,000 bootstrap replicates of relative mortality by stock using the bias-corrected percentile method (Efron, 1982; interval endpoints obtained from percentiles of the bootstrap replicates, as adjusted for 'bias'); an estimate of the acceleration constant necessary for construction of BCa intervals would require abundance data not available to the authors. Details of the statistical methodology used to construct the bootstrap replicates of relative mortality can be found in Hall and Lennert (1994).

In order to make a rough comparison of the level of fishing activity in 1993 with that of the previous year, estimates of the number of dolphin sets and the number of tons of yellowfin tuna caught in association with dolphins were computed. A preliminary tally of the number of dolphin sets obtained from the IATTC, NMFS and PNAAPD databases was used as an estimate of the total number of dolphin sets. An estimate of the number of tons of yellowfin tuna caught in association with dolphins was obtained by the method employed in previous years (Hall and Boyer, 1986) which uses data on tuna catches available from tuna vessel logbooks and cannery unloading weights, with the modification that observer data were used in place of tuna vessel logbook data whenever the observer data were available.

RESULTS AND DISCUSSION

Total dolphin mortality for 1993 was 3,601 animals, a decline of 77% relative to the 1992 estimates (Hall and Lennert, 1994) and of 97% relative to those of 1986 (IATTC, 1989). Estimates of species and stock mortality, SEs and approximate 95% CI are presented in Table 2. Implicit in the estimate of stock mortality for the Mexican fleet was the assumption that the stock proportions of the IATTC Mexican fleet mortality data were similar to that of the PNAAPD data. This appears to be a reasonable assumption because, whenever possible, IATTC and PNAAPD observers were placed aboard Mexican-flag vessels on alternate trips. In treating total dolphin mortality as a known constant, it has been assumed (as previously) that non-sampling error was negligible.

A rough point-estimate comparison of the average mortality per set (MPS) for 1993 (the ratio of total mortality to number of dolphin sets) to the estimate for 1992 showed a significant (65%) reduction in MPS (\(p = 0.001\), assuming MPS follows a normal distribution). A similar reduction occurred in the average mortality per ton.

Estimated relative mortalities in 1993 for all stocks were below 0.2% (Table 3). The highest levels of incidental take occurred for northeastern spotted dolphins (0.16%) and eastern spinner dolphins (0.13%). Upper endpoints of approximate 95% CI were below 0.25% for all stocks, with the highest values occurring for northeastern spotted dolphins (0.204%) and eastern spinner dolphins (0.205%).

The total number of dolphin sets decreased by 33% with respect to the 1992 estimate. Similarly, the estimated number of tons of yellowfin tuna caught in dolphin sets decreased by 36% with respect to the estimated 1992 tonnage. Dolphin sets represented an estimated 47% of all sets made by the fleet and contributed an estimated 54% of the tonnage of yellowfin tuna caught in the EPO in 1993. The decrease in total mortality was a result of both continued improvements in performance of vessel captains and crew members (a decrease in MPS of 65%) and a reduction in the number of dolphin sets.

A dramatic reduction in the level of mortality incidental to this fishery has been made since 1986, the first year with adequate coverage of the international fleet (Fig. 1). Relative to the estimated number of dolphin sets in 1986, the estimated number of dolphin sets in 1993 has decreased by 34% (Fig. 1). If the number of dolphin sets in 1993 had been comparable to that in 1986, estimated total dolphin mortality would have been approximately 5,450 animals.

Improvements to dolphin safety gear and in the performance of vessel captains and crew members have led to a 96% reduction in the MPS since 1986 (Fig. 1). Improvements to dolphin safety gear include a higher

percentage of vessels with dolphin safety panels that meet or exceed the minimum recommended dimensions, more rescue rafts and increased usage of such rafts and the usage of high-intensity flood lights during dolphin rescue efforts which take place in darkness. Educational seminars on mortality reduction techniques, and gear inspection and net alignment services (provided by the IATTC) have affected performance by improving the response of captains and crew members to problematic situations that could lead to high-mortality sets, thereby reducing the number of such sets that occur. As a result of improvements in performance, the percentage of sets with zero mortality increased from 43% in 1986 to 86% in 1993.

Possible Implications of Cohesive Social Structure for the Dynamics and Sustainable Yields of Cetacean Populations – Some Exploratory Calculations

G. Zabow and D.S. Butterworth

Department of Applied Mathematics, University of Cape Town, Rondebosch 7700, South Africa

ABSTRACT

An exploratory numerical investigation of the effects of exploitation on cetacean populations is undertaken to determine likely differences in dynamics between populations exhibiting cohesive social structure and ones in which such grouping either does not occur or is not pertinent given the exploitation pattern. A model with groups, each of which is age-structured, is developed, in which small groups of younger animals split from their parent groups once these exceed a certain size. Per capita growth rates are assumed to be less for these smaller groups, under the hypothesis (based on analogy with large land-based mammals) that such groups are less successful in protecting their young from predators. This effect, coupled to an exploitation pattern which removes only the larger groups, does lead to a lesser sustainable yield than could be taken from an ‘equivalent’ homogeneous population, but the difference is only a few percent for the set of parameter values investigated. The length distributions of animals captured also differ little. An interesting feature of the groups model is an approach to equilibrium levels under exploitation marked by long period oscillations of not inconsiderable amplitude and duration. While a more exhaustive evaluation of the hypothesis investigated here could be undertaken, the development and analysis of alternative ideas of how group structure might impact population dynamics would seem to have a higher priority.

KEYWORDS: MANAGEMENT; BEHAVIOUR-SOCIAL; ODONTOCETES; MODELLING

INTRODUCTION

Accurate predictions of the effects of different future exploitation levels on animal populations are of obvious importance for the soundly based formulation of harvesting regulations. Mathematical models have been developed to provide such predictions, but are normally based on the simplifying assumption of a homogeneous population from which removals, apart perhaps from an age-specific factor, are considered to be random.

However, certain cetacean species, particularly odontocetes (e.g. long-finned pilot whales – Amos et al. (1993)) exhibit a high degree of cohesive social structure, i.e. the animals in the population do not mix freely as implied by such assumptions of homogeneity. In addition, some of the harvesting techniques used for these species (e.g. drive fisheries) remove entire groups (schools) from the population, rather than individuals at random.

The aim of this paper is to provide an initial comparison of results obtained from modelling exploitation on a homogeneous population under random harvesting with results obtained when internal group dynamics and group harvesting techniques are taken into account in a relatively simple manner. Of particular interest is whether the difference (if any) is great enough to necessitate more complicated modelling techniques, or whether there is some way of obtaining an equivalent, yet far simpler, homogeneous model capable of satisfactorily predicting the effects of exploitation in such circumstances. Moreover, if some equivalent homogeneous model does exist, does it furnish the same predictions as do those models which are currently being used to determine sustainable exploitation levels? The section following details the ‘groups population model’ (GPM) developed to address this question. A variety of results from this model are then reported and their implications discussed.

METHODS

The population model developed describes a population divided into groups, each of which is age structured. The basic underlying equations used to model the growth of the (unexploited) population include a recruitment function of the logistic form, with a per capita growth rate which depends on the total adult population size only, and are as follows:

\[
\begin{align*}
N_{i,y+1,0} &= S \cdot N_{i,y} \cdot \left[ 1 - S + r \left( 1 - P_y/y/K \right) \right] \\
N_{i,y+1,a+1} &= N_{i,y,a} \cdot S \\
N_{i,y+1,m} &= (N_{i,y,m} + N_{i,y,m-1})S \\
0 &\leq a < m
\end{align*}
\]

where $n_{i,a}$ is the number of animals in group $i$ at the start of year $y$ which are of age $a$.

$N_{i,y}$ is the number of adult animals in group $i$ at the start of year $y$.

$P_y$ is the number of adult animals in the total population at the start of year $y$.

$m$ is the oldest age class considered (a ‘plus group’),

$S$ is the annual survival rate.

$t$ is the age at first parturition (in years).

$r$ is the per capita growth rate parameter, and

$K$ is the carrying capacity for the total adult population.

‘Adults’ are those animals that have reached the age at first parturition $t$, so that:

\[
\begin{align*}
N_{i,y} &= \sum_{a=t}^m n_{i,y,a} \\
P_y &= \sum_{i} N_{i,y}
\end{align*}
\]
For simplicity, the model ignores sex distinction. The primary reason that density dependence is assumed to depend on the adult rather than the total population, is to avoid complex recursive computations in evaluating equations (1). These density dependent effects on growth rate are then assumed, given the form of equation (1), to occur at the total adult population level rather than at the group level. This seems a plausible starting point for analyses, as the effect of a reduction in per capita food availability (say) as the total number of animals increases, would be likely to impact all the components of a mobile population. However, it does have the important implication that the overall population will behave identically to one which is homogeneous (see Appendix 1 for the corresponding model), irrespective of internal group dynamics or group-related methods of removal which do not depend on group size.

If the group structure is going to lead to different dynamics, a prerequisite – given the basic model of equation (1) – is that the per capita growth rate parameter \( r \) and/or the removal rate are dependent on group size. Incorporating such dependence in the growth and removal rates results in the internal group dynamics becoming important, since the differences they provide in group structure (which also depends on group size) then affect the overall population structure and size. For example, a harvesting mechanism which favours the capture of certain sizes of schools only, will be removing animals with an age structure which (on average) may differ from the overall population age structure.

Given that harvesting removes cohesive groups, the model must incorporate a mechanism for group division, to prevent the remaining groups growing until the population consists of a single super-group only. One mechanism, which is not biologically unreasonable, has been assumed for this initial exploration of the problem: once a group exceeds a certain size, a small group of younger animals (whose size has a random component) breaks away, so that two separate groups are formed which are unequal in both size and age-structure.

This then raises the question of how the (per capita) growth rate for a group might depend on the size of the group – the key feature which needs to be introduced into the model to allow for the cohesive social structure to impact the overall dynamics. There is almost no detailed information from cetology to address this directly (e.g. Tillman and Donovan, 1986). Discussions with zoologists experienced with land-based mammal populations with such a social structure (e.g. elephants) gave rise to the observation that the smaller breakaway groups are less effective in protecting their young from predators. If this is the dominant group-size-dependent mechanism, it indicates that the per capita growth rate parameter \( r \) should be modelled as an increasing function of group size. Details of how this has been effected are given in Appendix 2(1) and in the following sub-section. The net result is that the per capita growth rate of a school depends on two factors: it increases with the size of the school, but decreases with the size of the overall adult population (through the logistic density dependent term of equation (1)).

The model is initiated with a small initial population of random group/age structure, and is run in the absence of any harvesting for a time sufficient to enable it to reach carrying capacity with the associated group/age structure – see Appendix 2(2).

Harvesting is then introduced in the form of the capture of a certain number of groups each year from the overall population – see Appendix 2(3). This capture takes place in a pulse at the start of the year, as for the homogeneous model – see Appendix 1. Since an actual fishery would tend to harvest larger groups only, only groups larger than an independently fixed minimum size \( C_{min} \) are removed in this process. Except for this minimum size criterion, the groups are removed at random.

The equilibrium levels that result under different levels of such exploitation are compared with those that follow for an ‘equivalent’ homogeneous population model. To ensure comparability, a record is kept of the total number of animals (not just the number of groups) harvested each year, so that an identical sequence of annual removals can be considered when the homogeneous population model is run. In addition, in cases where the \( r \) parameter of equation (1) depends on group size, an effective \( r \) for the population as a whole (see Appendix 2(4)) is calculated for use in the comparison with the results of the homogeneous population model.

Finally, because of random factors in the model (see Appendix 2(5)), all results are averaged over several runs to reduce the influence of Monte Carlo variation.

Further model details and restrictions

Because of computer storage and processing restrictions, the numbers of groups and age classes considered are somewhat limited. The overall population in the model (which is normalised to an adult population size of 1 at carrying capacity) is divided into a number of groups, where this number typically fluctuates from slightly below 100 to, at times, as high as 250. This fluctuation arises from the combined effects of group splitting and harvesting, although the average number of groups is generally close to 100. The number of age classes considered is limited to 11 (\( a=0 \) to \( a=m=10 \) years), where the last class includes all animals of 10 years of age or older.

Ideally a much larger number of schools would be preferred, to reduce Monte Carlo variation. This has to be achieved instead by averaging results over several runs.

Because of the paucity of empirical data, certain assumptions are made to restrict the parameter space investigated to manageable proportions. One notable assumption of the model as described thus far is that of an annual survival rate \( S \) which is independent of age. Although clearly \( S \) does vary with age in reality (although the extent of this variation is seldom well estimated), such variation has little effect on the behaviour of homogeneous models, so that it would not seem a primary candidate for fuller investigation in this initial exploratory analysis.

Equation (1) incorporates an assumption that pregnancy rate is independent of age for all animals that have reached the age at first parturition \( t \). This age is set to 4 for the calculations carried out.

Assumptions also need to be made about the size at which groups split and the size ratio of the two groups which result. The model developed includes conditions which must be met in order for a group to split. These are:

(i) the group must have exceeded a certain size (the value used – a somewhat arbitrary choice – is 3% of the pre-exploitation adult numbers in the whole population; this value essentially determines the number of separate groups in the population at carrying capacity);

(ii) the younger animals (those of age 2 to 5 – only animals of these ages contribute to the breakaway group) must constitute at least 15% of the numbers in the group; were there no splitting, the proportion of the animals
of this age in a group would be in the 25%-35% range, for the values of \( s \) and harvesting rates considered (see Appendix 2(6)).

The percentage of the group's younger animals that breakaway is a random variable, drawn from a uniform distribution over the 10%-50% range.

A more realistic representation of the minimum size for splitting in (i) above would be a probability distribution centred on the value chosen, rather than the 'knife-edge' formulation assumed. The latter has been used here in the interests of simplicity, in association with the judgement that greater complexity in this respect is unlikely to be of great relevance to behavioural differences between the HPM and GPM.

A piecewise-linear model is used to represent the group size dependence of the intrinsic growth rate parameter \( r \). This parameter is constant above a critical group size, but decreases linearly with group size \( G \) below that critical value \( G_{crit} \):

\[
\begin{align*}
\hat{r}(G) &= \begin{cases} 
  r & G \geq G_{crit} \\
  r - \lambda (G_{crit} - G) & G < G_{crit}
\end{cases}
\end{align*}
\]

(Recall - see equation (1) - that \( G \) is the total number of animals in a group, whereas \( N \) refers to the number of adult animals in the group.)

To summarise, the values chosen for the parameters are as follows:

- \( S = 0.9 \) (annual survival rate)
- \( K = 1 \) (adult carrying capacity for whole population)
- \( r(G) = \begin{cases} 
  0.2 & G \geq G_{crit} \\
  0.2 - 0.15(G_{crit} - G) & G < G_{crit}
\end{cases} \) (intrinsic growth rate function)

where either \( G_{crit} = 0 \) (for \( r \) independent of group size \( G \)) or \( G_{crit} = 0.01 \) (when \( r \) depends on \( G \) - note that this is roughly one third of the size at which the group splits)

\( r_{eq} = 0.148 \) (the equivalent value of \( r \) for a homogeneous population to that for the groups model above with \( G_{crit} = 0.01 \) - see Appendix 2(4))

- \( t = 4 \) (age at first parturition in years)
- \( m = 10 \) (maximum age considered (a plus group), so that there are 11 age classes of ages 0 to 10+ years)
- \( T = 300 \) (harvesting period simulated in years - commences once the unexploited population has stabilised at carrying capacity)

\[
C_{min} = \begin{cases} 
  0.01 & \text{(the minimum size of groups removed by harvesting)} \\
  0 & \text{(if no such minimum size is imposed)}
\end{cases}
\]

The values chosen above are not intended to reflect any particular species. The choice of a lowish age at first parturition, for example, was motivated primarily to save computer storage space and running time. However, if the possibility of transformation of the time variable is taken into account, the results obtained will reflect behaviour under a wider range of scenarios than indicated by these particular choices alone. For example, the results would be qualitatively unchanged if \( t \) and \( m \) were doubled, while (1-S) and \( r \) were simultaneously halved (corresponding to doubling the time variable), which would provide parameters values that resemble those for long-finned pilot whales (ICES, 1993, table 6.1.1) more closely.

A limited exploration of the consequences of varying some of the values chosen was undertaken, but did not produce results showing major qualitative differences from those reported below.

**RESULTS**

Results from both the groups (GPM) and homogeneous (HPM) population models for several different cases are detailed below.

Figs 1 to 5 show sets of comparisons between the results for these two models. The quantities compared are (i) the 'average' age of the animals captured, (ii) an overall adult population size and (iii) the average number of groups removed each year. The results are shown for a range of 'equilibrium' levels under exploitation. Note that 'equilibrium' here does not necessarily imply a steady state, as population oscillations can occur under harvesting even after transient effects have died out (see Fig. 6); in such cases, the population level reported is essentially the average over such oscillations (see Appendix 2(8)). Note also that the 'average' age is not a true average, as animals in the plus group \((m=10)\) are all taken to have an age of 10 years. This is, however, not that serious a concern here, because the average age statistic is intended as a surrogate for the more easily measured average length of the animals captured, and growth is relatively limited for older (larger) animals, so that such an 'average' age would correlate well with average length.

For Figs 1 and 2, there is no lower bound on the size of the groups removed by harvesting \((C_{min} = 0)\). Fig. 1 shows results when \( G_{crit} = 0 \), i.e. the \textit{per capita} growth rate parameter \( r \) is independent of group size (labelled 'Constant \( r \)'), while Fig. 2 introduces such dependence \((G_{crit} = 0.01\), labelled 'Variable \( r \)'). Figs 3 and 4 give comparisons when there is a minimum size for the groups removed \((C_{min} = 0.01)\) and otherwise correspond respectively to Figs 1 and 2.

In the comparisons above, the HPM results are those for a value of \( r \) equivalent to that used in the groups model \((r_{eq} = 0.148 \text{ - see Appendix 2(4)})\). Fig. 5 repeats the comparison of Fig. 4 \((G_{crit} = 0.01, C_{min} = 0.01)\) for the GPM, where now the incorrect assumption is made that the value of \( r \) for the larger groups \((r=0.2)\) is the appropriate choice for the HPM (labelled 'Incorrect \( r \) comparison'). The purpose is to show the errors which might be made if inferences concerning sustainable levels of yield are based on parameter values pertinent to larger schools only.

Population trajectories are shown for various levels of exploitation in Fig. 6. A high value of the minimum size of groups removed \((C_{min} = 0.015)\) is used in Fig. 6A to better illustrate the population oscillations which can occur. Fig. 6B gives corresponding results in the absence of this restriction \((C_{min} = 0)\).

**DISCUSSION**

Comparison between the homogeneous and the groups population models

Fig. 1, for which \( G_{crit} = 0 \) ('Constant \( r \)') and \( C_{min} = 0 \) (no harvest selection by group size), serves to illustrate the point made at the start of this paper; in the absence of any
dependence of per capita growth or removal rates on group size, there is no difference in the results of the GPM and HPM.

Introduction of a minimum catch size only (see Fig. 3) does introduce differences into the results from the two models, but they are extremely small. What gives rise to these differences? Note that the groups population contains a few small breakaway groups of young animals, which for the first few years following their split from their parent group have a younger average age than does the rest of population. On the other hand, those groups from which the breakaway younger groups have just split, now have fewer young animals than before and hence have a slightly higher average age. Now the reduction in average age for the breakaway groups is considerably greater than the corresponding increase in the average age of those animals that remain behind; but these residual parent groups are also considerably larger than the breakaway groups, giving this increase in age difference a greater weighting when an average over the whole population is calculated. Taken together then, these two effects necessarily cancel exactly, so that when groups are removed at random (\(C_{\text{min}} = 0 - \text{Fig. 1}\)), the average age of the animals caught is identical to that for the HPM.

However, with a minimum size for the groups which are removed, these captures are biased towards groups with a slightly higher average age than that in the overall population. This leads (eventually) to a slight decrease in the average age of the animals caught. There is also a very slight drop in sustainable yield (in terms of numbers) because of an increase in the selectivity-at-age for older animals (on average over the population), and more of those animals will be lost to natural mortality before harvest than is the case for younger animals.

The differences resulting from the inclusion of a minimum size for the groups removed are small for two reasons. First, the breakaway group constitutes a small proportion of its parent group (<15%), so that the change in average age for the residual parent groups is slight. Secondly, the time to recover the age structure after the split of the group is generally very short (of the order of a few years only). This means that most of the large groups have an average age essentially identical to the overall average age of the population; on the other hand those that do not, nevertheless differ only slightly from that average. In the abstract then, maximisation of such a difference would therefore require preferential capture of residual parent groups immediately following splits. This, of course, could hardly be achieved in practice.
With the introduction of group size dependence in the *per capita* growth rate parameter \( r \) (Fig. 3), some slight differences in the average age of the catch become evident. However, only when this is considered in conjunction with a minimum size for the groups removed (Fig. 4), do differences in the sustainable yield from that for the HPM become noticeable. However the effect is still small – the yield for the GPM is only some 5% less than that for the HPM for an adult population size reduced to 65% of its pre-exploitation level.

The reason for these slight differences are as follows. The equivalent value of \( r_{eq} \) used for the comparable HPM is calculated from the growth rate of the groups population in the absence of exploitation (see Appendix 2(1)). With the introduction of harvesting with a minimum size for the groups removed, a slight change occurs in the distribution of group sizes. The main difference is that the number of small groups increases slightly, because of the bias towards the removal of larger groups. Because the small groups have a lower \( r \) value than the larger ones, this increase in their number leads to an overall decrease in the effective average growth rate parameter for the entire population. In consequence, the groups population is impacted to a slightly greater extent under harvesting than is the homogeneous one. As would be expected, these differences become larger for heavier levels of exploitation.

The differences in Fig. 3, where the growth rate parameter \( r \) depends on group size but any group may be removed, are less. This is because any slight change in the population structure which might be brought about through the group size dependence of \( r \) is effectively ‘averaged out’ by harvesting over the full range of group sizes.

In contrast to the small differences between the results of the two models evident in Figs 1–4, there are marked differences between them when the HPM is run with a *per capita* growth rate parameter equal to that for the larger groups \((r=0.2)\), instead of the equivalent value of \( r \) \((r_{eq})\) – see Fig. 5. Whilst the smaller differences of the earlier Figures suggest that it is feasible to use the simple HPM approximation for the population dynamics. Fig. 5 illustrates that it is crucial that an appropriate value of \( r \) is used.

Attempts are sometimes made to infer values of \( r \) from biological parameters, or observed changes in their values which are assumed to reflect density dependent responses of the population. The analyses presented here suggest that care needs to be taken that such values are appropriately averaged over the full range of group sizes. Values obtained from large groups only may not reflect the situation in the population as a whole – a problem exacerbated if the only data available are those from harvested animals which are representative of the larger groups alone. The differences in 'average age' (and hence average length) of the catch for the two models, as indicated by Figs 5b and 5c are not large, so unfortunately it would not seem likely that measures of this quantity would provide an effective diagnostic of the inadequacy of the predictions of HPMs for levels of sustainable yield.
the number of groups harvested exceeding the number of new young breakaway groups, so that there is a reduction in the number of groups. Now with fewer groups, the average group size becomes larger, so that the number of new breakaway groups begins to exceed the number of groups captured, thereby increasing the number of groups, i.e. the cycle is completed. Thus, since the population size is related to the number of animals harvested, which is in turn related to group size, the oscillation in the number of groups creates an oscillation in population size.

Oscillations
Oscillations occur in the total population size trajectories under harvesting, particularly when smaller groups are not removed (see Fig. 6). Grasping the dynamics which underlies this phenomenon requires first some understanding of the links between the following four quantities: the number of groups, the average size of groups, the average size of the groups harvested and the total population size. We ignore here the initial transient phase when the population is reduced from its pre-exploitation to its exploited 'equilibrium' level, since the oscillations occur about the latter level.

An 'equilibrium' situation requires that the total population size, which is equal to the number of groups multiplied by their average size, remains roughly constant. Therefore, an increase in number of groups must be accompanied by a decrease in the average group size and vice versa. Although a fixed number of groups are removed each year, the random nature of such removals (even when limited to groups above a certain size) means that the number of animals taken depends on the average group size. Furthermore, the population size obviously depends on the number of animals removed by harvesting. In summary then, the population size is linked to the number of animals harvested, which is linked to the group size, which is in turn linked to the number of groups because the population size is roughly steady. It is this circular connection which complicates any attempt to understand the dynamics involved.

Consider the situation where there is a relatively large number of groups. Most of these groups will therefore necessarily be small, so that few will split. This results in the number of groups harvested exceeding the number of new young breakaway groups, so that there is a reduction in the number of groups. Now with fewer groups, the average group size becomes larger, so that the number of new breakaway groups begins to exceed the number of groups captured, thereby increasing the number of groups, i.e. the cycle is completed. Thus, since the population size is related to the number of animals harvested, which is in turn related to group size, the oscillation in the number of groups creates an oscillation in population size.

Of course, whilst this mechanism for producing oscillations exists, there is no obvious method to predict how great their amplitude might be. Nevertheless, it is clear that the introduction of a minimum size for the groups removed enhances the effect. Consider what happens as the number of groups falls. The minimum size restriction results in particularly those groups which are more likely to split (i.e. the bigger groups) being removed. Thus the number of groups must fall to an even lower level before there is a sufficient number of large groups for the number of new breakaway groups formed in splits to exceed the number of groups being caught, so that the number of groups can increase. This results in amplitudes of the oscillations which increase for greater values of the minimum size of groups harvested ($C_{min}$). In fact, if $C_{min} = 0$, while some oscillations in size and the number of groups are evident, the overall effect on the total population size is not noticeable (see Fig. 6b and Appendix 2(8)).
While the value of $C_{\text{min}}$ affects the amplitude of the oscillation, the level of catches affects their period, with greater catch levels resulting in a shorter oscillation period (see Fig. 6a). Note that the number of animals removed annually depends not only on the number of groups harvested each year, but also on the value of $C_{\text{min}}$. For a set number of groups removed each year, a positive value for $C_{\text{min}}$ will clearly result in a higher number of animals harvested than when $C_{\text{min}} = 0$.

These oscillations in population size do eventually die out (or at least are reduced in amplitude), but the time required is very long (some 1,000 years, or considerably more, depending on the value of $C_{\text{min}}$). The ‘equilibrium’ results quoted here (taken from a 300 year run time) are therefore not the true final equilibrium results, but are obtained by averaging results over the last 100 years of this 300 year period (see Appendix 2(7)) of each simulation run (this averaging is in addition to an overall averaging over many simulation runs). This does not introduce any bias into the comparison of the models, however, because identical numbers of animals harvested for the HPM are also removed when the HPM is run.

CONCLUDING COMMENTS

The results of these exploratory calculations do not suggest that cohesive social structure effects or a capture process which removes whole groups of such animals, are likely to have a marked impact on the sustainable harvest levels (or the length distribution of the animals caught) which would be predicted were such factors ignored.

The key mechanism assumed in this study to lead to the relationship between group-size and per capita growth rates, which is necessary for some influence of the population structure on the dynamics, is that small breakaway schools of younger animals are less successful in protecting their young, and accordingly manifest smaller such rates. If this is the case, there is a danger of overestimation of sustainable yields if these are calculated from biological parameters estimated from data from larger groups only (which may be captured preferentially).

An interesting result of the GPM developed is that in certain circumstances, the total population executes quite sizable oscillations about its exploited equilibrium level, rather than approaches this monotonically, as a consequence of the internal group dynamics. However, this result needs to be considered in the context of the idealised nature of the GPM investigated. For a more complex structure involving intermingling subpopulations (each with slightly differing parameter values) at a larger scale, it may well be that such effects are damped out by the overall ‘averaging’ involved.

Obviously only a limited region of parameter space has been explored in this initial exercise, and there is scope for more work in that regard. However, it would seem more important first to elicit alternative qualitative ideas on how group structure might impact dynamics, so that the associated implications can also be explored in a quantitative manner similar to that attempted here. For example, an interesting observation from one of the referees is that the fact of group division necessarily implies that groups become disadvantaged if they grow beyond a certain size. This could mean that the intrinsic growth rate parameter decreases (to some extent, at least) with group size for larger groups, in addition to the increase at small group size considered in this paper.

ACKNOWLEDGEMENTS

The authors are appreciative of discussions with Drs Peter Best and Anthony Hall-Martín of the University of Pretoria and National Parks Board, South Africa, respectively, and of the comments of two anonymous referees.

REFERENCES

Appendix I

THE HOMOGENEOUS MODEL (HPM)

The equations governing the HPM are deliberately similar to those used in the GPM to ensure comparability, and are as follows:

\[
\begin{align*}
n_{y+1,0} & = S \cdot N_y \cdot \left[1 + S + r \left(1 - N_y/K\right)\right] \\
n_{y+1,s} & = \left(n_{y-1,m} - C_{y,m}\right)S, \quad 0 \leq s < m \\
n_{y+1,m} & = \left(n_{y,m} - C_{y,m} + n_{y,m-1} - C_{y,m-1}\right)S, \quad a = m
\end{align*}
\]

where

\[
\begin{align*}
n_{y,a} & \text{ is the number of animals at the start of year } y \text{ which are of age } a, \\
N_y & \text{ is the number of adult animals at the start of year } y, \\
m & \text{ is the oldest age class considered (a ‘plus group’)}.
\end{align*}
\]

is the annual survival rate.

\[r\] is age at first parturition (in years).

\[r\] is the per capita growth rate parameter.

\[K\] is the carrying capacity for the adult population, and

\[C_{y,a}\] is the number of animals caught at the start of year \(y\) which are of age \(a\).

Comparison with equations (1) for the GPM shows that the main difference is the extra catch term \(C_{y,a}\). This term is not appropriate in the HPM since there entire schools are removed (also in a pulse at the start of the year, as assumed above). In the HPM, the same total number of animals as
are in such groups are removed from the population. The catch sizes used are those recorded during the running of the GPM. The age structure of this catch is in the same proportions as in the population:

\[ C_{y,a} = n_{y,a} \cdot (C_y/n_y) \quad (A.1.2) \]

where \( n_y = \sum_{a=0}^{m} n_{y,a} \) and

\[ C_y = \sum_{a=0}^{m} C_{y,a} \]

---

**Appendix 2**

**TECHNICAL NOTES ON THE GROUPS POPULATION MODEL (GPM)**

1. The particular piecewise-linear functional form chosen for the per capita growth rate parameter (\( r \)) affects roughly 71% of the groups (i.e. 29% of the groups, on average, are of a size large enough to avoid any growth rate penalty, and instead grow at a rate determined by \( r=0.2 \)). It should be noted, however, that a large proportion of groups have sizes just below the value of 0.01 chosen for \( G_{crit} \) (see equation (2)), and as such are affected only very slightly; the percentage of groups for which \( r \) is markedly below 0.2 is well below 71%. In the absence of empirical data, we are unaware of what proportion of such groups really are likely to be affected, so that the choice of this value for \( G_{crit} \) is somewhat arbitrary and might not be the most plausible. Nonetheless, the calculated equivalent value of \( r (r_{eq} \) see (4) below) for the GPM investigated is roughly 0.15, which constitutes a sufficient difference from the \( r=0.2 \) pertinent to large groups for one to expect changes in overall dynamical behaviour (if there are any) to be apparent.

2. The process by which the initial pre-exploitation equilibrium state is reached in running the model is quite complicated and merits some clarification.

Since the distribution of group sizes in the population at pre-exploitation equilibrium is not known, we allow the computer to model the growth of the population to that level. Provided the initial population size is small (<10% of the adult carrying capacity, \( K \)), the overall population size and overall average age reached appear on investigation to be quite independent of the initial distribution chosen for group sizes. Unfortunately, however, changes to this initial distribution do result in other slight differences (e.g. to the final distribution of group sizes) in the equilibrium established.

The reason for this stems from the logistic equation governing recruitment (see equation (1)), in which the per capita growth rate depends on an overall carrying capacity. Once the population has reached its unexploited equilibrium level at this adult carrying capacity, no further growth occurs. The problem arises because not only does the overall population size then remain constant, but the size of each group and the number of groups stops changing as well (because a group must grow to reach the size of 0.03 before splitting can occur), something which is not an accurate reflection of what must surely occur in nature. (This problem could be addressed by the introduction of spatial variability in the model, but that is beyond the scope of an exploratory exercise such as this.)

Thus the distribution of groups at the unexploited equilibrium (in terms of both number and size) does unfortunately depend on the initial distribution chosen, because of this ‘freeze’ on all internal dynamics once the equilibrium level has been reached. This difference in the distribution of group sizes leads in turn to a difference in the equivalent value of \( r (r_{eq} \) see (4) below) that is calculated – a value which is crucial for an appropriate comparison between the groups and homogeneous population models. What is needed is a method of arriving at an unexploited equilibrium (with an associated \( r_{eq} \) which is independent of the initial distribution chosen. The only satisfactory method found was to repeatedly let the population grow to its equilibrium level, and then to discard 80% of the groups (these being selected at random). This reduces the population size, allowing growth (and hence internal dynamics) once again, but this now commences with roughly the same group size distribution as that which pertained to the previous unexploited equilibrium attained. (This process was repeated 10 times; a larger number of repetitions showed no further appreciable decrease in the variance of the \( r_{eq} \) values calculated.)

Two trade-offs are involved in deciding how much to reduce the population size in this process. Because the number of groups used in the model is necessarily not only finite, but also not too large for computer storage reasons, the removal of a small percentage of the population only can lead to large Monte Carlo variation. This is because if a very low number of groups is discarded, such removals may not be characteristic of the group size distribution which has been established. A similar problem occurs at the other extreme, where removal of too large a percentage of the groups leaves only a small number in the population. This again exacerbates Monte Carlo variation – to an even larger extent in this case. In fact, this variation can be so large as to entirely negate any convergence towards the unexploited equilibrium population structure by the procedure described above.

Further, because of the calculation of the \( r_{eq} \) value (which requires information on population sizes when the population is at a level close to half its carrying capacity – see (4) below), a reduction of more than 50% is needed. Any reduction will introduce Monte Carlo variation to some extent (because it is highly unlikely that the removal is an exact representation of the population structure established at equilibrium). Therefore one must allow some time for the
population to recover towards its equilibrium structure prior to performing such calculations. Clearly, the greater the reduction (beyond 50%), the more time available. On the other hand, too large a reduction once again introduces the large Monte Carlo variation mentioned above.

Testing indicated an 80% reduction level to be a reasonable compromise, so that that value has been used to provide all the results quoted.

(3) The number of groups removed each year must, of course, be an integer. This is very restrictive, since with a model for which the number of groups seldom exceeds 250, only a very small number can be removed annually without causing population extinction, which provides very few data points for analysis. This difficulty is resolved by allowing the effective number of groups harvested per year to be 'fractional', which is achieved as follows. For a catch of (say) 0.4 groups per year, each year the probability that one school is removed is set to 40%, with the decision as to whether or not the group is removed then determined by random number generation. For a catch of (say) 2.7 groups per year, 2 groups are removed each year, and there is a 70% chance of removing a further group. The number of groups actually removed in any year is therefore an integer (as it must be), but averaged over the running time of the simulation, the effect amounts to the removal of '2.7' groups per year (or whatever that fractional value may be).

(4) The equivalent $r$ value ($r_{eq}$) is a 'comparable' value used for the per capita growth rate parameter of the HPM when comparisons are made between the dynamics of that and the GPM. When $r$ is independent of group size in the groups model, $r_{eq}$ is simply set equal to the same value. However, when $r$ depends on group size, the overall growth rate shown by the groups model will clearly be different (in the case examined here, less than that corresponding to $r=0.2$). Thus, some equivalent value must be determined for the HPM, to allow for a 'fair' comparison. This equivalent value is determined from the effective per capita growth rate of the unexploited groups population as the number of adults grows through $K/2$ (half the adult carrying capacity, at which the logistic model has a per capita growth rate of $r/2$).

The calculation is performed after the last 80% population reduction (see (2) above). It involves taking a weighted average of the value of $r$ of each group (see equation (2), and note (1) above). The weighting is according to the number of adults in each group. The adult distinction is important here, because the $r$ value 'affects' only those animals which have reached the age at first parturition. The final value used is that obtained by repeating the entire process of establishing an unexploited equilibrium level many times, and then averaging the results. The value calculated for $r_{eq}$ (averaged over 150 repetitions of the above procedure) is 0.1478, with a standard deviation of 0.0094.

(5) These random factors are a fundamental and vital component of the modelling process. Apart from providing a more realistic representation of what must be occurring in nature, they allow unwanted (and unnatural) coincidences, which often lead to misleading results, to be avoided. A deterministic model, for instance, would have all the groups splitting the same time and in the same fashion, which would mean a periodic doubling in the number of groups, interspersed with a linear decline due to harvesting.

This could provide quite misleading impressions of sustainable harvest levels, for example.

(6) The percentage of younger animals in a group in the absence of splitting depends on the current level of harvesting. As this level increases, so the average age of the entire population, and consequently that of each group, decreases. Generally the value is close to 25% at the pre-exploitation equilibrium, while at the heaviest exploitation levels considered in this paper, a value of some 35% can be reached.

(7) The reason behind averaging over the last 100 years is not (yet again) just to reduce Monte Carlo variation, but primarily to deal with the problem of oscillations (in population size, not necessarily in group size). The 100 year period has been specifically chosen as it is, for the most part, of greater length than the population size oscillation period, hence reducing any effects of averaging over some local region in an oscillation cycle only (e.g. a peak or a trough).

(8) The oscillation in average group size is apparent even when there is no restriction on the size of the groups removed ($C_{min} = 0$) and when, therefore, no appreciable oscillation is noticeable in the population size. (It is the circular link mentioned under Oscillations in the paper’s Discussion section which complicates matters, and leads to oscillations which sometimes have quite different amplitudes.) Moreover, the oscillation period is considerably longer than that produced when $C_{min} > 0$: if the numbers of groups removed each year is low, this long period can complicate results.

The existence of these oscillations must be kept in mind when considering, for example, the effect of various harvesting levels on average group size. In particular, the long period leads to misleading results even when these are averaged over a large number of years (>100). This is because for oscillation periods of (say) 500 years (which do occur), the averaged result is still over only a small portion of a cycle, which need not be anywhere near a node of the oscillation. The associated error is not as pronounced for higher levels of harvest, since these lead to oscillations of shorter period in both the population and the group size, so that averaging over a reasonable period of time tends to eliminate the effects of the oscillations on results. Further, however, over-looking the oscillation effects can, for example, lead to results showing an apparent increase (or decrease) in group size with an increase in harvesting intensity, since as the period of oscillation is gradually reduced, the range of the cycle over which averaging occurs tends to shift upwards (or downwards). It is only once the oscillation period has fallen well below the period over which results are averaged, that the average group size obtained is a good approximation of its equilibrium value.
The Geographic Stock Structure of Female and Immature Sperm Whales in the South Pacific

Susan Dufault and Hal Whitehead

Biology Department, Dalhousie University, Halifax, NS, Canada, B3H 4J1

ABSTRACT

This study considers the range of movements of sperm whales (Physeter macrocephalus) within the South Pacific Ocean. Individuals photo-identified during a one-year survey of the South Pacific in 1992-93 were matched to existing identifications collected off the Galápagos Islands in previous years since 1985. None of the females and immatures identified in the earlier studies were found in the western South Pacific or in the eastern Pacific south of 10°S. However, some animals seen previously off the Galápagos Islands were found off the Ecuador/northern Peru area north of 10°S during this study. It therefore seems unlikely that the female and immature sperm whales in the South Pacific undergo trans-oceanic movements but rather that their movement is limited to approximately 1,000 km. No large mature males were seen in this study (all from the western South Pacific) were matched to any individual identified previously off the Galápagos Islands or off Ecuador/northern Peru. It is possible that the mature males observed in these two regions are from separate breeding stocks.

KEYWORDS: SPERM WHALE; SOUTH PACIFIC; STOCK IDENTITY; PHOTO-IDENTIFICATION

INTRODUCTION

A good understanding of the stock structure of a whale population is important in assessing the effects of previous exploitation and in making management decisions concerning future exploitation. Fox (1977) showed that movements between different biological stocks could alter the outcome of models used to assess populations by changing the yield relationship. Kuhn et al. (1993) made comparisons between exploited and unexploited stocks to assess density-dependent effects but acknowledged that migration between these stocks would compromise these comparisons. The IWC Scientific Committee has stressed the importance of stock identity whilst developing a revised management procedure to regulate baleen whaling (e.g. Donovan, 1989; 1991; IWC, 1990).

The stock structure of sperm whales (Physeter macrocephalus) in the Southern Hemisphere is not well understood (Donovan, 1991). Rice (1977) suggested that the eastern tropical Pacific may be either inhabited by Northern Hemisphere animals during the boreal winter and Southern Hemisphere animals during the austral winter or that the stock of sperm whales in equatorial waters may be distinct from those at higher latitudes. The idea of an equatorial stock was supported by Berzin (1978) and Ivashin (1978) who proposed that there is a separate population between 10°N and 10°S.

Dufault and Whitehead (1993) present evidence suggesting distinct Galápagos and coastal Ecuador/northern Peru populations (of adult females and immatures) within the eastern tropical Pacific.

Most of what is known about sperm whale distribution and stock structure in the South Pacific was derived from commercial whaling data (Best, 1979) or marking experiments (e.g. Ivashin, 1981; Clarke et al., 1978) which relied on the whaling industry for the recovery of marks. Throughout these studies, the recovery rate of marks was low: Clarke et al. (1978) reported that of 53 sperm whales marked in 1964, only two had been recovered; whilst Ivashin (1981) estimated the return of only 44 (3.1%) of 1,422 sperm whales marked over a 26 year study from 1952-53 to 1978-79. These marking studies showed some bias towards large males especially during recovery when whales tended to select larger animals. Little was learned from these investigations about the movement of sperm whales across the South Pacific especially in regard to females and immatures. The reliance of this technique on the whaling industry makes it no longer a viable method for studying sperm whales given the moratorium on commercial whaling since 1985 and the general trend towards non-lethal research techniques.

In the early 1980s, Whitehead and Gordon (1986) developed non-invasive techniques for studying living sperm whales. One of these techniques – photo-identification – uses photographs of characteristic markings along the trailing edges of the whales’ tail flukes to identify individuals (Arnborn, 1987). Since 1985, the population dynamics and social organisation of the female and immature sperm whales off the Galápagos Islands have been studied by this method (Whitehead and Arnborn, 1987; Whitehead et al., 1991; 1992). A catalogue of 1,550 (1,242 with high quality photographs) identified individual female and immature sperm whales from the Galápagos Islands has been compiled. In 1991, the study was expanded to include a second area off the coast of Ecuador and northern Peru. A catalogue of 285 (241 high quality) individual female and immature Ecuador/northern Peru (hereafter ENP) whales was compiled from data collected in 1991 in addition to the eight (three high quality) identifications collected in this area in 1985.

In contrast to studies using artificial marks, it is possible to photographically ‘mark’ many whales during short periods at sea (e.g. 385 high quality identifications in 39 days at sea off Ecuador in 1991; Dufault and Whitehead,
1993) and many individuals have been successfully resighted over periods of one to eight years (133 different individuals from within the Galápagos area with high quality photographs). Arnborn (1987) estimated that only 9% of sperm whales 'marked' through photo-identification had flukes which were not sufficiently distinct to allow reidentification.

Analysis of photo-identification data led Dufault and Whitehead (1993) to suggest that female and immature sperm whales off the Galápagos Islands probably belong to a different population to those off the coasts of ENP, based on the fact that complete mixing between the two geographical areas was not observed over a period of two years – the time between samplings. However, the complexity of the situation was illustrated by the fact that some whales were seen to move from the Galápagos to the ENP area, but none were found to move in the reverse direction. The authors hypothesised that recent whaling along the coast, which substantially reduced stocks in the area (Ramirez, 1989), may have created a vacancy in a better feeding area for these whales from further west to occupy. In an attempt to examine this, Kahn et al. (1993) examined defecation rates (an indication of feeding success) but found no significant difference between whales in these two regions. This paper provides some additional data needed to further elucidate the relationship between sperm whales in the eastern tropical Pacific.

During June 1992 to May 1993 an expedition was undertaken to study sperm whales throughout the South Pacific using non-invasive techniques including photo-identification. The movements of sperm whales within the ocean basin are examined here by comparing the individuals identified in the 1992/93 expedition to those on file in the Galápagos catalogue. Since approximately 40% of the individuals in this population are known (Whitehead et al., 1992), if many of them travel to other areas in the South Pacific it seems likely that some of them would be observed in the sampling from these other areas. If so, this should provide information on the range of movements of individuals from the Galápagos area. On a smaller scale, photo-identifications obtained off the western coast of South America are used to examine the relationship between female and immature sperm whales off the Galápagos Islands with those off the coasts of ENP and to define the extent of their movements in this area.

**METHODS**

**Field work**

Data were collected aboard the 13m sailing vessel *Balaena* during a survey of the South Pacific ocean originating at Panama 21 June 1992 and concluding at the same location 4 May 1993 (see Fig. 1). The route was selected to traverse areas (principally along the Equator, off the west coast of South America, northwest of New Zealand and near Tahiti and the Juan Fernandez Islands) in which sperm whales had been caught historically according to charts compiled using logbooks of American whaling ships (Townsend, 1938). Whilst in waters of greater than 1.000m depth, an omni-directional hydrophone (detection range – approximately 7km) was monitored every half hour for the distinctive clicks of sperm whales. When whales were heard and the weather was sufficiently good to track them, they were located and followed using a directional hydrophone and/or visual observation. In rough conditions, the presence of whales was noted but no attempt was made to locate or follow them. Photo-identification data were collected as in previous studies (see Arnborn, 1987; Dufault and Whitehead, 1993).

**Fluke matching and hypothesis testing**

Fluke photograph analysis followed the methods devised by Arnborn (1987) with refinements by Dufault and Whitehead (1993). Identifications were made by observing the negatives on a light table. A 2.5" x 3.5" print was made of each individual for the photograph catalogue and these photographs were digitised into a computer catalogue (Whitehead, 1990). Photographs with a quality rating (Q-value) of three or greater (on a scale of 1 to 5) were included in the catalogues. However, only photographs of Q-value 4 or 5 are considered sufficiently good to ensure positive identification of an animal and, hence, all others were excluded from statistical analyses.

A K-means cluster analysis was performed using the latitude and longitude position of the best photograph of each identified individual to see if these identifications could be combined into geographically sensible groupings. Individuals identified from 1992–93 were matched to existing individuals on file in the Galápagos and ENP catalogues, both visually and through the use of a computer matching routine (Whitehead, 1990).

Before attempting to match the new data to existing identifications, the current Galápagos and ENP catalogues were re-examined for mistakes and to ensure that the best photograph available of each individual was included. The hypothesis that Galápagos and ENP animals belong to the same stock was tested incorporating the new data and revisions to the old catalogues. Stocks (as defined by Dufault and Whitehead, 1993) were considered separate if the individuals from the two stocks did not mix randomly during the period between samplings (two years). Between-area resightings for 1991 and 1993 were combined and compared to the 1991 within-Galápagos resightings as this is the last year for which data are available from the Galápagos area. A likelihood ratio chi-squared (G) test was used to test the null hypothesis that the proportion of resights within the Galápagos was not different from the proportion of resights between the
Galápagos and ENP. A correction for the size of the stable groups in which the sperm whales are found was utilised (Dufault and Whitehead, 1993).

RESULTS

Fig. 1 shows the locations in which groups of sperm whales were photographed (encounters in which poor weather conditions or other circumstances prevented fluke photography are not shown, however, they were distributed in a broadly similar way to those in good weather). A total of 305 individuals was identified in this study. Of these, 100 were seen in the western South Pacific and 205 in the eastern South Pacific (Table 1). Cluster analysis allocated the identifications into the geographic groupings (termed here ‘concentrations’) shown in Fig. 1. Concentration 1 is in the same area that was sampled in the 1991 study (the current ENP catalogue). Although twenty (22.0%) of the 91 animals identified in this concentration matched with individuals in the current Galápagos catalogue, there were no matches with the ENP catalogue. These 20 matches consisted of one group of one animal and one group of 19 animals based on the criterion of having been seen within 24 hours of each other in more than one year (Dufault and Whitehead, 1993). No matches were found between whales identified in the western South Pacific or the eastern South Pacific south of 10°S and whales in either the Galápagos or ENP catalogues.

The re-examination of the Galápagos and ENP catalogues resulted in an additional match being found between the two catalogues bringing the number of matches from 1991 to 11 or 4.6% of the animals identified there. These 11 animals belong to groups of 1, 4 and 6 members. Four additional 1991 within-Galápagos resightings were found (new total of 31 or 44.3%). Group sizes for these 31 animals were 14, 7, 4, 4, 1 and 1. The revised resighting data are shown in Table 2. A contingency table combining the 1991 and 1993 ENP resightings and using the average group size of 5.63 was constructed from these data (Table 3). A G test on these data was highly significant ($G = 7.65; 0.01 < p < 0.005$). Hence, the null hypothesis that the within Galápagos resighting rate was not different from the between Galápagos and ENP resighting rate was rejected.
Mature males
As seen in Table 1, five large, mature males were identified in the western South Pacific during the study; the only other large male seen in the area (off Tahiti) was not successfully photographed. In the eastern South Pacific, only two males were seen but the photos taken were of poor quality (Q = 3). None of the five males photo-identified matched with known animals from the Galápagos (19 individual mature males identified from high quality photographs) or from the ENP area (two mature males with high quality photos).

DISCUSSION
No matches were found between the 1.550 female and immature sperm whales known from the Galápagos and those seen in 1992–93 in the western South Pacific \( (n=100) \) or the eastern South Pacific south of about 10°S \( (n=114) \). If many Galápagos animals travelled to these areas, we believe that some would probably have been observed, given the large proportion of the Galápagos population which we have identified (ca 40%). Of course, an alternative explanation is that any Galápagos animals that journey to these areas mix with a population so large that they are difficult to detect. However, if this is the case, one might expect that many individuals from these other areas would make the return journey to the Galápagos and therefore, be included in the Galápagos population estimate. Hence, unless this movement is one-way (Galápagos to these other areas only) it seems likely that stocks in these regions are distinct from those off the Galápagos, i.e. that there is little or no movement between them.

The only matches found between female and immature sperm whales seen off the Galápagos Islands and animals identified in the South Pacific in 1992–93 were found off ENP north of 10°S. Our results support the possibility that there may be a tropical population of animals which is distinct from those at higher latitudes in the South Pacific, as suggested by Rice (1977), Berzin (1978) and Ivashin (1978). Our results also indicate that the movement of these animals is probably restricted to distances in the order of about 1,000 kilometres (the distance between the Galápagos and ENP areas). This is in agreement with Best (1979) who found an average straight-line distance of approximately 688 km between marking and recapture of females in the Southern Hemisphere.

Although animals were seen to move from the Galápagos to the ENP area, a G test showed that the probability of a within-Galápagos resighting was significantly greater than the probability of a Galápagos to ENP resighting. Using the complete mixing criterion, the animals in these two areas can be considered to belong to separate geographic stocks (this is not to say that they are necessarily genetically distinct). The between-area resighting rate increased from 4.6% in 1991 to 22% in 1993. This may reflect sampling variation or it may be evidence of a slow mixing between the two areas. It is, as yet, unknown whether the movement of animals in this region is a one- (Galápagos to ENP only) or two-way occurrence. This would require the analysis of additional data collected off the Galápagos, which has to date not been possible.

For management purposes, in 1972 the IWC allocated the sperm whales of the Southern Hemisphere into nine divisions separated by lines of longitude; they have not been reviewed since Southern Hemisphere sperm whales were protected in 1980 (Donovan, 1991). The eastern Pacific Division 9 ranges from 100°W to 60°W. This paper suggests there may be three separate geographic stocks in this Division alone.

Mature males
There were no matches between the 21 mature males identified off the Galápagos Islands \( (n=19) \) or the ENP area \( (n=2) \) in previous years and the five identified in the western South Pacific during this study. Whilst this is perhaps not surprising given the very low sample sizes, it should also be noted that these five males were found during September and October in tropical and subtropical waters and may thus be on a ‘Southern Hemisphere reproductive schedule’ where the peak of the breeding season is thought to occur between October and December (Best et al., 1984). By contrast, sperm whales off the Galápagos Islands are thought to be on a ‘Northern Hemisphere reproductive schedule’ (Whitehead et al., 1989). Hence, it is possible that the mature males that we observed in the western South Pacific are from a separate breeding stock from those seen in the Galápagos (usually March-May).

No large males were seen in the eastern South Pacific during our voyage up the western coast of South America until we were off central Peru (around 11°30.5'S where we saw two large males although only one was photographed) and then again off Ecuador (around 0°14.5'S) where one mature male was photographed. Unfortunately, neither animal could be positively identified due to the poor quality of the photographs. One possible explanation for this distribution is that mature males on a Southern Hemisphere reproductive schedule would still have been in polar waters and thus would not have been ‘available’ to us whilst the males that were seen may have migrated from the Northern Hemisphere (i.e. on a northern schedule) to breed with females.

It is important to note that encounters with large, mature males have been scarce in all of our studies (only 19 high quality identifications in five field seasons off the Galápagos) possibly due to a reduction in their numbers as a result of whaling (Ramirez, 1989). Hence, it is difficult to make any firm conclusions regarding mature males using our photo-identification data. Genetic techniques which are currently being developed should aid greatly in determining the identity of breeding males leading to a better understanding of the genetic stock structure of sperm whale populations.

CONCLUSION
On a broad scale, it appears as though few, if any, female and immature sperm whales from the Galápagos Islands travel to areas in the western South Pacific or in the eastern South Pacific south of 10°S. On a smaller scale, some Galápagos animals travel to the waters off ENP where they mix with sperm whales from what appears to be a geographically separate stock. Thus, the movement of female and immature sperm whales within the South Pacific ocean is probably in the order of 1,000 km or so. The scarcity of photo-identifications of mature males and the lack of matches from different areas has not allowed us to make conclusions concerning their movements. It is possible that mature males seen by us in this study in the western South Pacific form a separate breeding stock from those seen by us in previous years off the Galápagos Islands.
ACKNOWLEDGEMENTS

This study was funded by the National Geographic Society and the Natural Sciences and Engineering Research Council of Canada. We extend gratitude to all the crew members of Balaena who assisted in the collection of data at sea. Thanks to M. Dillon and K. Richard both of the Biology Department, Dalhousie University, Halifax, NS, Canada, B3H 4J1 who kindly reviewed the manuscript, as did G.P. Donovan and two anonymous reviewers.

Status of Pacific Sperm Whale Stocks before Modern Whaling

Hal Whitehead

Department of Biology, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4J1

ABSTRACT

Catch profiles of the hunt for sperm whales in two areas of the Pacific have been estimated for the period 1800-1930. Sighting rates obtained from logbooks of whalers operating at the height of the hunt, and the estimates of population parameters contained in the IWC’s Sperm Whale Model, allow population trajectories to be constructed for these areas during the interval between the beginning of open-boat whaling (1790) and when modern whaling started in earnest (1946). The analysis suggests that sperm whale populations near the Galápagos Islands and in the western North Pacific were about 10-30% of their pre-whaling sizes in 1946. There is much uncertainty about the estimate of depletion for the Galápagos area and there are possible sources of bias which are likely to be more serious for the analysis of the western North Pacific. Levels of depletion for these two areas in 1946 may be higher than these estimates on account of modern whaling during the first half of the 20th Century. Sperm whale populations in other parts of the world were also likely to have been considerably depleted when modern whaling began.

KEYWORDS: SPERM WHALE; NORTH PACIFIC; EASTERN TROPICAL PACIFIC; HISTORICAL WHALING; ASSESSMENT; TRENDS

INTRODUCTION

Analyses of the status of sperm whale (Physeter macrocephalus) populations have assumed that at the start of intense modern whaling for this species, ca 1946, the stocks were at stable equilibrium in size and age distribution (Gambell, 1983), despite the fact that sperm whale stocks throughout the world were heavily exploited during the 19th Century by open-boat pelagic whalers (Best, 1983). Sperm whales appear to have a low potential rate of increase (<1% per year) according to models used by the Scientific Committee of the International Whaling Commission (IWC, 1982). Therefore, it is unclear whether assumptions that sperm whale stocks were at equilibrium size and had a stable age distribution in 1946 are valid (Gambell, 1983). If they are not, there are two important consequences (Anon., 1978): the degree of depletion (proportional reduction of pre-whaling stock size) will be underestimated; and during the early years of modern exploitation, recruitment rates will have been higher than assumed by models. This will generally lead to overestimates of current population size for analyses using catch-per-unit-effort or length distribution models.

In order to assess the cumulative effects of the open-boat hunt, estimates of changes in population size and effort are needed. The logbooks of 19th Century American whalers preserved in museums provide a valuable resource for examining the hunt and its effects (IWC, 1983). Using these logbooks, Bannister et al. (1981) have examined the sperm whale populations and their exploitation in the western North Pacific, as have Hope and Whitehead (1991) for the populations around the Galápagos Islands in the eastern tropical Pacific. Unfortunately, these analyses were restricted to the peak whaling periods (ca 1825-1855) as insufficient logbooks are available before or after this period. However, substantial numbers of sperm whales were killed outside the 1825-1855 period (Best, 1983) and the level of this exploitation may greatly affect the status of sperm whales in 1946.

In this paper, I estimate the profile of the take of sperm whales during the open-boat hunt. This is used together with the IWC’s ‘Sperm Whale Model’ (IWC, 1982) and the sighting rate information compiled by Bannister et al. (1981) and Hope and Whitehead (1991) to model the trajectories of the western North Pacific and Galápagos sperm whale populations up until the start of modern whaling.

MODEL

The purpose of this model is to examine the population trajectories of sperm whale stocks from the start of the open-boat hunt in the 18th Century until the start of modern whaling in the 20th Century. For the purpose of this paper, I define stock size to be the number of sperm whales within a particular ocean area. For each area the following information is used.

\( h(t) \) = an arbitrarily scaled estimate of the profile of the take during the period from the start of the primitive hunt \((t=0)\) until the start of the modern hunt \((t=t_{mod})\).

\( s(t) \) = rates of sighting sperm whales per whaling day during some part of this period \((t_1 \text{ to } t_2)\).

A population model for sperm whales – the model and its parameters are the ‘Sperm Whale Model’ of the IWC (IWC, 1982): age at maturity of females = 10 yrs; natural mortality of females = 0.053yr\(^{-1}\), males = 0.066yr\(^{-1}\), juveniles = 0.0926yr\(^{-1}\); unexploited pregnancy rate = 0.20yr\(^{-1}\); maximum pregnancy rate = 0.25yr\(^{-1}\); density dependent dependent exponent (relating pregnancy rate to population size) = 1.4. The part of the model which changes pregnancy rates as the ratio of large males to females falls below a critical value was not used as it was assumed that males and females were targeted equally (see below).

The following assumptions are made.

1. \( h \) is related to the true take by an unknown constant of proportionality, \( k \), which is invariant with time.
2. The sighting rate, \( s \), is assumed proportional to the stock size at that time.
3. The Sperm Whale Model is assumed to describe the dynamics of a sperm whale stock.
4. The sperm whales within any part of each study area are similarly affected by whaling.
5. In any area, at any time, hunting mortality is the same for both sexes and all age classes.
Let \( \{N(t)\} \) be the population trajectory for an area. \( N(t) \) is scaled (arbitrarily) relative to the maximum annual take, \( \max(h(t)) \). For any \( N(0) \), the stock size at the start of the primitive hunt, the parameters of the Sperm Whale Model and the profile of the take, \( \{h(t)\} \), can be used to produce a population trajectory \( \{N(t)\} \). \( N(0) \) is then chosen to fit the \( \{N(t)\} \) trajectory to the sighting rates, \( \{s(t)\} \), over the period for which sighting rates are available, by minimising:

\[
\sum_{t=t_i}^{t_f} \left( \frac{\log(N(t))}{\text{Mean}(N(t))} - \frac{\log(s(t))}{\text{Mean}(s(t))} \right)^2
\]

with respect to \( N(0) \).

For both the data sets which were used, with the fitted value of \( N(0) \), \( \log(N(t)) \) was approximately a linear function of \( t \) within the periods for which sighting periods were available. Thus, regression techniques could also be used to estimate \( N(0) \) and its standard error. If the slope of the regression line of \( \log(s(t)) \) on \( t \) is \( \alpha \) with confidence limits \( \alpha_1, \alpha_2 \), then \( N(0) \) and its confidence interval, can be estimated by choosing values so that the slopes of \( \log(N(t)) \) against \( t \), within the same time period, are \( \alpha, \alpha_1 \) and \( \alpha_2 \) respectively.

**THE DATA**

Sighting rates for the 10° square (1,234,765km²) around the Galápagos Islands (5°S-5°N, 85°-95°W) between 1830–1850 come from Hope and Whitehead (1991), and for a 12,767,000km² area of the western North Pacific (20°-40°N, 160°W-140°E) during the period 1825–1858 (but excluding 1827, 1851, 1852 and 1855) from Tillman and Breiwick (1983) based on the work of Bannister et al. (1981).

Catch profiles for the two areas during the period 1800–1930 were calculated using the summed estimated British and US sperm oil production for each decade (from Best, 1983, table 5). These were corrected for changing use of the different areas, estimated from the proportion of whaling ships which were recorded as visiting the Galápagos or Hawaii respectively during each decade, as given in Langdon (1978). The resulting catch profiles are shown in Table 1.

**RESULTS**

The results of the model are summarised in Figs 1–2 and Table 2. Estimates of \( N(0) \) were similar using least squares minimisation and regression techniques. In both areas, sighting rates fell at about 4% per year during the periods for which sighting rates are available. The analysis suggests that both stocks reached minima of approximately 10–20% of their initial size in about 1880 and then slowly rebuilt. Both stocks appear to have still been depleted in 1946. Estimates are more accurate for the western North Pacific where a longer series of sighting rates is available.

**VALIDITY OF ASSUMPTIONS**

1. **The estimated catch profile is proportional to the true take**
   This assumption is tenable if: (a) the sperm whale oil production figures given in Table 1 are proportional to the world catch of sperm whales; (b) the proportion of the total annual catch taken from an area is proportional to the rate with which the ships listed by Langdon (1978) visited islands in or near the whaling ground; and (c) there was no modern whaling before 1946.

   (a) **Oil production**
   Best (1983) considers the production figures in some detail. He suggests that they are incomplete for all whaling prior to 1804 and for non-US whaling after 1839. The estimates that Best (1983) presents for non-US whaling after 1839, suggest that it accounts for a rather small proportion (<10%) of the total production after 1839. These omissions will tend to lead to an underestimate of the importance of the early and late phases of the hunt, and an underestimate of the depletion in 1946. There was no significant change in mean oil yield per whale with time from particular classes of whaling vessel (Best, 1983).

   (b) **Catch: ship visits**
   The Galápagos Islands are in the centre of the Galápagos area. On the other hand, the Hawaiian islands are on the eastern edge of the western North Pacific area which is 5,800km across. At the western edge of the western North Pacific area are the Bonin Islands for which Langdon (1978) lists visits by ships. There are only 59 visits to the Bonin Islands as opposed to 908 for Hawaii, so that using the Bonin data to compute population trajectories is not practical. However, the rate at which ships visited the Bonin Islands per decade is closely correlated with that for Hawaii ($r=0.772, P=0.001$). Biases would result if ships tended to visit the whaling grounds, but not the islands, more often in some periods than others. It is hard to examine such biases. Some of the ships listed in Langdon (1978) were not sperm whalers and it is possible that the proportion of non-sperm whalers listed changed with time. Whaling for right whales (Eubalaena spp.) in the Pacific during the 19th Century shows a pattern of catches somewhat similar to that for sperm whales, peaking in the 1840s (Best, 1987). However, bowhead whales (Balaena mysticetus) were principally caught between 1850-1875. As bowhead whalers frequently visited Hawaii (Bockstoce and Botkin, 1983), the proportion of non-sperm whaling ships visiting Hawaii may have been larger during this period than earlier. An increasing proportion of non-whaling vessels (a few of which are listed by Langdon (1978)) visiting Hawaii may also have led to an overestimate of the index of the sperm whale catch ($b(t)$) in the western North Pacific (as listed in Table 1) after 1850. However, effort on the western North Pacific Grounds shifted westward during the course of exploitation (Bannister et al., 1981), with decreasing visits to Hawaii and increasing use of the Bonin Islands. These opposing sources of bias are hard to reconcile and it is possible that using visits to the Hawaiian Islands as an index of the importance of the western North Pacific area may have introduced a bias, of unknown size or direction, in the catch profile during the second half of the 19th Century. This problem is largely absent for the Galápagos area, for which the islands lie in the centre of the area and were rarely visited by bowhead whalers or traders.

   (c) **Modern whaling prior to 1946**
   A few hundred sperm whales were taken annually between 1910–1946 by modern whalers working in the coastal waters of Japan and the Kuril Islands, and the pelagic hunt in the North Pacific started taking over 100 animals per year in 1936 (Ohsumi, 1980). Similarly, pelagic catchers were taking a few thousand sperm whales a year off the ‘coast of Peru’ between 1936 and 1946 (IWC, 1980) in an area which borders and may overlap, the Galápagos area. These pre-1946 catches by modern whalers will have added to the depletion of the stocks in 1946.

2. **The sighting rate is proportional to the stock size**
   The use of sighting rates as indices of population density is discussed by Best (1983) and Tillman and Breiwick (1983); they are thought to be less biased by changing technology than catch rates. However, biases may have been introduced if whales changed their aggregative behaviour as the population was depleted. For example if they formed larger aggregations in response to exploitation, as suggested by Melville (1851), then sighting rates (expressed as schools rather than individuals) might fall faster than the stock size and the degree of depletion will be overestimated. If, on the other hand, aggregation sizes decreased in response to exploitation, then the sighting rate might fall more slowly than the stock size, understimating the extent of depletion.

3. **The Sperm Whale Model is valid**
   Changes in population parameters may affect the trajectories in two principal ways. If reproductive or survival rates were higher than those assumed by the IWC, then the initial population (relative to maximum annual catch) needed to produce a given decline in sighting rates will have been lower, but the populations will have recovered faster following the principal period of whaling (ca 1880–1946). Conversely, less resilient population parameters will result in a higher initial population (relative to maximum annual catch) but slower recovery. In Table 3 estimated rates of depletion are given for the
Galápagos and western North Pacific, using the Sperm Whale Model as outlined above with two types of change: the maximum pregnancy rate was varied from 0.23 yr⁻¹; and the natural mortality of females was varied from 0.055 yr⁻¹ (with juvenile mortality adjusted to give equilibrium populations before exploitation as in Allen and Kirkwood, 1977). Both populations show considerable depletion in 1946 for all maximum pregnancy rates and natural mortalities considered, and thus for a range of potential rates of increase.

Table 3
Estimated rates of depletion of Galápagos and western North Pacific sperm whale populations in 1946, and potential rates of increase per year, for a variety of maximum pregnancy rates and natural mortalities of females. The parameter values used in the IWC sperm whale model are marked by an *

</table>

As I assume that there was no selectivity in the hunt, the part of the Sperm Whale Model dealing with the effects of a relative reduction of mature males was not invoked. During the best-fit (least squares) runs for both the Galápagos and western North Pacific areas, the minimum ratio of socially mature males to mature females was 0.257, well above the level assumed to affect pregnancy rates by the Sperm Whale Model (IWC, 1982). However, it is possible that when the populations were substantially reduced in the mid 19th Century, females may have encountered mature males less often than previously and experienced lower pregnancy rates (Whitehead, 1987).

(4) Homogeneity of effects of whaling within areas
Sperm whales are probably fairly well mixed throughout the Galápagos area, with animals migrating across large parts of it (Dufault and Whitehead, 1993). Kasuya and Miyashita (1988) consider that the western North Pacific area of Bannister et al. (1981) principally contains only one breeding stock, the 'southwestern North Pacific stock.' Therefore, although whaling effort in the western North Pacific moved westward after 1850 as whaling declined (Bannister et al., 1981), the effects of this are probably small. Any inhomogeneity in the effects of whaling within an area will generally lead to underestimates of the degree of depletion as indicated by sighting rates because sighting rates will remain buoyant as new, relatively unexploited, concentrations of animals are encountered.

(5) Hunting mortality is the same for both sexes and all age classes
There is some uncertainty about whether the open-boat whalers selected for or against different age or sex classes (Best, 1983; Mitchell, 1983). Allen and Kirkwood (1977) showed that the rate of recovery of depleted sperm whale populations depended on whether the whalers did or did not select for larger whales. The consensus at the International Workshop on Historical Whaling Records was that there was little active selectivity by these open-boat whalers (IWC, 1983).

It is possible that there was inadvertent selection for or against large males because of their different migratory and schooling behaviour. If large males were proportionally spared (perhaps because of migrations to high latitudes where open-boat whalers worked less frequently), this will have little effect on the degree of depletion estimated in this paper as large males only constitute a small proportion of the population and the sighting rates used to calibrate the population trajectory are from the whaling grounds. However, if large males were inadvertently targeted (perhaps because of solitary schooling) and their relative reduction led to a reduced pregnancy rate of females (e.g. Whitehead, 1987), then the depletion in 1946 would be greater than estimated in this paper. However, Hope and Whitehead (1991) found the proportion of large males in the open-boat Galápagos catch to be close to the value predicted by the Sperm Whale Model, so that the assumption of homogeneous hunting mortality seems reasonable.

There may have also been intentional or inadvertent selection for or against other classes of whales (e.g. younger males, immatures, calves). However, the dramatic decline in sighting rates (Figs 1 and 2) supports previous conclusions (IWC, 1983) that there was no substantial and consistent intentional selection among sightable animals of these classes and that the Yankee whalers intensively whaled the ocean areas (mostly <40° latitude) where these classes of sperm whale are most common. Therefore, although considerable additional modelling would be needed to fully investigate the potential effects of such selection, it is unlikely to have had much effect on the degree of depletion in 1946.

DISCUSSION
The analysis in this and other papers (e.g. Tillman and Breivik, 1983) shows that the open-boat sperm whaling operations of the 19th Century probably reduced sperm whale stocks substantially, even though maximum annual catches were only about 3% of the pre-whaling population (Table 2). In 1946 sperm whale populations in the two areas of the Pacific examined here were still considerably depleted, perhaps 10–30% of their pre-exploitation sizes. There may be some biases in the estimates, especially for the western North Pacific where using the rate at which vessels visited Hawaii may not parallel the use they made of the western North Pacific Grounds. However, the direction of such a bias is not obvious. Catches by modern whalers before 1946 will have increased this depletion.
I have been unable to locate a copy of the manuscript by Allen and Kirkwood (1976) which examines the potential effects of the open-boat catch on more recent sperm whale population dynamics. However, their methods and results are described briefly by Anon. (1978) and Gambell (1983). They simulated a sperm whale population subject to a heavy catch for 30 years and then allowed to recover without exploitation for 100 years. The principal difference
between this study and that of Allen and Kirkwood (1976) is that they looked at the implications in 1946 of different catch intensities 100 years earlier, whereas I have tried to estimate the profile of the open-boat catch throughout the 19th Century and to extrapolate its effects up to 1946.

One of Allen and Kirkwood’s (1976) simulations showed that a population reduced to 20% of its initial value by a hunt directed at females and immatures, recovered to 65% a century later (Gambell, 1983). In comparison, the best-fit trajectory for the Galápagos presented here has a minimum level of 22% in 1880 (Fig. 1) and is at 49% of its initial level in 1880. The difference between these results is caused partially by the open-boat catches after 1880 which are included in my simulation, but probably principally by the different natural history parameters used by Allen and Kirkwood (1976).

The present analysis re-emphasises the paradox discussed by Tillman and Breiwick (1983): if open-boat whaling so reduced sperm whale numbers, why were modern whalers able to take more whales over a shorter period (Best, 1983) from smaller initial stocks and not drive the populations to extinction? Possible resolutions of the paradox include substantial underestimates of the open-boat catch, problems with modern estimates and changes in carrying capacity (Tillman and Breiwick, 1983). Unfortunately, because the analysis in this paper uses indices of abundance rather than absolute numbers, it cannot be extended readily to include the effects of the modern catch.

Even in the absence of modern whaling, the analysis suggests that populations may not have yet recovered from the effects of the open-boat hunt (Figs 1 and 2). Therefore, despite little evidence of modern whaling near the Galápagos, assumptions by my colleagues and myself that the Galápagos population was ‘unexploited’ (e.g., Kahn et al., 1993) were probably unjustified.

Open-boat whalers frequently exchanged information on the prospects for different whaling grounds. This suggests that different grounds within an ocean were probably exploited in such a way that they gave the whalers similar returns at any time (Whitehead and Hope, 1991). If so, it is likely that overall, the grounds may have experienced similar levels of depletion. Thus the results obtained for the Galápagos and western North Pacific areas may be reasonable approximations for all sperm whale stocks in the Pacific.

The sperm whales of the Indian Ocean were exploited with a similar historic profile to those in the Pacific (Wray and Martin, 1983) and thus may also have been similarly depleted by the open-boat hunt. The Atlantic sperm whales were exploited earlier than those in the Indian or Pacific Oceans (Gambell, 1983) and many of the whales continued to pass through Atlantic grounds on their voyages to and from the Pacific or Indian Oceans. Thus stocks in the Atlantic were probably at least as depleted as those in the Pacific when sperm whaling had largely ceased in the 1880s, and probably more so.

It is quite probable that sperm whale populations throughout the world were considerably depleted, relative to their pre-whaling level, when modern whaling for this species began in earnest in 1946.

ACKNOWLEDGEMENTS

This study was supported by the Natural Sciences and Engineering Research Council of Canada and the Whale and Dolphin Conservation Society. Paul Anderson kindly sent me extracts from Langdon (1978) when the inter-library loan was inoperative. I thank Justin Cooke (Center for Ecosystem Management Studies, Moso 1, D-79297 Winden, Germany) and Susan Dufault (Biological Department, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4J1) for speedy and useful reviews of the manuscript. Two anonymous reviewers made a number of important suggestions for improving the analysis and its presentation.

REFERENCES

REPORT

INTRODUCTION

During its 45th Annual Meeting, the International Whaling Commission (IWC) adopted a Resolution on research related to the conservation of large baleen whales in the Southern Ocean (IWC, 1994a). This resolution was based on a Japanese initiative that proposed to investigate the reasons for the low abundance of southern blue whales (Balaenoptera musculus) despite the protection given to this species since 1968 (Hatanaka and Komatsu, 1993). Blue whales were given protection in the Southern Hemisphere in 1964 south of 40°S, apart from an area between 0° and 80°E. This exemption was removed in 1966, but protection was only extended north of 40°S in 1968.

During an ad hoc intersessional meeting of specialists held to prepare and plan for such research (IWC, 1995), a proposal for a sighting survey in Melanesian waters was presented by the Japanese Government. The objective of the survey was to obtain data on the distribution, abundance and stock identity of whales, particularly blue and Bryde's whales, in waters off the Solomon Islands.

Documented observations of cetaceans in Melanesian waters are scarce. Ohsumi and Shigemune (1993) reported the results of a sighting survey conducted by whalers in lower latitudinal waters in August-September 1957. Blue, sei and sperm whales were seen around the Solomon Islands in August.

Ohsumi (1978; 1979; 1980) reported on the catch of Bryde's whales carried out under special permit in the Southern Hemisphere. Seven whales were caught from the Solomon Sea. Ohsumi (1980) presented a preliminary estimate of the population size of Bryde's whales in the Solomon Islands waters covered as 1,800 animals using sightings data obtained by Japanese scouting boats. The estimate, however, was not based on currently accepted survey design or methodology (e.g., see IWC, 1994b). In addition, he noted that the geographical range of the stock was unknown.

This paper describes the results of the sighting survey carried out around the Solomon Islands between 28 November and 11 December 1993. The survey was operated by the Institute of Cetacean Research (ICR) on a contract with the Fisheries Agency of the Government of Japan. The National Research Institute of Far Seas Fisheries (IFS), Fishery Agency, participated in the planning of the cruise and supervised the operation. The logistic aspects of the survey were coordinated with the Governments of the Solomon Islands and Papua New Guinea, who extended permits for conducting the survey within their EEZs.

MATERIALS AND METHODS

Research area and period

The research area was defined as that between 4°S-13°S and 154°E-165°E. Within this, two sub-areas were defined (Fig. 1), on the southwestern side of the Solomon Islands (Solomon Sea side) and on the northeastern side (Pacific Ocean side). Research was scheduled for 12 days, from 29 November to 10 December 1993.

Research vessels and personnel

Two research vessels the Shonan Maru No. 1 (SM1:916.96t) and the Shonan Maru No. 2 (SM2:916.44t), participated in the survey. The barrel height (20m) and the front bridge height (11m) are the same on both vessels. The SM1 covered the Pacific Ocean sub-area while the SM2 covered the Solomon Sea sub-area. One of us (HS) acted as cruise leader on board the SM2, while the other (LP) was on board SM1. E. Horiwara was on board SM2 as an
 observer on behalf of the Solomon Islands Government. Embarkation and disembarkation for the two researchers and the observer occurred at Honiara, Solomon Islands.

RESULTS

Brief narrative and sighting effort
The ships departed Honiara on 28 November and started the sighting survey on the morning of 29 November. Fig. 1 shows the tracklines covered by both vessels, specifying the daily noon positions. In this figure, those parts of the track not covered with solid lines show navigation without sighting effort. The survey track of SM1 partially covered the EEZ of Papua New Guinea.

The SM2 covered 1,041 n.miles of the planned 1,126 n.miles in normal closing mode while the SM1 covered 959 n.miles of its planned 1,209 n.miles. The weather conditions on both sides of the research area were moderate with frequent tropical showers of short duration in the first half and relatively strong winds and rain in the second half.

After completing the survey in the research area, the vessels arrived at Honiara on the morning of 11 December.

Cetacean sightings
The only large whale species observed by SM2 on the Solomon Sea side was the sperm whale, Physeter macrocephalus, a primary sighting involving one individual. Two schools of the short-finned pilot whale, Globicephala melaena (74 individuals) were observed as primary sightings and one school of this species (30 individuals) was observed as a secondary sighting. Dolphin species observed in this sub-area included the spotted dolphin, Stenella attenuata (three schools, 195 animals) and the spinner dolphin, Stenella longirostris (four schools, 665 individuals). One school of the Fraser's dolphin, Lagenodelphis hosei (30 animals) and one of the Risso's dolphin, Grampus griseus (three individuals) were also sighted. All the dolphin species were observed as primary sightings.

Two large whale species were sighted by SM1 in the Pacific Ocean side, the Bryde's whale Balaenoptera edeni and the sperm whale. Eleven primary sightings of Bryde's whale schools were made (20 animals). Three schools (three animals) of this species were observed as secondary sightings. All the sightings of the sperm whale were primary sightings (six schools, 11 individuals).

Other cetacean species observed in the Pacific sub-area were the false killer whale, Pseudorca crassidens (two schools, 17 individuals), the melon-headed whale, Peponocephala electra (two schools, 105 individuals) and the killer whale, Orcinus Orca (one school, 5 individuals). Two dolphin species, the spotted dolphin (one school, 170 animals) and the spinner dolphin (one school, 22 animals) were also observed in this sub-area. All of these schools were observed as primary sightings.

Geographical distribution
Fig. 2 shows the geographical distribution of the Bryde's whales sighted in the research area. All Bryde's whales were seen in the Pacific sub-area as were most of the sperm whales (Fig. 3). Figs 4 and 5 show the distribution of the sightings of the small cetaceans seen. The numbers of sightings are too few to examine distribution patterns.

1 Primary sightings are those made during normal searching on the trackline. Sightings made at other times, e.g. whilst closing with a sighting to confirm species and school size, are called secondary sightings.
Bryde's whales

The species most likely to be mistaken for the Bryde's whale is the sei whale, Balaenoptera borealis. The definitive feature of the Bryde's whale is the presence of three dorsal head ridges (e.g. Leatherwood and Reeves, 1983). A significant amount of time was spent for each rorqual sighting in the identification of the species and taking of photographs of individuals. All but two animals were identified by the three rostral ridges. The remaining individuals were identified as Bryde's whale from their dorsal fins, which were positioned about two-thirds back along the body and notably falcate and from their surfacing behaviour, with the head and blow appearing before the dorsal fin (e.g. see Martin, 1990). Furthermore, these two whales had heavily scarred skin as had most of the Bryde's whales identified by their head ridges. Both of the animals were secondary sightings (see Table 1).
Some of the Bryde's whales were observed in association with large shoals of pelagic fishes and flocks of sea birds. Table 1 shows relevant information of each Bryde's whale sighted around the Solomon Islands. Surface temperature in the areas where the Bryde's whales were observed, ranged from 28.8°C to 30.1°C. The estimated body length of the individuals sighted (excluding calves) ranged from 10.1m to 11.6m (Table 1), with a mean of 10.9m. The animal with an estimated body length of 7.0m in Table 1 could be a weaned calf, thus it was excluded from the range. On four occasions we observed calves accompanying the mother. The estimated average body length for the calves was 6.4m.

Bryde's whales were easily approached by the vessel, apart from the cow-calf pair, which showed evasive behaviour. Usually they dived near the vessel, showing their lateral side. In one instance an individual breached clear of the water.

**DISCUSSION**

Comparison with the previous survey in the area

In our survey, the only baleen whale species seen was the Bryde's whale. A previous sighting survey in this area conducted in August 1957, reported 21 schools (41 individuals) of the blue whale and five schools (11 individuals) of the sei whale (Ohsumi and Shimigun, 1993). A blue whale cow-calf pair was observed in the western part of the Solomon Islands. However, it should be noted, species identification might have been problematic for both these species. The blue whales may have been of the sub-species *Balaeonoptera musculus brevicuda* (pygmy blue whale), since the identification of this sub-species was made subsequent to that survey (Ichihara, 1963; 1966). Similarly, sei and Bryde's whales were not differentiated from each other in the sightings records and some if not all of the sightings recorded as 'sei' whales in Ohsumi and Shimigun (1993) may have been Bryde's whales.

The timing of the 1957 survey (August) was somewhat earlier than ours (November-December). It is possible that by the time of our survey, the orca group (including the blue whale) that feed in the Antarctic had already left the area on their southern migration. However, it should be noted that Butterworth et al. (In press) estimated the abundance of the true blue whale south of 60°S to be only 460 individuals (95% CI 212–996). Thus, the combination of the timing of our survey and the critically depleted level of the blue whale may explain why no individuals of this species were seen during our survey compared with that in August 1957.

The only other large whale species observed in our survey was the sperm whale. Sightings of this species (16 schools, 46 individuals) were also made during the August 1957 survey (Ohsumi and Shimigun, 1993).

**Comparison with catch distribution**

Perhaps the most distinctive feature of our survey was the fact that all the sightings of the Bryde's whale and all but one of the sperm whale sightings were made on the Pacific Ocean side of the research area, despite the fact that about half the total sighting effort was made on the Solomon Sea side. However, it should be noted that the seven Bryde's whales taken under special permit around the Solomon Islands in 1976/77 and the three additional sightings (Ohsumi, 1978) were from the Solomon Sea side.

**Distribution and environmental factors**

An attempt was made to investigate the relationship between distribution of the species sighted and bathymetry of the region surveyed; however, no conclusions could be drawn, which is perhaps not surprising given the relatively small number of sightings. The area surveyed by SM2 covered the South Solomon Trench with sea depths over 4,000m, where no sightings were made. All sperm and Bryde's whale sightings were made in waters with depths ranging from 2,000m to 3,000m. All cetaceans seen in both sub-areas were in fact sighted in waters of depths over 2,000m.

There are insufficient previous sightings data in the research area to examine any seasonal variation in the distribution of sightings. Bryde's whale distribution has been related to surface temperature data (SST) in some areas (e.g. Omura and Nemoito, 1955) and SST data were recorded hourly in the research area by both vessels but reveal little about the pattern of distribution observed. The SST range was similar in both sub-areas (28.5°C-29.6°C in the Solomon Sea sub-area and 28.3°C-31.3°C in the Pacific sub-area). The Bryde's whale sightings were all in waters with SST's between 28.8°C and 30.1°C.

Some Bryde's whales were seen in association with large shoals of pelagic fish and flocks of sea birds, suggesting that the distribution of Bryde's whales was more likely correlated to the presence of food. If this is true, information on the vertical distribution of sea temperature on both sides of the Solomon Islands and its variability with time, rather than merely SST, may provide information on the distribution of whales, as this is more likely to determine the distribution of possible prey species in the area. Such information was obtained experimentally by SM2 and any future surveys should be carried out in conjunction with more detailed oceanographic surveys.

**Stock identity**

The estimated body length of the largest Bryde's whale observed in our survey was 11.6m (range: 10.1–11.6m), the same as the actual length of the largest individual caught under a special permit around the Solomon Islands (range: 9.1–11.6m; all sexually mature) reported by Ohsumi.
(1980). The same author reported that the lengths of the largest Bryde’s whale caught under special permit in the Indian Ocean and in the western South Pacific were 14.3m (range: 5.8-14.5m) and 15.5m (range: 7.0-15.5m), respectively, and used this and other information to suggest that animals in Solomon Islands area may represent a separate stock. This was accepted by the IWC (see review by Donovan, 1991, pp.43-4). An allozyme analysis carried out by Wada and Numachi (1991) led these authors to consider that the “Solomon Island” animals probably represent a separate species.

The largest Bryde’s whale reported by Osumi (1977) for the North Pacific (pelagic ground) was 14.9m in length (range: 11.3-14.9m). Kato and Yoshioaka (1993), using data from the western Central Pacific estimated length at physical maturity as being 13.0m and 13.5m for males and females, respectively from examination of epiphysial fusion of vertebrae. Pastene et al. (1983) reported that the length of the largest of three Bryde’s whales caught on the Chilean coast in 1983 was 14.3m (range: 10.3-14.3m). Best (1977) reported modal lengths of 13.1m (males) and 13.7m (females) for the inshore form and 13.7m (males) and 14.6m (females) for the offshore form in South African waters. Thus, the estimated body length of the largest Bryde’s whale observed in our survey suggests, in accord with Osumi’s (1980) findings from the special permit catches, that Bryde’s whales in these waters are smaller than those from other geographical regions.

However, it must be remembered that the lengths of the Bryde’s whales sighted during our cruise were estimated visually by crew members. Although the estimates were made by experienced personnel from the vantage point of the ship’s crow’s nest, which allows the whole body to be seen, there is evidence that estimated lengths can be problematic. For example Best (1984) examined the precision of estimated lengths of Antarctic minke whales by comparing lengths of recaptured whales whose body length had been estimated at the time of marking. Although he found the estimates unbiased, the accuracy appeared to be poor. It may be that in addition to visual estimates, future surveys should incorporate other methods (e.g. Dawson et al., 1993) to obtain greater precision in the estimation of the body length of whales at sea.

Our results suggest that the range of the stock of Bryde’s whale proposed by Osumi (1978; 1980) for the Solomon Islands, could extend to the Pacific Ocean side of the islands. We strongly recommend that future sighting surveys in waters of the Solomon Islands should incorporate the collection of biopsy samples in order to conduct further studies on stock identity and, in particular, to investigate the possibility of sub-specific or specific differences (Wada and Numachi, 1991).

ACKNOWLEDGMENTS
Our gratitude to the Governments of the Solomon Islands and Papua New Guinea for extending a permit to conduct the research survey within its Territorial Waters and EEZ. Special thanks to Edward Honiara, the observer from the Solomon Islands, for his cooperation in the research. We express our gratitude to N. Watanabe, Embassy of Japan in Honiara, T. Iijima, Solomon Taiyo and Y. Sato in Solomon Islands, for logistic arrangements. We thank the captains K. Gomi and N. Yasunaga and the crew of the vessels for their hard work and dedication in the execution of the survey. The Chief Radio Operator of SM2, S. Chiba, entered data into the computer. Thanks are due to K. Inoue and T. Nakazato, Fishery Agency, for their contribution to the organisation of the research survey. We thank S. Osumi, The Institute of Cetacean Research, and H. Kato, The National Research Institute of Far Seas Fisheries, for valuable comments and suggestions on this manuscript. H. Kato also participated in the organisation of the research survey. The suggestions and comments of T. Kasuya, G. Donovan and an anonymous reviewer improved notably an earlier version of this paper.

Observations of Cetaceans in the Indian Ocean Whale Sanctuary, May – July 1993

Elizabeth J. Eyre
Marine Mammal Dept., Taronga Zoo, PO Box 20, Mosman, NSW 2088, Australia

ABSTRACT
A cetacean sighting survey in the Indian Ocean Sanctuary was conducted by Greenpeace during the 1993 austral autumn and winter aboard the sailing vessel the SV Rainbow Warrior. Over 45 days 9,165 nautical miles were covered within the Sanctuary from 130°E to Port Suez and 109 sightings were recorded. One hundred and thirty-five sightings were made during the transit from Sydney to Malta. Species seen during the voyage include Bryde’s, sperm, blue, minke and killer whales and bottlenose, common, Indo-Pacific humpback, Risso’s, rough-toothed, spinner, spotted and striped dolphins. Areas providing the greatest number of sightings include south of Java, northwest of the Seychelles, the Gulf of Aden and the Red Sea. Distribution, behaviour and interspecies associations were examined and general conditions within the Sanctuary were assessed from daily debris surveys and observations of high seas fisheries.

KEYWORDS: INDIAN OCEAN; DISTRIBUTION; INDO-PACIFIC HUMPBACKED DOLPHIN; COMMON DOLPHIN; SPOTTED DOLPHIN; SPINNER DOLPHIN; ROUGH-TOOTHED DOLPHIN; BOTTLENOSE DOLPHIN; RISSO’S DOLPHIN; KILLER WHALE; Sperm whale; MINKE WHALE; BRYDE’S WHALE; BLUE WHALE; PYGMY BLUE WHALE; SURVEY-VEssel.

INTRODUCTION
The Indian Ocean Sanctuary was established by the International Whaling Commission in October 1979, following the recommendation of the Seychelles (Leatherwood and Donovan, 1991). The Sanctuary encompasses the Indian Ocean from the east coast of Africa to 100°E north of the Equator and from 20°E to 130°E south of the Equator. It extends south to 55°S and also includes the Arabian and Red Seas and the Gulf of Oman. Total area is approximately 10 million square kilometres (Evans, 1987), including coastline in over 20 nations.

Under the terms of the Sanctuary, no commercial taking of whales is allowed in the region. There remain some direct takes of cetaceans in Indonesia and around islands off India for local consumption (Barnes, 1991) and incidental takes from local and international fisheries occur throughout the Sanctuary (Perrin, 1988; Klinowska, 1991; IWC, 1994b).

This paper details the findings made during a transit of the Indian Ocean Sanctuary by a vessel of the non-government environmental organisation Greenpeace. The objectives of the study were to provide further knowledge of the identity and distribution of cetacean species within the Sanctuary and to document fishing operations which may affect cetacean populations. The cruise track design and methodology do not allow estimates of abundance to be obtained (e.g. see IWC, 1994a).

METHODS
The Rainbow Warrior is a 55m steel-hulled 3-masted gaff schooner with a maximum speed of 13 knots. The ship left Sydney, Australia on 7 May 1993 proceeding north to pass through the Arafura and Timor Seas and then across the Indian Ocean at a latitude of approximately 12°S. At 54°E the vessel moved north again, passing into the Gulf of Aden on 3 July and then through the Red Sea, arriving in Malta on 16 July 1993. The course taken is shown in Fig. 1. Maximum use of the sails (thus avoiding the need to motor) was the primary reason for the course at 12°S, where prevailing winds could be utilised.

Position was recorded using a Furuno GP-500 satellite navigation system. Wind and course details were made using a Hercules System 300 display unit. A JRC JFV-90 echo sounder was used for water depth and temperature for the first three weeks of the voyage, after which time a standard towed thermometer and the ship’s navigational charts were used.

Opportunistic watches were carried out until arrival in the Sanctuary on 27 May 1993. Thereafter, watches consistently began at first light and continued until 1800 hours after which time incidental observations were made. Three individuals were involved, each watching for approximately eight hours a day. Generally, two observers were on watch, each searching 180°, with a combined searched angle of 360°. There were occasions when only one person was present and the whole area was systematically searched. Steiner 7x50 field glasses were used at all times by at least one observer and watches were carried out in all weather conditions.

Two areas of the boat were utilised. Most watching was done from the wheelhouse roof, approximately 6m above sea level. The crow’s nest on the forward mast was also used, at a height of approximately 20m above sea level but visibility was often restricted when the vessel was under sail. The bridge deck and wheelhouse were also used when weather was poor. Sightings distance was estimated based on the length of the vessel. Angle from the bow was determined using crude methods and is therefore not included for analysis. The vessel mostly continued along the trackline but speed and course were occasionally altered when large cetaceans were sighted to confirm identification and observe behaviour.

Photographs were obtained whenever possible using Nikon and Pentax SLR cameras with 200-400mm lenses. Detailed field notes were kept on position, animal behaviour, weather and sea conditions.
A debris survey was conducted daily, involving data collected visually and using a towed fine-mesh net (Grace, in prep.).

Regarding fishing operations, three days were spent in the Arafura Sea observing Taiwanese drift-netting practices and searches were made for purse seine fishing fleets in the international waters beyond the Exclusive Economic Zones of Madagascar and the Seychelles. A four-day transect was made of waters within 200 n.miles of the east coast of Somalia to search for distant water fishing activities.

RESULTS

The survey covered a total of 12,435 n.miles from Sydney to Malta, including 9,165 n.miles within the Sanctuary. A total of 644 hours were spent watching for cetaceans, including 507 hours within the Sanctuary.

Cetaceans were observed on 41 of the 70 days at sea. A total of 135 sightings were recorded, with approximately 1,030 individuals seen. One hundred and five delphinid sightings and 30 combined baleen and toothed whale sightings were recorded in the survey. During the 45 days within the Sanctuary, 109 sightings were made. No whales were seen outside the Sanctuary. Watch effort culminated in one sighting approximately every five hours watched.

Species seen included bottlenose (Tursiops spp.), common (Delphinus delphis), Indo-Pacific humpbacked (Sousa chinensis), Risso’s (Grampus griseus), rough-toothed (Steno bredanensis), spinner (Stenella sp.), spotted (S. attenuata) and striped (S. coeruleoalba) dolphins and Bryde’s (Balaenoptera edeni), minke (B. acutorostrata), blue (B. musculus sp.), killer (Orcinus Orca) and sperm (Physeter macrocephalus) whales (Table 1). Animals for which no identification could be assigned or where some doubt remained over positive identification were recorded as indeterminate species.

The most frequently seen delphinid and whale species were bottlenose dolphins and Bryde’s whales, comprising 22% and 18% respectively of the total identifiable sightings. A high proportion (39%) of indeterminate species was recorded, the highest proportion (n=30, or 58%) occurring in the Survey. The Gulf of Aden and Red Sea region.

The greatest concentrations of animals were in the Red Sea, Gulf of Aden, the eastern part of the Sanctuary and about 370 n.miles WNW of the Seychelles (Fig. 1). Forty sightings occurred in the Red Sea, 20 of these on a single day and 19 sightings occurred in the Gulf of Aden, with 16 on one day. Animals seen here included Risso’s, bottlenose, spinner, spotted and common dolphins. One baleen whale which could not be identified was seen in the southern end of the Red Sea (Fig. 1). Twenty-three sightings were made in the Sanctuary to the east of 110°E. Eleven of these sightings were of Bryde’s whales which were seen over a period of three days. The highest number of individual toothed and baleen whales seen on a single day occurred on 24 June (n=9), between 34°20’5”3934’3.6”E and 34°24’2”5854’6”E, WNW of the Seychelles (Fig. 1). Eleven sightings were recorded, including Bryde’s, sperm, killer and blue whales, along with two indeterminate species of whale and spinner dolphins. This was the only area where blue whales were seen, with non-cetacean species such as tuna (Scombridae) and red-footed boobies (Sula sula) also present. The lowest concentrations of cetaceans encountered during the survey occurred mid-ocean (Fig. 1). One unidentified whale seen mid-ocean in deep water was possibly a species of beaked whale. No verifiable sightings were made of pilot whales (Globicephala sp.), false killer whales (Pseudorca crassidens), melon headed whales (Pepenococephala electra) or pygmy killer whales (Feresa attenuata).

Species accounts and behaviour

The Bryde’s whales observed in the eastern Sanctuary were engaged in slow erratic swimming, usually with a single exhalation between highly variable submergence times. No interactions between individuals were seen nor was evidence of surface feeding activity observed. Feeding birds, including frigate birds (Fregatidae) and shearwaters (Procellariidae) were in the vicinity, so it is possible the whales were feeding underwater.

Sperm whales were most frequently encountered near the Seychelles and along the north east coast of Africa (Fig. 1) and comprised adult females and sub-adults. All sightings were made in depths greater than 1.000m. Behaviours seen included resting, travelling and probable feeding. On three occasions sperm whales were observed sounding in areas where brindled terns (Sterna anaethetus) and red-footed boobies were feeding on flying fish (Exocoetidae). A male sperm whale was found dead on 27 June at 23°36’4”4836’5.5”E.

The four blue whales seen on 24 June displayed unpredictable swimming patterns. Submergence times

Fig. 1. Ship's course and cetacean sightings (7 May-16 July 1993).
lasted 10–15 minutes and the animals would blow 4–6 times successively, rarely exposing the back or broad head as they did so. They were swimming slowly and although two individuals were at one stage less than 100m from each other no interaction was observed. No obvious surface activity associated with feeding was seen, but the erratic swimming may indicate feeding behaviour occurring below the surface.

There appeared to be two types of spinner dolphin observed during the survey. One was a small animal with light flanks similar to *Delphinus* but lacking the obvious cisscrossing pattern of the latter species. These animals were identified to the north of Australia and in the Gulf of Aden, and were only once observed in the characteristic spinning behaviour. The other type was slightly larger, uniform battleship grey with a long rostrum. They had low triangular dorsal fins and one large adult had a well developed anal keel and forward-canting dorsal. These animals were frequently seen engaged in aerial activity. They were recorded mid-Indian Ocean, east of Africa and in the Red Sea.

There was no evidence to suggest that bottlenose dolphins differed in size or colouration in different areas or water depths. One very large animal encountered in the Mediterranean possessed a prominent dark strip extending from the eye to the pectoral fins. The two types of bottlenose dolphin mentioned by Beadon (1991) were not evident. However, time and frequently distance, meant that detailed observations were often not possible.

General behaviour of delphinids included travelling, resting, aerial displays, courtship and elusive behaviour, bowriding, feeding and interacting with other species. Feeding behaviour was observed on at least eight occasions by killer whales, spinner dolphins, bottlenose dolphins and unidentified delphinids. Mating behaviour was observed twice amongst small groups of bottlenose dolphins in the Red Sea.

Five multispecies associations were recorded during this survey (Table 1). Risso’s dolphins appeared to be the most gregarious, associating with other species almost half of the time they were encountered. Of the small delphinid groups seen, 17% were bowriding. The most common to do so in order of decreasing frequency were common and spotted, striped, bottlenose and spinner dolphins.

Some ceteceans exhibited obvious elusive behaviour. Spinner dolphins and killer whales seen near the Seychelles appeared wary of the boat, staying submerged for prolonged periods of time, swimming rapidly away from the boat, or disappearing from view entirely once the boat was in the immediate vicinity. Of five such events, four occurred inside the French purse seine fishing grounds. The fifth occasion was east of the fishing grounds at 108°E and involved striped dolphins.

**Observations of fisheries**

Two dead dolphins, tentatively identified as spotted dolphins, were counted in the Taiwanese drift net catch in the Arafura Sea, along with various species of shark and bony fish. It is clearly not possible to use this information to determine bycatch numbers actually involved in the fishery. These dolphins were kept on board the Taiwanese vessel for the duration of time the Rainbow Warrior was alongside. It is not known whether the carcasses were later discarded. On one occasion a small group of dolphins was seen swimming approximately 200m from a drift net vessel hauling in its net.

No purse seine vessels were seen near Madagascar or the Seychelles, and no vessels engaged in fishing operations were observed off the Somali coast. Longline vessels were seen in the Arafura and Timor Seas and in the eastern sector of the Sanctuary and deployed lines were observed near Madagascar and the Seychelles and in the Mediterranean.

**DISCUSSION**

Data collected on species distribution were consistent with current literature (e.g., Gaskin, 1982; Leatherwood and Reeves, 1983; Evans, 1987; Gallagher, 1991; Kasuya and Wada, 1991). For example, sperm whales were seen near the Seychelles and off Somalia in June, no mature male sperm whales were observed and Bryde’s whales were noted principally east of 90°E but also in the zone 35°–65°E.

Few documented sightings exist of large ceteceans occurring in the Red Sea. The roqual sighting during this survey occurred at the southern end and was only seen once. The whale’s appearance and behaviour was similar to what had been observed in Bryde’s whales. This species has been reported in the Persian Gulf and Gulf of Aden (Evans, 1987: Small and Small, 1991).

Positive identification of pygmy blue whales (*Balaenoptera musculus brevicauda*) at sea is difficult to confirm (e.g., see Donovan, 1984). The blue whales seen during this survey may have been pygmy blue whales on the basis of their behaviour and appearance. Ichihara (1981) reports that the tail region behind the dorsal fin is conspicuously shorter in pygmy blue whales. This was seen on 24 June when one animal fished up: the small dorsal was positioned close to the flukes and both appeared simultaneously upon sounding. Unlike *B. musculus*, which often exposes its dorsal and blowhole concurrently when at the surface (Baker, 1983; Leatherwood and Reeves, 1983), the whales seen exposed very little of the body. The blow was characteristically high and narrow, however, little or no back was shown. ColURATION was medium grey, with mottling on the flanks. The flukes were tilted when raised. Body length estimates and clear photographs were not obtained, which would have facilitated in sub-species identification. Distribution of *B. m. brevicauda* is principally in the sub-antarctic portion of the Indian Ocean, however, there are reports of animals from the northern Indian Ocean (Yochem and Leatherwood, 1985).

Several factors contributed to the high number of unidentified ceteceans recorded in the survey. Thirty-three per cent of small delphinid sightings were made at distances greater than 500m, which made identification difficult. Unless animals displayed characteristic behaviour or features, positive identification became very difficult beyond 500m, even in ideal weather conditions. This was especially problematic in the Red Sea and Gulf of Aden where groups of dolphins appeared as dorsal fins and little else. The average Beaufort sea state over the 45 days within the Sanctuary was 4 (Fig. 2), with an average wind speed of 18 knots which made watching conditions arduous. Unfortunately, constraints on the time available for transit by the Rainbow Warrior precluded a route which would provide conditions more conducive to watching for ceteceans.

While the low number of sightings, especially mid-ocean, may result in part from the poor sightings conditions, it probably also reflects the actual abundance
and temporal distribution of Cetacea. The survey coincided with the period when most baleen whales were in transit to warmer waters for breeding and also reflects the low productivity of the South Equatorial Current region.

One area of high sightings concentration was in the tuna purse seining grounds to the west of the Seychelles, where large schools of fish, particularly tuna, and feeding seabirds occurred in the same locality as blue, sperm, Bryde’s and killer whales and spinner dolphins. Tuna were also seen north-east of Madagascar, just outside the purse seining grounds. This coincides with the time of the south-east monsoon and possibly indicates a correlation between the monsoon periods and whale distribution, suggesting that cetaceans may feed in areas at these times of increased upwelling and primary productivity.

A similar region supporting a variety of organisms is the Red Sea. This is an important marine habitat as reflected in the abundance and diversity of organisms which were recorded there during this survey. Thirty per cent of the total cetacean sightings made during the voyage occurred in this area and a variety of sea birds and fish species were abundant throughout.

**Interactions with fisheries**

During the three days spent with three Taiwanese driftnet vessels in the Arafura Sea, cetaceans tentatively identified as spotted dolphins were included in the catch twice, whilst one live group of delphinids were considered at risk. Harwood and Hembree (1987) reported that the Taiwanese fleet caught spotted dolphins among other species when it operated in northern Australian waters. It is not known how many cetaceans are currently taken in this fishery or whether numbers taken reflect seasonal distribution. Cetaceans caught may be sold or distributed later as the Taiwanese are known to consume dolphin (Perrin, 1988).

Several countries purse seine for tuna inside and outside the Exclusive Economic Zone of the Seychelles, including France, Spain and Japan. Unlike the Eastern Pacific Ocean, seiners in the Indian Ocean are not reported to encircle small cetaceans to catch the associated tuna (Sabadach and Hallier, 1993), though during this survey tuna were observed both with and without cetaceans. The elusive behaviour of cetaceans recorded within the purse seine zone is of interest in this light.

Purse seine sets are reported to be made on large cetaceans (Robineau, 1991; Sabadach and Hallier, 1993), although the fate of the animals is not reported. Robineau (1991) suggests that the whales may be mostly Bryde’s or sei whales, although blue whales were observed in the area during the present cruise.

Although fishing vessels from many countries have been reported to be engaged in illegal fishing off the west coast of Somalia, taking advantage of the collapse of the government, no vessels were seen along the transect run by the Rainbow Warrior. This is presumably due to the unfavourable conditions during the SW monsoon season which prevailed. There have been some documented accounts of cetacean bycatch (see Small and Small, 1991), but the extent remains unknown.

**ACKNOWLEDGEMENTS**

Roger Grace, Frank Hewetson, Menno Bos and Geoffrey Sheldon helped with watching. The crew of the Rainbow Warrior helped out with recording positions, informing of sightings and making the trip even more enjoyable. Michael Earle helped with updates on the fisheries information during the trip and commented on the manuscript and Hans Hoek prepared the figures. Thanks to Greenpeace International for asking me to go in the first place and Greenpeace Communications for their aid and facilities with the slides. Special appreciation to John Frizzell who helped in countless ways. Dr W. H. Dawbin of the Australian Museum, Sydney, Australia and Vassili Papastavrou, Department of Zoology, University of Bristol, UK, are gratefully acknowledged for their helpful comments in reviewing this paper.

ABSTRACT
Information on marine mammal mortality and strandings from the Pacific coast of Colombia was gathered from museum collections and field work between March and December 1993. Field interviews and examination of osteological remains were conducted between Bahía Solano and La Vigía on the Pacific coast of Colombia. A total of 219 strandings were documented between 1930 and 1993, for which osteological or photographic evidence exists for 101. Strandings comprised Balanopteridae (8), Physeteridae (14), Ziphiidae (2), Delphinidae (45) and Otaridae (1), while 22 were unidentified odontocetes. 17 were unidentified cetaceans and 8 were unidentified pinnipeds. Fifteen species were recorded, with Balanoptera edeni, Ziphius cavirostris and Globicephala macrocephalus being the first osteological records of these species for the Pacific coast of Colombia and Balanoptera musculus, Kopala sinuus, Peponocephala electra, Pseudorca crassidens, Stenella coeruleoalba and Otaria byronia being the first osteological records of these species for the whole of Colombia. The presence of O. byronia in Colombia represents its northernmost Pacific distribution. Two coastal communities were found to carry out directed captures of dolphins for fishing bait. Entanglement with multifilament and monofilament nets was also thought to cause high mortality rates in the area.

KEYWORDS: HUMPBACK WHALE; BLUE WHALE; BRYDE'S WHALE; SPERM WHALE; DWARF SPERM WHALE; PANTROPICAL SPOTTED DOLPHIN; STRIPED DOLPHIN; SHORT-FINNED PILOT WHALE; GOOSEBEAKED WHALE; MELON HEADED WHALE; SOUTH PACIFIC; STRANDINGS; INCIDENTAL CAPTURE; FALSE KILLER WHALE; PINNIPEDS

INTRODUCTION
The study of cetaceans in Colombia is relatively recent in comparison to many other Latin American countries. It was not until the mid-1980s that research on marine mammals began. On the Pacific coast, research has been carried out on the population dynamics and behaviour of migrating humpback whales, Megaptera novaeangliae (Flórez-González, 1989). Cuervo et al. (1986) and Vidal (1990) summarised sighting records of the different species. Pricot (1990) presented a preliminary report on fisheries interactions with small cetaceans.

Despite this, there is a dearth of information on the basic biology, life history and mortality of these species and consequently no government strategy for their conservation. In particular, the subject of mortality and strandings of these mammals has not been addressed, despite the large number of animals that have been found dead on shore or killed in the past 64 years.

This paper documents and analyses stranding and mortality records for the Pacific coast of Colombia and summarises information on marine mammals specimens in museum collections. It represents a first step towards systematic marine mammal research aimed at providing for their conservation along the Pacific coast of Colombia.

METHODS
The study area selected comprised a 820km strip of the Pacific coast of Colombia between Bahía Solano in the Department of Nariño (2°38'N, 78°25'W) and the Department of Nariño (2°38'N, 78°25'W) and the national parks of Utría (6°02'N, 77°22'W) and Isla Gorgona (2°47'N, 78°06'W).

Museum collections and archives were visited between January 1992 and March 1994. All available specimens and data on marine mammal deaths from the Pacific coast of Colombia were examined, identified using the species keys of De Blase and Martin (1974) and Ernst (1977), and documented by cranometry and photographs following the techniques of Hersh and Duffield (1990) and Ross (1984).

The study area was monitored between March and December 1993. The beaches were searched for stranded animals or osteological remains. Skulls and bones found during the field season were also examined and documented as above. Fishermen were interviewed to assess fisheries interactions with marine mammals. Local residents were interviewed to obtain information regarding previous stranding cases, particularly possible causes and whether they possessed marine mammal osteological remains.

Beaches or shores where strandings occurred were categorised for type (sandy, rocky or mangrove-lined), contour (concave, convex or straight) and the slope of the beach was measured.

RESULTS AND DISCUSSION
A total of nine museum collections in Colombian universities, government agencies, museums and foundations held marine mammal osteological remains. These were: Musco de Ciencias Naturales (Universidad de
La Salle), Museo del Mar (Universidad Jorge Tadeo Lozano), Unidad de Zoología del Departamento de Biología (Universidad del Valle), Fundación Yubarta, Museo de Ciencias Naturales 'Federico Carlos Lehmann V.'”, Universidad Tecnológica del Chocó – Seccional Bahía Solano, Oficina Regional del Norte del Pacífico (Instituto Nacional de Pesca y Acuicultura), Fikes de Fundación Natura, Museo Marino de Isla Gorgona and Parque Nacional Utría. In these collections, 11 species and 32 specimens of marine mammals were registered (Table 1).

</table>

During the field season, 69 previous stranding cases with osteological or photographic evidence were registered in 38 coastal communities visited. Four of these were the same cases found in museum collections (blue whale, Balaenoptera musculus; Bryde’s whale, B. edeni; humpback whale; and sperm whale, Physeter macrocephalus). Eleven strandings occurred in the area between January and September 1993, including: two humpback whales; a dwarf sperm whale, Kogia simus; two bottlenose dolphins, Tursiops truncatus; three pantropical spotted dolphins, Stenella attenuata; two unidentified cetaceans; and one southern sea lion, Otaria byronia.

Interviews with coastal residents led to the recording of an additional 118 stranding cases for which no osteological or photographic evidence was available, comprising 16 unidentified mysticetes, 94 unidentified odontocetes and eight unidentified pinnipeds. This brings the total number of stranding/mortality incidents for the Pacific coast of Colombia to 219. The proportion of mysticetes to odontocetes was about 1:4. Those species most frequently found dead or stranded were the bottlenose dolphin, sperm whale, pantropical spotted dolphin and short-finned pilot whale, Globicephala macrorhynchos.

All recorded strandings were of single animals with the exception of one school of short-finned pilot whales. Nine species not previously reported for the Pacific coast of Colombia were documented, including the Bryde's whale, blue whale*, dwarf sperm whale*, false killer whale* (Pseudorca crassidens), goosebeaked whale (Ziphius cavirostris), melonheaded whale* (Peponocephala electra), short-finned pilot whale, southern sea lion* and striped dolphin* (Sienella coeruleoalba). Those marked with an asterisk also mark the first osteological records for Colombia. Of special interest is the occurrence of the southern sea lion. All literature reviewed suggested that its northernmost Pacific range was Zorritos (4°S) in Peru (Vaz-Ferreira, 1981; King, 1983; Leatherwood and Reeves, 1983; Riedman, 1990; Reijnards et al., 1993) apart from one dead animal found on Abingdon Island (Pinta) in the Galápagos Islands (Wellington and de Vries, 1976). This record therefore represents a new northern limit for this species on the Pacific coast of South America.

The year of occurrence is only known for 61 cases, with the earliest being in 1930. Most cases occurred between 1975 and 1993, with the greatest number occurring in 1990 and 1993 with 11 cases each. This is probably merely a reflection of effort. No apparent relationship was found between strandings and the occurrence of El Niño. The exact month of occurrence is only known for 53 cases. If these are considered, a trimodal distribution is apparent, the first peak in March and April, the second between July and September and a third is observed in December (Fig. 1). More (62.3%) of the strandings were recorded during the winter (May to December) than in the summer (37.7%).

![Fig. 1. Seasonality of marine mammal strandings on the Pacific coast of Colombia.](image)

Most (65%) of the records were for the central and northern parts of the study area, while 20% were in the south and 14% were in Isla Gorgona. The strandings could be grouped into four distinct areas: Area 1 from Cupica (6°42′N, 77°30′W) to Punta Arusí (5°36′N, 77°30′W); Area 2 from Charambira (4°16′N, 77°00′W) to Naya River (3°19′N, 77°28′W); Area 3 from Cuerval (2°40′N, 77°49′W) to Yabo Manglares (1°36′N, 79°02′W); and Area 4 Isla Gorgona (2°47′N, 78°06′W). Some 69% of the strandings occurred on sandy beaches, 14% on sandy-rocky enclave beaches, 8% on rocky shores, 7% on mangrove shores and 2% in coral-sandy shores. Almost all shores where strandings occurred were of the straight type, slightly concave, but with a steep slope.

For various reasons, cause of death could not be determined for 82% of cases; 18% could be attributed to human interactions, either by entanglement, dynamite...
fishing or direct takes. Of twenty-seven fishing villages visited, only two communities, Charambirá (Chocó) and Conchériri (Cauca) were identified as conducting direct takes of pantropical spotted dolphins and bottlenose dolphins to use as bait for their requiem shark, cusk-eel and sea bass fisheries. Dolphin meat is used when usual bait (snake eel, morays and hammerhead shark) is scarce. Artisanal fishing using multifilament nets of 15 and 20cm mesh size occurred from the villages of Charambirá (Chocó) and La Viga (Nariño), reportedly producing a ‘high’ incidence of accidental marine mammal entanglement and a ‘high’ mortality rate of whales, dolphins and sea lions. Monofilament nets of 7–7.6cm mesh size used in the shrimp fisheries also entangled marine mammals, but with a low mortality rate as the animals seem to be able to break through them and escape. The species most commonly found entangled were the bottlenose dolphin and pantropical spotted dolphin.

It is clear that further studies to continue monitoring marine mammal deaths and strandings in the area are required to determine: (1) the degree of involvement of human interaction in marine mammal deaths; (2) the frequency of deaths and strandings; and (3) an assessment of deaths and strandings with the purpose of making recommendations for effective and efficient management of marine mammals in Colombia.

ACKNOWLEDGEMENTS

We thank the United Nations Environmental Programme (UNEP), the Centro de Investigaciones Marinas y Acuáticas de Colombia (CIMAC) and the Red Caribeña de Varamientos for sponsoring and partially funding this study. We appreciate the assistance of the curators of the museum collections visited, who allowed us to inspect and use their specimens for this study. Our colleague Martha Lucía Suárez assisted in the field with stranding cases. The research and collection of specimens in the field was carried out under permit number 0218 of the Instituto Nacional de los Recursos Naturales Renovables y del Ambiente (INDERENA). Our sincere thanks goes to Kathleen M. O’Connell (Whale and Dolphin Conservation Society), Ruby A. Montoya-Ospina (Red Caribeña de Varamientos) and Mauricio Prieto for their continuous encouragement throughout this study. Patricia Majul (NYZS Wildlife Conservation Society), Koen Van Waerebeek (Centro Peruano de Estudios Cetológicos), James G. Mead and Charlie Potter (Smithsonian Institution) assisted with species identifications. Fernando Trujillo-González and Sandra Beltrán-Pedreros (Fundación Omacha, AA 13001 Santa Fé de Bogotá, Colombia), Lilíán Plóez-González (Fundación Yubarta, AA 33141 Cali, Colombia) and Ernest H. Williams, Jr (University of Puerto Rico, Box 5000 Mayagüez, Puerto Rico 00680) reviewed the manuscript.

An Inexpensive, Stereophotographic Technique to Measure Sperm Whales from Small Boats

S.M. Dawson1,2, C.J. Chessum1, P.J. Hunt3 and E. Slooten1,2

ABSTRACT

Current methods of measuring live whales require either specialised aircraft or moderate-sized sailing vessels. We have developed a stereophotogrammetric system using inexpensive, non-metric 35mm cameras. The equipment is usable from small boats and in a wide range of sea swell conditions. Tests show that errors in measurement of known-size objects increased significantly with range and angle from the perpendicular to the baseline of the cameras. However, errors (including bias and imprecision) were <2% at ranges of 30-60m and at angles of up to 15° from the perpendicular. Unlike the targets used in calibration, whales flex and have poorly defined points to measure. Multiple measurements of photographically identified whales were sufficiently precise (mean coefficient of variation = 4.35%) to produce useful length estimates.

KEYWORDS: SPERM WHALE; SOUTH PACIFIC; PHOTOGRAMMETRY

INTRODUCTION

The ability to measure individual animals is central to many ecological studies. Measurement data can provide information on population structure (e.g. Croze, 1972; Waters and Whitehead, 1990), or growth rates (Whitehead and Payne, 1981) and can reveal size-class segregation (Cubbage and Calambokidis, 1987).

Because of their large size, aquatic habitat and the short time they spend at the surface, whales are among the most difficult animals to measure. Most data have come from dead whales, measured during whaling operations (e.g. Fujino, 1956; Clarke and Paliza, 1972). These data have obvious restrictions: (a) detailed information on individual growth rates is unobtainable because each whale can be measured accurately only after its death; (b) likewise, no detailed investigation of the behaviour of known-size whales is possible; and (c) because measurements are made out of water, body shape and proportions may be distorted (see also Klimley and Brown, 1983).

Photogrammetry is a powerful tool with which to measure wild animals, especially large species that are difficult to capture (e.g. elephants; Croze, 1972). Currently, it provides the only practical way to measure living whales. Photogrammetry can be done using either single-camera, or two-camera (stereo) systems. The cameras employed may be fully calibrated (metric) models specifically designed for photogrammetry (e.g. Rüther, 1983) or non-metric cameras designed for general photography (e.g. Klimley and Brown, 1983; Gordon, 1990). Single-camera systems require an independent measure of the scale of the photograph. This can be achieved by measuring the range from the camera to the animal. In aerial photogrammetry, range is usually measured via a radar altimeter (e.g. Davis et al., 1983). Scale can also be established by including an object of known size in the photograph (e.g. Whitehead and Payne, 1981). The measurement method developed by Gordon and others (Gordon et al., 1986; Gordon, 1990), the first technique usable from a reasonably small vessel (e.g. Rüther and Adams, 1984), employs a single camera to take lateral photographs of whales from a position up the mast of a yacht. Scale is established by knowing the height at which photographs were taken. The angle between the whale and the horizon is measured off the film and the range is calculated from the Earth's curvature.

Stereophotography has the considerable advantage of providing three-dimensional coordinates and hence does not require an independent measure of range. Scale is determined from the camera separation and the resulting horizontal displacement between the paired photographic images. Stereophotography also provides improved resolution of detail (Done, 1981). For these reasons it has been applied in a diverse range of studies including the growth of corals (Done, 1981), the spatial structure of schools of sharks (Klimley and Brown, 1983) and flying birds (Major and Dill, 1978), the foraging behaviour of bats (Jones and Rayner, 1988), and the population structure of elephants (Rüther, 1982), bowhead whales (Cubbage and Calambokidis, 1987) and right whales (Best and Rüther, 1992).

While aerial techniques for measuring whales have the advantage of measuring total body length, dorso-ventral flexing of the body during swimming may result in downwardly-biased length estimates (Cubbage and Calambokidis, 1987). The effect of flexing can be measured directly from the 3-dimensional co-ordinates provided by stereophotogrammetry, but not from the 2-dimensional co-ordinates from single camera systems. If body proportions are known well enough, measurement of part of the body can be used to estimate total size (e.g. Best, 1990). After surfacing from a long dive, sperm whales typically rest at the surface for several minutes, during which time the tip of the head and dorsal fin are often visible. The measurement method of Gordon (1990) and the one described here, measure this length. Total length is then calculated from the regression of this length against total length using whaling data (Best, 1990; Gordon, 1990).

Neither aerial stereophotogrammetry, nor Gordon's (1990) single camera method were suitable for our study of population structure and behaviour of sperm whales at Kaikoura (east coast, South Island, NZ). Aerial stereophotogrammetry was far beyond our budget, as was a large research vessel (Rüther and Adams, 1984), and Kaikoura's prevailing conditions are too rough for Gordon's method to be reliable. Lovell, Gordon and Hibi

(unpublished) worked on a simple stereophotographic system that did not rely on precisely controlled camera alignment, but on measuring alignment each time the cameras were mounted by taking photographs of very distant objects. However, despite initial promise, further investigations revealed substantial measurement errors and the system was not developed further (Lovell, pers. comm.). Here we present details of a stereophotographic method for measuring sperm whales. This method is broadly similar to that of Lovell et al., but camera alignment is controlled. The system is economical to implement and is usable from small boats.

METHODS

Design
The general design of our system broadly resembled that used by Major and Dill (1978) to quantify the 3-dimensional structure of bird flocks. Two standard 35mm cameras (Pentax MX) were mounted on an aluminium bar of rectangular section (50 x 40mm; wall thickness 2.5mm) so that the centres of their lenses were 2.401m apart. The limit on bar length (2.65m) was imposed by the space available on the aft deck of our 6.5m research vessel. The cameras butt against plates to the front and side. Screw-in plates on the rear locate the camera bodies firmly against these butt plates (Fig. 1). This system facilitated consistent alignment and invariant base length.

As we had access to Pentax 50mm f/2.8 macro and Pentax 50mm f/4.0 macro lenses we used them, but there is no reason why macro lenses should be preferred. Lens focussing rings were taped on the infinity focus setting during calibrations and measurements of whales. To standardise the effect of distortions inherent in each lens and camera body, each lens was always used with the same camera body and each camera body permanently assigned to one end of the bar. To minimise unsharpness caused by movement of the whale and the boat, camera shutters were set at 1/1000s. Camera shutters were triggered simultaneously using paired air-releases with a common bulb. Film was advanced manually, although motor drives may be added in the future. Kodak TMAX 100 and TMAX 400 films were used.

Calibration
Ideally, pairs of stereo images contain points of known distance apart, so that each pair is essentially self-calibrating. This is known as ‘affine scaling’, one of the ‘control’ methods used in photogrammetry (see Rüther, 1983). While this can be easily achieved in typical survey applications and even in some biological ones (e.g. Rüther, 1983), it would be difficult to achieve in our application. Providing that camera alignment remains undamaged and synchrony of exposure maintained, such control is not absolutely necessary if the system is initially calibrated and carefully set up for each use. Our calibrations consisted of determining the focal lengths of the lenses (at infinity focus) and determining the measurement errors with range, angle and mounting/remounting of the cameras to the bar.

Calculation of focal length of the lenses
For accurate stereophotogrammetry in the absence of control, the focal lengths of the lenses must be known precisely. Using an optical bench we measured the position of the external nodal point of each lens. In a nearby sports
field we placed a number of vertical survey stakes, each separated by about 4m. Using a digital theodolite (with intrinsic measurement error $\sim 3$ of arc) placed approximately perpendicular to the line of stakes, and at a range of about 60m, we measured the bearing to each of the stakes. With the external nodal point of the lens held over the vertical axis of the theodolite, we positioned the camera diagonally so that the line of stakes passed through the centre of the viewfinder and through opposite corners. The stakes were photographed with each camera.

Photographic negatives were oriented in a Cambridge comparator used to measure the co-ordinates of the base of each stake (SE $\leq 5\mu m$ at negative scale). Kilford (1979) describes the mathematics to arrive at a calibration of focal length and the location of the centre point of symmetry in the focal plane of the cameras. Since we were interested in solving only for focal length, we were able to employ a simpler version of this method.

**The effect of range**

To examine the effect of range on measurement error we photographed survey stakes placed ca 2m apart in a field. Distances between the inside edges of the stakes were measured carefully with a steel tape measure. The camera bar was clamped in a portable workbench and stereo pairs of photographs were taken with the lens axes perpendicular to the line of stakes, at 5m intervals of range between 30m and 60m (this covers the range at which we take stereo pairs of whales). Three replicate stereo pairs were taken at each interval of range.

Pairs of negatives were measured using a Wild A9 stereo plotter (measuring dot size $= 40\mu m$). Once a negative pair is properly aligned in the plotter, the instrument provides a 3-dimensional model within which distances can be measured in $x$, $y$ and $z$ dimensions. However, errors are easily possible in the precise alignment of negatives and in their measurement. To quantify variation induced via analysis errors, each negative pair was measured three times. Before each measurement the negative pair was deliberately misaligned and re-aligned.

Measurements were made of four 'whale-sized' distances between the stakes (6, 8, 10, 12m), which, using the regression equation given by Best (1990), correspond to sperm whale total lengths of 10–18.3m. The data used for statistical analyses were the differences between photogrammetric and true measurements of distances between stakes, expressed as a percentage of the true distance.

**The effect of angle**

A theodolite was placed in the centre of the row of stakes used in the range experiment. The first set of three replicate stereo pairs was taken with the camera axes perpendicular to the line of stakes, with the centre point of the camera baseline at 90° to the line of stakes, at a range of 40m. The cameras were then moved in a horizontal arc of radius 40m and three replicate stereo photographs were taken at each of 95, 100, 105, 110, 115 and 120° to the line of stakes.

**Mounting/dismounting**

The camera system was again placed at 40m from the stakes, with the camera axes perpendicular to the stakes. The cameras were removed from the bar and remounted eight times. Three replicate photographs were taken at each mounting.

**Remeasurements of photographically identified whales**

The most powerful test of the utility of a photogrammetric system is made during its use in the field. Such tests incorporate all errors inherent in the system and measurement process. Following the methods of Arnhold (1987), we have photographically identified 86 individual sperm whales from Kaikoura (Childerhouse et al., in press). These whales typically dive for ca 40min, then spend ca 10min at the surface, swimming very slowly (<3 knots). We approached whales from the left side (so that the blow hole is visible) to within a range of <60m (ideally <40m). We attempted to take three stereo pairs, each showing the blow hole and dorsal fin. The best quality pair (least tilted, closest, sharpest) was measured three times on the plotter. Before each measurement the negatives were deliberately misaligned and re-aligned.

We calculated total lengths (TL) from our measurements of the distance from the centre of the blowhole to the posterior emargination of the dorsal fin (BD) using Best's (1990) regression equation $[TL = 1.3797(BD) + 1.7212; r^2 = 0.9706]$. Where individuals were measured on several occasions the median measurement was used.

**RESULTS**

Our two 50mm lenses had slightly different focal lengths. The f2.8 lens had a focal length of 51.67mm and the f4.0 lens had a focal length of 51.54mm.

**Range**

We have attempted to quantify errors in measurement due to bias and imprecision. A plot of means of measurements from each negative pair, versus the range at which they were taken, shows that accuracy is very good at close ranges but decreases systematically with range, showing a positive bias (Fig. 3). The slope of the regression line is a useful estimator of the bias at any given range and could be used to correct measurements of whales once the range is known.

![Fig. 3. The effect of range on photogrammetric error. There are nine points at each range, representing three replicate analyses of three replicate negative pairs. The slope of the regression line is $y = -1.192 + 0.048x$ ($r^2 = 0.520$).](image-url)
Detrending the measurement data with respect to range (by subtracting each measurement from the mean of each range) allows testing of the contribution of different negative pairs, and different analyses of the same pair, to the imprecision of measurements. The effect of different negative pairs was marginally significant ($p=0.048$), while the effect of replicate analysis of the same negative pair was highly significant ($p<0.001$), underscoring the need for good technique when using the stereo plotter. However, performing replicate analyses tripled measurement time; yet did not greatly influence the absolute magnitude of errors. When measurements were corrected for bias, imprecision was always less than 1%. We considered this inconsequential when dealing with photographs of whales which flex and have rather poorly defined points to measure from.

**Angle**

As expected, photogrammetric errors increased with angle; angles greater than about 10° from the perpendicular resulted in downwardly biased measurements (Fig. 4). This experiment tested a wider range of angles than those at which we take stereo pairs at sea. Errors varied significantly with angle (ANOVA: $p<0.0001$), but not with replicate pairs taken at the same angle ($p=0.29$).

![Fig. 4. The effect of angle on photogrammetric error. Plotted values are means (±95% CI) from three replicate negative pairs.](image)

**Mount/dismount**

Photogrammetric errors varied significantly with mount (ANOVA: $p=0.0003$) but not with replicate pairs taken at each mount ($p=0.629$). This indicates that the mounting system did not ensure consistent camera alignment. However, the absolute value of errors introduced by the mounting system was small (max=1.77%).

**Remeasurements of photographically identified whales**

Forty-one photographically identified sperm whales have been measured in this study. Using Best’s (1990) regression, calculated total lengths ranged from 9.32 to 15.83m.

Twelve individuals had been measured on three or more surfacings (Fig. 5) and are used here to examine the precision of the measurement method at sea (see Table 1). Mean blowhole to dorsal fin emargination distances from these 12 ranged from 7.31m ($TL=11.41m$) to 9.44m ($TL=14.75m$). Confidence intervals (95%) of measurements gained from individual whales ranged from 0.19 to 1.04m (mean=0.56m; see Table 1). While most measurements were reasonably precise, some individual measurements were highly imprecise. This is true also for Gordon’s masthead camera method (Whitehead, pers. comm.), but in our case the most likely culprit is imperfect synchronisation of the camera shutters. On a very few occasions the cameras’ shutters could be heard separately during exposure of a single pair. The mean CV value was 4.35%, suggesting a 95% confidence interval from a single photograph of ca 8.6%.

![Fig. 5. Frequency of measurement of individually identified whales.](image)

**Table 1**

Summary of measurement data from all photographically identified whales measured on ≥3 surfacings. Measurements are from blowhole to dorsal fin emargination (in metres).

Three individuals were measured over more than one year, but there was no evidence that growth in the intervening period contributed significantly to the variance of mean lengths. As expected, differences between stereo
pairs were far greater (ANOVA; \( p<0.001 \)) than between replicate measurements taken from the same stereo pair \( (p>0.9) \).

**DISCUSSION**

Our analyses of the calibration experiments found several sources of statistically significant error. However, all cases which fall within the quality criteria we apply to stereo pairs taken at sea (e.g. discarding all pairs taken at angles greater than \( 10^\circ \) or ranges greater than 60m) show small absolute errors (bias and imprecision included), almost always substantially less than 2%. Considering the inaccuracies inherent in measuring whales at sea, these errors appear of little consequence. That the system achieved far better precision in calibration trials than in remeasurements of the same whale is probably due to three factors: (1) the difficulty in consistently locating the points to measure; (2) the flexibility of whales; and (3) imprecise synchronisation of the camera shutters. The first two of these suggest that gains in accuracy and precision via the use of metric cameras or non-metric mid-format cameras would probably not justify their much greater cost.

The system described here was inexpensive to build (replacement cost \( \leq \$800 \)) and operate, yet provides measurements of useful precision and accuracy. Measurements of objects of known size suggest that our stereophotogrammetric technique is at least four times more accurate than Gordon’s single camera method (Gordon et al., 1986; Gordon, 1990). However, our remeasurements of photographically identified whales are only slightly more precise than his (mean \( CV=4.35\% \) vs 5.1%). We expect that improvements to our system would enhance precision (see below), but it is possible that the accuracy and precision achieved here, and by Gordon (1990), are close to the best that can be achieved from boat-based measurements of living whales. Gordon’s technique is simpler in that it requires no specialised equipment, but it requires calm seas and a vessel with a tall mast from which photographs can be taken. Our stereophotogrammetric system could be used on almost any vessel larger than 5m and in any swell conditions as long as the points to be measured are visible.

Making accurate measurements from stereo pairs should not depend on the availability of a precision stereo-plotter. It may be possible to make measurements of suitable accuracy from photographic prints, either directly, or using a digitising tablet. Our early attempts at measuring prints produced highly inaccurate results. All our subsequent analyses were made on a stereo-plotter (see also Rutherford, 1983). However, other methods of measuring the images deserve further exploration because stereo-plotters are neither easy to use nor widely available. A programmable analytical plotter (Adam MPS-2) was not suitable for this application because of a lack of clearly defined points in the images which could be used to centre the negatives correctly on the stage plates.

A number of changes would improve the accuracy and usefulness of our system. Electronic shutter release would probably achieve much better synchronisation than the current paired air-release system. When stereo pairs are taken of moving animals from a moving boat, poor synchronisation alters the effective camera separation and can drastically affect the accuracy of measurements from a single stereo pair. Motorised film advance would make our system easier to use and would aid in getting optimal images, but it would also add another source of alignment error in the attachment of the motor-drive to the camera body. Neither of our Pentax MX cameras was capable of shutter speeds higher than ca 1/500s, despite being set at 1/1000s. This is apparently not uncommon in cameras with cloth focal plane shutters (Borrell, pers. comm.). To minimise blur, higher shutter speeds would be useful. Modern cameras with electronically timed shutters and built-in motor drives would seem ideal. We would advise anyone building a stereophotogrammetric system based on non-metric cameras to test alternative cameras and lenses carefully before they commit themselves to purchasing a particular pair. We would also suggest that it is advisable to photograph a field calibration target (e.g. two precisely marked floats separated by a rigid tube) each time the cameras are remounted. We did not do this and have to, therefore, rely on recalibration of the system between seasons and remeasurement of photographically identified animals, to provide evidence that the alignment of the system has not changed.

Using a regression relationship to estimate \( y \) from a given value of \( x \) obviously involves error, depending on the closeness of the relationship. For this reason it is obvious that analyses (for example of individual growth or size-class separation) should be conducted using the raw measured data (in this case the length from the blowhole to the dorsal fin) rather than the estimates of total length from the regression equation.

Our system is designed to measure sperm whales, but could be adapted to other species (e.g. by measuring from the tip of the rostrum to the blowholes in baleen whales). Where data are available to relate photographically measurable features to total length, boat-based photogrammetry could become a powerful tool in studies of cetacean biology.

**ACKNOWLEDGEMENTS**

Funding for this project was supplied by the New Zealand Lottery Board, Telecom NZ Ltd (via WWF NZ) and by the Zoology Department of the University of Otago. Reckitt and Coleman, Ocean Electronics, and Hutcheson Wilson & Company generously sponsored equipment used in the field study. Zoology Workshop technicians Murray McKenzie, Bede McCormick and Peter Sontag built the camera mounting system and the directional hydrophone equipment we used to locate whales. Albert Chong provided helpful advice on photogrammetry and Andrew Chessum assisted with measuring whales on the stereoplotter. Bruce Borrell measured the shutter speeds of the cameras and Ian Hodgkinson helped us measure the nodal planes of the lenses. The manuscript was improved significantly by Hal Whitehead (Department of Biology, University of Dalhousie, Halifax, Nova Scotia, Canada B3H 4J1) and Jonathan Gordon (Wildlife Conservation Research Unit, Department of Zoology, South Parks, Oxford OX1 3PS, England) and an anonymous reviewer.

Copies of the full papers are available at cost price from the IWC Secretariat.
Southern Hemisphere Whales

The current proposal for establishing a circumpolar whale sanctuary in the Southern Hemisphere specifies its northern boundary at 40°S. This is appropriate as a broad general definition of ‘the Southern Ocean’ which is bounded by the Sub-Tropical Convergence (SS-TC) at about that latitude in most sectors. It is also appropriate as an extreme outer limit for the feeding grounds of the migratory species of baleen whale populations (i.e. excluding Bryde’s whales). In particular, sei whales and especially the younger individuals, feed to the north of the feeding zones of the other species, though south of the SS-TC. However, it is not necessary for the boundary to be as far north as 40°S in all latitudes to fulfill the sanctuary’s prime purpose of protecting these whales when on their feeding grounds. Evidently it need only be set at 55°S in the Indian Ocean Sector (20°E to 130°E) where the waters north of that latitude are already included in the Indian Ocean sanctuary. An alternative suggestion has been that the CCAMLR boundary would be appropriate: the CCAMLR boundary in the Indian Ocean sector is at or north of 55°S. The sanctuary boundary could arguably be set further south than 40°S in the eastern South Pacific sector. The fine line marking on the charts represents the average latitude in each sector of what is both a variable location from year to year and the mid-latitude of a transition zone. This transition zone is rather narrow in most sectors, but wide and widening from west to east, in the southeastern Pacific. In the sector east of 120°W the SS-TC veers northwards (ultimately, in fact, well to the north of 40°S) and is relatively weak, getting progressively so as it approaches the coastal waters of Chile, where it eventually runs nearly parallel with the coast before fading completely. In the Pacific east of 130°W the SS-TC does not determine the northward limit of the distribution of feeding sei whales, as indicated by official pelagic catch records and associated biological studies. In the main period of Antarctic sei whaling, from 1962/63 to 1971/72, hardly any were caught in that region north of 50°S and only about 16% of the total were caught north of 60°S (as compared with 67% in the western Pacific). The records show that catcher boats attached to pelagic expeditions searched the zone between 60°S and 40°S but found few sei whales there. Evidently, in the southeastern Pacific a sanctuary boundary at about 55°S or 60°S would protect the feeding sei whales as well as the other migratory baleen species. In the Atlantic generally and the southwest Pacific sectors 73% and 56%, respectively, of the sei whales were caught between 40°S and the CCAMLR boundary; the latter is clearly not appropriate there for the protection of feeding sei whales. However, neither the catch data nor the oceanographic information give unambiguous indications of where a scientifically determined sanctuary boundary would best be set in the sector between the coast of Argentina and the approximate longitude of the Malvinas/Falkland Islands.

SC/46SH4. PARAMETERS OF THE SOUTHERN MIGRATION OF HUMPBACK WHALES (MEGAPTERA NOVAEANGELIÆ) ON THE WEST COAST OF SOUTH AFRICA. Peter B. Best and Keiko Sekiguchi, Mammal Research Institute, University of Pretoria, Pretoria, 0002 South Africa.

Between 5 October and 19 November 1993, 195 sightings of 356 whales (of which 62 were sightings of 155 humpback and 68 sightings of 117 right whales) were made from the lighthouse at Cape Columbine, South Africa. Humpback whales seemed to occur in three episodes about nine days apart, whereas right whales showed a reciprocal pattern. For humpback groups tracked by teledolite, the average distance offshore peaked at 2–2.5 km, whereas for right whale groups the main peak was at 0.5–1 km from the coast with the suggestion of a second peak at 3.5–4 km offshore. Independent information on the offshore distribution of these two species was obtained from 1,122 km searched by the ski-boat Eclatant in the vicinity of the Cape Columbine between 12 October and 10 November. The

NOT TO BE CITED WITHOUT AUTHOR’S PERMISSION.
proportions of humpback whale groups in two strata (0-5 and >5km) from the shore as seen from the lighthouse did not differ from those expected from the boat data, although they did differ for right whales. Net directions of movement for fin humpback whale groups for which more than two theodolite fixes were available were distributed equally to all four quadrants of compass and those groups showing a consistent directionality of movement were headed equally to the north and to the south. Of the same 51 groups, 70% travelled at net speeds of less than 1.5km/hr. Migratory indices for individual groups (the average speed divided by the net speed) ranged as high as 82 and those with the lowest indices (corresponding to those most likely to be migrating) were distributed equally to all four compass quadrants. Individual identification photographs taken of 27 humpback whales over 20 days revealed only 10 individuals. Five of which were resighted on more than one occasion and up to 20 days apart. Apparent feeding behaviour by humpback whales was seen on 10 occasions over a span of 38 days and the production of reddish particulate faeces indicative of recent feeding was seen on seven occasions, at a defecation rate of 0.22 whale/hour. Faecal samples collected indicated the consumption of euphausiids (possibly E. lucens) on two occasions and amphipods on another. Overall, the data indicate that the southward migration of humpback whales expected at this time of year on the west coast of South Africa had been suspended probably in response to locally abundant prey.

The Hitter-Fitter population model is used to fit series of sighting survey data for humpback whales off the west and east coasts of Australia. Single surveys carried out in the early 1960's on each of these coasts are suggestive, when compared to the results of later surveys and their trends, of undeclared catches of these animals during the 1960's and early 1970's. These undeclared catches are needed to account for the contrast of little population change over this earlier period, followed by rapid increases after the late 1970's. The model (in its principle) allows the size of these catches to be estimated. An interesting result of the exercise is the requirement of a sex ratio at birth slightly favouring males, to prevent extinction of the male component of the population in the early 1960's - foetal sex ratio data provides supportive evidence for such an effect. Given the many uncertainty in and the crude approximations required for the analysis, not much confidence should be placed in the results of what should be regarded as an exploratory exercise only. The point estimate of undeclared humpback catches from Areas IV and V over the 1963-71 period is some 900, with very wide associated confidence limits. This is rather less than the figure of 7,207 recently announced by Yablokov (Nature: 367 (1994): 108) for the undeclared humpback catches by a single Soviet factory vessel, though that figure applies to a longer period and presumably also to a larger region of the Southern Hemisphere.

SC/46/SH9. SOUTHERN HEMISPHERE PELAGIC FOR PYGMY BLUE WHALES: REVIEW OF CATCH STATISTICS. Robert L. Brownell, Jr and Meghan A. Donahue, Southwest Fisheries Science Center, PO Box 271, La Jolla, CA 92038, USA.

Two forms of blue whales, Balaenoptera musculus, are generally recognised in the Southern Hemisphere (true blue and pygmy blue). The 'true' blue whales summer in the Antarctic and are the largest of all whales. This population is distinguished from the nominate Northern Hemisphere form, B. m. musculus, and known as B. m. intermedius. The pygmy blue whale is much smaller and is recognised as a very distinct subspecies B. m. brevicuda.

This subspecies' summer range is mainly in the region around the Sub-Antarctic islands. The two southern subspecies are believed to segregate at between 55-60°S in the Indian Ocean. Smaller than normal blue whales were reported in early Antarctic records. As early as the 1929-30 season. Norwegian expeditions reported catches of small adult blue whales. These were called Myhjønn. This is a semi-adult whale which is a blue whale under 65m, but the gunner earns only half a bonus for a whale of this kind. This is something the companies have introduced to ensure that as few of this species as possible are killed. No additional catches of these small adult blue whales were reported for 30 seasons. During the 1959/60 Antarctic pelagic season, a total of 1,236 blue whales was killed by all countries. About 25% (311) of the total was taken by the countries of March (an honorary member of the IWC region (the waters between Kerguelen Islands and Heard Island). All 311 whales were identified as pygmy blue whales. The USSR started exploitation of pygmy blue whales during the 1962/63 Antarctic pelagic season and continued through the 1971/72 season. This paper reviews the final phase of pelagic exploitation of blue whales in the Southern Hemisphere and the actual catches of pygmy blue whales by Japan and the USSR. Additional information on the distribution and conservation of Southern Hemisphere pygmy blue whales is also reviewed.

SC/46/SH9. ICE-EDGE DATA FROM THE US NATIONAL SNOW AND ICE DATA CENTER FOR INCLUSION IN ANALYSIS OF SOUTHERN HEMISPHERE WHALE DISTRIBUTION. C. Holland and S. Reilly, Southwest Fisheries Science Center, P.O. Box 271, La Jolla, CA 92038.

The ice-edge is one of the most important ecological boundaries in the Southern Ocean. Its importance to the distribution of krill and through krill to foraging whales has long been recognised. This importance has led whale biologists to investigate the spatial and temporal patterns of ice-edge distribution. This brief note extends that effort by making available relevant summaries from the massive amount of data on ice distribution collected by satellite imagery and by providing software to compute distance to the ice-edge from locations of whale sightings. Accurate ice-edge data, along with other variables representing habitat use by whales in the Southern Ocean, can contribute to the work of the IWC Scientific Committee in a number of ways, including: (1) additional information for improved fit of a general linear model (GLM) to extrapolate whale density to areas unsurveyed by the IDC cruises – in particular, it was agreed at the 1993 meeting that this should be pursued to allow incorporation of ice-edge data into analyses of sightings from Japanese Scouting Vessels; (2) improved post-stratification of within-year data for more precise and perhaps less-biased abundance estimation; (3) improved estimation of line transect parameters from inclusion of habitat variables (including distance to ice-edge) as covariates.

In 1993 the IWC Scientific Committee identified three possible objectives for a research programme on blue and other large baleen whales in the Southern Hemisphere: (i) to refine estimates of abundance in feeding areas; (ii) to evaluate the potential for competition for krill between blue whales, other baleen whales and other high level predators; (iii) to determine the distribution of breeding areas and whether animals that utilise a particular low-latitude breeding area utilise particular feeding areas in the Southern Ocean. A subsequent meeting to examine this further stated that 'The analysis of historical data (Discovery marks, catches, environmental and other Discovery data, sightings rates) should also be undertaken to improve the efficiency of future
surveying, both on feeding grounds to assess abundance and to locate breeding grounds and their linkages to feeding areas. The reference to 'environmental' and other Discovery data' refers to data from the 'Discovery' cruises in 1925–1937 and other historical data collected until 1967 by the UK Whale Research Unit. These data include information on whale stomach contents and net hauls for krill and associated location and oceanographic data. Much of this material has been analysed and published in the 'Discovery' Reports series. But different aspects of the research have been published separately and the data remain in the form of data sheets, index cards, logbook entries. The data are neither computerised nor catalogued. It is currently impossible, therefore, to integrate this unique set of information to allow analyses to address the objectives listed above. However, analyses of a fully computerised database could provide a valuable insight into changes in patterns of distribution and feeding ecology over a wide area of the Southern Ocean in the period during which the stocks of large baleen whales were depleted. In addition, analyses of these data will allow investigation of the characteristics of historical concentrations of blue and other large baleen whales in the Southern Ocean. This information could be extremely valuable in attempts to address the objectives listed above and to help the Scientific Committee direct future research efforts in an effective and efficient way.

SC46/SH11. PATTERNS OF SEGREGATION OF MINKE WHALES IN ANTARCTIC AREAS IV AND V AS REVEALED BY A LOGISTIC REGRESSION MODEL. Yoshihiro Fujise, The Institute of Cetacean Research, 4–18, Toyomi-cho, Chuo-ku, Tokyo 104, Japan and Hirohsa Kishino, Department of International and Social Relations, University of Tokyo, 3–8–1, Komaba, Meguro-ku, Tokyo 153, Japan.

In order to examine the spatial and seasonal changes in segregation of minke whales in the feeding ground, the proportion of males and sexual maturity rates of males and females were analysed using a logistic regression model. In this analysis, we used minke whale samples from the Japanese Whale Research Programme Under Special Permit in the Antarctic (JARPA), conducted in Antarctic Areas IV and V from 1992/93 to 1999/2000. By adopting a logistic regression model, the segregation of minke whales in the feeding ground show the following features. Males, especially mature males, were dominant in Area IV and the proportion of males increases with progress of the season and with their school size. Mature females were dominant in Area V and they were concentrated in the ice-edge and the southernmost area such as the Frydza Bay (Area IV) and Ross Sea (Area V) later in the survey. Immature animals were distributed in the northern part of the research areas. The pattern of longitudinal distribution of immature animals varied by survey season.

Abundance estimates of southern minke whales in Areas IV and V were obtained using sighting data collected during the Japanese Research Programme Under Special Permit in Antarctic (JARPA) in 1991/92 and 1992/93; in particular, they were used to correct analyses of age distribution. In order to investigate the effect of sampling activity and seasonality on the abundance estimates, the sighting strategy in 1992/93 was modified as follows: (1) one dedicated sighting vessel (SV) was exclusively engaged in sighting throughout the research area following an independent trackline to that of the sighting/sampling vessels (S/S); (2) a sighting survey was conducted, with survey effort concentrated during the peak season of minke whales in the Antarctic, to follow the procedures used during the IDCR cruises as closely as possible. The abundance of minke whales in Area V was estimated to be 159,640 (CV 0.383) by the S/S in 1992/93 compared with a closing mode estimate of 211,190 (CV 0.174) for the IDCR cruise in 1985/86. The JARPA abundance estimate although some 24% lower than the 1985/86 IDCR estimate is not statistically different from it.

Restriction fragment length polymorphisms of mitochondrial DNA (mtDNA) in the ordinary form minke whale were identified and used to examine population structure in Areas IV and V. We examined 1,257 minke whales sampled under special permit on the feeding grounds in five survey seasons, two in Area IV and three in Area V. Mitochondrial DNA extracted from liver tissues were digested with six kinds of six-base polymorphic restriction enzymes. A total of 123 mtDNA haplotypes were discriminated on the basis of the combination of digestion enzymes. Spatial and temporal factors were considered in the grouping and analysis of the samples. Haplotype frequencies were employed to determine the genetic relationship between groups of samples. Our results suggest that: (a) there is not a significant difference in the mtDNA haplotype distribution of the sexes; (b) in both Areas IV and V there is not a significant difference in the mtDNA haplotypes composition between survey seasons in a determined longitudinal and latitudinal area; and (c) after partitioning samples from different survey seasons, we found a marked spatial and temporal heterogeneity in mtDNA haplotype frequencies distribution in Areas IV and V. The use of this type of heterogeneity in determining stock structure in Areas IV and V was examined. A group of whales distributed in the western part of Area IV in December (group A) was significantly different in haplotype composition from all the other spatial and temporal groups analysed in Areas IV and V. The possibility that this group belongs to a relatively discrete breeding stock is discussed.

SC46/SH14. WORLD-WIDE POPULATION STRUCTURE OF MINKE WHALES DEDUCED FROM MITOCHONDRIAL DNA CONTROL REGION SEQUENCES. Horatio Iori, Yoshitaka Besho, Ryo Kawahata, Issui Watanabe, Akihiko Koga, Department of Biology, Nagoya University, Chikusa, Nagoya 464–01, Japan and Luís A. Pastene, The Institute of Cetacean Research, 4–18, Toyomi-cho, Chuo-ku, Tokyo 104, Japan.

Two morphological forms of the minke whale have been recognised by the IWC Scientific Committee, a larger 'ordinary' form and a smaller so-called 'diminutive' or 'dwarf' form. To elucidate the phylogenetic relationship between them, we determine the DNA sequence of a 343 base-pair of the mtDNA control region isolated from 15 diminutive form (DM) and 14 ordinary (10 from the Southern Hemisphere and 4 from the North Pacific) minke whale samples. A phylogenetic tree was constructed from 117 sequences determined in this study and published data from the North Atlantic minke whale. The tree clearly showed that DM and ordinal minke whales from the Southern Hemisphere (SH), the North Pacific (NP) and the North Atlantic (NA) are separately related to each other, suggesting independent genetic populations. This is quite different from the case of the humpback whale species that appears to show a single world-wide population structure. The tree also showed that DM was more closely related to NA than either was to SH. Thus DM is very remote from SH in spite of their overlapping geographic niche. This result supports previous analysis of morphological data that DM should be separated from the ordinary form, at least at the subspecific level.

NOT TO BE CITED WITHOUT AUTHOR'S PERMISSION.

The seventh cruise of the Japanese Whale Research Programme Under Special Permit in the Antarctic (JARPA) was carried out with one research base and three sighting and sampling vessels in the Antarctic Area IV from 3 December 1993 to 19 March 1994. The research consisted of two different surveys, one conducted throughout the entire research area and the other in the Special Monitoring Zone (SMZ, 110°E to 130°E). The former was synchronized with the IWC/IDCR survey to concentrate sighting efforts on the peak migration period of minke whales. The survey in the SMZ was conducted twice, before and after the main survey in the entire research area, in order to investigate seasonal changes in the migration of minke whales. The sampling method was the same as in the previous JARPA survey. Dwarf form minke whales were not sampled. One dedicated sighting vessel (SSV) which was exclusively engaged in the sighting survey, covered the whole research area following independent sighting track lines. Two sighting/sampling vessels (SSVs) had two track lines for sighting and sampling activities. These three vessels surveyed a total of 17,932.6 n.miles. During the research period, 688 primary (1,619 animals) and 267 secondary (1,200 animals) sightings of ordinary form minke whales were recorded. Out of 433 schools (940 animals) primarily sighted by the SSVs, 360 ordinary form minke whales (200 males and 130 females) were randomly sampled. The distribution pattern of minke whales sighted was not considerably different from those in the previous surveys, with the exception of Prydz Bay. The ratio of mature males in the sample was higher with the exception of Prydz Bay, where the ratio of mature females was higher. It should be noted that the ratio of mature females was lower than in the previous research surveys. Several experiments were conducted during the survey. On 15 March 1994, a tow-type satellite telemetry tag was attached to a minke whale. Five schools (nine animals) of the blue whale, 29 schools (48 animals) of the humpback whale and three schools (four animals) of the right whale were photographed for natural markings. Twenty biopsy skin samples were taken from humpback whales, while five samples were taken from right whales.

Japan has been conducting research on minke whales under the ‘Program for the Research on the Southern Hemisphere minke whale and for the Preliminary research on the Marine Ecosystem in Antarctica’ since the 1987/88 season in compliance with Article VIII of the International Convention for the Regulation of Whaling, 1946. After the feasibility research conducted in part of Area IV in 1987/88 and part of Area V in 1988/89, Japan commenced the full-scale research activity from 1989/90 season. Japan has carried out research in Area IV three times in 1990/91, 1992/93 and 1993/94, and in Area V twice in 1990/91 and 1992/93. Each year the Government of Japan (GOJ) submits a research plan for the following Antarctic season to the Scientific Committee of the IWC. The present research plan for 1994/95 is the sixth of the long-term programme made in 1987 and amended in 1989. At the 45th Annual Meeting of the IWC, GOJ submitted the research plan in Area IV in 1993/94 as a document SC/45/SH/10. Although constructive and positive comments were made by some of the members of the Scientific Committee (IWC/45/47), the Plenary of the IWC passed a resolution calling for the reconsideration of the programme (IWC/45/47). The IWC also passed two other Resolutions on ‘Research Related to Consideration of Large Baleen Whales in the Southern Oceans’ (IWC/45/38) and ‘Research on the Environment and Whale Stocks’ (IWC/45/41). The GOJ reconsidered the research plan, respected comments made by the Scientific Committee, the three resolutions and consequently improved the plan as reported in the IWC Circular Communication (Circular RG/VI/1991). The research area in Area IV in 1993/94 was conducted by the improved plan and it was successful as reported by Nishiwaki et al. (SC/46/SH/15). Therefore, the research in Area V in 1994/95 season will be conducted based on the improved plan as in Area IV in last season.

The sixth cruise of the Japanese Whale Research Programme Under Special Permit in the Antarctic (JARPA) was conducted during the period from 3 December to 23 March 1993, using one research base and three sampling vessels. The survey covered the waters between 130°E and 170°W south of 60° including the whole of the Ross Sea. The research vessels were engaged in a systematic sighting and sampling survey for minke whales and carried out XBT observations in order to analyse oceanographic conditions. The relationship between oceanographic conditions and the distribution pattern of minke whales was examined using data obtained from this survey. Two environmental gradient indices were introduced to express upper strata of oceanographic condition simply. The first index was the integrated value of water temperature from the surface to 50m in depth ($Q_{50}$), which indicated the condition of the Summer Surface Water. The second index was the integrated value of water temperature from the surface to 200m in depth ($Q_{200}$), which indicated the distribution patterns of the Antarctic Surface Water consisting of the Summer Surface Water, the Winter Water and the Warm Deep Water. The distributions of the density indices of minke whale were compared with the isotherms of temperature at each depth, $Q_{50}$ and $Q_{200}$. Although the distribution of minke whales was recognised especially to north during the first period, it shifted south during the later period. The isotherm (e.g. 0°C of $Q_{50}$, which tended to be parallel with the ice edge, also shifted from 62°S in the first period to 65°S in the latter period were distributed in the waters between 1.0 and –1.7°C of $Q_{200}$, especially the Shelf Water and the possible upwelling.

SC/46/SH/18. STABLE ISOTOPES IN SOUTHERN RIGHT WHALE (EUBALAENA AUSTRALIS) BALEEN AS INDICATORS OF SEASONAL MOVEMENT AND GROWTH. P. B. Best, Mammal Research Institute, University of Pretoria, Pretoria, 0002 South Africa and D. M. Schell, Institute of Maritime Science, University of Alaska, Fairbanks, Alaska, USA.

Ratios of stable carbon and nitrogen isotopes were examined in the baleen of eight southern right whales originating from South Africa, including one neonate, three juveniles and four adults. Oscillations in carbon isotope ratios were marked and indicated
feeding north of or at the Subtropical Convergence (STC) alternating with feeding south of the STC. The agreement between the size of the baleen at one year of age as estimated from the rate of baleen growth in calves and as estimated from the size of baleen in (nominally) two-year-old juveniles, suggested that the oscillations in carbon isotope ratios were annual events. A comparison of the timing of the formation of the first enrichment peak in juveniles (as estimated from the amount of predicted baleen growth over the first year) with the timing of the last enrichment peak in all non-calves (assuming that the peaks were annual events) indicated that both were formed over the period January to April (mean in February). A similar analysis indicated that valleys in the nitrogen isotope ratios were formed between March and June (mean in April), with peaks between June and January (mean in October). These patterns were not consistent with previous scenarios of southern right whale migration, if the enrichment peaks in carbon isotopes were taken to represent feeding just north of the STC, the subsequent decline in enrichment levels to represent feeding south of the STC in autumn and the persistence of an isotope signature characteristic of high latitude plankton throughout the winter and early spring to indicate that feeding essentially ceased when the northern migration began, and did not resume until the southern migration was under way. The oscillations in nitrogen isotope ratios would support this interpretation, if they were assumed to represent cycles of starvation and recovery. The size of the three apparently two-year-old juveniles (averaging 9.87 m in length) compared to the lengths and growth rates of calves measured photogrammetrically suggested that growth in body length of southern right whales might slow drastically between weaning and two years of age, although the baleen continued to grow in length.

The present paper examines changes in age distribution of southern minke whales related to year or season using data collected from the Japanese Whale Research Program under Special permit in the Antarctic (JARPA) in the 1991/92 and the 1992/93. The Area IV samples showed typical age distribution having a peak in 1-6 year olds and the proportion decreased with age with no specific changes seen over the years. The Area V samples showed apparent changes in age distribution. However, this seemed to be due to bias as low sampling efficiency in smaller animals and the improved sampling efficiency provided a similar age distribution of males to that of the 1988/89 survey in Area V. However, the age distribution for females showed a different pattern having a peak of the 16-21 year age class which seemed to be caused by the fact that the older females originated from another stock(s) which migrated to the Ross Sea area or the lack of younger individuals in this area. It appears that younger individuals of those sampled in Area IV migrated later to the research area, whilst younger animals in Area V arrived earlier.

In this note we summarise the activities related with the experiments of photo-identification on southern baleen whales being conducted by the Institute of Cetacean Research (ICR) in cooperation with the Western Australian Museum. The ICR has been involved in the taking of photographs of natural markings in three species - humpback, right and blue whales - in Antarctic Areas IV and V. Pictures have been obtained during the cruises of the Japanese Whale Research Programme under Special Permit in the Antarctic (JARPA). We outline the objectives of the photo-ID study, describe the methodology used and summarise the number of individuals and pictures obtained. Visual analysis of pictures taken of humpback whales within and between survey seasons, in the same management area has been carried out. However, no matching of the same individual has been achieved. An outline of the future research plan on photo-ID is given.
SC/46/SH24. ESTIMATES OF ABUNDANCE FOR SOUTHERN HEMISPHERE BLUE, FIN, SEI HUMPBACK, SPERM, KILLER AND PILOT WHALES FROM THE 1978/79 TO 1990/91 IWC/IDCR SIGHTING SURVEY CRUISES. WITH EXTRAPOLATIONS TO THE AREA SOUTH OF 30°S FOR THE FIRST FIVE SPECIES BASED ON JAPANESE SCOUTING VESSEL DATA. D.S. Butterworth, D.L. Barchers*, S. Chalik*. J.B De Decker, Department of Applied Mathematics, University of Cape Town, Rondebosch 7700, South Africa and F. Kasamatsu*. The Institute of Cetacean Research, Tokyo Suisan Building, 4–18 Toyomi-cho, Chuo-ku, Tokyo 104, Japan. Current address: Wildlife Population Assessment Research Group, Mathematical Institute, North Haugh, St. Andrews. Fib K16 9SS, U.K. Current address: Marine Ecology Research Institute, Tetokoki-shoin Building, 3–29 Jinbo-cho, Kanda, Chiyoda-ku, Tokyo 101, Japan. Estimates of abundance based on primary sightings data from effectively all survey modes on the IWC/IDCR Antarctic cruises are developed for the species listed, using essentially the methodology agreed by the IWC Scientific Committee for the estimates of minke whale abundance from data from these cruises. Small sample sizes necessitate considerable pooling and data from all the cruises are combined to estimate the effective mean sample size and search half-life for each species. The resultant abundance estimates (with CV’s in parenthesis) for the first and second circumpolar sets of IWC/IDCR surveys, which respectively covered 65% and 80% of the open ocean area south of 60°S, are:

[Note: During the meeting, an error in the manner in which data from the 1990/91 cruise had been incorporated into the analysis was noted. Corrections for this have yet to be effected, but will not modify the values reported above substantially.]

Comparisons of the ratio of secondary to primary sightings in closing mode suggest that when compared to minke whales, any negative bias in abundance estimates introduced by the neglect of secondary sightings is larger for fin whales, but smaller for sperm and humpback whales. Mean school size for killer whales is significantly larger in strata adjoining the ice-edge: if this is taken into account, abundance estimates for that species drop by about 10%. The estimates for sei and pilot whales are each based on less than 20 primary sightings over the 13 cruises and are, therefore, unreliable. With the exception of sperm whales, these estimates are not sufficiently precise to allow inferences to be drawn about possible trends in abundance with time. The assumption made for each of these species that all schools on the trackline are sighted (q(t)=1) seems likely to lead to substantial negative bias in the estimates for sperm whales, given their typically long dive times. The estimates for the five larger species are extrapolated northwards under the assumption that sighting rate data from Japanese scouting vessel (JSV) operations over the 1965/66 – 1977/78 period provide a reliable relative measure of density variation with latitude, which results in the following estimates for abundance in the area south of 30°S: ‘True’ blue whales 610 (0.63); pygmy blue whales 4,300 (0.77); fin whales 18,000 (0.47); sei whales 17,000 (0.70); humpback whales 15,000 (0.30); sperm whales 290,000 (0.46). These results are preferred to ones based on JSV operations over the 1978/79 — 1987/88 period (for which the data were recorded on a different basis) because of the greater amount of searching effort applied in the earlier period and the associated greater precision of estimates. The differentiation between true and pygmy blue whales is based on the assumption that these species are separated by the 50°S line of latitude.

[Note: This paper combines and revises results previously reported in SC/41/O 20, SC/42/SHM18, SC/43/Me34 and SC/44/SHB19.]

SC/46/SH25. IDENTIFICATION OF THE HUMPBACK WHALE POPULATION ALONG THE ECUADORIAN COAST. Ben Huse and Fernando Félix G., Fundacion Ecuatoriana para el Estudio de Manifesteris Marinos (FEMM), Casilla 9001 6637, Guayaquil, Ecuador.

As in 1990 and 1991, personnel of the FEMM, biology students of the State’s University at Guayaquil and three invited specialists from abroad (Belgium and United Kingdom) made a series of surveys in coastal waters, in order to extend the data bank on the humpback whale along the Ecuadorian coast, that was set up in 1991. In 1992, 14 new whales could be identified and added to the fluke-collection that was set up in 1991. For the first time during the projects, at least three calves were observed. Some good recordings of singing whales were made.

North Atlantic

The Implementation Trials for North Atlantic minke whaling, are carried out for the Catch Limit Algorithm tuned to 60%, 66% and 72% respectively, and with internal protection level 0.5. The results are compared to those obtained for the tuning level chosen by IWC.

SC/46/NA2. STUDIES OF MINKE WHALE (BALANOPTERA ACUTO ROSTRA) ECOLOGY IN THE NORTHEAST ATLANTIC: DESCRIPTION OF THE 1993 SCIENTIFIC CATCH OPERATIONS AND PRELIMINARY RESULTS FROM STOMACH ANALYSES AND RESOURCE SURVEYS. Tore Hauge and Kjell T. Nilssen, Norwegian Institute of Fisheries and Aquaculture, PO Box 2511, N-9002 Tromsø, Norway. Ulf Lindstrom, Norwegian College of Fisheries Sciences, University of Tromsø, N-9037 Tromsø, Norway and Ingolf Rottingen, Institute of Marine Research, PO Box 1870, Nordnes, N-5024, Bergen, Norway.

Ecological studies of the Northeast Atlantic minke whale (Balaenoptera acutorostrata), initiated in 1992, were continued in 1993. The field work was carried out in spring (15 April-15 May), summer (15 June-12 July) and autumn (25 August-20 September) using four chartered small-scale whaling vessels which operated in four selected subareas. To ensure random sampling of whales, stringent sampling procedures, where the vessels searched for

NOT TO BE CITED WITHOUT AUTHOR’S PERMISSION.

In order to evaluate the feeding ecology and importance of minke whales Balaenoptera acutorostrata in Norwegian waters, a scientific whaling programme was initiated in 1992. The research plan for this program was presented both to the Scientific Committee of the International Whaling Commission and to the Marine Mammal Programme of the International Council for the Exploration of the Sea. The main objective of the research is to provide information on minke whale feeding ecology based on whale stomach sampling and concurrent estimates of prey availability and changes in energetic status of the species in certain key areas of the Northeast Atlantic during the period March-October. The sampling design permits evaluation of both food selection and the relative contribution of various food items to the minke whale diet. The research, therefore, will provide a better basis for the incorporation of minke whales in multispecies models (e.g. MULTSPEC) which is now being developed for the Northeast Atlantic area. In addition to the information needed for the feeding ecology studies, other information of relevance to the management of whales as well as their surrounding biotic and abiotic environment (demography, productivity, stock identification, pollution, parasites, etc.) will be obtained from the whales sampled.

The most recent estimate of abundance of minke whales in the Northeastern combination area was based on ordinary surveys conducted in 1988 and 1989 as well as independent observer experiments conducted in 1989 and 1990 and measurement error experiments in 1990. As part of the development of a Revised Management Procedure (RMP) for baleen whales undertaken by the Scientific Committee, requirements have also been made for regularity of data. The management area to which the Catch Limit Algorithm is applied should normally be surveyed at intervals not exceeding six years. In addition, the IWC has developed guidelines for conducting surveys and analysing the data. The latter document requires that plans for survey design and methods of analysis shall be reviewed by the Scientific Committee prior to carrying out the survey, although an approval from the Committee is not formally necessary. With the aim of conducting a full-scale survey in the summer 1995, a cooperative project between the Institute of Marine Research and the Norwegian Computer Center under the Marine Mammal Research Programme/Research Council of Norway has been initiated this year to make the necessary preparations and facilitate the detailed planning for conducting a survey in 1995. The preparations include consideration of several aspects of the previous surveys, with respect to further developments as well as providing the necessary documentation for a preview of the survey. This note points to some of these aspects.

SC46/NA5. YONAH (YEARS OF THE NORTH ATLANTIC HUMPBACK): FINAL REPORT ON FIELD WORK AND PRELIMINARY DATA ANALYSIS. David DeKing, Phillip Clapham and David Mattila, Center for Coastal Studies, Provincetown, Mass. 02657, USA.

Work performed or subcontracted by the Center for Coastal Studies in 1992 and 1993, as part of the Years of the North Atlantic Humpback (YONAH) project, is summarised. YONAH is an international collaborative effort which used photoidentification and molecular genetics to study humpback whales, Megaptera novaeangliae, across their entire known North Atlantic range. The International Whaling Commission and US State Department partially supported field work or data management and analysis in the West Indies breeding range and in two summer feeding areas, the Gulf of Maine and Eastern Canada. West Indies field work was conducted in four locations: Silver Bank, Navidad Bank, Samana Bay and northwestern Puerto Rico. Work in the Gulf of Maine was undertaken in a variety of areas from Massachusetts to Nova Scotia. In eastern Canada, field work took place off Newfoundland and Labrador, and in the Gulf of St. Lawrence. All field work was conducted using standardised protocols. During the study period, a total of 3,520 humpback whales were individually identified, including 1,894 in the West Indies, 403 in the Gulf of Maine and 1,223 in Eastern Canada. The total number of biopsies obtained was 2,142, including 1,615 from the West Indies, 200 from the Gulf of Maine and 297 from Eastern Canada. Overall, the YONAH project has identified approximately 4,000 individual whales and biopsied more than 2,300. Analysis of photographs taken in the West Indies, Gulf of Maine and Eastern Canada is complete, and copies have been submitted for matching, together with relevant sighting data, to the YONAH Photographic Archive at College of the Atlantic, Bar Harbor, Maine. Biopsy samples have been sent (or are awaiting permits for shipment) to the YONAH Genetic Archive at the Institute for Population Biology, Copenhagen, Denmark.

SC46/NA7. THE GENETIC STRUCTURE OF FIN WHALES, BALAENOPTERA PHYSALUS, FROM THE GULF OF ST. LAWRENCE AND WEST GREENLAND. Martine Bérubé, Institute of Zoology, Department of Population Biology, University of Copenhagen, DK-2100, Copenhagen, Denmark and University McGill, Campus MacDonald, Ste-Anne de Bellevue, Quebec, Canada, H9X 1CO.

This progress report is based on genetic analyses of DNA extracted from samples collected as skin biopsies and from the aboriginal hunt between 1988 and 1993 in the Gulf of St. Lawrence (n=97) and at West Greenland (n=25). The first 288 basepairs of the mitochondrial D-loop were sequencing defining 31 different haplotypes. The homogeneity tests revealed no significant level of heterogeneity between the West Greenland and Gulf of St. Lawrence samples. Thus the result lends no support to the current division of eastern Canadian fin whales, including the Gulf of St. Lawrence and West Greenland fin whales into two different stocks. Pairwise comparisons between subsets, based on sampling days in the Gulf of St. Lawrence, suggest the possibility of a 'hard-based' population structure. Males in the Gulf of St. Lawrence as well as in West Greenland have a higher degree of diversity, which could be explained by males being more mobile than females. A highly skewed male:female ratio (2.7:1) was found in the Gulf of St. Lawrence sample. In the spring most males seem to congregate in larger groups while in the fall an equal proportion of males was found in pairs and larger groups.

YONAH is a large-scale international effort which uses photographic identification and molecular genetics to study humpback whales (Megaptera novaeangliae) across their entire known North Atlantic range, from the West Indies to the Arctic. The intention has been to obtain as large a sample as possible of individual identifications and skin biopsies in order to provide reliable answers to questions regarding the size, structure (both demographic and genetic), migratory movement, vital rates and mating system of this population. YONAH began in January of 1992 and completed the second and final year of field work in the autumn of 1993. Field work was conducted during both years in the West Indies breeding range and in all known high-latitude feeding areas. Work in the West Indies took place in four locations: Silver Bank, Navidad Bank and Samana Bay (all in the waters of the Dominican Republic) and in the Mona Passage, Puerto Rico. High-latitude areas include the Gulf of Maine, Newfoundland, Labrador, the Gulf of St. Lawrence, the Strait of Belle Isle, West Greenland, Iceland, Norway, Bear Island and Jan Mayen. At the completion of field work, YONAH has photographically identified approximately 4,000 humpback whales and biopsied almost 2,600. While matches between areas (notably breeding and feeding grounds) will inevitably reduce these totals, these sample sizes remain unprecedented for a marine mammal study. Preliminary results of YONAH sampling, by area, are summarised below (flukes/biopsies): West Indies (1,850/1,650); Gulf of Maine (380/200); eastern Canada (1,250/500); West Greenland (220/90); Iceland (200/100); and Norway (100/50). Important results from the two years of field work include: (i) the collection of a body of fluke photographs from Iceland and Norway, including (for the latter) from previously unsurveyed Arctic areas; (ii) the collection of the first biopsies from Norwegian waters; (iii) the discovery of concentrations of humpback whales off Baffin Island; (iv) the collection of biopsy samples from whales of all group and behavioural classes, including more than 170 mother/calf pairs; (v) the first large sample of fluke photographs from Navidad Bank, one of the major breeding grounds in the West Indies; and (vi) the collection of a large body of data on variables which may influence or bias estimates of abundance. The third year of the project, 1994, is devoted to analysis of the huge volume of photographs, data and tissue samples. All photographs are being submitted to the YONAH Photographic Archive at the College of the Atlantic (Maine, USA), where they are being compared and matched; this process will be completed before the end of 1994. DNA has been extracted from virtually all tissue samples at the YONAH Genetic Archive at the Institute of Population Biology, University of Copenhagen, and determine (using a molecular techniques) of the sex of all individuals will be complete by midsummer 1994. Principal genetic analyses include an assessment of population structure using mitochondrial DNA and microsatellite systems. Subsequently, in 1995, a variety of analyses will be conducted, including the calculation of estimates of abundance.

In 1987 and 1989 several North Atlantic countries joined forces to conduct a wide ranging sightings survey throughout the North Atlantic Ocean with the aim of estimating the distribution and abundance of cetaceans (whales and dolphins) in coastal and offshore areas. The surveys were conducted from vessels and aircraft allocated by national laboratories in Faroese Islands, Greenland, Iceland, Norway and Spain in all eight vessels and two aircraft in 1987 and 15 vessels and two aircraft in 1989 respectively. Apart from the scientists from the sponsoring laboratories, scientists from Japan, New Zealand, UK and USA were involved in the planning and conduct of the surveys. Also during the planning stage, useful discussions and consultations took place in the Scientific Committee of the IWC (International Whaling Commission). The surveys were conducted in late June-early August and were stratified with particular reference to distribution of fin, sei, minke and pilot whales throughout the survey area, which extended from the coast of Spain as far south as 500N and as far north as Spitzbergen at 800N, and from the coast of Norway in east to the western coast of Greenland. The surveys gave the first abundance estimates for several species of whales in the North Atlantic, including the recently exploited fin, sei and minke whales and other species subject to drive-fisheries, less recent exploitation or indirect takes, such as long-finned pilot, blue, humpback, killer and northern bottlenose whales, and harbour porpoises. This paper puts forward plans for similar surveys in 1995 and requests co-operation from the IWC Scientific Committee.

SC/46/NA11. RECENT OBSERVATIONS OF BOWHEAD WHALES OFF WEST GREENLAND. Randall R. Reeves, Okapi Wildlife Associates, 27 Chandler Lane, Hudson, Quebec, Canada, JOP 1H0 and Marks Peter Heide-Jørgensen, Greenland Fisheries Research Institute, Tagensvej 135, DK-2200 Copenhagen N, Denmark.

Bowhead whales (Balaena mysticetus) belonging to the Davis Strait stock winter in areas of open water from as far north as the ‘North Water’ in northern Baffin Bay (750N) to at least as far south as the entrance of Cumberland Sound (640N). Some individuals migrate southwards along the west coast of Greenland and overwinter in the loose pack ice near the entrance of Disko Bay. Bowheads have not been studied in West Greenland waters, but opportunistic observations have been made during research on other marine mammals such as white whales (Delphinus leucas) and walruses (Odobenus rosmarus). This paper reviews previous reports and summarises new observations of bowheads made during systematic aerial surveys of white whales off West Greenland in March 1990, 1991 and 1994 and in April 1991. It also provides documentation for two kills of bowheads that were overlooked in previous reviews of the recent (post-1915) catch history.

North Pacific Whales

A three-day Working Group meeting to consider the application of the RMP to the northwestern Pacific minke whale was held prior to the 45th Annual Meeting of the IWC Scientific Committee in 1993. The meeting formulated a series of working hypothesised models based on available information. However, a doubt was raised as to whether it is meaningful to advance the work in circumstances where the possibility of a zero catch limit is not precluded because of a shortage of information. Information is conspicuously lacking for the stock structures, differentiation

NOT TO BE CITED WITHOUT AUTHOR’S PERMISSION.
and mixing pattern of the Sea of Japan-Yellow Sea-East China Sea stock (hereinafter referred to as J stock), the Okhotsk Sea stock (hereinafter referred to as O stock) and Western Pacific stock (hereinafter referred to as W stock). In this regard, the Scientific Committee also noted the desirability of obtaining improved data on stock identity and migration patterns, and further noted that such information would reduce the range of plausible hypotheses that need to be considered. The Working Group established 32 sub-areas in the northwestern North Pacific, three sub-stocks in J stock and four sub-stocks in O stock as well as W stock in the northwestern Pacific. The Working Group also established 22 cases as options for trials of the RMP. As regards minke whales in the area around Japan, the 2-stock theory has been propounded, but the Working Group has established a complicated scenario hypothesised with O stock and W stock existence, etc. This paper describes a research programme to allow the number of hypotheses to be reduced and to provide information on mixing rates. It addresses all of the guidelines to review scientific permit proposals detailed by the Scientific Committee and the Commission.

The Working Group on North Pacific Minke Whale Management Trials (hereunder referred to as the Working Group) did not adopt the assumption that there are two separate stocks of minke whales in the western North Pacific, i.e. the Japan Sea-Yellow Sea-East China Sea stock (J-stock) and Okhotsk Sea-West Pacific stock (O-stock). This assumption had been previously considered by the Scientific Committee in 1991 and had been based on biological information. Instead, the Working Group adopted the assumption of dividing the J-stock into three sub-stocks (J-I to J-III) and the O-stock into four sub-stocks (O-I to O-IV), and adding Western Pacific stock (W-stock). In this paper, the assumption by the Working Group is called 'sub-stock scenario'. This scenario assumes the presence of eight stocks/sub-stocks, which all move and mix in spatio-temporal terms. This paper is aimed at clarifying the basis for such a sub-stock scenario and at assessing the scientific validity in the light of materials and knowledge made available to date.

This paper examines the current summer distribution of the western North Pacific Bryde's whales using sightings and oceanographic data collected from 40 sighting surveys in August and September, from 1983 to 1993 which covered 10°N to 50°N. Bryde's whales were seen over a wide latitudinal range to the south of 45°N and the southern boundary of the North Pacific populations was not confirmed although it seemed to the south of 10°N in the present study. The density was low in the Kuroshio current and apparently high in the waters to both sides of it. This suggests a coastal stock off southern Japan.

The abundance of minke whales was estimated using the program DISTANCE with sighting data collected by Kyomaru No. 1 in the Okhotsk Sea in 1992, Toudamurra No. 18 in the Sea of Japan in 1992 and Shoyo-maral off the Pacific coast of the northern Japan in 1991 and 1992. The research areas were stratified by the distribution of the cruise tracks and the boundaries of the sub-areas used in the implementation of RMP trials. The effective search half-width was estimated by applying the smeared perpendicular distance distribution after truncation. The expected mean school size was estimated based on regression of log(school size) on detection probability. The abundance in the Okhotsk Sea was estimated as 10,897 whales (CV=0.46, 95% CI 4,617–25,717) with coverage of 91% of the sub-area 12 of RMP trials. For the Japanese 200 n.miles EEX in the part of RMP sub-area 10 (Sea of Japan), the abundance was estimated as 707 whales (CV=0.57, 95% CI 250–1,999) with coverage of 30% of RMP sub-area and that of sub-area 6,893 whales (CV=0.67, 95% CI 271–2,946) with 57% of RMP sub-area covered. The abundance off the Pacific coast of the northern Japan (western part of sub-area 7) was estimated as 1,377 whales (CV=0.55, 95% CI 502–3,772) with 39% of RMP sub-area covered. Those estimates may have downward bias due to neglecting animals missed on the track line. Considering the low coverage of the research area and the wide confidence intervals, the present estimates are not significantly different from values estimated previously (sub-areas 7 and 12).

Stocks Subject to Aboriginal/Subsistence Whaling

SC/46/AS1. GRAY WHALE DAY/NIGHT MIGRATION RATES DETERMINED WITH INFRARED SENSORS. Wayne L. Perryman, SWFSC, PO Box 271, La Jolla, CA 92038, USA and Jeff L. Luake, AFSC, NMML, 7600 Sand Point Way, Seattle, WA 98115, USA.

The lack of an unequivocal measure of night migration rate for California gray whales has added a source of uncertainty to the estimation of population abundance from shore counts. In the absence of knowledge about diel variation in migration rate at various times, estimates of abundance were made assuming that night migration rate for gray whales was either slower, faster or the same as those observed during daylight hours. Whatever the assumption, if the night migration rate is underestimated, the abundance estimate based on this assumption will be negatively biased and conversely, an overestimate of night migration rate will lead to a positive bias. The evidence for assumptions concerning day/night migration rates has been largely circumstantial. However, in one study 20 southbound gray whales were radio-tagged and tracked and no difference was reported for their day/night migration rate. Subsequent analysis of these data indicated that the rate of travel at night was greater than during the day, but the results varied depending on the subset of the data used. Starlight scopes and night vision goggles have been used to collect data on night passage rates, but the number of whales detected has been small and the results unconvincing. However, recent tests have demonstrated that whales and their blow can be detected with instruments that sample in the thermal or far infrared region of the electromagnetic spectrum. We obtained an infrared sight from the US military and designed an experiment to test the hypothesis that cows offshore migrate past the census site at Granite Canyon, California at the same rate both night and day. In this report we describe our methods and present results of analysis of a sub-sample of the data we collected. Our analyses

NOT TO BE CITED WITHOUT AUTHOR'S PERMISSION.
include day/night comparisons of surfacing behaviour (number of blows/pod, respiration interval), pod size and passage rate. We also present a small sample of daytime offshore distance data.

SC/46/AS. AERIAL OBSERVATIONS OF THE DISTRIBUTION OF BOWHEAD AND BELUGA WHALES NEAR POINT BARROW, ALASKA, IN THE SPRING. David J. Rugh, Kim E.W. Sheldon, Robyn P. Angliss and David E. Witworth, National Marine Mammal Laboratory, Alaska Fisheries Science Center, National Oceanic and Atmospheric Administration, 7600 Sand Point Way NE, Bin C1 5700, Seattle, WA 98115-0070, USA.

Aerial surveys have been conducted by the National Marine Mammal Laboratory in the spring near Point Barrow most during years since 1978. Some of these surveys were designed to study the distribution of bowhead and beluga (white whales) during their spring migration past ice-based census stations; other aerial surveys were designed to collect photographs of bowheads to obtain length measurements and for identification of individual animals. Percent ice cover and ice type were recorded in conjunction with whale sightings during most of these surveys. This report summarises unpublished information, focusing on results from 1992. Most of the ice seen in the spring of 1992 was categorised as floes or sheets covering 50% or more of the area. The sighting rate of bowhead and beluga whales varied significantly with percent ice cover and ice type. A significant difference in ice preference was observed between juvenile and adult bowhead whales. A scattering of bowhead and beluga whale sightings were reported as far as 33 km north of the shorefast ice edge, with most sightings of bowheads occurring within 8 km and most beluga sightings occurring between 4-18 km.

In recent years, activities related to hydrocarbon exploration and drilling along the North Slope of Alaska have taken place concurrently with Eskimo subsistence whaling. An understanding of the timing of the harvest activities in each village may contribute to the design of an operation window which minimizes the impact on bowhead whales and the native subsistence communities. General information on the timing of the spring and fall migration of bowhead whales has been published, but the timing of the harvest activities themselves may be more illuminating, as they illustrate when animals become available for subsistence use. This paper synthesizes the available data on the timing of the bowhead whale migrating through the examination of harvest records, since access to these data is limited. Two distinct distribution patterns are evident. The spring hunt occurs between 1 April and 15 June and the fall hunt occurs between 16 August and 31 October. Whales at St. Lawrence Island (Savoonga and Gambell) have been taken most often during the month of April. Further up the coast in Pt. Hope, along the migration route, most whales are landed between mid-April and mid-May. Around Barrow, most are taken in May. In the fall, whales are most often landed in September and October with peak numbers in Kaktovik the last two weeks of September and in Barrow the first two weeks of October. In most years, Barrow in the only village which hunts bowheads both in the spring (as the whales migrate east to the Beaufort Sea) and again in the fall (when they migrate back to the Chukchi and Bering Seas). The number of whales landed at Barrow between 1973 and 1993, separated by 15-day intervals and by year are given. The subsistence takes from Barrow vary between years for a variety of reasons, including ice conditions, weather and quotas. Nevertheless, the timing of the hunt between mid-April and mid-June in the spring and between the beginning of September and end of October in the fall, is consistent through the years. Oil exploration activities and subsistence hunting, at least in the fall, are often constrained to the same general time frame (i.e. the ice free period). The bowhead whale westward migration, although not stopped by ice, is highly correlated with periods of open water. It is hoped that this study may help those planning industrial activities to minimise impacts on the whales and the availability of whales to the subsistence hunters.

The annual migration of the gray whale, Eschrichtius robustus, has been documented offshore of the Diablo Canyon Power Plant (DCPP) since 1981. The objectives of the project were to document the nearshore distribution, patterns in abundance and timing of the gray whale migration each year. The 1992/93 census was the seventh since the beginning of the commercial operation of the power plant. As the whales migrated along the coastline offshore of DCPP during winter and spring months, observations were conducted for an average of 2.8 hours per day, three days a week from a coastal peak 915 ft above sea level. From 1981 through 1993 a total of 3,317 whales were observed during 1,195.6 hours of observation on 429 separate days. The first southerly migrating whale was usually sighted around 28 December and the last northerly migrating whale was usually sighted around 3 May. Within the DCPP study area, no significant nearshore distribution as well as a bimodal pattern in abundance of the northerly migrating whales was apparent throughout the study period.

SC/46/AS.13. BOWHEAD WHALE, EUBALAENA MYSTICETUS, POPULATION SIZE ESTIMATED FROM ACOUSTIC AND VISUAL CENSUS DATA COLLECTED NEAR BARROW, ALASKA IN 1993. Adrian E. Raftery and Judith E. Zeh, Department of Statistics, GN-22, University of Washington, Seattle, WA 98195, USA.

The Bayes empirical Bayes method for estimating bowhead whale, Eubalaena mysticetus, population size is used to obtain a preliminary estimate based on the 1993 combined visual and acoustic census off Point Barrow, Alaska. The estimate is preliminary because only part of the acoustic data could be analysed in the time available since the 1993 census. The most probable value of 1993 population size is found to be 6,600 and 95% of the posterior probability is concentrated between 5,700 and 7,600. An alternative method is based on observer estimates of the number of whales that passed within viewing range of the census perch and a correction for whales that passed too far offshore from the perch to be seen. The estimate of whales within viewing range is based on visual census data only and the offshore correction is based on acoustic locations directly offshore from the hydrophone arrays. This estimate for 1993 is 8,000 with a 95% CI of 6,900 to 9,200. The current IWC estimate, based on the Bayes empirical Bayes analysis of the 1988 visual and acoustic census, is 7,500 with 95% of the posterior probability concentrated between 6,400 and 9,200. Although the estimate for 1993 presented here is lower, this is not evidence that the population is decreasing. Indeed, there is a very strong evidence from other analyses that the population is increasing. The estimate is lower for 1993 because the whales were concentrated close to shore in 1993 and estimation methods based on the tracking algorithm are more conservative in this situation. The 1993 Bayes empirical Bayes is conservative and several pieces of information indicate that it may well be downwardly biased.
SC/46/AS16. ESTIMATES OF POPULATION PARAMETERS FOR THE EASTERN PACIFIC GRAY WHALE, *ESCHRICHTIUS ROBUSTUS*, USING A BAYESIAN METHOD. Paul R. Wade, Southwest Fisheries Science Center, National Marine Fisheries Service, Box 271, La Jolla, CA 92038, USA.

A Bayesian statistical method was used to fit an age-structured population dynamics model to the time-series of abundance estimates available for the eastern Pacific gray whale. The joint posterior distribution for the parameters was approximated using the Sampling-Importance-Resampling numerical integration algorithm. Fitting the model to the available censuses from 1966/67 to 1987/88 gave results consistent with previous analyses using different methods, as the observed rate of increase of the population from 1968 to 1988 was estimated to be 3.2% per year. Two years now have census data available for them, 1992-93 and 1993-94. Fitting the population model to the entire time-series from 1967/68 to 1993/94 led to significantly different results from the analysis without the two most recent censuses. Although the population trajectory was still estimated to have a similar rate of increase from 1968-88 (2.9% per year), the population was estimated to have shown a substantial decrease in its growth rate in recent years, leading to a posterior mean estimate of equilibrium population size of 29,160 (22,000, 45,860 CI, p=0.95), with the posterior mode closer to 25,000. Conditional upon the assumed population dynamics model and prior distribution for maximum net productivity level (MNPL), this led to relatively precise estimates of 0.053 (0.036, 0.079) for the maximum net recruitment rate, 0.033 (0.023, 0.044) for the recruitment rate at MNPL and 389 (281,508) for the replacement yield in 1994. Population status was estimated to currently be at 80% (51%, 97%) of the equilibrium level and the ratio of current population size to the MNPL level was estimated to be 1.34 (0.946, 1.594).

An acoustic study was conducted off Point Barrow, Alaska in the spring of 1993 as part of a major effort to census the Bering-Chukchi-Beaufort Sea population of the bowhead whale, *Balaena mysticetus*. Previous studies have been conducted in close coordination with visual census studies in 1984, 1985, 1986 and 1988. Early studies demonstrated the utility of passive acoustics for detecting and locating vocalizing whales, especially for whales that were too far away to be counted by visual observers. When acoustic and visual data are combined, results have been instrumental in revising the present estimates of the bowhead whale population. Here we provide preliminary results on the distributions and behaviours of whales on an analysis of 452hrs of the acoustic array data from the 1993 season. We also describe several modifications to the analysis processes used to compute acoustic locations, associated ranges and bearing errors.

---

**Small Cetaceans**

Since 1983, the IWC Scientific Committee has repeatedly expressed concern over the status of the harbour porpoise (*Phocoena phoocoena*) and it has made recommendations for research and management actions. As its 45th Annual Meeting the IWC passed a Resolution on the Harbour Porpoise in the North Atlantic and the Baltic Sea, requesting Range States to implement the recommendations made by the Scientific Committee on the harbour porpoise and to report progress of this activity to the 46th meeting of the IWC. In Norway, research and management action has been undertaken to implement the various aspects of the recommendations made by the Scientific Committee in 1983, 1990, 1991 and 1992 and action is made to implement the IWC resolution on harbour porpoise. The present paper reports on the progress of this work within Norway.

SC/46/SM6. PRESENT WAYS IN WHICH THE SMALL CETACEANS SUB-COMMITTEE IDENTIFIES STOCKS FOR REVIEW. Arne J. Bjorge, Norwegian Institute for Nature Research, PO Box 1037 Blindern, 0315 Oslo, Norway.

At its 44th meeting, the IWC established a Working Group to consider a mechanism to address small cetaceans in the IWC. This Working Group met prior to the 45th Annual Meeting and the IWC passed a Resolution on Addressing Small Cetaceans in the IWC. The Resolution identified four topics for future discussion within the Working Group. The way in which the Scientific Committee sub-committee on small cetaceans identified stocks for review was one of these topics. The small cetaceans sub-committee identifies stocks for review by selecting priority topics for its meetings. Each year since 1982 the sub-committee has proposed a priority topic for the following annual meeting. This paper summarises the present practice of the sub-committee for selecting priority topics and it is aimed at facilitating the Commission's examination on how the sub-committee identifies stocks for review.

SC/46/SM14. GENETIC DIVERSITY OF HARBOUR PORPOISE POPULATIONS AROUND THE BRITISH ISLES: PRELIMINARY ANALYSIS OF RESULTS. Michael Walton, NERC, Sea Mammal Research Unit, elo British Antarctic Survey, High Cross, Cambridge, CB3 0ET, UK.

Nothing is known about the population structure of harbour porpoises, *Phocoena phoocoena*, found in the waters around the British Isles and Ireland. Gaskin (1984, *Rep. int. Whal. Commn* 34: 569–86) and Yuriak & Gaskin (1987, *Ophelia* 27: 53-75) proposed that the population of harbour porpoises could be divided into 14 main sub-populations in the North Atlantic. Around the British Isles they proposed the following possible sub-populations: (1) Biscay and the English Channel to the Dover Straits, (2) East England/North Sea and (3) West British and Ireland. In surrounding waters they also proposed sub-populations around the Faroes, off Norway, off the Netherlands and in the Baltic. A number of techniques are available to study these proposed sub-populations in more detail. For instance, Andersen (1993, *North Atlantic Mar. Biol. 116: 1-7*) used isoenzyme electrophoresis to investigate porpoise populations in the North Sea and the Baltic Sea side of Denmark. Out of 30 enzyme loci tested two were polymorphic and these were used on 196 animals to measure the heterogeneity in genotype frequencies among different locations and seasons. A significant difference was seen between the two Danish groups in the summer. In the winter the North Sea population appeared to be a mix of sub-populations, probably due to the winter migration of porpoises from other areas. Polymorphism of isoenzymes has generally been found to be low in marine mammals and greater resolution can be achieved by examining the differences in DNA. Various
regions of DNA may be studied to help elucidate population structure, but for a number of reasons, such as its greater rate of mutation compared to the average nuclear gene, the region most widely examined is mitochondrial DNA (mtDNA). Differences in mtDNA may be examined indirectly by looking for restriction enzyme length polymorphisms (RFLPs) or directly by sequence analysis. Although it is more expensive and time consuming than RFLP analysis, sequence analysis enables the detection of all mutations within a given segment of DNA and, therefore, provides an ideal tool for genetic comparison of populations. The method used in this study involves the amplification by PCR (polymerase chain reaction) of the non-coding control region followed by direct sequencing of the double-stranded product. This procedure has the advantage that it can be performed on relatively poor tissue samples which are often obtained from stranded animals. The distribution patterns of the various sequence patterns (haplotypes) found among the proposed populations are then examined.

**SC/46/SM15. BIOLOGICAL RESULTS OF BEAKED WHALES SURVEYED BY THE JAPANESE WHALE RESEARCH PROGRAMME UNDER SPECIAL PERMIT IN THE ANTARCTIC AND THE NEED OF THEIR RESEARCH TAKE.**

Seiji Ohashi, Masahiro Kawasaki and Shigetoshi Nishiwaki, The Institute of Cetacean Research, 4-18, Toyomicho, Chuo-ku, Tokyo 104, Japan.

Using the results of the IWC-IDCR whale sightings survey and data collected by the Japanese Whale Research Programme under Special Permit in the Antarctic (JAPRA) from 1987/88, distribution, migration, morphology, biological parameters, diving behaviour, food and feeding, biochemical components, catch history and current population sizes of beaked whales (Family Ziphiidae) in the Antarctic were examined. Thus, it was recognized that biological knowledge of this whale group still remains very poor. However, we found that beaked whales, most of which are Southern bottlenose whales, are distributed widely and abundantly in the Antarctic, play an important role in the Antarctic ecosystem and may be good indicators of change in the Antarctic environment. Therefore, it is considered that we should commence research take of beaked whales in the Antarctic as soon as possible for the development of biological knowledge of them and for the monitoring of environmental change in the Antarctic.

**SC/46/SM17. SUMMARY OF RESEARCH ON HARBOUR PORPOISES IN THE NORTH ATLANTIC AND BALTIC SEA.**

Debra Palka, NMFS/Northeast Fisheries Science Center, Woods Hole, MA, USA and Philip Hammond, Sea Mammal Research Unit, Madingly Road, Cambridge, CB3 0ET, UK.

In 1993, the Commission passed a Resolution stating that ‘Range States should take action to meet the Scientific Committee's request for the collection and analysis of additional data on population distribution and abundance, stock identities, pollutant levels and bycatch mortality levels of harbour porpoises in the Northern Atlantic and Baltic. To determine what additional data needs to be collected and analysed, it is necessary to first identify what research activities are currently underway. The following countries were contacted and asked to provide a summary of research projects pertaining to harbour porpoises that are currently being conducted in their country: Canada, Denmark, Greenland, Iceland, Ireland, Netherlands, Norway, Sweden, United Kingdom and United States. Research activities were divided into six major categories. For each project, the following information was requested: descriptive title, status, principal investigators, collaborators, sources of materials, methods, recent publications or manuscripts in preparation and which category the research pertains to. Research activities are summarised. Currently, research projects are investigating activities from all categories. Some of the specific research activities from the various countries are highlighted. For each country, project titles and their principal investigators are listed. This compilation of research activities is not complete. It is hoped that during the

**SC/46/SM18. SUMMARY OF A SCIENTIFIC WORKSHOP TO EVALUATE THE STATUS OF HARBOR PORPOISES (PHOECOENA PHOECOENA) IN THE WESTERN NORTH ATLANTIC AND AN INTERNATIONAL PROPOSAL TO INVESTIGATE POPULATION STRUCTURE.**

Debra Palka, NMFS/Northeast Fisheries Science Center, Woods Hole, MA, USA.

The findings from a workshop which assessed the status of harbour porpoises (Phocoena phocoena) from the western North Atlantic (from the US to Newfoundland) are reported. Information on population structure, estimates of abundance, bycatch and population growth rate were reviewed. Because of uncertainties in all of these factors, it was not possible to assess the status of harbour porpoises in the western North Atlantic. The workshop participants recommended that to complete an accurate assessment of status the following was needed: (1) genetic population structure and seasonal movements, (2) estimates of summer abundance in the Gulf of St. Lawrence and around Newfoundland, and (3) estimates of bycatch from the US mid-Atlantic region. Bay of Fundy and around Newfoundland. In addition, research was needed from the Gulf of Maine as were re-calculated estimates from the Gulf of Maine which account for recently discovered biases. To determine the degree of discreteness of animals in the North Atlantic, a multidi-ciplinary approach was proposed to include mtDNA sequencing, microsatellite DNA methods, tooth ultrastructure characteristics, life history parameters and individual movement studies.

**SC/46/SM19. LIFE HISTORY OF THE VAQUITA, PHOECOENA SINUS.**

A recent sample of vaquita, Phocoena sinus, killed in fishing nets provided an opportunity to evaluate the life history of this poorly known species. The age structure was bimodal, with 62% of the specimens from 0–2 years and 31% of the specimens from 11–16 years; no specimens occurred from age 3–6. The oldest individual was estimated to be 21 years. All specimens less than three years old were sexually immature and all greater than six years old were mature. The asymptotic length of females (140.2cm) was greater than that of males (134.6cm), although no difference was seen in asymptotic girth or mass. Near-term fetuses and young calves were seen only between late February and early April with maximum testes activity occurring from mid-March until at least mid-April. The ovaries contained unusual calcified corpora and preliminary counts of the number of corpora relative to estimated reproductive age suggest that the calving interval may not be annual. Sample sizes were too small for many quantitative analyses, although it appears that lifespan, patterns of growth, sexual dimorphism in asymptotic length, seasonal reproduction and large testes size are very similar to its congener, the harbour

NOT TO BE CITED WITHOUT AUTHOR'S PERMISSION.
porpoise, *P. phocoena*, in a highly exploited and well-studied population from the Bay of Fundy. Although the bounds for age at maturation in vaquita (3–6 years of age) are large, they do include the age at maturation of harbour porpoise. One possible significant difference is that the rate of increase in vaquita is likely to be lower than that in the Bay of Fundy harbour porpoise population.

SC/46/SM20. HARBOUR PORPOISE ACOUSTIC SURVEYING METHODS: DEVELOPMENT OF EQUIPMENT FOR AUTOMATED RECOGNITION AND COMPUTERISED LOGGING OF VOCALISATIONS. Jonathan Gordon, Wildlife Conservation Research Unit, Department of Zoology, South Parks Road, Oxford. OX1 3PS and Oliver Chappell, Chappell Hydrophones, c/o International Fund for Animal Welfare, Tubwell House, New Road, Crowborough, Sussex. TN6 2QH.

Over the last three years the International Fund for Animal Welfare has been developing equipment and techniques for assessing harbour porpoise populations acoustically. Acoustic techniques for census cetaceans often offer advantages over visual methods, for example: (1) the acoustic range of vocalisations is typically more predictable than visual range; (2) acoustic range is less affected by meteorological conditions than visual range; (3) often (particularly when small research vessels are used) acoustic range is superior to visual range; (4) acoustic surveys are less onerous than visual surveys so smaller survey teams can be used; (5) acoustic surveys can be conducted 24 hours a day; (6) there is a greater potential for automation of data collection and detection, further reducing the size of survey teams and reducing the scope for inter-observer biases; and (7) generally, acoustic surveys are well suited to completion from small platforms of opportunity. This can greatly reduce the cost of surveys. Harbour porpoises are shy undetected creatures that are extremely difficult to spot at sea. Visual surveys can only be attempted in the calmest conditions (which are rare in northern Europe) and rigorous surveys usually require expensive dedicated platforms and substantial teams of observers. Harbour porpoise vocalisations consist of ultrasonic pulses centred in a narrow band at around 130kHz. They can be readily detected in the field using a high frequency hydrophone and appropriate detection equipment. Field tests, carried out using towed high frequency hydrophones and amplitude modulation detection equipment during joint visual surveys in 1992 and 1993, showed that: (1) harbour porpoises can be detected acoustically at substantial ranges (possibly as great as 800m); (2) they can be more reliably heard than seen; and (3) they were never seen and not heard. Further, the acoustic detectability of harbour porpoises seems to be unaffected by sea state. Encouraged by these results it was decided to develop equipment to automatically discriminate harbour porpoise clicks and to log their occurrence to a portable computer. Such equipment makes acoustic surveys even easier to perform and eliminates errors due to inter-individual variation in workers’ abilities to distinguish harbour porpoise vocalisations. The first version of this computerised equipment has just been tested in the field and has performed very well. Construction of a series of Mark I production models is now underway.

Methods for estimating relative abundance of seven dolphin stocks in the eastern Pacific Ocean, using sightings data collected on commercial tuna vessels by observers, have been developed in previous years, as has a method for estimating the underlying trends in abundance and assessing their significance, using a smoothing procedure and bootstrap resampling. This paper analyses the 1993 tuna vessel data and estimated trends in relative abundance are updated. The results indicate that for most dolphin stocks, there is no evidence of trends in population size in recent years.

SC/46/SM22. HARBOUR PORPOISE IN THE NORTH ATLANTIC AND BALTIc SEA.

At the 45th Annual Meeting of the International Whaling Commission held in Kyoto, Japan, 10–14 May 1993, a Resolution was adopted on harbour porpoise in the North Atlantic and Baltic Sea. This calls on range states to report to the Small Cetaceans sub-committee of the IWC Scientific Committee on their progress in implementing the recommendations. The only report received was submitted by Germany.

Management

SC/46/Mg1. A SURPRISINGLY SHORT NOTE ON THE REVISED MANAGEMENT SCHEME (RMS) AND ‘MONITORING’. D.S. Butterworth, Department of Applied Mathematics, University of Cape Town, Rondebosch 7700, South Africa.

It is argued that apparent differences of opinion expressed in Annex O of the Report of the 1993 Annual Meeting of the Scientific Committee concerning monitoring and the RMS do not really indicate divergent views. Rather, they reflect terminological confusion and an (understandable) lack of full appreciation of what constitutes an 'Implementation Review', in particular the process of ‘conditioning’ the simulation trials which will usually form part of this process. This ‘conditioning’ incorporates the ‘traditional stock assessment process’ referred to in Annex O and so addresses the concern expressed in one of the Annex O viewpoints that the RMS lacks such a process. It is suggested that the apparent differences can be resolved in a simple manner, by the clarifying addition to the Annotations to the RMP Specification Document which pertain to Implementation Reviews, worded as follows: ‘Implementation (Review) trials must cover the range of plausible hypotheses for the species and Region under consideration. As such, they must be consistent with the available data for that species and Region, which is to be achieved by ‘conditioning’ the trials on those data. In essence, such ‘conditioning’ is the process usually referred to in fisheries as ‘stock assessment’, but with there being particular emphasis in this context on the range of uncertainties associated with the results of this process. This ‘conditioning’ must take account of all available biological and operational data, which are thus not necessarily restricted to past catches and estimates of absolute abundance alone.”

SC/46/Mg2. DEPENSATORY NET RECRUITMENT FUNCTIONS. Sidney Holt, Podere Il Falco, 06062 Città della Pieve (PG), Italy.

A family of population growth functions, due to S. Kapiza, and a simple but more restricted variant of that, are suggested for use in simulations for the conduct of trials according to recommendations from the ad hoc Review Group for the RMP established by the US authorities.

NOT TO BE CITED WITHOUT AUTHOR’S PERMISSION.
SC/46/Mg3. COMMENTS ON THE NMFS REVIEW OF THE REVISED MANAGEMENT PROCEDURE. D.S. Butterworth, Department of Applied Mathematics, University of Cape Town, 7700 Rondebosch, South Africa.

The report of the review panel is analysed critically under a number of headings: its underlying basis; the trials which the panel conducted and their interpretation of the results thereof; nomenclature; an alleged lack of ‘learning’ by the Revised Management Procedure’s (RMP’s) Catch Limit Algorithm (CLA); its recommendations for further trials of the RMP; its comments relating to abundance estimates from surveys and questions related to stock identity; and finally a few miscellaneous points. It is argued that the panel seems to have been under the misapprehension that the RMP was designed to meet ‘test standards’ in trials and in particular, to meet a specific standard under the Commission’s objective related to risk of extinction. To the contrary, the RMP was selected on the basis of trade-offs in performance related to the Commission’s three (mutually incompatible) objectives for the RMP. Such ‘test standards’ might in any case need to vary depending on the trial – for example, the panel appears not to have taken into account that an acceptable level of depletion depends upon the actual MSY level. No procedure can be robust to every possible circumstance and there would not seem to be any need to require robustness in circumstances more extreme than apply in reality (e.g. 90% of historic catches not having been reported, as in one of the trials conducted by the panel). Even if ‘test standards’ had existed, there would appear little point in determining (as the panel suggests) the level of some factor (e.g. extent of positive bias in a survey) at which standards were no longer met, if that level was clearly outside the plausible range. The panel seems to have misunderstood the nature of an Implementation (Review), though this is probably the fault of the Scientific Committee for failing to clarify this adequately in the RMP Specification Document. In criticising the RMP’s lack of ‘learning’, the panel appears again to have failed to take account of the inevitable trade-offs involved – in this instance, better ‘learning’ would necessitate diminished performance on the Commission’s risk of extinction and industrial stability criteria. The panel’s concern about the possibility of positive bias in abundance surveys is justified, but needs to be seen in the context of the pains generally taken by the Scientific Committee to avoid this possibility in the abundance estimates which it adopts. While the panel’s suggestions for additions to activities undertaken on such surveys merit consideration, they would require time and manpower to implement, and care needs to be taken that this possible implementation not jeopardise the primary objective of a survey cruise which relates to intensity of coverage. An important conclusion reached is that the panel’s specific recommendations for additional trials of the RMP (in respect of dispensatory effects, stochastic variation in population parameters, multispecies effects and combination trials) all relate to matters already addressed by the Scientific Committee. It is unclear whether the panel was unaware that this was the case, or was aware of this but had reservations about what had been done. If the panel did indeed have such reservations, unfortunately their failure to detail these in their report leaves the Scientific Committee with no proper basis for further deliberation thereof.

SC/46/Mg4. RMP MISCELLANY. D.S. Butterworth, Department of Applied Mathematics, University of Cape Town, Rondebosch 7700, South Africa and A.E. Punt, School of Fisheries WH-10, University of Washington, Seattle, WA 98195, USA.

A number of issues related to the Revised Management Procedure (RMP) are discussed and associated proposals made. A method of subjecting block quota proposals for Southern Hemisphere minke whales to simulation testing is put forward. This includes detailed suggestions of how to model the annual breakdown of catches by Small Area in such circumstances. Modifications to the Implementation Trials for that resource, which would allow the testing of an increase of the Small Area size from 10° to 15° of longitude, are proposed. These specifically make allowance for the possibility that whaling could concentrate on the boundaries of such larger Small Areas – a phenomenon which was found to cause major problems for management based on the traditional 6° longitude management Areas. Problems with the current definition of the continuing catch statistic as a measure of long-term yield are raised; these are related to transients in this measure still present at the end of 100 year (and longer) management periods. An attempted modification to this statistic, which tries to adjust explicitly for this shortcoming, proves unsuccessful. It is suggested that the continuing catch statistic be replaced by total catch over years 151–300 of the management period – this would provide a direct measure of the quantity of interest (long term catch), while also eliminating transient effects during the initial period of management. The integration over the prior for the productivity parameter m in the Catch Limit Algorithm (CLA) also needs to be conducted by a more accurate numerical procedure than that used at present for trial computation purposes. For simulations of management periods exceeding 100 years (or more frequent or precise surveys than such trials usually assume), Butterworth and Best (RIWC-40: 301–15) put forward a method for inferring a lower bound on MSY rate based on observations of growth rates at low population levels. Counts to the basis for their argument imply that MSY is less than 0.5K, and would hence necessitate a revision of values for quantities such as the 0.54 ‘protection level’. The present trials approach of considering the combination of MSY > 0.5K and MSYFPmax = 1% in relation to a ‘protection level’ of 54%, for risk assessment is inconsistent with available data. In the context of Implementation Trials, attention needs to be given both to what constitutes a sufficient basis to assume the presence of sub-stocks, and to what would constitute sufficient observational evidence to negate (components of) such an hypothesis. A simple scheme is proposed for weighting the results of combinations of Implementation Trials for a more reasonable basis for risk assessment. This is considered preferable to taking account only of the trial which leads to the worst performance in stock-related statistics in that regard. The scheme involves giving equal weight to trials with MSYFPmax = 1% when computing risk-related statistics. Inconsistencies in the specification of 54% ‘protection level’ and the Commission’s objective of ensuring the highest possible continuing yield under the RMP are pointed out. The Scientific Committee needs to present the Commission with suggestions on a range of scientifically self-consistent options for a standard trial in this regard. Both the point and that in relation to sub-stock structure, have pertinence to catch limit recommendations to be made in regard to the Bering-Chukchi-Beaufort Seas bowhead stock, following the assessment of this resource to be conducted at this meeting. Aspects of results of the Southern Hemisphere minke whale Implementation Trials presented at the 1993 meeting are examined. The somewhat poor performance in terms of standard deviation relative to normal use principles on the ANT-1 trial under half-Area cascading, is found to be a result in part (but not completely) of the enforced neglect of historic catches off Brazil under the RMP because these fall beyond the northern boundaries of the Small Areas as presently specified – the associated specifications merit reconsideration and suggestions are made in that regard. The basis under which partial cascading (in some, but not all, half-Areas) might be considered in the future in Implementation Trials requires clarification. On the possible objections that the existing Implementation Trials are too ‘easy’ in this context, because of the exact match between stock and half-Area boundaries, revised trial specifications which preclude this are put forward.

SC/46/Mg5. THE ROLE OF INDEPENDENT MONITORING OF LIVING MARINE RESOURCES AND THE RMP. Steven L. Swartz, US National Marine Fisheries Service, Silver Spring, Maryland, USA.

Holt and Talbot (1978, Wildlife Monographs No. 59) conclude in their monograph on ‘New Principles for the Conservation of Wild Living resources’ that the ‘privilege’ of utilising a living resource carries with it the obligation to monitor and assess its use. One of these principles states that ‘surveys or monitoring, analyses and assessment should precede planned use and accompany

NOT TO BE CITED WITHOUT AUTHOR'S PERMISSION.
actual use of wild living resources’ and that ‘the results should be made available promptly for critical public review’. They further note that ‘continual improvement in our understanding of processes in the ecosystems and of methods and predict the directions and rates of those processes’ is of equal importance to data collection. Their view exemplifies the importance of baseline information and of basic research on ecological processes for retrospective analyses of the effects of resource utilisation, and the fundamental importance of these for sustained use of renewable resources. It is questionable whether the information required by the Revised Management Procedure (RMP) be (i.e. catch and abundance information) is or would be adequate to undertake retrospective analyses of the dynamics of whale populations harvested under its regime, or be sufficient to further our basic understanding of whale population dynamics. It is argued that evaluation of the success or failure of the RMP requires ancillary information on key population and environmental parameters in addition to that information required by the RMP itself.

SC/46/Mtg6. TOWARDS UNDERSTANDING THE PERFORMANCE OF THE CATCH LIMIT ALGORITHM. Barbara L. Taylor, NMFS/Southwest Fisheries Science Center, La Jolla, CA 92038, USA. Tim Smith and Debra Pulka, NMFS/ Northeast Fisheries Science Center, Woods Hole, MA 02543, USA.

The Scientific Committee (SC) has adopted a Catch Limit Algorithm (CLA) created by Justin Cooke as the central piece of the Revised Management Procedure (RMP). An elaborate series of simulation trials designed to represent a generic population of baleen whales were used to choose Cooke’s procedure out of five candidate procedure. The trials were termed ‘base case’ and ‘robustness tested’ and populations considered were to be at different initial abundance levels and having different rates of productivity. The latter considered various errors in the specification of dynamics of populations and in data used in calculation of catch limits. The results of the comparison of candidate procedures from both of these sets of trials have been summarised and published. The SC is now in the process of applying the RMP to specific species for possible commercial harvest. Specific or stocks are considered in detail in an initial ‘Implementation’ and in subsequent ‘Implementation Reviews’. As stated in the RMP, implementation for specific applications must consider stock identity and movements to delineate Management Areas which the CLA will be applied to and to determine if Catch-cascading and/or Catch-capping is appropriate. All available information is used in implementation simulation trials to determine the effect of the chosen Management Areas on the productivity of depleting stocks in the Management Region. The inclusion of spatial complexity of multi-stock populations into Implementation Trials is a daunting task and has preoccupied Implementation Trials done to date. However, implementation ‘simulation trials should encompass, as far as possible, the full range of plausible hypotheses consistent with the biological data available for that species and region’. Thus, the focus on Management Areas should not be to the exclusion of considerations of combinations of errors in abundance estimation, historical catch, etc., that may be of concern for the population of interest. A US panel of scientists who were not associated with the procedure’s development expressed this concern by stating: ‘In order to gain insight into the algorithm’s performance [trials] should probe the limits under which the CLA’s performance successfully meets the test standards, not only under the extreme cases for a single trial but also for combinations.’ To determine what should be included in Implementation Simulation Trials, it is essential to understand the behaviour of the CLA with respect to various errors which may be likely in a specific case. Scientists responsible for the creation and testing of the CLA were familiar with the mathematics behind the models and the consequential behaviour of the models. Scientists responsible for implementation of the RMP are more diverse and cannot be expected to be familiar with the mathematical basis of the CLA itself. The goals of this paper are: (1) to propose ways in which the performance of the CLA should be communicated to ensure that scientists who are contributing their knowledge to the design of Implementation Trials fully understand where difficulties with performance are most likely to be encountered and (2) to raise the issue that criteria for what constitutes acceptable performance of robustness trials have not yet been documented, but should be.

SC/46/Mtg7. EXPLORATIONS OF THE BEHAVIOUR OF COOKE'S CATCH LIMIT ALGORITHM. Tim D. Smith and Debra Pulka, Northeast Fisheries Science Center, Woods Hole, MA, USA and Nancy Friday, University of Rhode Island, Narragansett, RI, USA.

The behaviour of the Catch Limit Algorithm (CLA) was explored by using it to determine catches in a simple population model. The population model was constructed to explore the behaviour of the CLA in populations with dynamics different from those assumed in the development and testing of the CLA, especially the possibility of bounded but not deterministic behaviour. It includes density dependent survival and reproductive rates, including depensatory effects, that are subject to variable levels of random variability. The behaviour of the population model itself was explored by simulating population size over time for different combinations of parameter values. The behaviour of the CLA was examined by examining the behaviour of the population model subject to removals as determined by the application of the CLA for ranges of parameter values determining the dynamics of the population model, levels of stochastic variability and varying inputs to the CLA itself, especially the variability of the population abundance estimates and the population size when harvesting is begun. The results illustrate the behaviour of the CLA under a wider variety of conditions than tested by the Scientific Committee. The behaviour does not depend critically on the choice of population dynamics model parameters and stochastic variability under moderate levels of variability. However, for very high levels of precision in abundance estimates the behaviour of the population dynamics model under harvesting can become undesirable in two ways. One occurs regardless of the level of stochastic variability in population productivity and is a failure of a population to increase when the initial population size is set low and there is no catch history. This could occur if the population had high stochastic variability or if there were complete non-reporting of catches. The second occurs when there is stochastic variability and a tendency to have high catch variability. Neither of these situations are plausible, but it is important to better understand the causes of such behaviour to ensure that such situations are avoided in actual practice.

SC/46/Mtg8. INFORMATION REQUIREMENTS FOR MULTI-POPULATION APPLICATION OF THE CATCH LIMIT ALGORITHM. Tim D. Smith, Northeast Fisheries Science Center, Woods Hole, MA 02543, USA and Tom Polacheck, CSIRO, Tasmania, Australia.

Based on the RMP Implementations completed and under development, a gap in the information required to ensure that Management Areas defined and tested in the Implementation Simulation Trials in fact do meet the requirements of the RMP is identified. This gap is that no information is actually required to be collected, analysed and presented to the SC which would allow the determination of the adequacy of any adopted set of Management Areas during subsequent Implementation Reviews. Types of data which have proved interpretable are identified and the possibility of determining minimum standards for their collection and analysis are described. Because the multi-population implementation of the CLA is central to its application and because of the inadequacy of the CLA in the absence of the required management area definitions, it is argued that the collection, analysis and presentation of suitable data from the candidate and potentially from other populations should be required under the RMP in the same sense that abundance data are required.
SC/46/Mg9. ADDITIONAL DATA REQUIREMENTS FOR THE REVISED MANAGEMENT SCHEME. Tim Smith, Northeast Fisheries Science Center, Woods Hole, MA, USA. Tom Polacheck, CSIRO, Hobart, Tasmania, Australia and Steve Swartz, National Marine Fisheries Service, Silver Spring, MD, USA.

The adequacy of the Revised Management Procedure (RMP) recommended by the Scientific Committee in 1993 as a basis for scientific management of whaling is reviewed. The management objectives and principles developed during the ongoing dialogue within the International Whaling Commission are reviewed and it is argued that RMP does not make adequate provision for ensuring the adequacy of the principles of management previously adopted. A context for determining what additional data collection and analysis would allow these principles to be better met is suggested. Extensions to the Revised Management Scheme of the Commission are suggested which would require adequate data collection, analysis and availability of results to ensure that whaling might more likely to be conducted on a sustainable basis. Further, the need for a formal process outside the RMP itself for periodically evaluating its performance as a scientific hypothesis is identified.

SC/46/Mg10. A SIMULATION TRIAL FOR THE BERING-CHUKCHI-BEAUFORT SEAS STOCK OF BOWHEAD WHALES. Eiji Tanaka, Tokyo University of Fisheries, Konan 4-5-7, Minato-ku, Tokyo 108, Japan.

The Catch Limit Algorithm (CLA) was applied to the data of the Bering-Chukchi-Beaufort Seas stock of bowhead whales. The used data were the catch history and the Scientific Committee’s best estimate of stock abundance (7,500 whales, CV = 0.09) in 1988. The application of the CLA made zero catch limit in 1991. The values of the %-ile of the marginal posterior distribution and its 95% confidence interval were 0.51 and 0.56, respectively. The results of the D1 trials indicate that the tuning level corresponding to the 72%-ile was 0.41K.

SC/46/Mg11. TESTS OF THE SENSITIVITY OF THE RESULTS OF THE NORTH PACIFIC MINKE RMP TRIALS TO ASSUMPTIONS FOR VALUES IN THE MIXING MATRIX FOR THE HYPOTHESISED W STOCK. A.E. Pett, School of Fisheries, WH-10, University of Washington, Seattle, WA 98195, USA and D.S. Butterworth, Department of Applied Mathematics, University of Cape Town, Rondebosch 7700, South Africa.

The North Pacific minke RMP trials incorporate only a limited evaluation of sensitivity to the mixing matrix assumed for the hypothesised W stock, with just two possibilities for this matrix being considered. This sensitivity is examined further by considering more extreme mixing matrices for the W stock than those assumed for the existing RMP trials, by examining trials without as well as with sub-stock structure in this particular context and by investigating the interaction between the mixing matrices assumed for the O stock and those assumed for the W stock. A total of 28 trials is considered, all for the case where catch limits are set by Small Area (assumed identical to subareas) and all with MSYR = 1% for every stock/sub-stock as such trials usually prove to be the most taxing from a resource conservation perspective. Three further matrices are added to the existing two mixing matrices for the W stock; one increases the extent of mixing previously considered and two reduce this. The results show a generally consistent pattern. If there is little mixing between the O and the hypothesised W stocks (i.e. W stock animals hardly move into regions relatively close to Japan), application of the RMP does not lead to any concerns about the O stock from a conservation standpoint. However, this conclusion weakens the greater the extent of mixing. At present there are no data upon which to condition the values in the W stock mixing matrix (in contrast to the situation for the J and O stocks). Collection of data to shed more light on the extent of the mixing between the O and the hypothesised W stock is therefore a high priority. If the results of the North Pacific minke trials are to provide a more clear-cut basis for the provision of advice in regard to the selection between various RMP variants for implementation for this resource.

SC/46/Mg12. SIMULATION TRIALS OF THE RMP CATCH LIMIT ALGORITHM IN THE PRESENCE OF ADVERSE EXTERNAL INFLUENCES ON WHALE POPULATIONS. Joop Cooke, Centre for Ecosystem Management Studies, Moes 1, 79297 Wisden, Germany.

The Catch Limit Algorithm (CLA) of the Revised Management Procedure (RMP) is subject to Simulation Trials in which the exploited whale population is subject to adverse external influences not accounted for in the RMP (such as effects of environmental degradation, etc.). The full range of severity of external effects is tested from nil to catastrophic. The performance of the CLA in terms of depletion of the stock relative to the unexploited population is influenced by the presence of adverse external effects, but the impacts are moderate in extent, ranging from 4% to 21%. The greatest effect is found when the survey interval is 10 years instead of the standard 5 years.

This note outlines the proposed structure and method of implementation of the IWC database for abundance estimated by Small Area and describe the data sets that will initially comprise the database.

SC/46/Mg14. RESULTS OF NORTH PACIFIC MINKE TRIALS. This paper presents results of the North Pacific trials specified in IWC/45/4, Annex G, Appendix 3. The trials are summarised in section I and the output statistics in section II. Some extra details of the conditioning process are given in section III.

Other

SC/46/0 1. NEW CRITERIA TO AMEND THE CITES APPENDICES. CITES Secretariat.

The CITES Secretariat has circulated for comments (including from the IWC) the draft criteria for amendment of Appendices I and II of the Convention on International Trade in Endangered Species of Wild Fauna and Flora. The Secretary circulated this request together with the most relevant parts of the proposed amendments to the criteria, prepared by IUCN to the members of the IWC. Comments have been received from South Africa, UK, Norway, Mexico and Spain. From these it can be seen that both South Africa and the UK suggest referring the matter to the next Annual Meeting, while Norway, Mexico and Spain have identified some specific points needing clarification and resolution in the proposed criteria.

NOT TO BE CITED WITHOUT AUTHOR'S PERMISSION.
SC/46/O 2. PREDICTIONS OF ANTARCTIC CLIMATIC AND ECOLOGICAL RESPONSE TO INCREASING CO₂ AND DECREASING OZONE. Cynthia T. Tuyan, Research Associate of the National Research Council, Alaska Fisheries Science Center, 7600 Sand Point Way, NE, Seattle, WA 98115, USA and Douglas P. DeMaster, National Marine Mammal Laboratory, 7600 Sand Point Way, NE, Seattle, WA 98115, USA.

The temporal and spatial response of the Southern Ocean ecosystem to climate change is uncertain. Concerns over CO₂-induced global warming and chlorine-catalysed ozone depletion over Antarctica have generated the development of sophisticated global circulation models (GCMs) and networks to monitor levels of ultraviolet radiation. Despite these efforts, predictions are still preliminary and resource management programs need to incorporate large uncertainty in estimates of environmental response. To assist this process, the following sections review model predictions for climate change in the Southern Ocean and effects of increased exposure of marine life to enhanced levels of ultraviolet-B radiation (UV-B).

SC/46/O 5. STRANDINGS AND FISHING GEAR ENTANGLEMENTS OF CETACEANS ON THE WEST COAST OF CANADA. In 1993, Robin W. Baird, Stephen G. Wischowalski, Tunan J. Guenette, Malcolm L. McAdie and Tracy E. Cornish, Marine Mammal Research Group, Box 6244, Victoria, BC, Canada. V8P 5L5. [Robin W. Baird also at Department of Biological Sciences, Simon Fraser University, Burnaby, BC, Canada, V5A 1S6.]

Fifty-seven records of eight species of cetaceans that stranded or collided with fishing gear in British Columbia (BC), Canada, in 1993 are presented. Although the number of incidents is greater than in any previous year, these records represent only a small proportion of the cetaceans stranded or caught in fishing gear in the region. A large number of these records (24) were associated with an unusual mortality event of porpoises (both Dall's, Phocoenoides dalli, and harbour, Phocaena phocaena) around southern Vancouver Island, despite detailed necropsies on 17 of these animals and extensive laboratory analyses, no underlying cause for this event was found. A record of a live stranded common dolphin (Delphinus delphis) is only the second occurrence of this species in the province and possibly the northern-most record in the eastern North Pacific. Three animals were recorded colliding with commercial salmon (Oncorhynchus spp.) drift gillnets. Two harbour porpoise were killed and a grey whale (Eschrichtius robustus) collided with a net but was unharmed. Other species recorded as stranded during 1993 include killer whale (Orcinus Orca), sperm whale (Physeter macrocephalus), Cuvier's beaked whale (Ziphius cavirostris) and minke whale (Balaenoptera acutorostrata).

This paper discusses briefly the potential effects of climate change on Antarctic marine ecosystems. Examples are given on complex relationships among ice, plankton and cetaceans. The author further emphasised the need to incorporate discussions on current theoretical ecology (global change, ecosystems, long-term ecology) as a framework for a workshop on cetaceans and global change.

Levels of contaminants in cetaceans have been reported for decades throughout the global marine ecosystem. Biomagnification of trace elements and persistent chlorobiphenyls as well as transfer of both groups of compounds to their offspring, have given rise to concern about long term, global impact of contaminants in marine mammals. In some case studies, immunological and reproductive disorders in marine mammals can be linked to tissue residues of environmental pollutants in grey and ringed seals in the Baltic, Californian sea lions, harbour seals in the Wadden Sea, Atlantic bottlenose dolphins in the US, striped dolphins in the Mediterranean and in belugas in the St. Lawrence River. However, in most cases the underlying mechanisms remain unclear, making it difficult to extrapolate observed effects to other species. With regard to reasons for concern about contaminants and the different cetacean species, it is necessary to assess first what the chances are in the different species and what their respective responses are in the process between uptake and elimination. This paper elaborates on these aspects, evaluates the present knowledge and discusses future risk assessment.

SC/46/O 11. PINNIPED AND CETACEAN MORTALITY IN CALIFORNIA GILLNET FISHERIES: PRELIMINARY ESTIMATES FOR 1993. Fred Julian, Southwest Fisheries Science Center, National Marine Fisheries Service, NOAA, PO Box 271, La Jolla, CA 92038, USA.

The number of marine mammals killed in two California gillnet fisheries, the halibut setnet fishery and the swordfish/shark gillnet fishery, is estimated for the calendar year 1993 based on observations made by biological technicians placed aboard commercial fishing vessels. The number of fishing days per California Department of Fish and Game (CDFG) block is currently the only available measure of effort for the set and driftnet fisheries; therefore, these effort-days are used to extrapolate from observed mortality to total estimate mortality using mean-per-unit and ratio estimators. Overall observer coverage rates for the setnet and driftnet fisheries were 15% and 13.5%, respectively; however, in some areas the set and driftnet fisheries had coverage rates of less than 5%. For the calendar year 1993, the estimated mortalities of marine mammals with the CV and the number observed entangled (in parentheses) for the setnet fishery are: 12 (0.64, 2) harbor porpoise, 43 (0.70, 7) unidentifiable pinnipeds, 1,984 (0.12, 239) California sea lions, 480 (0.12, 71) harbor seals and 71 (0.27, 11) northern elephant seals. The estimated mortalities for the driftnet fisheries were 153 (0.53, 3) Guerin's beaked whales, 170 (0.32, 23) common dolphins of unknown stock, 37 (0.55, 5) short-beaked common dolphins, 52 (0.39, 7) northern right whale dolphins, 15 (0.66, 2) Pacific white-sided dolphins, 30 (0.73, 4) Risso's dolphins, 67 (0.44, 9) Dall's porpoise, 81 (0.43, 11) short-finned pilot whales, 22 (0.69, 3) sperm whales, 7 (0.93, 1) pygmy sperm whales, 7 (0.93, 1) unknown whales, 89 (0.39, 12) California sea lions and 103 (0.26, 14) northern elephant seals. These estimates and their standard errors are based on the assumption that the fishing effort is known without error. Errors and biases in determining total fishing effort are examined and a second set of estimates incorporating these errors is presented.

The occurrence and distribution of planar chlorinated hydrocarbons (PCHs) such as polychlorinated biphenyls (PCBs), polychlorinated dibenzo-p-dioxins and polychlorinated dibenzofurans (PCDDFs), have been extensively investigated in the Northern Hemisphere. However, limited information is available on the concentrations of PCHs in the less industrialised Southern Hemisphere.
SC/46/O 13. CONFERENCE ON MARINE MAMMAL GENETICS, WITH WORKSHOP ON THE ANALYSIS OF GENETIC DATA TO ADDRESS PROBLEMS OF STOCK IDENTITY AS RELATED TO MANAGEMENT. William F. Perrin and Andrew E. Dixon, Southwest Fisheries Center, PO Box 271, La Jolla, CA 92038-0271, USA.

Abundance estimates and status of cetacean stock assessments require knowledge of intraspecific population structure. The Southwest Fisheries Science Center (SWFSC) has developed a laboratory that uses molecular tools to determine genetic diversity at various levels of genetic resolution. These tools include, among others, enzymatic amplification of DNA (PCR), RAPD, cycle sequencing and fragment and sequence analysis. With these tools, we are using information from both nuclear (RAPD and microsatellite analyses) and mitochondrial DNA (mtDNA) to gain an understanding of the stock structure of marine mammals taken in various types of fisheries. Although we have benefited substantially from the incredibly rapid progress in the molecular arena, development of quantitative means for using the information gained in the laboratory to define biologically meaningful stock units has not been fully realized. Methodologies using molecular data to estimate molecular phylogenies, gene flow and dispersal distance, etc. are certainly available, but there has been a growing realization that this area is much more complex and pitfalls-ridden than had previously been thought, especially when the methods are applied to incompletely defined populations. The continuing rapid advances in molecular methods, the reality of laboratory automation and the ability to measure genetic diversity directly from pooled samples will provide data of heretofore unavailable breadth and scope. A concentrated research effort focussing directly on how to use these data to define stock units is required.

SC/46/O 14. THE SIGNIFICANCE OF POLLUTION FOR MARINE CETACEANS. Anna Mascalop and Mark P. Simmonds, The Conservation Research Group, The University of Greenwich, Rachel Macmillan Campus, Creek Road, London, SE8 3BU.

This paper reviews the interactions between cetaceans and various types of marine pollution: bioaccumulating substances (i.e. organochlorines and heavy metals), oil, polynuclear aromatic hydrocarbons, persistent synthetic marine debris and sewage effluent. These interactions have been little studied, but relevant information continues to accrue. Moreover, the available information can be augmented by information from other species (including our own). Expert opinion has been incorporated into the evaluation and a broad picture of significant threats from pollution to marine cetaceans is developed. The precise nature of these threats cannot be defined but the magnitude of at least some (e.g. those caused by certain organic chlorinated compounds and marine debris) is increasing. Although the threat is impossible to quantify there are already strong indications of significant impacts.

SC/46/O 15. A FRAMEWORK FOR THE COMPREHENSIVE ASSESSMENT OF THREATS TO CETACEANS: AN ILLUSTRATED HOLISTIC APPROACH. Kevin Brown, Centre for Overseas Research and Development, Department of Geography, University of Durham, South Road, Durham, DH1 3LE, UK.

In the recognition by the IWC for the need to review environmental threats in the Comprehensive Assessment of all whale stocks and in recognition of the current absence of an holistic approach to cetacean management, a framework for the identification, quantification and evaluation of threats to cetaceans is presented. The framework is based on the assumption that all known threats to cetaceans must be considered collectively, defined as the absolute threat, because of the existence of synergistic interactions between individual threats. The framework also puts into context the relationship between environmental threats to cetaceans and the threat through deliberate killing. There is a need to constantly update the baseline data on all threats to cetaceans in order to respond to changes in the impact of existing threats and the incidence of new threats in the future. In this way, policy decisions can then be based on relevant data and on sound management practices.

SC/46/O 16. REQUIREMENTS FOR A COMPREHENSIVE ASSESSMENT OF POLLUTION IN CETACEANS: QUANTIFICATION, EVALUATION AND ABSOLUTE THREAT OF POLLUTANTS. Kevin Brown, Centre for Overseas Research and Development, Department of Geography, University of Durham, South Road, Durham, DH1 3LE, UK.

The requirements for carrying out an accountable and representative comprehensive assessment of pollution in cetaceans are extensive because of the complexities involved in quantifying pollutants both in the marine environment and in marine biota and, more specifically, the problems involved in evaluating the effects of pollutants and their synergistic interactions in cetaceans. The collective threat of pollutants to cetaceans, the absolute threat, is largely unknown, due to the absence of relevant baseline data and limitations in the research methodology. To redress the absolute pollutant threat to cetaceans the most up-to-date information must be compiled, appropriately analysed and responsibly acted upon. Efforts should also be made to develop and implement international pollution monitoring programmes and to improve existing methods and analytical techniques. In view of our current lack of understanding of pollution in cetaceans, it is recommended that the IWC, in taking a precautionary approach to cetacean management, carries out a comprehensive assessment of pollution and other threats to cetaceans before making any decisions on the future of the moratorium on commercial whaling.

SC/46/O 17. INFORMATION NOTE ON THE STATUS OF ENVIRONMENTAL CHANGE STUDIES RELEVANT TO THE MARINE ENVIRONMENT SUPPORTED BY UNEP. Monica Borohia, United Nations Environment Programme, Oceans and Coastal Areas Programme Activity Centre, PO Box 30552, Nairobi, Kenya.

The Oceans and Coastal Areas Programme, co-ordinated by the Oceans and Coastal Areas Programme Activity Centre (OCA/PAC) of UNEP, is supported by the intensive cooperation of many international, regional intergovernmental organisations as well as national institutions. It consists of three closely linked components dealing with: (a) the Global Marine Environment; (b) the Regional Seas Programme; and (c) Living Marine Resources. Some of the global issues relevant to the marine environment, such as expected impacts of climate change also form an integral part of other programmes of UNEP contributing to the implementation of international agreements. In particular, these conventions form the basis on which the Ozone Layer and its Montreal Protocol, the Convention on Climate Change and the Regional Seas Conventions for the
Protection of the Marine Environment. This paper briefly outlines the nature of programmes directly supported by the Oceans and Coastal Areas Programme on climate change and describes the general state of knowledge of some aspects in this field based on UNEP’s overall programme. This overview was produced in response to the IWC efforts in addressing the effects of global environmental changes on marine ecosystems and whale stocks. There is a vast number of initiatives on marine pollution, which comprise a large component of the Regional Seas Programmes. These will need to be brought in detail to the attention of the IWC in the future. The information contained in this paper was compiled from available UNEP documentation or publications, co-sponsored by UNEP and some of the references work therin, which are based on scientific material and exposed to peer review.

SC/46/O 18. A CONCEPTUAL MODEL OF THE ANTARCTIC MARINE FOOD WEB BASED ON AN ECOSYSTEM APPROACH TO RESOURCE MANAGEMENT. Cathy M. Liscata and Eileen E. Hofmann, Center for Coastal Physical Oceanography, Old Dominion University, Norfolk, Virginia 23529, USA.

A distinctive feature of the Antarctic marine food web is the dependence upon a single species, Antarctic krill, Euphausia superba, as the primary food source for many components in the food web. This species is widely recognised as an important trophodynamic link in energy transfer from primary producers to larger carnivores, such as whales, seals, seabirds, penguins, squids and fishes. Variability in the biomass and production of krill greatly affects the structure and function of the Antarctic ecosystem. This takes on an added significance now that krill has become the object of an expanding fishery. The Antarctic Treaty nations formed an international organisation (Committee for the Conservation of Antarctic Marine Living Resources, CCAMLR) to manage the exploitation of all living marine resources of the Southern Ocean, including krill. CCAMLR recommended an ‘ecosystem approach’ to natural resource management instead of the more typical fisheries approach i.e. management of single species in isolation. The management goals of the ecosystem approach require that stable recruitment of harvested populations be maintained; irreversible changes in the marine ecosystem be avoided; and that ecological relationships be maintained among harvested, dependent and related populations. The objective of this paper is to provide a conceptual model of Antarctic krill that embodies an ecosystem approach. This conceptualisation is intended to provide a framework to organise future simulation modelling efforts. The conceptual model will be too complex to treat as a single simulation model and instead a set of coupled sub-models will be identified each of which examine specific processes. The sub-models will span a wide range of disciplines and this modular breakdown allows each sub-model to be investigated independently by various research groups. However, the framework of a complete conceptual model is necessary, so that sub-modelling efforts can be interpreted in the context of the entire system.

SC/46/O 19. INCIDENTIAL SIGHTINGS OF CETACEANS IN THE CHILEAN FJORDS DURING MARCH 1994. Robert L. Pitman and Lisa T. Ballance, Southwest Fisheries Science Center, 8604 La Jolla Shores Drive, La Jolla, CA 92037, USA.

We report incidental sightings of cetaceans made during a four day cruise aboard a ferry through the Chilean fjords from Puerto Montt to Puerto Natales, 9–12 March 1994. Observation conditions were excellent, with seas never greater than Beaufort three and mostly less than Beaufort two. We recorded 12 sightings of four species of cetaceans. Burmeister’s porpoises (Phocoena spinipinnis) were sighted four times, all on the same day, all off the northeast coast of Isla Chiloé. This is more than 2° south of the published southern limit for this species, although its distribution off the coast of southern Chile is poorly known. Peale’s dolphins (Lagenorhynchus australis) were sighted three times on two days; they occurred only in small schools (six or fewer animals) and was present only in the inland waterways. Dusky dolphins (L. obscurus) were sighted three times, all on the same day and occurred in schools of hundreds or thousands on the open ocean, offshore of the Tutuao Peninsula. The other cetacean was an unidentified roqual, probably a sei or Bryde’s whale (B. borealis or B. edent), offshore of Tutuao Peninsula. Chilean dolphins (Cephalorhynchus australis) were sighted three times, all on the same day and occurred only in the coastal waters. These data are presented to aid in the study of these species, their distribution and habitat use. The incidental observations recorded in this cruise can be used to help identify key areas for future study.

Data are presented on the biomagnification rates, accumulation and concentrations of heavy metals in cetacean species. Concentrations of metals occur predominantly in the soft tissues, although zinc and lead occur in high concentrations. The concentrations of the metals are dependent upon metal availability, the species’ dietary preference and inter-meral relationships. Differences in concentrations occur according to the sex and age of the animal with certain metals displaying age related trends. Mercury is the only metal which shows both high levels of biomagnification at all levels of the food chain and a positive correlation with age at all stages during the cetacean’s life. Differences in concentrations occur between baleen species and toothed cetaceans. Levels tend to be lower in baleen whales, primarily due to a shorter food chain (resulting in lower biomagnification factors) and principle prey species taken from lower parts of the food chain. A number of storage and detoxifying mechanisms have been recorded in many species that would alter the effects of high metal concentrations. Data on heavy metal toxicity in cetacean species are sparse but tolerance limits have been proposed for mercury and cadmium. These are compared with high concentrations recorded in certain species. Regional hot spots where background pollution levels are high are compared with the concentrations of mercury recorded in a range of cetacean species.

SC/46/O 21. MORTALITY OF CETACEANS IN DRIFTNETS IN THE MEDITERRANEAN CONTINUES. A. Aguilar and L. Silvani, Department of Animal Biology, University of Barcelona, Barcelona, Spain.

Last year, fishing interactions caused a significant toll on cetaceans in the Mediterranean. From May to August, 13 sperm whales (four of them newborns or young calves) and an undetermined number of dolphins washed ashore on the coast of northeastern Spain and the Balearic Islands. Most of these cetaceans showed indications of having died because of a fishing interaction and, indeed, six sperm whales were still wrapped in pieces of nets. Illegal Italian drift-nets operating in the area were blamed for the killing. The United Nations General Assembly Resolution 46/215 and the European Community Regulation 345/92, which prohibits electric vessels from using driftnets in excess of 2.5 kilometers of net per vessel, are systematically violated by the Italian swordfish drift-nets fleet operating in the Mediterranean. This fleet, consisting of 600 or 700 boats, continues fishing out of control all over the Mediterranean. It operates from April to September both in territorial and international waters using nets averaging 10–12 kilometers in length, although nets up to 20km are known to be used. Sicilian harbours gather up to 70% of the fleet; 13% are based in the Italian Ionian coast and another 13% along the south coast of Tyrrenhenian Sea. The local fishing areas include the Tyrrenhenian, Sardinian and Ionian Seas. They have been reported fishing in Greece, both in the Ionian Sea, from Creta up to Karpfagos Island, where approximately 70 boats were fishing last year, and in the Aegean Sea, around the islands of Zakynthos and Kefallonia, an area where dolphins are abundant and monk seals are not.
barely survive. Moreover last summer at least 20 Italian drift net vessels were sighted in the vicinity of the Balearic islands (Spain) in the western Mediterranean, although the total number of boats was probably larger. These boats set their nets in both Spanish territorial and international waters. Although the Italian fleet is by far the one causing the greatest concern, boats from other nations also use this fishing gear in the Mediterranean. In the Alboran Sea, about 30 Spanish boats based in the harbours of Algeciras and Tarifa also use drift nets measuring up to 5km long to catch swordfish close to shore from July to September. This fleet is illegal, because the Spanish law bans the use of swordfish drift nets since 1990 (OM 22/10/1990) and they therefore operate out of control. Moreover, an unknown number, but probably not lower than to 200, of small Moroccan drift net boats operate in the same area from May to November. This fleet is mainly based in the harbours of Cabo de Agua (20 boats), Nador (30-60 boats), Alhucemas (20 boats) and Tanger (up to 50 boats recorded). The length of the nets used by these boats appears to be very variable, although in many cases it exceeds 2.5km. The Spanish and Moroccan fleets appear to be responsible for numerous dead dolphins that appeared washed ashore on the coast during the last year and also for the catch of at least one monk seal that fortunately survived the encounter. In northern Morocco, fishermen have been reported to continue fishing with dynamite in waters inhabited by monk seals, bottlenose and common dolphins and a dolphin killed for use as bait continues at low but stable rates in southern Spain, southern Italy and probably many locations in northern Africa. The total number of cetaceans killed every year in drift fishery in the Mediterranean Sea is unknown, but it has been estimated that more than 8,000 cetaceans are entangled in the Italian drift net fishery per year. The Workshop on the Mortality of Cetaceans in Passive Fishing Nets and Traps held in La Jolla in 1990 concluded that Mediterranean striped dolphins were unable to sustain current levels of mortality and concern was expressed for the situation of the sperm whale. It was therefore recommended to reduce immediately the killings of striped dolphins in the Mediterranean, something that has apparently not happened. In spite of this situation, initiatives for protecting marine mammals in the Mediterranean progress at a rather slow pace. The proposed agreement for the conservation of small cetaceans in the Mediterranean and Black Seas under the Bonn Convention, which was first drafted in February 1991 and further reviewed in 1992, is still pending comments by signatory states and appears to be stuck by diplomatic bureaucracy. Also in 1991, a meeting of the Barcelona Convention in Cairo, adopted in the rush, an action plan for the protection of the Mediterranean marine mammals was included. Among other measures, monitoring systems and restrictions for fisheries susceptible of causing increased mortality of cetaceans and pinnipeds was noted, but again no action followed this adoption. Recently, in March 1994, during the annual conference of the European Cetacean Society, a meeting of interested scientists was held to give impetus to this Action Plan, but, in the outcome it was not clear which financial or political instruments the Convention was going to use to implement its provisions.

This paper outlines Japanese whale sighting surveys in the North Pacific in 1994/95 and in the Southern Hemisphere low latitudes in September-October 1994. The National Research Institute of Far Seas Fisheries plans to conduct a total of seven cruises of whale sightings with the cooperation of other relevant organisations. Respectively, there are about two more transect sampling method and biopsy skin sampling at opportunistic base. The critical issue for the surveys must be the availability of research or entry permits to the EEZ of the relevant countries to the research areas.

SC46/O 23. METHODS FOR ESTIMATING g(0) AND ESW. Yasushi Tago, The Institute of Cetacean Research, 4-18 Toyomi-cho, Chuo-ku, Tokyo 104, Japan.

New methods for estimating g(0) and ESW (Effective Strips Width) are presented, based on the independent observer experiment (IO) data which are classified into several stages corresponding to the observation conditions from the viewpoint of practical feasibility in the surveys in the Antarctic. It is noted that the estimation of g(0) and ESW should be made also corresponding to the school size of whales.

This report summarises the cetacean research activities conducted or supported by the Institute of Cetacean Research (ICR), Tokyo, from May 1993 to April 1994, with the cooperation of the Fisheries Agency of the Government of Japan, the Tokyo University of Fisheries, the National Research Institute of Far Seas Fisheries (NIRIFSF), the Institute of Systematic Mathematics, the Faculty of Agriculture of the University of Tokyo, the National Polar Research Institute and other related research organisations.

SC46/O 26. OCEANIC DEBRIS OBSERVATIONS IN THE INDIAN OCEAN WHALE SANCTUARY AND EASTERN MEDITERRANEAN SEA. Roger V. Grace, Biological Consultant, PO Box 12-012, Penrose, Auckland, New Zealand.

Observations of man-made and natural megafauna, macrolitter and microplastics in the Indian Ocean Whale Sanctuary and the eastern Mediterranean Sea from May to July 1993 are reported. In the eastern Indian Ocean moderate but variable amounts of mega and microplastics of both natural and man-made types were present, whereas the central and western Indian Ocean showed very low densities. Man-made megafauna was common in the Red Sea and abundant in much of the eastern Mediterranean. In most areas plastic items and fragments were the major man-made forms of debris. Plastic megafauna was present in the eastern Indian Ocean at a mean density of 22.1 particles per hectare, in the central and western Indian Ocean at 1.8 particles per hectare, in the Red Sea at 3.5 particles per hectare and the eastern Mediterranean Sea at 175.8 per hectare but peaking at 600.2 per hectare. Biological associations with debris included perches for birds, accumulations of fishes near debris items, a possible correlation with cetacean sightings and encrusting organisms.

SC46/O 28. TOWARDS A FRAMEWORK FOR INVESTIGATING THE EFFECTS OF ENVIRONMENTAL CHANGE ON WHALE POPULATIONS. P.S. Hammond and Ying Zheng, Sea Mammal Research Unit, Natural Environment Research Council, High Cross, Madingley Road, Cambridge, CB3 0ET, UK.

This paper describes the rationale for and some preliminary results of a study to develop a framework for investigating the effects of environmental change on whale populations. The work will concentrate on developing methods to relate information on whale populations to environmental information in order to take advantage of data which are expected to be more widely available in the future. Two approaches are proposed. A broad scale approach is to investigate whether cetacean distribution and abundance can be described in terms of biological and physical oceanographic and environmental data. A preliminary analysis on predicting Southern Hemisphere abundance from purely physical data is presented to illustrate the approach. A fine scale approach is to investigate whether the foraging and breeding behaviour of individuals can be best described by models utilising oceanographic and environmental data. This work will initially use existing data on southern elephant seals obtained by telemetry and will require similar data on cetaceans to progress further.
Guide for Authors

1. INTRODUCTION

There are two major categories of IWC publications: Annual Reports and Special Issues.

Annual Reports arise out of the Annual Meetings of the Commission and contain two sections. The first deals with the political and business workings of the Commission, and includes the Chairman's Report of the Annual Meeting which details management and other action taken by the Commission. The second is scientific and includes the Report of the Scientific Committee and a selection of key papers presented to that Committee. These papers may cover any aspect of cetacean biology, from population dynamics, ecology and behaviour to stock assessment, age determination and genetics.

Special Issues are similar to the second section of Annual Reports in that they are usually the result of a special meeting of the Scientific Committee on a particular topic (e.g. right whales, reproduction). However, in the papers section, in addition to papers presented at the meetings, additional relevant papers (either from other meetings or specially requested) may be included.

2. REVIEW PROCEDURES

(essentially the same for both Annual Reports and Special Issues)

Submission

Any author may submit a paper to a meeting of the Scientific Committee by sending it to the Commission Office. In general, a paper sent at the beginning of April will arrive in time to be submitted to the Annual Meeting (usually held in May or June). Contact the office of the Commission for more precise dates. General guidelines for the style of submitted documents are given in Section 4.

Initial review at the meeting

Papers are usually discussed initially by sub-committees who submit a list of papers they believe should be considered for publication to the Editorial Board. The Editorial Board comprises the Scientific Editor, the Chairman and Vice-Chairman of the Scientific Committee and the Chairmen of the sub-committees. The Board then finalises a list of papers to be considered for publication, subject to review.

First stage of revision

The author is asked to submit a revised version to the Scientific Editor, which takes into account any comments made in the Report of the Scientific Committee and which has been reviewed by two professional colleagues whose names and addresses must be included in the Acknowledgements.

Anonymous review

The revised manuscript is then sent to two (or more) reviewers who are given the option of remaining anonymous. Their comments are then sent to the author with an invitation to submit a revised version which incorporates the comments or a written explanation of why they are considered to be invalid. On the basis of this, the paper is either accepted or rejected for publication.

3. PUBLICATION PROCEDURES

IWC volumes are supplied to our printers on disc. It is much cheaper if authors can supply their final manuscript on discs which can be read and edited at the IWC office. Detailed guidelines are given below.

The author will normally receive one set of proofs. This is not to provide an opportunity to rewrite the paper but merely to check for any typographical errors which may have slipped through! Authors will be asked to pay for major changes at this stage.

On publication, each primary author receives a free volume and 50 free reprints (shared by co-authors).

4. NOTES ON PRESENTATION AT VARIOUS STAGES OF PUBLICATION

General

Underneath the title, the full names and postal addresses of all authors must be given.

All papers must contain an Abstract of no more than 400 words, which should include information on the objectives, the principle results and the conclusions of the study.

Documents to be submitted to a meeting

Manuscripts should be single spaced. As little blank space as possible should be included; e.g. there is no need to put each figure and table on a separate page.

The style guide given below should be followed.

Documents to be submitted for consideration for publication

Manuscripts should be double spaced if possible.

Authors must arrange for two professional colleagues to review the paper and their names and addresses must be included in the Acknowledgements section.

The style guide given in Section 5 must be followed or the paper will be returned to the author.

Artwork

There is no need to submit original artwork at this stage.

Tables

It is very expensive to print tables which are more than a single column width when published. Authors should therefore try to ensure that as many tables as possible do not exceed 60 characters (including spaces) in width. The maximum permitted width of any table is 120 characters (including spaces).

Submission of final versions of papers for publication

After revision to take into account the comments of anonymous reviewers, wherever possible, final versions of papers (including tables and figure legends) should be supplied on disc. Provided that an IBM-compatible machine is used with MS-DOS version 3.0 or later, we can accept text formulated with any of the major word-processing packages. Please give the text and tables
5. STYLE GUIDE

Heading styles
If you have the ability to use bold face the following heading styles should be followed in the text (the style for the title of the paper can be chosen by the author).
Level 1 – BOLD, CAPITALS, CENTRED followed by one line space
Level 2 – Bold, upper and lower case, side heading followed by no space
Level 3 – Italic (or Underlined), upper and lower case, side heading, followed by no space
If you cannot use bold face then:
Level 1 – CAPITALS CENTRED followed by one line space
Level 2 – Upper and lower case, side heading followed by one line space
Level 3 – Underlined, upper and lower case, side heading followed by no space
Please note that for Levels 2 and 3 only the first word should have an initial capital letter unless the word would normally have an initial capital letter (see ‘Capitals’ below).
Do not number sections unless absolutely necessary (e.g. where substantial cross-referencing occurs).

Preferred spellings
English spelling should be used unless the author is from the United States, in which case American spellings may be used.
Words ending –ise/ize
The –ise ending is preferred wherever either is permissible.

Hyphens
These are used in compound adjectives preceding a noun; e.g.
- age-length key, length-specific method
- but not where part of the compound adjective consists of a numeral; e.g.
  - 3cm long earplug, a 500kW lamp

Hyphens are also omitted where a compound noun is sufficiently familiar to be printed as one word; e.g.
- ultrasonic, daytime, interspecific, overexploitation, northeastern
except where this would result in an awkward spelling; e.g.
- infra-red, night-time, photo-identification
The most important point to remember, however, is to be consistent.

Capitals
Common examples are given below:
Area (when referring to Area I, etc.), Sector, Division, Initial Management Stock, Antarctic, South Atlantic Ocean, Northern Hemisphere, Scientific Committee, Table 1, Fig. 1, Chairman, Vice-Chairman, Bryde’s whale and Hector’s dolphin (i.e. where named after a person);

- central North Pacific, sub-committee, sub-arctic, sei whale, common dolphin, etc.

Numbers, dates, map references
(a) In the text numbers under 10 should be spelt out where used individually. Figures should be used for a sequence of quantities and in reference to percentages (where % rather than percent is used); e.g.
- six sperm whales but 6% of sperm whales;
- 1 blue whale, 3 Bryde’s whales and 6 sperm whales were observed.

(b) Commas should be inserted with four or more figures; e.g.
- 6,789; 2,060,313

(c) Decimal points should be indicated by full stops, not commas. Zeros should be included; e.g. 0.12

(d) There should be no space between numbers and abbreviated units; e.g. 6m, 25kg

(e) Dates should be in the form:
- 17 March 1983 not May 15, 1958

(f) Map references should be in the form: 42°6’S, 23°42’W

Abbreviations
(a) Where the last letter of an abbreviation is the same as the last letter of the full word then no full stop is necessary; e.g.
- Fig. 1 but Figs 1–7

(b) Capital abbreviations do not require full stops; e.g.
- IWC, USA, MSYR, 60°N, CV, SD, etc.

(c) Commonly used abbreviations for quantities have no full stop; e.g.
- 6cm, 22m, 14ft, 456kg

(d) The generic name (e.g. Balaenoptera physalus) must be originally written in full but may subsequently be abbreviated (e.g. B. physalus).

(e) If a personal communication is used, abbreviate as ‘pers. comm.’.
Italics
These should be used for
(a) references to titles of books and periodicals (e.g. Moby Dick)
(b) names of vessels (e.g. Shonan Maru No. 2, Moonlight Tango, Adolf Jensen)
(c) Latin names of plants and animals (e.g. Eubalaena glacies)
(d) foreign words not part of everyday English (e.g. et al., daïninn)
(e) trade names (e.g. Guinness).
If italics are not available they can be indicated in the text by underlining.

Quotations
Use single quotation marks. Double quotation marks are only to be used for a quote within a quote.
Within a quotation follow the style and punctuation of the original. If omitting a section, indicate by three full stops . . .
If interpolating a word or phrase please use square brackets [my italics].

Equations, mathematical references
(a) Ensure that superscripts and subscripts are easily discernible.
(b) Show all symbols clearly and, in the margin, spell out Greek letters the first time they occur.
(c) Clearly distinguish between: the letter l and the number 1 (e.g. by underlining the letter); and the letter O and the number 0.
(d) If possible, use italics for letters indicating parameters, e.g. \( y = mx + 66c + \sqrt{Z} \)

Odds and ends
(a) Do not use a comma prior to 'and' in a list (e.g. green, white and orange).
(b) Data are, NOT 'data is.
(c) If a colon is used prior to a list of points, the points should not begin with a capital letter and should be separated by semi-colons.

References
(a) In the text
(i) Where more than two co-authors are involved use: O’Flaherty et al. (1983).
(ii) If more than one reference is made then a semi-colon is used; e.g.
Irving, 1982; James, 1881; Watterson, 1987
(iii) In references to the Scientific Committee or other International Whaling Commission reports, IWC is used; e.g.
‘It was agreed last year (IWC, 1983) that . . .’
(iv) Where an author has more than one paper in the same year use 1981a, 1981b, etc.
(b) In the reference list
(i) All the author’s names are written irrespective of the numbers of authors.
(ii) Surnames always precede initials.
  e.g. Bannister, J.L., Best, P.B. and Cawthorn, M.W. except for editors of books in example (v) below.
(iii) If the reference is to an article in a journal then the title of the paper (in lower case except for words which would normally have initial capitals), the title of the journal (in italics and abbreviated using the FAO World List of Scientific Periodicals except for certain preferred modifications, e.g. Rep. int. Whal. Commn), the volume number and the page numbers of the article must be given; e.g.
(iv) If the reference is to a whole book, then the title of the book (in italics, and with initial capitals for major words in the title), the name of the publisher, the city of publication and the total number of pages must be given; e.g.
(v) If the reference is to an article or chapter within a book, then the title and page numbers of the article, the editor’s name, the title of the book (in italics), the name of the publisher, the city of publication and the total number of pages of the book must be given; e.g.
(vi) If the reference is to an unpublished paper from the Scientific Committee or any other meeting, then the title of the paper, the number/reference of the paper, the title and date of the meeting and the number of pages should be given; e.g.
(vii) The reference list should be arranged in alphabetical order and, within this, by date of publication. A hypothetical list is given below.

REFERENCES

Annex E

Members: Donovan (Chair), Allison, Brandão, Bravington, Breiwick, Butterworth, Clarke, C., Cooke, George, Dereksdottir, Givens, Johnston, Kell, Kingsley, Magnusson, Mate, Matsuda, O’Hara, Okamura, Oosthuizen, Punt, Rademeyer, Skaug, Suydam, Tanaka, Wade, Witting, Zeh.

1. INTRODUCTORY ITEMS

1.1 Convenor’s opening remarks
Donovan welcomed the participants. He reminded the members that the primary task for the SWG this meeting was to work towards the selection of preferred candidate SLA(s) for the Bering-Chukchi-Beaufort (B-C-B) Seas stock of bowhead whales. He drew attention to the remarkable quantity of work undertaken by developers and Allison during the period since the last meeting. Before considering the results of the trials and determining the preferred candidate(s), he wished to congratulate and thank all of the developers for their work during recent years. Progress has only been possible because developers have shared their thoughts, approaches and code – equally important lessons have been learned from approaches that have not succeeded as well as those that have. Whichever procedure is finally chosen, it will owe a considerable debt to the other developers and members of the SWG who have worked in a spirit of cooperation and collaboration throughout.

1.2 Election of Chair
Donovan was elected Chair.

1.3 Appointment of rapporteurs
Givens and Punt acted as rapporteurs, with assistance from the Chair.

1.4 Adoption of agenda
The adopted agenda is given as Appendix 1.

1.5 Review of documents

For ease of reading, unless another reference is given, ‘Last meeting’ refers to SC/53/Rep1. A glossary of terms is given as Appendix 2.

2. PROGRESS SINCE SEATTLE

2.1 Computing tasks
The Common Control Program is the computer code used to run the Evaluation, Robustness and Cross-validation trials. This program also calculates the performance statistics and the information needed to compare the performance of candidate SLAs. The only portion of code that an AWMP developer needs to supply is that implementing their candidate SLA.

Allison reported she had updated the Common Control Program to implement the modifications to the Evaluation and Robustness trials agreed at the last meeting. A version of the program was distributed to the developers in January to allow them to finalise their SLAs. Allison reported that she had received code implementing the five SLAs (and their variants) described under Item 3, and that she had been able to replicate the results for the Evaluation trials obtained by the developers. She reported that she had applied all SLAs to the 26 Evaluation trials, and had applied the ‘central’ version of each SLA to 101 of the 103 Robustness trials and the five Cross-validation trials. In addition, she had written the software to produce the graphical summaries developed at the last meeting. Trials for the eastern North Pacific gray whales were nearing completion but some of the specifications were incomplete and advice would be needed from the SWG. Allison expressed thanks to Punt for the assistance and advice he had given during the year and also to David Poole who had conducted the conditioning for some of the trials. The SWG thanked Allison for her diligent and timely work on these matters, without which the progress made would have been impossible.

2.2 Other
Givens reported that the SWG web site (http://www.stat.colostate.edu/~geof/wwcawmp.html) had been updated intersessionally. It includes reference information and subject- and date-indexed archives of all correspondence of the AWMP intersessional e-mail group. The SWG thanked Givens for the upkeep of the web site. The SWG noted that the AWMP intersessional e-mail group had once again provided a valuable means of communication among members of the SWG. It recommended that this e-mail group continue to coordinate the intersessional activities of the SWG.
3. DESCRIPTION OF POTENTIAL PROCEDURES FOR BOWHEAD WHALES

Potential Strike Limit Algorithms developed by four groups of Scientific Committee members were considered by the SWG. Non-technical descriptions of the procedures written by the developers themselves are given below.

3.1 The Derekdottir-Magnússon (D-M) SLA

The procedure is described in detail in SC/53/AWMP7 and Derekdottir and Magnússon (2001). It centres on the ‘Kalman filter’, a tool widely used in engineering to estimate the state of a stochastic system with noisy observations, i.e. a system with both ‘process’ noise and observation noise. In order to apply the Kalman filter, mathematical models of the dynamics and the relationship between the observations and the true state are required. In what is called the Adaptive Kalman Filter Strike Limit Algorithm (AKF-SLA), a simple Pella-Tomlinson population model without age structure and without a delay in the dynamics, is used to describe the stock dynamics. A linear relationship between observed stock size and true stock size is assumed. The noise is taken to be additive and Gaussian after a log-transformation of the variables (i.e. stock size).

The way the Kalman filter works is that the most recent stock estimate is projected forward in time (a prediction) until a new observation is available. The prediction is then compared to the observation and an updated estimate of the state calculated. If we call the updated estimate \( x_{\text{new}} \), the prediction \( x_{\text{old}} \) and the observation \( z \), the updating formula is:

\[
 x_{\text{new}} = x_{\text{old}} + \tilde{K}(z - x_{\text{old}})
\]

where the time-dependent coefficient \( \tilde{K} \) is known as the Kalman gain. This updating of the most recent stock estimate is carried out whenever a new observation of the stock size (a survey estimate) is made.

The term in brackets in the updating formula is the difference between the actual observation (the survey estimate in this case) and the prediction from the model based on past history. Thus, a large difference between the predicted observation and the actual observation will result in a large update whilst a small difference results in a correspondingly small update. The Kalman gain depends on the magnitude of the measurement noise and the ‘process’ noise. The gain decreases (giving a small update) with increasing measurement noise (low confidence in the measurement) and increases (giving a large update) with increasing process noise (high confidence in the observations relative to model prediction).

The stock dynamics model and the observation model contain a number of unknown parameters. In the version of the AKF-SLA that is applied to the B-C-B stock of bowhead whales, two of the parameters (i.e. \( MSYL \) and natural mortality) are fixed. The remaining parameters (i.e. \( MSYR, K \) carrying capacity and \( B \) observation bias) are estimated by Bayesian methods. Each of the three parameters \( (MSYR, K, B) \) range over a sequence of discrete values that thus gives a three-dimensional grid of parameter values. A prior probability distribution is given to the parameter combinations in the grid and a Kalman filter is associated with each combination.

The probability associated with each parameter combination is updated by Bayesian methods each time a new survey estimate becomes available. The estimate of the state associated with each of the combinations is updated at the same time by the corresponding Kalman filter. For each \( (MSYR, K, B) \) combination in the grid, there corresponds therefore a posterior probability for the particular combination and an estimate of the state (i.e. stock size) given this particular parameter combination. This combination of Kalman filtering and Bayesian methodology is known as Adaptive Kalman Filtering (AKF). The overall estimate of the present state (stock size) is then obtained by summing all the stock estimates corresponding to the different parameter combinations, weighted by the respective probabilities.

When a catch control law is specified, a strike limit can be calculated - conditional on the values of three parameters \( (MSYR, K, B) \) and the corresponding stock estimate. Associated with each conditional strike limit is the most recent posterior probability of the particular parameter combination.

The catch control law used in the present version of the AKF-SLA is the minimum of pre-specified aboriginal need and the strike limit given by the \( H \)-rule (IWC, 2001a). Thus, when all the Kalman filters corresponding to each of the parameter combinations have been applied, a sequence of strike limits (the same number as the number of parameter combinations) and associated probabilities are available. Arranging all the strike limits in an increasing sequence, the associated probability distribution makes it possible to construct the cumulative probability distribution for the strike limit. Setting a percentile of this distribution gives the eventual strike limit. This percentile is the tuning parameter of the SLA; the higher the percentile, the higher the final strike limit. In the basic version of the procedure applied to the B-C-B bowhead stock, the bias factor is taken to be unity (i.e. no bias) in all the filters so that a two-dimensional grid of \( (MSYR, K) \) values is used.

The AKF strike limit algorithm is based on well-established methodologies, i.e. Kalman filtering techniques and Bayesian methods, and therefore stands on sound theoretical ground.

The results of the evaluation trials are good with regard to final depletion and need satisfaction for most of the trials (value of tuning parameter = 70%). However, the stock is under-utilised in trial BE04 due to a negative bias in the stock estimate (this can be improved by including bias filters) and the final depletion is too low in trials BE09, BE12, BE13 and BE16, especially BE12. The depletion in some of these low productivity trials can be improved somewhat but only by compromising need satisfaction in the higher \( MSYR \) trials. Strong points of the SLA are the ability to fully satisfy need in the first 20 years of management, catch variability is generally low, and the SLA is fairly stable in the sense that there is a small spread in strike limit trajectories. A weak point of the SLA is the inability to cope satisfactorily with situations with low \( MSYR \), historical survey bias and future positive bias (trial BE12). Although performance in low productivity trials without future positive bias (BE09) can be improved somewhat by choosing a more conservative tuning, BE12 can be improved only slightly.

3.2 The Givens SLA 1 (G-G)

This SLA (see SC/53/AWMP3 for technical details) was designed for conservative management, ensuring vigilant protection for the stock while fulfilling moderate subsistence need.

The strike limits are calculated from a linear model fit using a strategy known to provide Bayes rule optimality as described by Givens (1999). Like the procedure adopted for
use in the RMP, this SLA places greater weight on ensuring at least moderate catch in all cases where this is appropriate, rather than trying to obtain a high but unreliable or even risky catch in some cases. Furthermore, it places greater priority on the satisfaction of subsistence need in the first 50 years of management than it does for high need in years 75-100. In fact, it gives complete need satisfaction in the first 20 years on every deterministic bowhead Evaluation trial.

The SLA was designed to place conservation as the highest goal. For example, on trial pairs where need is high and MSYR is either high or low, the SLA guarantees stock protection in the low MSYR trial, at the expense of some catch in the high MSYR trial. It rejects the reverse strategy of fully satisfying need in the high MSYR trial at the expense of depletion risk in the low MSYR trial. Conservatism is achieved by controlling for 5th percentile - rather than median - depletion performance, and by giving the most risky trials heavier weighting in the tuning. The tuning also reflects the goal that after 100 years of management, the stock should show at least some recovery, even in the 5th percentile performance.

The SLA produces extremely stable strike limits. This was a design goal reflecting the concern that highly variable limits are disruptive to subsistence hunters and may even serve to reduce the operational feasibility of satisfying need.

Finally, the SLA produces relatively narrow ranges of performance (both depletion and need satisfaction) on most trials. The appeal of this feature is that it enables one to set (via tuning) SLA performance closer to desired levels with better control against poor performance. For example, if the main goal is good median risk, a target level can be met while better controlling against poor 5th percentile risk or poor need satisfaction performance.

Subject to the conservation and recovery of the stock, subsistence need is met to the greatest extent possible.

The strike limit calculation proceeds as follows. Given survey abundance data, the model and estimation procedure of SC/53/AWMP5 are used to estimate five quantities: carrying capacity, next year's yield (truncated) given a current-year catch of 120, current stock size, the default SC/53/AWMP5 strike limit, and a sort of trailing mean estimated stock size. The raw strike limit in years 0-34 is a linear function of the first three of these and the ratio of yield to carrying capacity. From year 35 onwards, the slope with respect to yield is modified. The coefficients of these linear functions are determined to achieve a Bayes rule optimality.

The raw strike limit is bounded above by need and bounded below by 90% of the previous limit. To this raw strike limit, several adjustments are made.

1. If three or more consecutive strike limits each equal 90% of their predecessor, the raw strike limit is averaged with 75% of the default SC/53/AWMP5 strike limit (see Item 3.4).
2. The strike limit must not be less than 90% of the previous limit, nor exceed the previous limit by the maximum of 15 whales/year or 15%.
3. If the strike limit would satisfy at least 95% of need, it is raised to 100% of need.
4. From year 35 onwards, if the trailing mean stock size is less than 6,700, the strike limit is reduced by 30%; if it is less than 6,000 in year 50 or later, the strike limit is reduced by 50%. In any year, if the estimated total stock abundance based on all available past data is less than 2,000, then the strike limit is set to zero.

This results in a strike limit algorithm with the following general behaviour: strike limits increase as estimated stock size or yield increases, and decrease as carrying capacity increases. For a stock near MSYL, the strike limit is essentially a linear function of carrying capacity, replacement yield, current stock size and MSYR.

The SLA can be tuned using several tuning parameters, and/or by re-optimisation using alternative Bayesian priors and loss functions. Sensitivity to tuning seems to be low for the former approach, and moderate for the latter. To match the extent of risk associated with candidate SLAs, a much more risk-tolerant tuning of this SLA was developed; it is described in SC/53/AWMP8. It has the strengths mentioned above plus it fulfils more needed strikes in scenarios where need is very high.

3.3 The Givens SLA 2 - (G-M)

This SLA (see SC/53/AWMP4 for technical details) is a simple merging of the SLAs described in SC/53/AWMP1 (Punt) and SC/53/AWMP5 (Johnston-Butterworth). It combines the better short-term performance of the former with the better long-term performance of the latter (see Items 3.4 and 3.5 below).

The strike limit calculation depends on the strike limits output from these two SLAs, omitting their quota variability dampening and phase-out features. For years 0-20, the raw strike limit is set equal to the corresponding result from the SC/53/AWMP1 SLA. Thereafter, the raw strike limit is set equal to the maximum of the output of the SC/53/AWMP5 SLA and a weighted average of the outputs of the two SLAs. This weighting is parameterised by a single tuning parameter. The weighted average equals the SC/53/AWMP1 output when the tuning parameter is 1 and the SC/53/AWMP5 output when the tuning parameter is 0. For tuning values between 0 and 1, the weighting shifts linearly.

Two adjustments are made to the raw strike limit. First, the strike limit is not allowed to be less than 90% of the previous limit. Second, when the strike limit would satisfy at least 95% of needed strikes, then the limit is raised to 100% of needed strikes.

The performance of this SLA can be adjusted through the choice of the tuning parameter, or by changing the tuning of the two individual SLAs.

One appeal of this SLA is its simplicity. For example, with the tuning parameter set to zero, this SLA essentially uses the SC/53/AWMP1 strike limits for the first 20 years and the SC/53/AWMP5 strike limits thereafter.

This merging approach generally provides superior need satisfaction - especially over the 20-year time span and at the 5th percentile at any time span - while maintaining risk to the stock at a level between the individual SLAs.

3.4 The Johnston-Butterworth (J-B) SLA

This SLA (see SC/53/AWMP5 for technical details) is based upon the same simple population model as the CLA of the RMP. This model is fit to the available data by a penalised maximum-likelihood method, rather than adopting a Bayesian-like approach as in the CLA. The rationale for this is that although Bayesian estimation is appealing in its presentational simplicity, in practice the development of computer code for its accurate implementation is a lengthy and expensive process. A maximisation instead of an integration process is simple to implement numerically.

A penalty function is added to the log-likelihood for two reasons: (1) to stabilise estimates of model parameters; and (2) to 'bias' initial model estimates in a manner that reduces
the risk of unintended depletion while nevertheless not causing strikes to drop too much below need levels. The SLA sets strike limits equal to need unless the model both estimates the population to be below MSYL and not to be achieving a specified rate of increase.

This SLA incorporates an option to constrain the inter-5-year strike variation levels. The base-case (and both tunings) of the J-B SLA use a 15% downwards only inter-5-year strike constraint without restricting increases. This assists in reducing variability in need satisfaction without compromising conservation objectives.

The J-B SLA has three tuning parameters. A preferred SLA is selected by the authors, as well as two alternative tunings. The one tuning improves on need satisfaction, whilst the other tuning improves on resource recovery.

The strengths of the preferred J-B SLA include:

1. simple and relatively easy to explain to both managers and whalers;
2. easily ‘tuned’ to improve on either need satisfaction or resource recovery; and
3. reasonable performance on most trials.

The weakness of this preferred SLA include:

1. higher variability in need satisfaction over the full management period;
2. largish reductions in strike limits for some ‘difficult’ trials;
3. poor resource recovery when need is high and MSYR1s = 1%; and
4. poor need satisfaction when future surveys are negatively biased.

3.5 The Punt (A-P) SLA

This SLA (see SC/53/AWMP1 for technical details) determines the strike limit as the greatest future catch which, if continued over the next 20 years, is consistent with either the population in 20 years exceeding MSYL with a pre-specified probability, or the population in 20 years exceeding a target fraction of the current population size with a pre-specified probability. The strike limit for a 5-year block is constrained not to differ by more than 20% from that for the previous 5-year block. The calculation of these probabilities is based on a Bayesian-like estimation approach where a prior is placed on MSYR, and the only data included in the likelihood function are the estimates of abundance from surveys (assumed to be unbiased). The coefficients of variation assigned to these estimates of abundance are downweighted to give less weight to recent abundance estimates. The population dynamics model used is that which underlies the CLA of the RMP. This SLA explicitly includes precaution when setting strike limits by using a prior for MSYR which assigns highest probability to values for MSYR \( \leq 0.01 \). This SLA includes the phase-out rule presently included in the RMP.

The A-P SLA has eight tuning parameters. These parameters determine the relative prior probability for MSYR \( \leq 0.01 \), MSYL, the extent to which historical survey estimates are downweighted, the target value for the ratio of the population size in 20 years to that at present, the probability of being above MSYL in 20 years, the probability that the population size in 20 years relative to that at present exceeds the target value, and the extent by which strike limits for a future block may differ from that for the previous block. The values for these parameters are selected to achieve a desired balance between need satisfaction, risk avoidance and stability of strike limits. Three tunings of this SLA are available (low, high and central). These tunings were selected to achieve a range of risk-need satisfaction trade-offs for trial BE12.

The design criteria for this SLA include being as generic as possible (so that the SLA can be tailored straightforwardly to additional aboriginal whaling operations), to be as similar to the CLA of the RMP as possible (to avoid the introduction of a completely new algorithm for managing whale populations), to include Bayesian features (so that greater uncertainty implies lower strike limits), and to be consistent with the spirit of paragraph 13(a) of the Schedule. The current version of the A-P SLA is reasonably generic and is based roughly on paragraph 13(a). In principle, the only modification needed to apply it to an additional aboriginal whaling operation would be to select the values for the eight control parameters to achieve the desired risk-need satisfaction balance. In contrast, the SLA does not include a formal Bayesian estimation framework (although it does include a Bayesian-like framework that achieves essentially the same outcome), and the only features of the CLA of the RMP included in this SLA are its population dynamics model and phase-out rule.

The performance of the central tuning of this SLA is generally adequate in terms of allowing populations to recover to above their present sizes and satisfying need when this is possible. The most notable exception to this in terms of risk avoidance occurs when MSYR is low (1% of the total population size at MSYL) and the data are poor, when the lower 5th percentile of the 1+ population size in 100 years expressed relative to that at present is only 77%. Performance, terms of need satisfaction, is poorest when future survey estimates are negatively biased. This SLA (particularly its ‘low’ tuning) also leads to relatively wide distributions for the performance statistics.

4. PRINCIPLES OF SELECTION OF SLAS

The IWC’s objectives for aboriginal whaling management given by the Commission are:

1. ensure that the risks of extinction to individual stocks are not seriously increased by subsistence whaling;
2. enable aboriginal people to harvest whales in perpetuity at levels appropriate to their cultural and nutritional requirements, subject to the other objectives; and
3. maintain the status of stocks at or above the level giving the highest net recruitment and ensure that stocks below that level are moved towards it, so far as the environment permits.

The first objective has been accorded highest priority by the Commission. The SWG noted discussions on this matter during previous meetings. It then agreed that the first phase of the selection process would involve identifying the SLAs that meet the Commission objectives satisfactorily and that the second phase would involve choosing amongst those.

Equivalence tuning is a way to provide SLA developers with the opportunity to adjust their SLAs to strive towards a pre-specified balance of risk, satisfaction of need and...
recovery. The tuning criterion agreed at the last meeting (matching the (1+) median final depletion achieved by \( H \) for trial BE14 to within 0.005) was not, in fact, appropriate for the purposes of equivalence tuning. At the present meeting, the SWG reconsidered the merits of equivalence tuning in this case. It was noted that performance differs markedly across trials and performance statistics, even when equivalence tuning is achieved. Given this, the SWG agreed to group the 13 SLA variants into three categories based on a rough evaluation of the emphasis each SLA placed on risk avoidance. The SWG noted that equivalence tuning was different from performance tuning which involves evaluating the risk-need satisfaction trade-off achieved by a single SLA.

In the context of Commission objective (2), the SWG has placed emphasis on consultation with hunters via the Commission’s Aboriginal Subsistence Whaling Sub-Committee. Issues covered have included the importance of catch stability and need satisfaction in the shorter term versus that in the longer term. In addition, this year the SWG noted comments made by the Alaska Eskimo Whaling Commission (AEWC) provided in SC/53/AWMP3. The AEWC emphasised the high importance they attach to satisfying need in the near future compared with the relatively low importance to attempting to satisfy large increases in need in the distant future (50-100 years from now). They also indicated that emphasis should be placed on ‘realistic’ levels of future need (rather than the upper limits of the need envelope\(^1\)). They further stressed that SLA performance was extremely important and that they would not be concerned if the Commission adopted a ‘complicated’ SLA in order to ensure the best performance. Finally, they indicated that they saw no urgency for the adoption of a new SLA for the B-C-B bowhead whales since the existing management process seemed to be working well.

The SWG considered whether to assign relative weights to each of the Evaluation trials. The SWG agreed that weights could be assigned to trials based on their biological plausibility (e.g. MSY rate, time-trend in survey bias) and on the realism of the need trajectory. Weights could also be based on the ability of the trial to distinguish SLA performance, i.e. whether the trial provides a challenge in terms of need satisfaction or risk avoidance. Based on the comments by the AEWC and earlier comments by the Commission, the SWG agreed that the trials with final need levels of 201 should be assigned a lower weight than those with final need levels of 67 and 134 (especially with respect to need satisfaction) and that if two SLA(s) perform similarly, satisfaction of need for the first 20 years of the 100-year projection period would be given emphasis when selecting a preferred SLA.

Apart from these general considerations, the SWG did not a priori assign weights to each Equivalence trial although it acknowledged that each member of the SWG would assign their own weights to each trial during the selection process. It agreed that a more formal weighting of trials may be necessary once the number of candidate SLAs is reduced. If the number of trials on which performance differs is small, the number of trials that would need to be weighted would be reduced from the current 26.

The SWG noted its earlier comment that, performance being equal, a substantially simpler SLA might be preferred if, for example it greatly reduced future computational requirements and eased the process of validating the computer code for the preferred SLA. The SWG agreed however, that all candidates identified in Item 5.2 may be sufficiently complex as to render complexity differences between them irrelevant, at least with respect to explaining them to the Commission or hunters.

5. REVIEW RESULTS OF THE BOWHEAD WHALE TRIALS

5.1 Graphical presentation and performance statistics

Allison provided the SWG with examples of the tables and plots it developed at the last meeting. The SWG reviewed these example plots and refined them to simplify interpretation of the results. The SWG agreed that the full suite of tables and graphs will be available in a Master Summary. The SWG agreed that following seven graphical summaries (see Appendix 3 for examples) would be included in the Master Summary:

1. **Plot 1**: Time-trajectories of total (1+) population size for \( H \) by simulation and trial, pointwise median time-trajectories of total (1+) population size by SLA and trial, and time-trajectories of total (1+) population for simulations 1-5 by SLA and trial.
2. **Plot 2**: Time-trajectories of total (1+) population size for \( H \) and each of the SLAs by simulation and trial.
3. **Plot 3**: Time-trajectories of strike limit against time for \( H \) and each of the SLAs by trial.
4. **Plot 4**: Pointwise median strike limits and time-trajectories of strike limit for simulations 1 – 5 by SLA and trial.
5. **Plot 5**: Box plots summarising the distributions for the mandatory statistics for each trial and candidate SLA.
6. **Plot 6**: Need satisfaction (N9) versus final depletion (D1; 1+ population component) for 13 variants of the base-case trial that span a range for MSYR\(_1+\), from 1 to 4% in steps of 0.0025 for each SLA. The historical survey bias changes linearly from 0.67 to 1.00 as MSYR\(_1+\) changes from 0.01 to 0.025 so that the trial with MSYR\(_1+\) = 0.01 matches trial BE01. MSYR\(_1+\) ranges linearly from 0.6 to 0.8 for 0.025 ≤ MSYR\(_1+\) ≤ 0.04 so the trials with MSYR\(_1+\) = 0.025 and 0.04 are the same as trials BE01 and BE10. Need doubles over 100 years in every trial, and each trial was conditioned to provide appropriate biological parameter sets. The dots show actual outcomes for each trial and SLA; the lines merely connect the dots. The top set of lines connects medians, and the bottom set the lower 5\(^{th}\) percentiles. The hash marks on the x-axis indicate the 5\(^{th}\) percentile D1 values for trials where MSYR\(_1+\) < 0.025.
7. **Plot 7**: Scatter plots for each SLA of the median final depletion (1+ population component) expressed relative to that achieved by \( H \) versus the average need satisfaction (N9) expressed relative to that achieved by \( H \) (median performance) and of the lines joining the joint 5% and 95% points for the final depletion expressed relative to that achieved by \( H \) and for the average need satisfaction expressed relative to that achieved by \( H \) (boundary performance).

Tabular summaries available to the SWG included lists of the values of the performance statistics (5\(^{th}\), 50\(^{th}\) and 95\(^{th}\) percentiles) for each SLA.

The SWG agreed that the process of selecting preferred candidate SLA(s) would be divided into two stages. The first

\(^1\) The need envelope sets bounds on the situations that an SLA has to be able to cope with in the AWMP simulations.
stage involved examining the results for the Evaluation trials in tabular form and using the plots 3, 5, 6 and 7, from which it would eliminate any unsuitable candidates.

5.2 Initial consideration of preferred candidate(s)

The SWG agreed that the task of summarising the performance statistics and hence selecting preferred SLAs would be considerably simplified if the number of candidates could be reduced from 13. The SWG therefore considered plots 2 and 4 and the tabular results for some of the trials, and agreed that it was possible to reduce the number of candidate SLAs from 13 to 4. Nine candidate SLAs were eliminated from further consideration for the following reasons.

A-P(L) and J-B(L): Poor performance in terms of satisfying need over the first twenty years of the 100-year management period for trials (such as BE01) in which need can be fully satisfied.

D-M(H): This SLA drives the resource to low levels in some trials (e.g. BE12) and its performance is, in any case, not very different from those for D-M(L) and D-M for most trials.

A-P(H) and J-B(H): Very poor performance in terms of resource conservation for trial BE12. The time-trajectories of population size for these SLAs drop monotonically over the 100-year period for this very difficult trial. For most of the trials, the SLA performance tends to be worse than that for the G-G and G-G(H) SLAs on several performance statistics for several trials.

A-P and J-B: These SLAs are far more variable than the two D-M and two G-G SLAs.

During the review, Cooke commented that in some cases the performance of the SLAs was poorer than simply setting the strike limit equal to need (i.e. those trials for which need can be fully satisfied). In addition, for several of the trials in which need cannot be satisfied, the SLAs nevertheless still lead to upper 95th percentiles for the total need satisfaction (N9) statistic very close to 1. In order to investigate this further, the SWG therefore compared the performances of the 13 SLAs with that of the (hypothetical) Strike Limit Algorithm that involves always setting the strike limit equal to need. This ‘catch = need’ Strike Limit Algorithm performs perfectly (as expected) for many of the ‘easy’ trials but leaves the resource at unacceptably low levels for Evaluation trials in which MSYR$_{10}$ = 0.01 (for example, trials BE09, BE12 and BE16), and in many of the Robustness trials.

The SWG therefore agreed to proceed by considering only the following variants: D-M, D-M(L), G-G, G-G(H). The Chair drew attention to his earlier comments regarding the invaluable contributions made to the overall process by all developers (Item 1.1).

5.3 Comparison of SLAs using the Evaluation trials

The SWG contrasted the performance statistics for the D-M, D-M(L), G-G and G-G(H) SLAs for each of the 26 Evaluation trials. The aim of this comparison was to identify differences and similarities in the performance for these four SLAs. The intention was not to produce a mechanical scoring system from which automatically to choose the SLA with most points. The ultimate decision would be made via a composite view of all of the factors discussed in Item 4. During the examination of the Evaluation trials, the basis and method of comparing performance evolved and expanded as the SWG learnt more about how to interpret and summarise trial results. It also recognised that the various statistics all provided insight into the performance of the SLAs and that in any one trial it was possible for individual statistics to imply different relative performance inferences.

The SWG noted that performance on the lower 5th percentile statistics reflected the ‘guaranteed’ performance of an SLA while performance on the median statistics reflected its ‘expected’ performance. Final evaluation requires human integration over a number of factors including the assignment of relative weights to performance in terms of ‘guaranteed’ versus ‘expected’ performance, overall plausibility of trials and the magnitude of any observed differences. Given these provisos, the SWG examined each of the trials and attempted to identify the ‘best’ SLAs for each trial as detailed below. Trials indicated by asterisks are trials for which setting the strike limit equal to need performs perfectly and those indicated by ampersands involve need increasing to 201 over the 100-year period – such trials are considered less plausible than the trials in which need is constant or increases to 134. The comments on each trial below were based on an initial examination by the full SWG and finalised by a small group comprising Allison, Punt and Witting.

BE01, BE01-SE*: This is the baseline trial. The G-G(H) SLA performs best in terms of the lower 5th percentile of the N9(100 years) statistic. This SLA also outperformed the other SLAs in terms of the fraction of years in which the strike limit equals need.

BE02*. The four SLAs perform equally well for this trial.

BE03, BE03-SE*. The G-G and G-G(H) SLAs perform best as they achieve the greatest need satisfaction over the last 80 years.

BE04*. All four SLAs fail to satisfy need for this trial. The D-M SLA outperforms the other three SLAs given its performance in terms of satisfying need over the last 80 years.

BE05*. The D-M SLA performs best as a result of its higher lower 5th percentile of the N9(100 years) statistic.

BE07*. The D-M and G-G(H) SLAs perform best as they are better able to satisfy need over the last 80 years.

BE08*. The G-G(H) SLA performs best as it achieves the highest lower 5th percentile of the N9(100 years) statistic.

BE09. This is a trial in which need cannot be fully satisfied so performance is measured in terms of risk avoidance. The G-G and D-M(L) SLAs perform equally well in terms of preventing further declines in population size (D10; lower 5th percentile). The D-M(L) SLA achieves the highest lower 5th percentile of the final depletion distribution for this trial and is therefore considered to perform best.

BE10*. The G-G(H) SLA performs best as it achieves a higher lower 5th percentile of the N9(100 years) statistic and because most of the time-trajectories for the annual strike limit are close to need.

BE11*. The G-G and G-G(H) SLAs set the strike limit equal to need for all but a few years so perform best for this trial.

BE12. This trial is the most difficult from the viewpoint of resource conservation. Performance is not particularly good for any of the SLAs for this trial (they reduce the resource well below its initial level in many of the simulations) although it is considered to be only marginally plausible. The G-G SLA performs best for this trial because it achieves the highest values for the lower 5th percentile for the final depletion (D1) and relative increase (D10) statistics.

BE13. There is little to choose among the four SLAs for this trial. The G-G and G-G(H) SLAs perform better in terms of avoiding low final depletions while the D-M and D-M(L)
SLAs allow some recovery and achieve greater need satisfaction.

BE14*. The D-M SLA performs best overall for this trial as it achieves the greatest level of need satisfaction over the last 80 years. The G-G and G-G(H) outperform the D-M and D-M(L) SLAs in satisfying need over the first 20 years.

BE16&. Need cannot be fully satisfied in this trial so the key aspect of performance relates to risk avoidance. The G-G SLA performs best for this trial by achieving full need satisfaction over the first 20 years and the highest lower 5th percentile of the final depletion distribution for the N91(100 years) statistic.

BE20&. The D-M SLA performs best in terms of median need satisfaction over the last 80 years while the G-G(H) SLA achieves the highest lower 5th percentile of need satisfaction. The G-G SLA outperforms the D-M(L) SLA in terms of the lower 5th percentile and median need satisfaction for this trial.

BE21+. The G-G(H) SLA outperforms the other SLAs in terms of satisfying need over the last 80 years.

BE22. All four SLAs perform equally well for the deterministic version of this trial. The performances of the two G-G(H) SLAs are marginally better than those of the two D-M SLAs in terms of need satisfaction when allowance is made for stochastic dynamics,

BE23&. The D-M SLA outperforms the other three SLAs in terms of median need satisfaction and the G-G(H) SLA achieves the highest lower 5th percentile of the need satisfaction distribution (100 years). The G-G and G-G(H) SLAs better satisfy need over the first 20 years.

BE24. This trial is difficult to interpret. All four SLAs allow substantial recovery of the resource. The G-G(H) SLA appeared to perform best as it achieved the highest need satisfaction over the 100-year period.

5.4 General features of the D-M and G-G SLAs

Examination of the results of the Evaluation trials and the technical specifications of the SLAs led to some preliminary observations regarding the four SLAs.

The G-G and G-G(H) SLAs perform better at satisfying need over the first 20 years of the 100-year period than the D-M and D-M(L) SLAs although the difference in performance is often insubstantial (the largest difference is 5% but most differences are less than 1%) and some of these differences may be due to the ‘snap-to-need’ feature that forms part of the G-G and G-G(H) SLAs. Over the entire set of Evaluation trials, 95% of the strike limits set by the G-G and G-G(H) SLAs were between 67 and 129; 95% were between 67 and 132 for the D-M and D-M(L) SLAs.

Upon inspection of the time trajectories of strike limits for Evaluation trials, the SWG noted that there were instances where each SLA provided strike limits that became more variable as time progressed, even though both procedures generally satisfied need well in the first 20 years.

In response to queries from the SWG, both developers noted that their SLAs were easily performance tuned, and in both cases tunings to increase risk avoidance were easier to achieve than tuning to increase need satisfaction. The D-M SLA has one explicit tuning parameter, but it was noted that in order to achieve a wider range for the need satisfaction-risk avoidance trade-off, it might be necessary to add additional tuning parameters. The G-G SLA has several tuning parameters, and can also be tuned through a revised H-optimisation step.

It was noted that both the G-G and D-M SLAs employed a protection level below which harvest could be limited. In both cases, the estimated stock size based on all available data must be above 2,000 to avoid the possibility of a zero strike limit. It was noted that these protection levels had never been invoked by either SLA in any of the bowhead Evaluation trials, and that the location and severity of such protection levels could be easily adjusted or removed with no effect on Evaluation trial results and probably limited effect on Robustness trials. It was also noted that such a protection level was broadly consistent with the current management scheme expressed in sub-Paragraph 13(a) of the Schedule i.e. there is some minimum population level below which catches should not be taken.

The preliminary calculations of advisable catch used by the G-G SLA are a piecewise linear function of time, and the final strike limits are subject to two intermediate protection levels that are invoked only after 35 years of management. Many members believed that the performance gains produced by this strategy were not sufficient to warrant reliance on an SLA that produced strike limits that were not guaranteed to be a continuous function of time. Small changes in the abundance data could have disproportionately large impacts on strike limits. It was noted that the SWG had previously agreed to place no limitations on the use of the time variable in SLAs. However, some uses of time-dependence are less desirable than others. This aspect of the G-G SLA is one that might be improved with future work.

It was noted that both SLAs included design aspects that the SWG believed could be improved with further opportunity for development, but it was unclear whether these changes would result in substantial improvements in performance.

In order to observe how the SLAs react to a sharp decline in abundance, the SWG agreed that an exploratory trial should be conducted in which the population size drops to 2,000 in the first year of the projection period. This is not because the SWG believes that such a scenario is even remotely plausible (and thus it is neither an Evaluation nor a Robustness trial) but it will provide information that can be used to assess the relative speed at which the SLAs react to large changes in population size. However, the SWG noted that such a trial would be difficult to interpret since there are both positive and negative aspects of reacting quickly to such a change. The SWG believed that large changes in population size approaching this magnitude would lead to an Implementation Review; the SLA would not be applied blindly for 100 years even though the survey estimates dropped markedly.

5.5 Comparison of SLAs using the Robustness and Cross-validation trials

The purpose of the Robustness trials is to examine whether a preferred SLA performs as expected when it is used to manage scenarios that are plausible but (occasionally much) less likely than those that underlie the Evaluation trials. They may also be used as a method of selecting between two SLAs that are ‘tied’ after examination of performance on the Evaluation trials.

The SWG considered the performance of the four SLAs on the Robustness trials. All four SLAs perform well for the Robustness trials. The BR12-9 and BR06-12S trials were most notable in terms of distinguishing among the SLAs. The G-G and G-G(H) SLAs achieve better risk avoidance than the D-M and D-M(L) SLAs for these trials. The SWG did not have the full set of results for trials BR16E-9S (large and temporally correlated environmental variability) and
BR-11a (reductions in natural mortality). The results for the modified versions of these trials should be examined at the proposed intersessional workshop.

The SWG reviewed the current Robustness trials and agreed to modify them as follows:

1. Delete trials BR01-10 and BR08a-20 as they lead to unrealistic time-trajectories of population size.
2. Delete all Robustness trials based on a constant need of 67 and MSYR1 = 2.5% as these trials are not informative.
3. Delete trials BR05a-1, BR05b-1, BR12-10, BR12-108, BR14-10 and BR17-9 as these trials are not informative.
4. Delete trials BR07b-1 and BR08a-16 as their stochastic variants are more challenging.
5. Recondition trial BR06b-1 in hope of eliminating several highly atypical trajectories produced by the currently conditioned parameter sets.
6. Improve the interpretability of the plots that show time-trajectories of population size for all Robustness trials in which carrying capacity changes with time. The plots would be clearer if there was a dotted line showing the pointwise median time-trajectory of population size under zero catch for comparison with the simulated trajectories.
7. Reduce the extent to which natural mortality increases over time for the BR11a trials so that the population can avoid extinction under zero catch.

Cross-validation trials are case-specific trials to be held aside from SLA development so that resulting SLAs can be subjected to a subsequent independent test. Cross validation is an informal check for whether the selected SLAs perform roughly as expected. The Cross-validation trials conducted intersessionally examine whether unpredictable behaviour occurs within the interior of a tested region of parameter space due to over-fitting.

No evidence for over-fitting is evident from the results of the five Cross-validation trials, which are interpolative, nor from the Robustness trials which examine behaviour for scenarios beyond the Evaluation trials. The SWG agreed to increase the number of Cross-validation trials from five to 10 to better sample the distributions for the model parameters considered in the Cross-validation trials. It also agreed to increase the range for the estimated survey CV from 0.1-0.25 to 0.1-0.4 so that the value that forms the central value for the Evaluation trials is also the central value for the Cross-validation trials.

5.6 Selection of preferred SLA(s)
The SWG considered an enormous quantity of tabular and graphical material at this meeting as part of the evaluation and selection process. It was clear from this that it had two excellent procedures available (four variants) which exhibited very similar performance. Given the similarity, selection of a single procedure from the vast array of results is not a trivial task, even if more time was available. In addition, the SWG had identified a number of issues that it wished to consider in more detail, in terms of further plots for some of the Robustness trials, modifications to certain Robustness trials, additional Cross-validation trials and further work on certain issues concerning each of the procedures (see Item 13). The SWG agreed that given the importance of the decision, the complexity of integrating the performance results before it and the additional work identified, it preferred to postpone a final decision.

In the ‘ideal’ workplan given in SC/53/Rep1, the SWG had stated that it would ‘examine trial results and determine ‘preferred’ candidate(s)’. Given the importance of the decision, the SWG agreed that it would still be able to meet its ‘ideal’ timetable if it did not choose a single candidate for presentation at the present meeting. It therefore recommends that the work identified in Item 13 be undertaken and that the results be examined at an intersessional workshop. The SWG agreed that this would enable it to make a recommendation for an SLA for the Bering-Chukchi-Beaufort Seas stock of bowhead whales to the Committee at the 2002 Annual Meeting.

6. REVIEW OF GRAY WHALE TRIALS

There was insufficient time to consider the further development of gray whale trials at this meeting, and no new SLAs for this fishery were presented. SC/53/AWMP6, in an application to gray whales, further elucidated the features of the inertia dynamics model whose development was encouraged by the SWG in recent years. Although the SWG did not have time to review this document, it was discussed in some detail in Annex F. It was agreed to informally consider aspects of gray whale trial development after the close of the SWG meeting and via the intersessional working group.

7. PROGRESS ON DEVELOPMENT OF POTENTIAL SLAS FOR GREENLANDIC FISHERIES AND THE GREENLAND RESEARCH PROGRAMME

As noted in previous years, little progress is envisioned in this regard until results from the Greenland Research Programme become available. The SWG considered the Greenland Research Programme (e.g. see SC/53/Rep1) in the context of possible data needs for a management procedure for Greenlandic whaling. It builds upon previous discussions (e.g. IWC, 2001b). It was agreed to focus on West Greenland, since catches off East Greenland are few.

7.1 The fisheries
Currently exploited species are fin and minke whales. Basic information on the geographic and seasonal distribution of fin and minke catches is given in Witting (2000). Catches of minke whales are now mainly inshore within the West Greenland archipelago.

7.2 Stock structure, range, movement
A major problem is the lack of information on the identity and range of the stocks from which the catches are taken (see IWC, 2001b). Witting et al. (2000) and SC/53/O2 reported on feasibility studies of biopsy sampling of minke whales in this area. Despite certain problems with the design and execution of these feasibility studies (e.g. see IWC, 2001b and SC/53/Rep1), the SWG concluded that it is unlikely to be possible to biopsy sufficient animals for the stock structure studies proposed last year.

SC/53/O2 reported on a fin whale that was satellite-tagged on 30 September 2000 in coastal West Greenland (68°42’N 52°50’W). It remained in the area until at least 13 October. On 16 and 17 October it was found further south, about 175 km off the coast of West Greenland. On 20 October it had moved approximately 250km southeast to another inshore area. It moved another 100km south along the coast and up to 50km off the coast until 2 November, then appeared back in the area it was located at on 20 October. The last position
The SWG noted that although satellite tagging was no easier, the technique is more promising because useful information on movements of animals in the hunted stock can be obtained from a smaller sample size than that required for a biopsy programme.

7.3 Abundance and trends

Inshore surveys within the archipelago are relatively feasible due to the more favourable weather conditions. Witting indicated that an annual shipborne survey of the inshore area might more readily get support, given that the survey could record other wildlife in addition to cetaceans. The surveys could sample an area in which approximately 80% of the catches occur, and could thus provide an index of abundance directly related to the stock components being exploited. Since a relative abundance series first becomes useful after about 10 annual data points have been collected, it is a long-term project that should preferably be conducted within the means available within Greenland for research.

The usual data collection protocols for shipborne line transect surveys, including dual platforms, could be followed. Survey designs within the archipelago will be constrained by navigational conditions, so it not certain that sighting rates could be expanded to abundance estimates. In any case, such a study area presumably represents only a small part of the summer range of the stocks. A fixed-track design, repeating the same track each year, would be the best approach for producing an abundance index. The surveys should be conducted in late summer in the period of maximum minke whale abundance. One would also expect greater inter-annual consistency at this time, given that the time of the arrival of whales early in summer can vary considerably.

The SWG recognised that an abundance index alone would probably not provide a sufficient basis for a management procedure, and would need to be supplemented with surveys covering a larger area for which absolute abundance should be estimated. A large-scale survey at ca 10-15 year intervals may be realistic, but would require external funding. The logistics of offshore surveys are less favourable than inshore surveys, with much time lost to poor weather.

Satellite tracking data, even of a limited number of individuals, is important for determining the summer range of whales from the hunted stock, and hence the area that should be surveyed. Satellite tagging could be conducted from survey vessels, but would require dedicated time during which ordinary survey mode is suspended.

7.4 Preliminary consideration of management procedures

Work done during the development of the RMP indicated: (1) absolute abundance surveys conducted at 10-year intervals were nearly as useful as five-yearly surveys; (2) annual indices of relative abundance can provide a valuable supplement to the absolute abundance estimates, provided the indices are reasonably valid, albeit not linearly proportional to abundance.

The SWG agreed that preliminary trials of simple management procedures using an annual inshore abundance index coupled with 10-yearly surveys be conducted before the next Annual Meeting. These must cover cases where there is inter-annual variability in the index. The results of these would help determine the utility of proceeding with the annual series of inshore surveys starting in late summer 2002.

A problem with a relative abundance index is that it could decline for reasons possibly unrelated to exploitation. In such circumstances, it might be necessary to bring forward the next absolute abundance survey of the larger area.

The group recognised that sightings of fin whales in the annual inshore surveys would be few in number, such that it might not be possible to obtain a useful index for this species. Given the poor prospects for obtaining substantial information on this species in the area, due to its low numbers and other factors, it might be appropriate, at some future time, to consider management approaches in which the specified need (640 tonnes of meat annually) is met without any hunting of fin whales.

7.5 Biological data

Greenland intends to collect tissue samples from as many caught animals as possible. These should be analysed on an ongoing basis and compared with samples from other countries (e.g. Iceland, Canada, USA), with a view to determining possible relationships of West Greenland minke whales to those in other areas based on haplotype frequencies. It may be possible to have this work undertaken at no cost to Greenland or the IWC, by geneticists who have a scientific interest in the material.

7.6 Recommendations

7.6.1 Annual inshore surveys

Planning should proceed for an annual series of inshore surveys starting in late summer 2002, with a view to producing a relative abundance index, preferably within the research resources available within Greenland. Survey design should take account of the available information on the distribution of the target species. Detailed survey plans and methodology should be developed during the intersessional period and presented to the AWMP group for review. Funding for such surveys should be considered the responsibility of the Greenland Home Rule Government.

7.6.2 Exploratory simulation studies

Preliminary simulation studies of management procedures should be conducted utilising a combination of an annual relative index and infrequent absolute abundance estimates. Witting, Magnússon, Deroeksdotir and Cooke agreed to cooperate on this issue and present results to the 2002 Annual Meeting. It was agreed that this would be a suitable case for funding from the AWMP Developers’ Fund. Results from this preliminary work may or may not indicate modification of the plans for the inshore index surveys.

7.6.3 Satellite tagging

An annual programme of satellite tagging in conjunction with the inshore surveys should be started in 2002, with the aim of gradually building up records of animal movements, based on a target of four informative tracks per year. IWC funding should be provided to cover the costs themselves, equipment, personnel and some ship time from the surveys for the tagging. It was agreed that the remaining £36,000 from the funds allocated to the Greenland Research programme last year should be spent on this work, over the next two years as follows:
Summer 2002: personnel £4,000, travel £1,000, 4 tags £8,000, 5 days ship time £5,000 (Total £18,000).
Summer 2003: personnel £4,000, travel £1,000, 4 tags £8,000, 5 days ship time £5,000 (Total £18,000).

7.6.4 Planning for a large-scale survey
Based on the results of the first few years of satellite tagging, which are used to determine the area to be surveyed, plans should be drawn up for a large-scale survey to be held in about five years time. The intention is that subsequent surveys would be conducted at infrequent (10-15 year) intervals, with the area to be covered to be based on the state of knowledge on stock range at the time.

8. PROGRESS ON CONSIDERATION OF FISHERY TYPE 3
The SWG has defined a type 3 fishery to be characterised by a small total population size (of the order of 300 animals) where demographic and environmental stochasticity may have potentially critical effects on the survival of the stock and aboriginal harvest of even a few whales would be a matter for very careful scrutiny.

The SWG regretted that it did not have time to consider the interesting and important work described in SC/53/AWMP2 submitted for consideration under this item. It urged Punt and Breiwick to resubmit this paper at the next opportunity because the SWG was enthusiastic about studying its implications for the management of a type 3 fishery.

9. SCIENTIFIC ASPECTS OF AN ABORIGINAL SUBSISTENCE WHALING SCHEME
The SWG agreed that it was premature to consider the appropriateness of developing detailed specifications for the AWMP at the level that now exists for the RMP (IWC, 1999a) and its associated guidelines with respect to surveys and data.

However, there are a number of issues the SWG wished to draw to the Commission’s attention.

9.1 ‘Rules’
9.1.1 Carry-over
Last year, the Committee presented the Commission with the following illustration:

For the purposes of illustration only, it is assumed that the block is 5 years, that the total strike limit over the 5 year period is 500 and that an inter-annual carryover allowance of 50% is permitted. The block length and the percentage inter-annual carryover allowance are numbers for which explicit advice is required from the Commission. The total block quota is then divided by the number of years to provide an average annual quota. The strike limit set for any one year should normally be allowed to exceed this average annual quota by 50%, provided that the total strikes allowed during a block do not exceed the block limit (plus any carryover brought into the block). The same 50% allowance may be carried over between the last year of one block and the first year of the next block; it does not impact the overall block limit.

In response the Commission agreed:

that blocks of five years with an inter-annual variation of fifty per cent were satisfactory in terms of allowing for the likely variability in hunting conditions. It therefore agreed that these values are appropriate for use in trials. It was recognised that this does not commit the Commission to these values in any final aboriginal whaling management procedure.

In order to allow the Commission to consider this further, the SWG notes that if under a recommended SLA, current need is met (and there is no indication from the present results that this will not be the case), then a revised Schedule paragraph might look something like that below:

For the years [2003-2007] inclusive, the total number of strikes shall not exceed [330]. The Strike Limit in any one year shall not exceed [100].

9.1.2 Phase-out (and survey interval)
Weather and ice conditions often prevent the completion of a successful bowhead abundance survey even when all best efforts are made. Since 1988, three successful censuses have been made (1988, 1993 and 2001) in six attempts.

Phase-out is the process by which annual strike limits should be gradually decreased to zero in the absence of a new abundance estimate. The SWG recommends that phase-out should begin in the 10th year after the year of the most recent abundance estimate. Since it might require several attempts to obtain a successful abundance estimate, this could mean that an attempt to undertake a census might begin after about seven years from the most recent success. This will probably result in a survey interval of about 7-10 years in practice. The SWG draws attention to the fact that the risk and need satisfaction performance of the G-G and D-M SLAs was not diminished in Evaluation trials when surveys occurred at 10-year rather than 5-year intervals.

The SWG also discussed the appropriate length and abruptness of the phase-out itself. One phase-out method might be to reduce the strike limit by 20% for each year starting in the 10th year after the most recent abundance estimate. This would be in line with the rule in the RMP. However, in the limited time available for discussion, the SWG noted that there are several other potentially useful approaches to phase-out that require further consideration. It agreed that it would consider this issue further during the coming year.

Finally, the SWG considered the issue of the quantity to which any phase-out rule would be applied. SLAs generally estimate a maximal allowable catch, which is then reduced to the need level if it exceeds need. If the phase-out rule was applied to the maximal allowable catch before comparison with the need level, this could eliminate the gradualness of the phase-out and delay its invocation. If instead the phase-out rule was applied to the strike limit after it was bounded by the need level, this could provide an inducement for the hunters to seek increases in the need level to soften the potential effects of phase-out.

The SWG requested that the Commission review its progress on survey interval and phase-out to confirm that the introduction of phase-out in the 10th year after the most recent abundance estimate would be an approach compatible with its management goals. Furthermore, the SWG asked the Commission to indicate if it wished to impose any constraints on: (1) the type of phase-out rule employed; (2) the maximum length of time it would take for phase-out to reach zero strikes; and (3) the quantity to which phase-out should be applied.

9.2 Guidelines for surveys
The SWG considered three issues related to abundance estimates for use in an SLA. It restricted itself at this stage to considering SLAs that require an absolute abundance estimate. This is the case for the SLAs for bowhead whales currently under consideration.
The SWG agreed to the principles below.

9.2.1 Survey/census methodology and design
The SWG agreed that plans for undertaking a survey/census should be submitted to the Scientific Committee in advance of their being carried out, although prior approval by the Committee is not a requirement. This should normally be at the Annual Meeting before the survey/census is being carried out. Sufficient detail should be provided to allow the Committee to review the field and estimation methodology. Considerably more detail would be expected if novel methods are planned.

9.2.2 Committee oversight
The SWG agreed that it was appropriate that should it desire, the Scientific Committee could nominate one of its members to observe the survey/census to ensure that proposed methods were adequately followed. This would be more important if novel methods were being used.

9.2.3 Data analysis
The SWG agreed that it was appropriate that all data to be used in the estimation of abundance were made available to the Scientific Committee suitably in advance of the Annual Meeting at which an estimate was to be presented. If new estimation methods are used, the Committee may require that computer programs (including documentation to allow such programs to be validated) shall be provided to the Secretariat for eventual validation by them.

9.3 Guidelines for data/sample collection
The SWG agreed that data from each harvested animal should be collected and made available to the IWC. The following information should normally be provided for each whale: species, number of animals, sex, season, position of catch (to the nearest village), length of catch (to 0.1m). It further requested that information/samples on reproductive status and samples for genetic studies be collected where possible.

10. PRESENTATION TO THE COMMISSION
The Committee reiterated the importance it attached to continuing dialogue with the Commission and hunters throughout the development process. It referred to Item 9 above and recommends, as in previous years: (1) a presentation by the Chairman of the SWG of its report and a less technical Chairman’s discussion paper; and (2) informal discussions among the SWG Chairman and interested Commissioners.

11. MANAGEMENT ADVICE FOR MINKE AND FIN WHALES OFF GREENLAND
The SWG noted that in 2000, 142 minke whales (102 females, 36 males, 4 unknown) were taken off West Greenland and three were struck-and-lost. In the same year, 10 minke whales (2 males and 8 females) were taken off East Greenland and 6 fin whales (3 males and 3 females plus 1 struck-and-lost animal) were taken off West Greenland.

The SWG recalled that the Committee has never been able to provide satisfactory scientific advice on either the fin or minke whales off Greenland. It reflects the lack of data relating to both stock structure and abundance and is the reason the Committee first called for a Greenland Research Programme to be established in 1998 (IWC, 1999b). This inability to provide advice is a matter of great concern, particularly in the case of fin whales where the best available abundance estimate is from 1987/88 and is only 1,096 (95%CI 520-2,106), and the SWG urges continued funding of the research discussed under Item 7 above at the requisite levels, by both Greenland and the IWC. It reminds the Commission that without such information it may be many years before it is able to provide satisfactory scientific advice on these stocks. Even with the success of the programme, it is difficult to envisage that the SWG will be able to develop a suitable SLA (or SLAs) for the Greenlandic fisheries before 2006.

12. WORK PLAN
The SWG agreed that a small working group chaired by Donovan would continue to meet after the close of the SWGs business to: (1) develop a detailed work plan related to the work necessary to be completed on the D-M and G-G SLAs including deadlines for both developers and for computing tasks; (2) to determine the timing, costs and venue of an intersessional workshop; and (3) to refine the work needed to move towards final specification of Robustness trials and Cross-validation trials for the gray whale. Item 1 is reported in Appendix 4.

The SWG recommended the continuation of the AWMP developers’ fund at the level of £8,000. Donovan noted that this fund had been critical to the SWG’s rapid AWMP development pace and to the excellent quality and quantity of SLAs submitted for consideration thus far.

13. ADOPTION OF REPORT
The SWG congratulated Allison for completing the many tasks requested of her during this year’s meeting and during the last meeting. The report was adopted at 9:00am on July 14, 2001.

Dr N. Grandy, Secretary to the Commission, 25 April 2005
Preface

Welcome to the seventh of the series, the ‘Annual Report of the International Whaling Commission’. Subscription details for the publications of the International Whaling Commission can be found on the Commission web site (www.iwcoffice.org), by e-mailing subscriptions@iwcoffice.org or by the more traditional means of writing, telephoning or faxing the Office of the Commission (details are given on the title page and on the back cover of this volume).

This report contains the Chair’s Report of the Fifty-Sixth meeting of the IWC, held in Sorrento, Italy in July 2004. The text of the Convention and its Protocol are also included, as well as the latest versions of the Schedule to the Convention and the Rules of Procedure and Financial Regulations. The Chair’s Report includes the reports of the Commission’s technical and working groups as annexes.

This year has seen the retirement of one of the longest-serving members of the Secretariat, Daphne Ransom, the Assistant to the Executive Officer. Daphne had served the IWC admirably since the establishment of a permanent Secretariat in 1976. The Commission offers its best wishes for her in the future.

Cover photograph: Statue of St Antonino, an Abbot and the patron Saint of Sorrento, thought to have died on 14 February 830AD. He is a popular saint amongst seamen. The most famous miracle attributed to him was that he freed a young boy swallowed by a whale.

G.P. DONOVAN

    Rules of Procedure of the Scientific Committee ..................................................... 168
Chair’s Report: Contents

1. INTRODUCTORY ITEMS ......................................................................................................................... 5
   1.1 Date and place .......................................................................................................................................................... 5
   1.2 Welcome address ....................................................................................................................................................... 5
   1.3 Opening statements .................................................................................................................................................. 5
   1.4 Credentials and voting rights ................................................................................................................................. 6
   1.5 Meeting arrangements .............................................................................................................................................. 6

2. ADOPTION OF AGENDA. .............................................................................................................................. 6

3. SECRET BALLOTS ............................................................................................................................................. 7
   3.1 Proposed amendment to Rule of Procedure E.3(d) ................................................................................................. 7
   3.2 Commission discussion and action arising ............................................................................................................. 7

4. WHALE STOCKS .............................................................................................................................................. 7
   4.1 In-depth assessment of western North Pacific common minke whales ............................................................... 7
   4.2 Antarctic minke whales .......................................................................................................................................... 7
   4.3 Southern Hemisphere whales other than minke whales ....................................................................................... 8
   4.4 Other small stocks – bowhead, right and gray whales ......................................................................................... 9

5. ABORIGINAL SUBSISTENCE WHALING ........................................................................................................ 10
   5.1 Aboriginal subsistence whaling procedure ........................................................................................................ 10
   5.2 Aboriginal subsistence whaling scheme (AWS) ..................................................................................................... 12
   5.3 Aboriginal subsistence whaling catch limits ......................................................................................................... 13
   5.4 Revision of Schedule paragraph 13 ....................................................................................................................... 15

6. REVISED MANAGEMENT SCHEME. ........................................................................................................... 17
   6.1 Revised Management Procedure (RMP) ............................................................................................................... 17
   6.2 Revised Management Scheme (RMS) .................................................................................................................... 21

7. WHALE KILLING METHODS AND ASSOCIATED WELFARE ISSUES ....................................................... 28
   7.1 Reporting on data on whales killed and on improving the humaneness of whaling operations ....................... 30
   7.2 Commission discussion and action arising ......................................................................................................... 30

8. SANCTUARIES ............................................................................................................................................... 32
   8.1 Review of the Southern Ocean Sanctuary ........................................................................................................ 32
   8.2 Improvements to the review process ........................................................................................................................ 33
   8.3 South Pacific Sanctuary ....................................................................................................................................... 34
   8.4 South Atlantic Sanctuary ..................................................................................................................................... 35

9. SOCIO-ECONOMIC IMPLICATIONS AND SMALL-TYPE WHALING ............................................................ 36
   9.1 Proposed Schedule amendment for the taking of minke whales in the North Pacific ........................................ 36
   9.2 Proposed Resolution on Japanese Community-Based Whaling ............................................................................. 37
   9.3 Proposed Schedule amendment for the taking of Bryde’s whales from the Western Stock of the North Pacific. 37

10. SCIENTIFIC PERMITS. ............................................................................................................................. 37
    10.1 Report of the Scientific Committee .................................................................................................................. 37
    10.2 Commission discussions and action arising ..................................................................................................... 38

11. ENVIRONMENTAL AND HEALTH ISSUES. ............................................................................................ 39
    11.1 Integration of environmental concerns with other Scientific Committee work and habitat-related issues .... 39
    11.2 Reports from Contracting Governments ........................................................................................................ 40
    11.3 Health issues ...................................................................................................................................................... 40

12. WHALEWATCHING. ................................................................................................................................. 40
    12.1 Report of the Scientific Committee .................................................................................................................. 40
    12.2 Commission discussions and action arising ..................................................................................................... 40

13. CO-OPERATION WITH OTHER ORGANISATIONS. .............................................................................. 41
    13.1 Report of the Scientific Committee .................................................................................................................. 41
    13.2 Commission discussions and action arising ..................................................................................................... 41

14. OTHER SCIENTIFIC COMMITTEE ACTIVITIES, ITS FUTURE WORK PLAN AND ADOPTION OF THE SCIENTIFIC COMMITTEE REPORT ........................................................................... 42
    14.1 Small cetaceans .................................................................................................................................................. 42
    14.2 Other activities ................................................................................................................................................... 43
    14.3 Scientific Committee future work .................................................................................................................... 44
    14.4 Adoption of the Report ................................................................................................................................... 46
15. CONSERVATION COMMITTEE.  
15.1 Report of the Conservation Committee.  
15.2 Commission discussions and action arising.  
16. CATCHES BY NON-MEMBER NATIONS.  
17. FUTURE SUSTAINABLE WHALING.  
17.1 Introduction by Japan.  
17.2 Commission discussions and action arising.  
18. INFRACTIONS, 2003 SEASON.  
18.1 Report of the Infractions Sub-committee.  
18.2 Commission discussions and action arising.  
19. LEGAL ADVICE IN RELATION TO THE IWC.  
19.1 Proposal regarding legal advice in relation to the IWC.  
19.2 Commission discussions and action arising.  
20. ADMINISTRATIVE MATTERS.  
20.1 Annual Meeting arrangements and procedures.  
20.3 NGO participation.  
21. FORMULA FOR CALCULATING CONTRIBUTIONS.  
22. FINANCIAL STATEMENTS AND BUDGETS.  
22.3 Secretariat offices.  
22.4 Budgetary Sub-committee rota.  
22.5 Other matters.  
23. ADOPTION OF THE REPORT OF THE FINANCE AND ADMINISTRATION COMMITTEE.  
24. DATE AND PLACE OF ANNUAL AND INTERSESSIONAL MEETINGS.  
24.3 Other.  
25. ELECTION OF THE CHAIR AND VICE-CHAIR.  
26. ADVISORY COMMITTEE.  
27. SUMMARY OF DECISIONS AND REQUIRED ACTIONS.  
28. OTHER MATTERS.  
29. AMENDMENTS TO THE SCHEDULE.  

Annex A Delegates and Observers Attending the 55th Annual Meeting.  
Annex B Agenda for the 55th Annual Meeting.  
Annex C Resolutions Adopted during the 56th Annual Meeting.  
Annex E Chair’s Proposals for a Way Forward on the RMS.  
Annex F Statement from Henrik Fischer, Chair of the Commission, to the Private Meeting of Commissioners/Alternate Commissioners on the 16th July 2004.  
Annex N Amendments to the Schedule Adopted at the 56th Annual Meeting.
### SUMMARY OF MAIN OUTCOMES, DECISIONS AND REQUIRED ACTIONS
### FROM THE 56TH ANNUAL MEETING

The main outcomes, decisions and required actions arising from the 56th Annual Meeting of the IWC are summarised in the table below.

<table>
<thead>
<tr>
<th>Issue</th>
<th>Outcomes, decisions and required actions</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Status of stocks</strong></td>
<td><strong>Antarctic minke whales</strong>&lt;br&gt;• Completion of the revised abundance estimate for Antarctic minke whales continues to be a high priority given that there is no agreed current estimate.</td>
</tr>
<tr>
<td></td>
<td><strong>Western North Pacific common minke whales</strong>&lt;br&gt;• The Scientific Committee expects to begin an in-depth assessment of western North Pacific common minke whales, with a focus on the J stock, at next year’s Annual Meeting.</td>
</tr>
<tr>
<td></td>
<td><strong>Southern Hemisphere blue whales</strong>&lt;br&gt;• The Scientific Committee agreed that (1) on average, the Antarctic blue whale population is increasing at a mean rate of 7.3% per year; (2) had an estimated circumpolar population size of 1,700 (95% CI 860-2,900) in 1996; and (3) that this population is still severely depleted compared with pre-exploitation levels.</td>
</tr>
<tr>
<td></td>
<td><strong>Right whales</strong>&lt;br&gt;• The Scientific Committee again reiterated its recommendation that it is a matter of absolute urgency that every effort be made to reduce anthropogenic mortality in the North Atlantic right whale stock to zero. Right whales continue to die or become seriously injured by entanglements in fishing gear or ship strikes. The remaining population is estimated at between 300 and 350 animals.</td>
</tr>
<tr>
<td></td>
<td><strong>Western North Pacific gray whales</strong>&lt;br&gt;• The Scientific Committee noted with great concern that the evidence is compelling that this population (only about 100 whales) is in serious danger of extinction and that it faces an obvious and immediate threat from industrial activities, including noise, vessel traffic and the potential for a catastrophic oil spill. It recommended as a matter of urgency that measures be taken to protect this population and its habitat off Sakhalin Island and that research and monitoring programmes on this stock by range states continue and expand.</td>
</tr>
<tr>
<td></td>
<td>• The Commission adopted Resolution 2004-1 that inter alia: (1) endorsed the Scientific Committee’s conclusions and recommendations; (2) called on range states to actively pursue all practicable actions to eliminate anthropogenic mortality in this stock and to minimise anthropogenic disturbances in the migration corridor and on breeding and feeding grounds; and (3) requested the Secretariat to offer its services and scientific expertise to organisations concerned with oil and gas development projects and exploration projects in the Sakhalin area.</td>
</tr>
<tr>
<td></td>
<td><strong>Small cetaceans</strong>&lt;br&gt;• The Scientific Committee reviewed the status of franciscana and made a number of recommendations including the need for improved estimates of abundance and bycatch. The Committee expressed concern over the status of the vaquita and West Greenland stocks of white whales and narwhals.</td>
</tr>
</tbody>
</table>

<p>| Aboriginal subsistence whaling | <strong>Aboriginal Whaling Management Procedure</strong>&lt;br&gt;• The Commission endorsed and adopted the <em>Strike Limit Algorithm (SLA)</em> for eastern North Pacific gray whales proposed by the Scientific Committee. This follows the 2002 adoption of an SLA for the Bering-Chukchi-Beaufort stock of bowhead whales. The Committee will now work to develop a similar approach for the management of Greenlandic whaling. |
| Catch limits | • The Commission agreed that no changes to the block quotas renewed in 2002 were needed. The Scientific Committee reiterated its grave concern at being unable to provide management advice on Greenlandic whaling. |
| Review of Schedule paragraph 13 | • Schedule language dealing with the different aboriginal subsistence hunts was consolidated and harmonised. |</p>
<table>
<thead>
<tr>
<th>Issue</th>
<th>Outcomes, decisions and required actions</th>
</tr>
</thead>
</table>
| **Whale killing methods and associated welfare issues** | • The Commission passed Resolution 2004-3 requesting further work from the Working Group on Whale Killing Methods and Associated Welfare Issues, and in particular to:  
  ➢ examine methods for reducing struck and lost rates;  
  ➢ consider the welfare implications of methods used to kill whales caught in nets;  
  ➢ advise the Commission on establishing better criteria for determining the onset of irreversible insensibility and death, methods for improving the efficiency of whale killing methods and reducing times to death and other associated welfare issues. |
| **The Revised Management Scheme (RMS)** | • The Commission endorsed the Scientific Committee’s Requirements and Guidelines for Implementations and the revised Requirements and Guidelines for Conducting Surveys and Analysing Data within the RMS.  
  • The Commission endorsed the Scientific Committee recommendation to initiate a pre-implementation assessment for North Atlantic fin whales and the plans to hold a Workshop on the pre-implementation assessment of western North Pacific Bryde’s whales.  
  • The Commission reviewed a proposal from the Chair for an RMS ‘package’ of measures.  No agreement was reached but Resolution 2004-6 was adopted aimed at having draft text and technical details of an RMS ready for consideration, including for possible adoption, at IWC/57, and/or to identify any outstanding policy and technical issues. The Resolution included a plan of work that revived the RMS Working Group (that last met at IWC/54 in 2002), established a Small Drafting Group and various technical specialist groups and required considerable intersessional work. |
| **Sanctuaries** | • **Southern Ocean Sanctuary (SOS)**  
  • The Scientific Committee completed its review of the sanctuary as required by the Schedule. The Committee agreed that: (1) whales are not effectively protected from whaling in the SOS, because such Sanctuaries apply only to commercial whaling, and because (apart from stocks that migrate to the IOS) whales also migrate outside of the SOS boundaries; (2) the boundaries of the SOS were appropriately established for some, but not for all stocks; (3) it was not possible to completely evaluate the effectiveness of the SOS because the scientific objectives are not clear and are not associated with quantifiable performance measures. The Committee respectfully requested that the Commission considers clarifying the objective(s) of the SOS in order to allow the Committee to discriminate among designs that would, *inter alia*: protect whales; protect whale species diversity; and increase whaling yields outside the Sanctuary.  
  • A proposed Schedule amendment that would abolish the Southern Ocean Sanctuary and authorise the take of 2,914 minke whales for each of the 2004/05 to 2008/09 seasons was not adopted.  
  • The next SOS review will take place in 2014 unless the Commission decides otherwise.  
  **Proposals for new sanctuaries in the South Pacific and South Atlantic**  
  • As last year, two Schedule amendments were proposed to create sanctuaries in (1) the South Pacific and (2) the South Atlantic. Neither was adopted. |
| **Socio-economic implications and small-type whaling** | • Two proposed Schedule amendments that would allow the resumption of community based whaling in Japan were not adopted. One proposal was for the taking of 100 minke whales each year for 3 years from the Okhotsk Sea-West Pacific stock. The other was for the taking of 150 Byrde’s whales each year for 5 years from the western North Pacific stock.  
  • Resolution 2004-2 was adopted, reaffirming the Commission’s commitment to work expeditiously to alleviate the continued difficulties to the Japanese coastal communities of Abashiri, Ayukawa, Wadaura and Taiji caused by the cessation of minke whaling. |
| **Scientific Permits** | • Discussions of the Scientific Committee focused on reviewing the results and future plans for the ongoing programmes of Japan (i.e. JARPA and JARPNIII) and Iceland. No consensus recommendations were made. Given that 2004/05 would be the last year of JARPA, the Committee agreed that it will undertake a full review of results from this 16-year programme once they are available, i.e. some time after the Annual Meeting in 2005.  
  • Last year, the Commission adopted Resolution 2003-3 that *inter alia*: (1) called on the Government of Japan to halt the JARPA programme or limit it to non-lethal research methodologies; and (2) recommended that no additional JARPA programmes be considered until the Scientific Committee has completed a review of (a) all JARPA results and (b) its abundance estimates for Southern Hemisphere minke whales. The Resolution also recommended that any future programmes should be limited to non-lethal research. As this Resolution remains in force, and to save time, Australia and other co-sponsors withdrew a similar proposed Resolution this year. |
<table>
<thead>
<tr>
<th>Issue</th>
<th>Outcomes, decisions and required actions</th>
</tr>
</thead>
</table>
| **Environmental issues**                                             | • The Scientific Committee agreed that there is now compelling evidence that military sonar has a direct impact on beaked whales in particular and that evidence suggests that some sound from other sources, including ships and seismic activities, gives cause for concern.  
• The Committee reported on progress with work on other habitat-related issues, including POLLUTION 2000+, collaborative research in the Antarctic, SOCER, Arctic issues and the habitat degradation workshop scheduled to take place in Siena in November 2004.  
• Discussions on ways to advance collaboration between the Standing Working Group on the Environment and the assessment-related sub-committees and working groups was initiated. |
| **Conservation Committee**                                           | • The first meeting of the Conservation Committee took place. It addressed general issues relating to the establishment and purpose of the Committee and considered: (1) its relationship with other bodies within the Commission; (2) terms of reference and working methods; (3) items that should fall under its auspices; (4) collaboration with other organisations; and (5) the development of a Conservation Agenda. |
| **Co-operation with other organisations**                            | • The Commission adopted Resolution 2004-5 that requested the Secretariat, *inter alia*, to explore possible synergies between IWC and the Global Environment Facility, including possible support of the involvement of developing country IWC members in projects related to scientific research and/or policies for scientific research concerning the conservation and management of whales. |
| **Future work of the Scientific Committee**                         | • The Commission adopted the report from the Scientific Committee, including its proposed work plan for 2004/2005 that includes activities in the following areas:  
  • Revised Management Procedure (RMP), particularly with respect to (1) finalising the guidelines and requirements for implementing the RMP; (2) completion of the *pre-implementation assessment* for western North Pacific Bryde’s whales; and (3) development of stock structure hypotheses as part of the *pre-implementation assessment* for North Atlantic fin whales.  
  • Estimation of bycatch based on genetic data and data from fisheries and observer programmes.  
  • Aboriginal Subsistence Whaling Management Procedure development particularly in relation to Greenlandic whaling.  
  • Annual reviews of catch data and management advice for eastern North Pacific gray whales, BCB bowhead whales, minke and fin whales off Greenland and humpback whales off St. Vincent and The Grenadines;  
  • In-depth assessments, with particular emphasis on abundance estimates for Southern Hemisphere minke and humpback whales;  
  • Review of the stock identity concept in a management context;  
  • Environmental concerns, with a focus on reviewing the report of the Habitat Degradation Workshop and the outcome of the special session on sea ice and whale habitat;  
  • Whalwatching (WW), with a focus on assessing possible population level impacts of WW on whales and the development of a scientific foundation for WW guidelines;  
  • Small cetaceans, including a review of the status of the finless porpoise.  
• The Scientific Committee also agreed, that given the case- and area-specific nature of the bycatch problem, to hold a series of broad-based regional Workshops focusing on regions where bycatch problems: (1) have been given priority by the Scientific Committee as part of its normal review process; and (2) are not already being addressed. |
<p>| <strong>Secret ballots</strong>                                                    | • A proposed amendment to the Commission’s Rules of Procedure that would increase the opportunities for using secret ballots was not adopted. |
| <strong>Dealing with legal issues</strong>                                        | • The Commission reviewed a paper outlining options on how it might address future legal issues arising within the IWC. The matter was referred to the meeting of the F&amp;A Committee at IWC/57. |
| <strong>Administration</strong>                                                   | • The Commission agreed that from IWC/57 next year, equipment facilities for simultaneous interpretation into French and Spanish should be provided for the Commission’s sub-groups (but not the Scientific Committee), the Commission plenary and private meetings of Commissioners. Governments wishing to make use of these facilities would have to provide the interpreters at their own cost. |</p>

<tr>
<td><strong>Administration cont.</strong></td>
<td>• The Commission also agreed to establish a small Task Force to work with the Secretariat to develop cost estimates and implications for the provision of document translation at Annual Meetings and to report to the F&amp;A Committee at IWC/57.</td>
</tr>
<tr>
<td><strong>Amendments to the Rules of Procedure and Financial Regulations</strong></td>
<td>• The Commission adopted revised rules regarding the procedure for the appointment of the Chair and Vice-Chair of the Scientific Committee.</td>
</tr>
<tr>
<td><strong>Frequency of meetings</strong></td>
<td>• Via Resolution 2004-7 the Commission decided to explore the principle of IWC meetings being held less frequently than annually as at present. It agreed to establish a working group to investigate and make recommendations on the implications of less frequent meetings. The Working Group should report to the Commission next year.</td>
</tr>
<tr>
<td><strong>Financial Contributions</strong></td>
<td>Interim Measure</td>
</tr>
<tr>
<td></td>
<td>• The Commission adopted Resolution 2004-4 designed to take into account the special position of very small countries in calculating financial contributions. Under the Interim Measure for calculating contributions, member countries are allocated into four capacity-to-pay groups based on their GNI and GNI per capita. Via Resolution 2004-4, the Commission decided that Monaco and San Marino should be transferred from capacity-to-pay Group 3 to Group 2 in view of their much smaller GNI compared with other countries in Group 3. This has the effect of reducing the financial contributions of Monaco and San Marino.</td>
</tr>
<tr>
<td><strong>Finance and Budget</strong></td>
<td>Finance statements and budget estimates</td>
</tr>
<tr>
<td></td>
<td>• The Commission approved the Provisional Financial Statement for 2003-2004 subject to audit. It also approved the budget for 2004-2005, including the research budget, and increases in the NGO observer fee from £570 to £590 and in the media fee from £30 to £35 for 2005.</td>
</tr>
<tr>
<td></td>
<td>Secretariat office accommodation</td>
</tr>
<tr>
<td></td>
<td>• The Commission agreed that for a number of reasons it would not be practical to relocate the Secretariat’s offices away from the Cambridge area, but requested the Secretariat to explore alternative premises locally.</td>
</tr>
<tr>
<td></td>
<td>Budgetary Sub-committee</td>
</tr>
<tr>
<td></td>
<td>• The Commission agreed changes to the membership rota for the Budgetary Sub-committee that included extending the term of members from two to three years, appointing a Vice-Chair as well as a Chair and creating two ‘open seats’ in addition to the nine allocated on the basis of the capacity-to-pay grouping. The Budgetary Sub-committee was requested to clarify the term for the open seats and the status of observers from Contracting Governments not members of the Sub-committee.</td>
</tr>
<tr>
<td><strong>Non-governmental organisations</strong></td>
<td>Participation</td>
</tr>
<tr>
<td></td>
<td>• The Commission requested the Secretariat to work with the Advisory Committee to explore how the Rules of Procedure might be amended with respect to criteria and fees for NGO participation (e.g. removal of the current requirement that NGOs must have offices in more than three countries; allowing NGOs to have more than one observer in the meeting room at any one time; revising the fee structure such that the effect of these changes, if put in place, would not have a significant impact on fees).</td>
</tr>
<tr>
<td><strong>Code of Conduct</strong></td>
<td>• The Commission agreed to establish a Working Group comprising Dominica, Iceland (convener), Japan, the Netherlands, New Zealand, St. Kitts and Nevis, Sweden and the USA to develop a draft Code of Conduct for NGOs for review at IWC/57. The code was to focus on NGO activities during the Annual Meeting and could, if appropriate, include provisions related to the loss of accreditation.</td>
</tr>
<tr>
<td><strong>Date and place of Annual Meetings</strong></td>
<td>• The 57th Annual and associated meetings in 2005 will be held in Ulsan, Republic of Korea during the period 30 May to 24 June.</td>
</tr>
<tr>
<td></td>
<td>• The 58th Annual Meeting in 2006 will be held in St Kitts and Nevis. The dates are to be determined.</td>
</tr>
<tr>
<td><strong>Election of the Vice Chair</strong></td>
<td>• Horst Kleinschmidt (South Africa) was elected as Vice-Chair to replace Carlos Dominguez Diaz (Spain).</td>
</tr>
<tr>
<td><strong>Advisory Committee</strong></td>
<td>• The Commissioner from Dominica was elected onto the Advisory Committee for a further two years to join the Chair (Denmark), the Vice-Chair (South Africa), the Head of Finance and Administration (Norway) and the UK Commissioner.</td>

Chair’s Report of the 56th Annual Meeting

1. INTRODUCTORY ITEMS

1.1 Date and place
The 56th Annual Meeting of the International Whaling Commission (IWC) took place from 19-22 July 2004 at the Hilton Sorrento Palace Hotel, Italy. In the absence of the Chair, Henrik Fischer (Denmark) and Vice-Chair, Carlos Dominguez (Spain) who were both unable to attend, the Commission elected by consensus Rolland Schmitten (USA) and Minoru Morimoto (Japan) as Acting Chair and Vice-Chair respectively for the duration of the meeting. A list of delegates and observers attending the meeting is provided in Annex A. The associated meetings of the Scientific Committee and Commission sub-groups were held at the same venue in the period 28 June to 16 July.

1.2 Welcome addresses
On the first morning of the meeting, Dr Giuseppe Ambrosio, Italy’s Commissioner to IWC welcomed all participants on behalf of the Government of Italy. He began by noting that while Italy gives great importance to the protection of cetaceans and is against the resumption of commercial whaling, it also respects those having different cultures and beliefs. He believed that because the concept of conservation is inextricably intertwined with the sustainable use of natural resources, it is logical that the conservation of whales be given due attention. Referring to Italy’s concern with regard to degradation of the marine environment, Dr Ambrosio was pleased to note that an IWC workshop on the effects of habitat degradation on cetaceans was scheduled to take place in Siena later in the year. He stressed the importance Italy gives to the use of sanctuaries and marine protected areas in cetacean conservation, given the uncertainties regarding the effects global changes have on the environment, and noted that together with France and Monaco, Italy had established a large sanctuary for the protection of cetaceans in the Mediterranean – 50% of which is in the high seas. Dr Ambrosio indicated that Italy would support the establishment of new sanctuaries in the Southern Hemisphere. Finally, he hoped that the pleasant setting of the Hilton Sorrento Palace Hotel, Italy. In the absence of the Chair, Henrik Fischer (Denmark) and Vice-Chair, Carlos Dominguez (Spain) who were both unable to attend, the Commission elected by consensus Rolland Schmitten (USA) and Minoru Morimoto (Japan) as Acting Chair and Vice-Chair respectively for the duration of the meeting. A list of delegates and observers attending the meeting is provided in Annex A. The associated meetings of the Scientific Committee and Commission sub-groups were held at the same venue in the period 28 June to 16 July.

1.3 Opening statements
The Chair welcomed the following six new Contracting Governments who had adhered since the last Annual Meeting:

- Mauritania – adhered on 23 December 2003;
- Hungary – adhered 1 June 2004;
- Tuvalu – adhered 30 June 2004;
- Côte d’Ivoire – adhered 8 July 2004;
- Belgium – adhered 14 July 2004; and

Reminding the meeting that the Commission’s practice is to invite oral opening statements only from new Contracting Governments – existing Contracting Governments and observers can submit written opening statements – the Chair invited the new member countries to address the meeting.

Mauritania noted that as a state with a coastline of over 700km, fishing has a predominant role, generating more than 50% of export income and about 25% of budgetary income. Its strategy for the exploitation of marine fishery resources is based on their sustainable use, but it also supports the protection of endangered marine species. Mauritania explained that this strategy is also the basis for its adherence to the IWC and to all other institutions involved in the regulation and management of marine resources. It noted that it will base its decisions on science and, where insufficient data are available, on the application of the precautionary principle.

Hungary noted that as a small country with high biodiversity, it has made great efforts to protect its environment. These efforts have been further strengthened by its recent accession to the European Union. It reported that over 10% of its territory is protected, with 10 national parks – one of which was established over 30 years ago. It has more than 1,000 protected species for which trade is prohibited. Although it is a land-locked country, Hungary believed that it could contribute to the preservation of the oceans – a common heritage of mankind.

A welcome address was also given by the On. Scarpa, Undersecretary of State, Ministero delle Politiche Agricole e Forestali at the opening of the second day of the meeting. Recognising fisheries as an ancient activity on the one hand but at the same time a modern and very topical activity, the On. Scarpa noted that regulating fisheries is as hard, if not harder than regulating other sectors of the economy because of the pressure placed on those responsible. He further noted that fisheries is an area where new policies are being tested to find the right balance between the conservation of natural resources and their commercial use, and referred to work within the European Union to develop a set of shared goals for fisheries in the Mediterranean. He stressed the need to involve all stakeholders, including the fishermen themselves. While being aware of the need to manage the social and cultural problems encountered in conservation, the On. Scarpa believed that cetacean conservation also requires scientists, governments, NGOs and the few whalers left to reflect on how this resource can be protected, noting the multiple risks to which cetaceans are exposed. He considered that the notion of a common resource is particularly cogent for cetaceans and referred to the United Nations Convention of Law of the Sea (UNCLOS) that allows governments to adopt more stringent conservation measures for cetaceans that those that might apply to other species. He also referred to the Monaco Agreement of November 1996 that acknowledges cetaceans as an integral part of the ecosystem and an agreement that has led governments to adopt a common approach to addressing a problem of common interest. Finally, he did not want the negative opinion expressed by some on whaling (an activity in which few are engaged) to influence the general opinion on fisheries (an activity that affects everyone). He saw no need for conflict between the environment and fishermen, stressing that there must be a relationship of mutual understanding with shared goals.
Tuvalu noted that its territory comprises eight low-lying atolls and reef islands scattered across the central Pacific Ocean. While its total land area is only 26 square kilometres, its ocean area covers almost one million square kilometres. Tuvalu therefore relies heavily on marine resources and is keenly aware of the impact of overfishing. It wishes to use and conserve marine resources wisely and prevent overexploitation. Since 1978, its national policies have tried to increase fish catches in Tuvalu waters, identify new stocks that have the potential for commercial exploitation, maximise financial returns from foreign fishing operators, and to improve the domestic management of its marine resources. Although whales migrate through its waters, there is no reliable inventory of species and numbers. Tuvalu wishes to establish a long-term whale research programme and would be pleased to receive any technical support, assistance and guidance from IWC or from any of its members in launching such an initiative. It looked forward to working closely with members of the Commission to achieve the Commission’s long term goals.

Côte d’Ivoire noted that it has given full support to Conventions aimed at the rational and sustainable exploitation of natural resources, particularly marine resources and adheres fully to the spirit and word of the International Convention for the Regulation of Whaling. It would support Commission resolutions for a sustainable and responsible use of whale resources based on sound science and to this end suggested that the RMS should be completed and implemented. It also noted its determination to work with other Contracting Governments to ensure the preservation of whale stocks.

Belgium noted that its adherence to the Convention was supported strongly by its parliament and civil society. It believed its adherence is coherent with Belgium’s early expeditions in Antarctica and its participation as founding members of the Antarctic Treaty and CCAMLR. It also believed it significant that Belgium was joining IWC at the time the Conservation Committee is being launched. It noted that it will work actively and constructively with all Commission members towards a high level of governance, transparency and efficiency with a view to taking the right decisions for the benefit of present and future generations and in collaboration with other international bodies.

Suriname noted that it supports the principle of the sustainable use of all marine living resources, including cetaceans. As part of the Amazon region, it is well-endowed with freshwater and arable land as well as valuable fishery resources. Deep-sea fishing is the largest exporting industry within Suriname’s agricultural sector. Suriname has made significant investments to make its fishing industry viable and has taken measures to comply with all international regulations regarding sustainability and biodiversity. It has followed the debate in IWC for many years and is surprised that whales, which consume large quantities of fish, are regarded by many as a resource that should remain unutilised at a time when nations are striving to maintain food security. Suriname recognised IWC as the global authority in relation to the management of whales and the regulation of whaling, but expected it to respect the interests of both the resources and the users of those resources and to base decisions on the best scientific advice available.

1.4 Credentials and voting rights
The Secretary reported that the credentials committee, comprising Japan, New Zealand and the Secretary, agreed that all credentials were in order. She noted that voting rights were suspended for Costa Rica, Côte d’Ivoire, Morocco and Senegal and that when voting commenced she would call on Gabon first. Senegal’s voting rights were restored later in the meeting.

1.5 Meeting arrangements
The Chair asked Contracting Governments to:

1. keep Resolutions to a minimum and to consult widely in their preparation; and
2. be brief and to the point in their interventions, and to associate themselves, where possible, with earlier speakers who had similar views.

He reconfirmed previous arrangements regarding speaking rights for Intergovernmental Organisations (IGOs), i.e. that he would allow them to make one intervention on a substantive agenda item and that any IGO wishing to speak should let him know in advance. The Secretary drew attention to the arrangements for the submission of Resolutions and other documents.

2. ADOPTION OF THE AGENDA
The Chair drew attention to the provisional annotated agenda and to his proposed order of business. He noted that because of the change in responsibilities of Carlos Dominguez that prevented him from continuing as Vice-Chair of the Commission, a new Vice-Chair needed to be elected. He proposed that a new Item 25 be inserted to deal with this matter. The adopted agenda is given in Annex B. Noting that he was aware of differing views among Contracting Governments as to whether some of the items should be on the agenda, he proposed that, as in previous years, these differences be noted and the agenda adopted with all items retained.

As last year, Japan indicated that it believed a number of items on the agenda were contrary to the objectives or outside the scope of the Convention and that discussion of these matters detracts from the time and resources available to address what in its view were more serious and substantive issues. Japan therefore proposed deletion of Item 7 on whale killing methods and associated welfare issues, Items 8.3 and 8.4 on sanctuaries for the South Pacific and South Atlantic respectively (which had already been discussed thoroughly and rejected by the Commission many times), Item 11 on environmental and health issues, Item 12 on whaling activities, Item 14.1 on small cetaceans and Item 15 on the Conservation Committee. Benin, Republic of Palau, Republic of Guinea, Norway, Gabon, Iceland, St. Kitts and Nevis, St. Lucia, Dominica, Nicaragua, Mauritania, and Morocco spoke in support of Japan. However, the UK, supported by Germany, New Zealand, Italy, India, the USA, Mexico, Brazil, Monaco, Peru, Australia, Spain, and Sweden, could not agree to Japan’s proposals. The UK referred to the lengthy discussion on the same issue at last year’s Annual Meeting, noted Japan’s views, but considered that the items mentioned were legitimate and that it was vital they remained on the agenda and were discussed.
Japan noted the many views both for and against its proposals. Not wishing to prolong the discussion, it withdrew its proposals to delete certain items but indicated that it would make its positions on them clear when those items were discussed.

3. SECRET BALLOTS

3.1 Proposed amendment to Rule of Procedure E.3(d)

Japan again introduced its proposed amendment (that was unsuccessful at the 2001, 2002 and 2003 Annual Meetings1) to broaden the application of secret ballots, i.e.

‘Votes can be taken by show of hands, or by roll call, as in the opinion of the Chairman appears to be most suitable, or by secret ballot if requested by a Commissioner and seconded by at least five other Commissioners except that on any matter related to aboriginal subsistence whaling, voting by secret ballot shall only be used when all the Commissioners representing the Contracting Parties where the aboriginal subsistence take or takes will occur requests the use of a secret ballot and where such requests are seconded by at least five other Commissioners.’

In addition to being available for electing the Chair and Vice-Chair of the Commission, appointing the Secretary of the Commission and selecting Annual Meeting venues – the current situation, Japan believed that voting by secret ballot should be possible for setting catch limits and deciding other regulatory measures. It again noted that the secret ballot is a system commonly used in other international organisations including fisheries management bodies and saw no reason why its proposal should not be accepted by the Commission.

3.2 Commission discussions and action arising

Iceland, Republic of Guinea, Dominica, Antigua and Barbuda, Mauritania, Republic of Korea, Republic of Palau, Norway, Benin, St. Kitts and Nevis, Grenada, St. Vincent and The Grenadines, St. Lucia, Nicaragua, China, Gabon, Tuvalu, Morocco and Dominica spoke in support of Japan’s proposal. Iceland noted that national elections are performed by secret ballot and that the same principles should apply internationally. It felt it important that less powerful nations should be able to work without undue pressure from others. As in previous years, Norway believed that transparency should be employed wherever possible but supported Japan’s proposal given the real threats of coercion and intimidation surrounding the whaling debate. Others made similar remarks.

The USA, New Zealand, Germany, Italy, UK, Kenya, Australia, Brazil, Monaco, Mexico, Sweden, South Africa, India, Peru, Netherlands, Argentina, Finland, Denmark, Spain, Portugal, France and Switzerland indicated that they could not support the proposal believing it to be contrary to the principles of openness and transparency. Referring to Iceland’s comment, Switzerland accepted that secret ballots are appropriate at the level of the individual citizen, but that in the context of intergovernmental organisations, it believed it important that the public be aware of how their countries vote.

In response to a question from Argentina regarding why, in the proposal, there were additional conditions related to secret votes for aboriginal subsistence whaling, Japan explained that this had been included in view of the frequent calls for matters related to aboriginal subsistence whaling to be decided by consensus. Regarding the number of seconds required for a secret ballot, Japan noted that within CITES, a secret ballot can proceed if requested by one country and seconded by 10 others. As IWC has fewer member governments than CITES, Japan proposed that a call for a secret ballot need only be seconded by five countries.

On being put to a vote, the proposal failed to achieve a majority and was therefore not adopted. There were 24 votes in support of the proposal and 29 against.

4. WHALE STOCKS2

4.1 In-depth assessment of western North Pacific common minke whales

4.1.1 Report of the Scientific Committee

The Committee reviewed the progress made by an intersessional steering group established last year to plan for the in-depth assessment of western North Pacific common minke whales, with a focus on ‘J’ stock. The Committee developed a series of priority research items that needed to be accomplished before an assessment could be undertaken, including: analysis of survey data; further work on stock identity; and consideration of ways to elucidate the proportion of ‘J’ stock animals found in the Sea of Japan. It entrusted this work to a further intersessional group.

4.1.2 Commission discussion and action arising

Japan believed that a reported increase in bycatch of ‘J’ stock animals is a sign of increasing abundance of this stock which its own research suggests to be greater than 15,000 animals. It anticipated that this would be elucidated by the in-depth assessment. The Republic of Korea was pleased to have started work on this stock around the Korean Peninsula. It too believed that the ‘J’ stock is increasing, but believed that it should be referred to as the ‘Korean peninsular stock’.

The UK, supported by Australia, was concerned by the apparent change in position regarding the abundance of this stock. It recalled that last year, the Scientific Committee had taken a very precautionary variant when determining stock abundance. While it did not dispute that bycatch could be increasing, it suggested that this could be due to a number of reasons, including changes in the distribution of the animals or the effort expended in setting nets.

The Commission noted the Scientific Committee report and endorsed its recommendations.

4.2 Antarctic minke whales

4.2.1 Report of the Scientific Committee

The Committee has carried out annual surveys in the Antarctic (south of 60°S) since the late 1970s. The last agreed estimates for each of the six management Areas for minke whales were for the period 1982/83 to 1989/90. At the 2000 meeting, the Committee agreed that whilst these represented the best estimates for the years surveyed, they were no longer appropriate as estimates of current abundance. An initial analysis of available recent data had

---

2 For details of the Scientific Committee’s deliberation on this item see J. Cetacean Res. Manage. 7 (Suppl.).
suggested that current estimates might be appreciably lower than the previous estimates.5

Subsequently, considerable time has been spent considering Antarctic minke whales with a view to obtaining final estimates of abundance and considering any trend in these. This has included a review of data collection methods and analytical methodology. After considering many of the factors affecting abundance estimates, there is still evidence of a decline in the abundance estimates, although it is not clear how this reflects any actual change in minke abundance. Three hypotheses that might explain these results have been identified:

1. a real change in minke abundance;
2. changes in the proportion of the population present in the survey region at the time of the survey; or
3. changes in the survey process over time that compromise the comparability of estimates across years.

A considerable amount of work has been undertaken and further work is ongoing. The final part of the Third Circumpolar Survey undertaken as part of the IWC’s SOWER research programme has been completed. This work will again be a priority item for discussion at next year’s Scientific Committee meeting. Particular attention will be given to the potential relationship between minke whale distribution and the extent and nature of sea ice.

4.2.2 Commission discussion and action arising

Japan considered that the difference in abundance estimates between CPII and CPIII cannot be fully explained by biological reasons and that the employment of different survey designs, survey methods and timing between the series, as well as differences in sea ice, may have had an impact. It was therefore pleased to see that the Scientific Committee is now working on elucidating the reasons for these differences and awaited the outcome with interest. Japan noted that results from JARPA do not show any sign of declines in abundance and concluded that stock abundance is stable, supporting the view that the differences between CPII and CPIII are apparent.

Australia noted that Japan’s suggestion that abundance estimates are stable is not the consensus view of the Scientific Committee. Rather it believed it to be clear that uncertainty surrounding stock abundance continues and drew attention to the high priority given by the Scientific Committee on this issue. Referring to its comments on this matter in earlier years, Australia again expressed concern that a large number of minke whales are being taken in the Antarctic despite the uncertainty in stock abundance. The USA and Germany agreed.

St. Lucia congratulated those involved in the SOWER series and thanked Japan for providing the vessels and support to this work. It urged other governments with similar resources to contribute in a similar fashion to ensure continuation of this important work.

The Commission noted the Scientific Committee report and endorsed its recommendations.

4.3 Southern Hemisphere whales other than minke whales

4.3.1 Report of the Scientific Committee

4.3.1.1 HUMPBACK WHALES

Considerable progress has been made in recent years in working towards an assessment of humpback whales. Attention has focussed both on data from historic whaling operations and on newly acquired photo-identification, biopsy and sightings data. The Committee made a number of research recommendations to further progress towards an assessment. An intersessional group was established last year to review progress and determine whether it is feasible to set a deadline for the assessment to be completed. Further work was identified this year and progress was reviewed. Further work remains to be completed.

4.3.1.2 BLUE WHALES

The Committee is beginning the process of reviewing the status of Southern Hemisphere blue whales. An important part of this work is to try to develop methods to identify pygmy blue whales from ‘true’ blue whales at sea and progress is being made on this. Work on genetic and acoustic differentiation techniques is continuing and there is considerable progress with morphological methods. The Committee has agreed on a number of issues that need to be resolved before it is in a position to carry out an assessment, which it believes should commence in 2006.

This year, the Committee reviewed a paper by Branch et al. (20044). The Committee agreed that this research supported the conclusions that: (1) on average, the Antarctic blue whale population is increasing at a mean rate of 7.3% per annum (95% CI 1.4–11.6%); (2) had an estimated circumpolar population size of 1,700 (95% CI 860–2,900) in 1996; and (3) that this population is still severely depleted with the 1996 population estimate estimated to be at 0.7% (95% CI 0.3–1.3%) of the estimated pre-exploitation level.

4.3.2 Commission discussion and action arising

Australia was encouraged that Southern Hemisphere humpback whales are apparently increasing in and around its waters and reported that it is good news for its whalewatching industry that relies on increasing numbers of humpback whales. Believing that some sightings surveys and modelling exercises may be over-estimating the numbers of some humpback populations, Australia looked forward to greater clarity of what it believed were apparent anomalies.

Japan reported that results from JARPA indicated sharp increases in the numbers of humpback and fin whales. It quoted estimates of 41,000 for humpback whales and 15,000 for fin whales in the north of the survey area (suggesting an estimate of 68,000 for the total stock). Australia, the UK and New Zealand believed these estimates to be flawed. Japan responded that the areas where these increases have been seen are south of 60°S. It believed that there are certain biological reasons for these increases but also suggested that some animals may have moved south from Australian waters. Japan also suggested that the increase in numbers of various large whale species in the Southern Hemisphere may not be helpful to the recovery of blue whales, given interspecific competition.

Brazil, supported by Australia did not agree.

5 J. Cetacean Res. Manage. 3 (Suppl.): 29-32.

The Commission noted the Scientific Committee report and endorsed its recommendations.

4.4 Other small stocks – bowhead, right and gray whales

4.4.1 Report of the Scientific Committee

4.4.1.1 SMALL BOWHEAD WHALES

The Committee received information of a number of analyses on the stock identity, movements and abundance of bowhead whales from the Davis Strait/Baffin Bay and Hudson Bay/Foxe basin regions. There were no reports of any catches in 2004.

4.4.1.2 NORTH ATLANTIC RIGHT WHALES

The Committee has paid particular attention to the status of the North Atlantic right whale in the western North Atlantic in recent years (e.g. see JCRM Special Issue 2: Right Whales: Worldwide Status). The Committee is extremely concerned about this population, which, whilst probably the only potentially viable population of this species, is in serious danger (ca 300 animals). By any management criteria applied by the IWC in terms of either commercial whaling or aboriginal subsistence whaling, there should be no direct anthropogenic removals from this stock.

This year, the Committee once again noted that individuals from this stock are continuing to die or become seriously injured as a result of becoming entangled in fishing gear or being struck by ships. It repeated that it is a matter of absolute urgency that every effort be made to reduce anthropogenic mortality in this population to zero. This is perhaps the only way in which its chances of survival can be directly improved. There is no need to wait for further research before implementing any currently available management actions that can reduce anthropogenic mortalities.

The Committee reviewed progress on a number of research and management recommendations concerning this stock.

4.4.1.3 NORTH PACIFIC RIGHT WHALES

The Committee received reports of sightings of the endangered North Pacific right whales, including news of one biopsy sample and three photo-identification photographs.

4.4.1.4 SOUTHERN RIGHT WHALES

The Committee received reports of continuing increases in Southern right whale numbers off South Africa. It was estimated that there are more right whales there now than at any time in the last 150 years. The Committee recommends that the over 30 year monitoring programme be continued, noting its value to conservation and management.

The Committee also received reports of right whales off Brazil and Argentina, and reviewed the report of a photo-identification workshop held in Adelaide, Australia.

4.4.1.5 WESTERN NORTH PACIFIC GRAY WHALES

This is one of the most endangered populations of great whales in the world. It numbers less than 100 animals and there are a number of proposed oil and gas-related projects in and near its only known feeding ground. The Committee held a Workshop in October 2002 to review this further. The Workshop report was published in J. Cetacean Res. Manage. 6 (Suppl.). Overall, the Workshop agreed with the conclusions of previous reviews on western gray whales. Specifically, that the population is very small, and suffers from a low number of reproductive females, low calf survival, male-biased sex ratio, dependence upon a restricted feeding area and apparent nutritional stress (as reflected in a large number of skinny whales). Other major potential concerns include behavioural reactions to noise (notably in light of increasing industrial activity in the area) and the threat of an oil spill off Sakhalin which could cover all or part of the Piltun area and thus potentially exclude animals from this feeding ground. The Workshop had noted that assessments of the potential impact of any single threat to the survival and reproduction of western gray whales were insufficient and had strongly recommended that risk assessments consider the cumulative impact of multiple threats (from both natural and anthropogenic sources). Last year, the Committee adopted the Workshop report and endorsed its recommendations, including the research and monitoring plan.

In reviewing progress this year, the Committee noted with great concern that the evidence is compelling that this population is in serious danger of extinction. It reiterated that the population is small (only about 100 whales) and appears to have biological problems (only 23 reproductive females, three or more years calving interval, male biased sex ratio, and apparent low calf survival). Furthermore, there is only a single known coastal feeding habitat (approximately 60km long and 5km wide) used by females and calves which faces an obvious and immediate threat from industrial activities, including noise, vessel traffic and the potential for a catastrophic oil spill. Noting, its similarly strong concerns for North Atlantic right whales, the Committee recommended as a matter of absolute urgency that measures be taken to protect this population and its habitat off Sakhalin Island.

Plans for the Russia-USA research collaboration and national research plans from Russia and Korea were presented. As in previous years, the Committee strongly recommended that the ongoing Russia-USA and Russian and Korean national programmes on western gray whale research and monitoring continue and expand into the future. Results from these programmes will be the only way to monitor and assess the status of this critically endangered population.

The Committee also strongly recommended that all range states develop or expand national monitoring and research programmes on western gray whales. The Committee noted particularly that the precise location and status of the breeding grounds of this highly endangered whale (presumably in Chinese waters) are still unknown.

4.4.2 Commission discussion and action arising

New Zealand welcomed the news that there are more southern right whales now than there have been for the past 150 years but noted that the global population is still only around 10% of its estimated pre-exploitation level. It also noted that all these small stocks were once abundant and suggested that it will be centuries, if ever, before they recover.

Further discussion focused on the western North Pacific stock of gray whales. Noting the concern expressed by the Scientific Committee regarding this stock, the Russian Federation considered that as yet there is no evidence that the oil development programme off Sakhalin Island is having an actual impact on the gray whales. The Republic of Korea shared the Scientific Committee’s concern and believed that more studies were needed to assess the impact, if any, of the oil industry’s activities. It noted the historic and cultural importance of this species to the
Korean peoples and that in 1962, the Korean Government had declared its migration corridor a national treasure. It reported that it had conducted a national census that would complement the work of the Scientific Committee, and stressed the importance of involving range states in work on this stock. The USA, Germany and Italy also expressed concern regarding the status of this stock and welcomed the Scientific Committee’s recommendations. Japan considered that the countries in which the headquarters of the major oil companies involved are based should work closely with range states on this issue.

The Commission noted the Scientific Committee report and endorsed its recommendations.

**RESOLUTION ON WESTERN NORTH PACIFIC GRAY WHALE**

The UK introduced a draft Resolution on western North Pacific gray whales of behalf of the other co-sponsors South Africa, Belgium and Germany. Among other things, the draft Resolution:

1. endorsed all of the Scientific Committee’s conclusions and recommendations;
2. requested the Secretariat to offer its services and scientific expertise to the organisations concerned with oil and gas development projects and to participate actively in any international panels convened to consider the impacts of these projects on the western gray whale; and
3. requested all range states to develop, begin or continue scientific research programmes on the migration, distribution, breeding, population assessment and other research of the entire range of this stock.

While the general sentiment of the draft Resolution was supported by all, the Republic of Korea, Norway and Japan questioned whether it was necessary given that it was largely a repeat of the Scientific Committee recommendations. Referring to the third pre-ambular paragraph, the Russian Federation repeated its earlier comments that there is no evidence that oil and gas exploration is having an impact on the population and that this population was under threat of extinction prior to these activities beginning. It proposed some revisions to the text to reflect its view. Japan questioned why the co-sponsors had not consulted with the range states. Iceland objected to the last pre-ambular paragraph referring to IWC as the international recognised body for the conservation of whale stocks and believed this statement to be contrary to UNCLOS.

The UK explained that the key difference between the draft Resolution and the Scientific Committee recommendations was that the former urges governments to involve IWC in the independent work taking place around Sakhalin Island. It could not support the Russian Federation’s proposed amendments since these would not reflect the Scientific Committee views, and it believed that it had consulted with range states and invited them to comment on the draft Resolution.

Sensing strong support for the draft Resolution, the Chair requested parties to consult to try to resolve differences. Such consultation took place and a revised draft Resolution was submitted with Germany, Italy, Switzerland and Austria being added to the list of sponsors. The Russian Federation believed that the revised proposal would help it in its discussions with the oil and gas industry and called on range states to participate. It hoped that the draft Resolution could be adopted by consensus. The Republic of Korea associated itself with these remarks and urged members to be cognisant of the sovereign rights of range states. Norway’s view on the need for a Resolution remained unchanged, believing it to be superfluous. It indicated it would abstain from any vote. Japan was of a similar view and indicated that it too would abstain. In the end, the revised Resolution (2004-1, see Annex C) was adopted by consensus, noting the views of Norway and Japan.

### 5. ABORIGINAL SUBSISTENCE WHALING

The meeting of the Aboriginal Subsistence Whaling Subcommittee took place on 14 July chaired by Andrea Nouak (Austria). Delegates from 30 Contracting Governments participated. The Chair of the Scientific Committee’s Standing Working Group on the Development of an Aboriginal Whaling Management Procedure (SWG) reported the outcome of the Committee’s work and discussions. A summary of the discussions of the Subcommittee is included below. The full Sub-committee report is available as Annex D.

#### 5.1 Aboriginal subsistence whaling procedure

**5.1.1 Report of the Aboriginal Subsistence Whaling Subcommittee**

As anticipated, the Scientific Committee had been able to recommend a Strike Limit Algorithm (SLA) for eastern North Pacific gray whales to the Commission. This was the second SLA that the Scientific Committee has recommended in the development process, the first being that for the Bering-Chukchi-Beaufort stock of bowhead whales at the Annual Meeting in 2002.

The candidate procedures for the gray whale case were tested for a broad range of uncertainty in a variety of factors, including: changes in MSYR and MSYL; model uncertainty; time dependent changes in carrying capacity, natural mortality and productivity; episodic events; stochasticity; survey bias and variability; survey frequency and errors in the historic catch series. The overall performance of candidate SLAs was judged by a combination of an examination of the detailed conservation and need satisfaction statistics for each of the Evaluation Trials and Robustness Trials and human integration of these results in the context of the relative plausibility each member assigns to the individual trials.

Two procedures, J-B2 and the GUP2 (Grand Unified Procedure) based on J-B2 and D-M2 procedures, had performed equally well in the trials. However, after examination of other features that may be used to separate the two SLAs (see Annex D for further details), the Scientific Committee unanimously recommended that the GUP2 SLA (hereafter the ‘Gray whale SLA’) be forwarded to the Commission. It believes that this SLA meets the objectives of the Commission set out in 1994 and represents the best scientific advice that the Committee can offer the Commission with respect to the management of the Eastern North Pacific stock of gray whales.

In making this recommendation, the Scientific Committee had noted the integral importance of Implementation Reviews to the whole process. These would

---

5 For details of the Scientific Committee’s deliberation on this item see J. Cetacea Res. Manage. 7 (Suppl.).
occur every five years and would normally involve at least reviews of information: (1) required for the SLA (i.e. catch data, abundance estimates); and (2) to ascertain if the present situation is as expected and within tested parameter space. In addition, to enable swift reaction to new information that gives rise to serious concern, Unscheduled Implementation Reviews can be called. There are a variety of possible outcomes of Implementation Reviews, including:

(a) the continuation of use of the SLA;
(b) the setting of a zero strike limit;
(c) the running of further simulation trials;
(d) the undertaking of a new census immediately; and
(e) a combination of some of the above.

The Sub-committee endorsed the Scientific Committee’s recommendations.

5.1.1.2 GREENLANDIC FISHERIES

The Chair of the Standing Working Group (SWG) had reminded the Sub-committee that an urgent need for a Greenland Research Programme was first identified in 1998, primarily due to the lack of recent abundance estimates and the poor knowledge of stock structure. He had noted that it would be extremely difficult, if not impossible, to develop an SLA for the Greenlandic fisheries that would satisfy all of the Commission’s objectives without such information. This is particularly important in the light of the Scientific Committee’s grave concern at its inability to provide management advice for these fisheries.

In reporting to the Sub-committee, the SWG Chair separated out this item into four main issues: stock structure; abundance estimates; biological data and SLA development. With respect to the former, the problem was that although the available information suggested that the animals found off West Greenland did not comprise either separate fin or common minke whale stocks, the identity and size of the complete stocks is unknown. The Scientific Committee had agreed to follow a two-step process to further the essential work needed to provide information suitable for management; namely an initial simulation study to focus appropriate genetic analyses.

Regarding genetic analyses, the Scientific Committee had expressed disappointment at the lack of progress in obtaining genetic samples, even though it is mandatory under local regulations to return a sample from each whale caught. It noted that new procedures are in place but repeated its strong recommendation that samples for genetic analysis be collected from the catch as a matter of very high priority. It urged the Commission to encourage the Government of Denmark and the Greenland Home Rule authorities to assist with logistical and, if necessary, financial support and encouraged Greenlandic scientists to investigate other potential sources of samples. The news that some 50 samples are available from the eastern USA and Canada was welcomed and the Scientific Commission urged that these be analysed.

With respect to abundance estimates, last year the Scientific Committee had strongly recommended that a traditional aerial cue-counting survey be carried out in summer 2003 in Greenland. Unfortunately, for logistical and financial reasons it had not been possible to undertake such a survey, but some valuable experimental work had been carried out in 2003 that had been discussed by the Scientific Committee. Greenlandic scientists had presented a plan for a full aerial photographic survey (not cue-counting) to take place in summer 2004. The Scientific Committee had noted the great need for new abundance estimates and, in order to facilitate presentation of appropriate analyses as quickly as possible, had established an intersessional advisory group. The Chair of the SWG noted that the difficult environmental conditions (notably fog and high winds) in Greenland make the undertaking of successful surveys problematic.

In terms of developing an SLA, it was noted that the differences between the relatively ‘easy’ data-rich cases of the bowhead and gray whales and the data-poor Greenlandic cases, may warrant a different approach to the examination of the trade-off between risk and need satisfaction. The SWG had also considered how best to proceed with the development of one or more SLAs given the continuing uncertainties about stock structure, abundance, and mixing in the region. One approach would be to postpone SLA development until more and better data become available. The SWG had rejected this approach, instead believing that SLA development was a matter of considerable urgency. The SWG therefore intends to develop the best SLA(s) it can given the data available, and, noting the potential of the simulation approach to help identify appropriate data collection programmes, it recognised that it might become necessary to improve the SLA(s) at future Implementation Reviews when more information is available. The Scientific Committee had endorsed this approach.

The catch data for 2003 were: 6 landed fin whales (2 males and 4 females), with 3 struck and lost; 178 landed West Greenland common minke whales (58 males, 117 females, 3 unknown sex) and 7 struck and lost; and 13 landed East Greenland common minke whales (1 male, 11 females, and 1 unknown sex). An analysis of recent catch data will be provided to the next Committee meeting.

Other aspects of the Scientific Committee’s discussions of the Greenlandic fisheries, including the provision of management advice, are given under Item 5.3.1.3

In the Sub-committee New Zealand stated that it considered the data provision by Greenland unsatisfactory and questioned whether restrictions should be imposed on its catch quotas. It asked Denmark to explain how they intended to remedy this situation. Denmark responded that information on the importance of returning samples has been given to the hunters and that efforts are being made to improve communication. The Greenland Home Rule Government regrets the low number of samples collected and, for the 2004 season, letters and phials have been sent to the municipalities and will be handed out to the hunters when licenses are issued. The UK expressed its concern with this response. It recognised that policing of the hunt is difficult, but stated that the conditions under which aboriginal subsistence whaling in Greenland is allowed are known to the hunters and are included in licences. The UK felt that non-compliance with conditions required more serious action.

The Sub-committee endorsed all recommendations of the Scientific Committee on this item.

5.1.2 Commission discussions and action arising

Discussion in the Commission focused on the Greenlandic fisheries.

Following the discussions in the Aboriginal Subsistence Whaling Sub-committee and the Infractions Sub-committee (see section 18 and Annex I) a statement on the Greenland
Research Programme had been prepared and submitted to plenary by Denmark. In this statement, Greenland pointed to the following:

- that the International Whaling Commission has accepted that the West Greenland need for meat from large whales is 670 tons annually;
- that the current IWC quotas do not meet the accepted need;
- further that the Greenland need for whale meat is supplemented by whale meat from stocks not covered by the IWC;
- that Greenland has regularly submitted substantive information on whaling issues to the Commission for decades;
- that the Greenland Home Rule Government has allocated DKK 1.2 – 1.4 mill in each of the years 2002, 2003 and 2004 to surveys and the development of survey methods;
- that attempts were made to carry out aerial surveys in 2002, but due to bad weather these were not carried out as planned, and furthermore, a camera survey test flying was conducted successfully in 2003 in Iceland;
- that Greenland has collected 301 genetic samples from 1998 to 2003, and that 166 samples collected in West Greenland and 30 collected in East Greenland have been analysed in connection with investigations of stock structure of North Atlantic minke whales;
- that the IWC has supported the Greenland Research Program with a total amount of £69,552 in the years 1999 – 2004 to both feasibility study, biopsy study and satellite telemetry;
- that the Commission has decided not to implement the AWMP until the RMS has been implemented;
- that the Greenland annual harvest of the central North Atlantic minke whales constitutes less than 0.01% of the stock;
- that a harvest of minke whale of West Greenland waters has had a larger proportion of females; and
- that the present Schedule foresee a review if new scientific data become available within the present 5 year period (2003-2007) and if necessary amended on the basis of the advice of the Scientific Committee.

Greenland and Denmark further:

- find that the lack of adequate data on abundance and stock structure of West Greenland minke and fin whales is a matter of concern;
- want to complete the research recommended by the Scientific Committee as soon as possible and to continue to facilitate hunters to collect and submit samples from each whale landed; and
- want the Scientific Committee to further discuss the existing results and to guide future analysis of genetic samples.

The statement further requested the Scientific Committee if possible and in concurrence with its own agenda to:

1. continue development of and complete an AWMP for Greenland whaling when adequate data become available;
2. continue cooperation and guidance of Greenland scientific activities;
3. establish adequate guidelines in relation to analysis of the collected samples; and
4. continue further dialogue with Greenland scientists in order to ensure that the appropriate research activities are successfully undertaken.

The UK referred to the discussions between Denmark/Greenland and the UK and New Zealand during the Sub-committee meeting. It urged Greenland to carry on its research programme and to try to address the question of sex bias in the catches. The UK also urged the Scientific Committee to consider urgently the effect of this bias in catches on the population dynamics of the stocks involved and to consider what might be done to recognise the difficulties of hunting in the Arctic. It welcomed Denmark’s statement and hoped that work could proceed on this basis. New Zealand, Germany and Australia echoed the UK’s remarks.

The Minister of Fisheries and Hunting of the Greenland Home Rule Government stressed that his Government recognizes the need to complete the survey and genetic research required for developing abundance estimates. He reported that Greenland is working hard to fulfil its research programme but sought the Commission’s understanding of the difficult conditions under which it must be carried out. He requested that a formal review of aboriginal subsistence whaling in Greenland be kept as planned, i.e. a review at the Annual Meeting in 2007.

Japan commented on the different approach being used to develop SLAs for aboriginal subsistence whaling (i.e. stock-specific) compared with that for the RMP (i.e. generic), noting that if applied to the B-C-B Seas stock of bowheads the RMP would not give a catch limit. It did not believe these different approaches to be scientifically justified and considered that double standards were being applied. In response, the USA noted that the approaches to the SLA and CLA are different because the Commission has given different policy advice for the different types of hunt. The USA considered it inappropriate to apply the CLA to a stock subject to subsistence whaling. It further noted that the Scientific Committee has indicated that the bowhead SLA will have to be reviewed if new information on stock identity comes to light. The Commission noted this part of the Sub-committee’s report and endorsed its recommendations.

5.2 Aboriginal subsistence whaling scheme (AWS)
5.2.1 Report of the Aboriginal Subsistence Whaling Sub-committee
As for the last two years, the Scientific Committee recommended a number of scientific aspects of an eventual AWS. These included strike-limit related issues (block limits, carryover, grace period), survey-related issues (survey/census methodology and design, Committee oversight, data analysis and availability), guidelines for data/sample collection and Implementation Reviews. During the Sub-committee, Australia recognised that the focus of discussion was on science, but registered its concern over whaling management regimes that it considered should be given equal attention. The USA stated that they have previously expressed concerns over certain provisions of the AWS and that their reservations should continue to be noted. The Sub-committee endorsed the recommendations of the Scientific Committee.

5.2.2 Commission discussions and action arising

In the Commission, the USA expressed appreciation for the work of the Scientific Committee on the AWS, but believed that some aspects are not appropriate for the B-C-B Seas stocks of bowhead whales. It noted that the ‘grace period’ (i.e. a mechanism to deal with a hypothetical situation of no abundance estimates being made available with the specified time frame) does not take into account the difficulties of conducting abundance surveys in the Arctic and in any case is redundant as the Commission can request an Implementation Review at any time. It further noted that although it agrees in principle with the concept of block quotas, it would like some flexibility regarding their duration; five years would be a minimum. The USA believed that the current management regime provided in paragraph 13(a) of the Schedule has worked well for over 25 years and that any revised scheme must provide a true improvement over the status quo.

The Commission noted this part of the Sub-committee report and endorsed its recommendations.

5.3 Aboriginal subsistence whaling catch limits
5.3.1 Report of the Aboriginal Subsistence Whaling Sub-committee

5.3.1.1 BERING-CHUKCHI-BEAUFORT SEAS STOCK OF BOWHEAD WHALES

The Chair of the SWG had noted that this year, the Scientific Committee undertook an in-depth assessment of the B-C-B bowhead whales. The Committee had agreed that substantial progress has been made in investigating possible stock or population structure among B-C-B bowheads but that there is insufficient information at this stage to fully support or refute the hypothesis of a single stock; in fact it is premature to reject any of the hypotheses, or even to draw conclusions about their relative plausibility. The Committee was pleased to receive information on an extensive research programme to address this issue further. Catch information was provided for 2003 by the USA and the Russian Federation (see Annex D).

In terms of management advice, the Scientific Committee agreed that the Implementation Review of bowhead whales, due to begin at the 2006 Annual Meeting in time for the major review of subsistence quotas in 2007, will include stock structure issues as a major component, examining the robustness of the Bowhead SLA with respect to plausible stock hypotheses via simulation trials.

The Scientific Committee had also noted:

(1) the continuing increase in the abundance estimates derived from the census under the recent catch limits and record high calf counts;
(2) the spatio-temporal distribution and opportunistic nature of the hunt and the low numbers of whales struck annually in St. Lawrence Island and Chukotka; and
(3) the development of an extensive research programme that will address questions of stock structure and allow the formulation of one or more plausible stock structure hypotheses.

Given these factors, the Committee agreed that the Bowhead SLA remains the most appropriate tool for providing management advice for this harvest, at least in the short-term. Consequently the results from the Bowhead SLA indicate that no change is needed to the current block quota for 2003-2007.

In the Sub-committee, the USA and the Russian Federation commented on planned co-operative research. Noting the Scientific Committee’s recommendation on the need for additional research on the bowhead stock identity issue, the USA expressed its commitment to undertake this research so that when the bowhead quota is next reviewed in 2007, management of the stock will be based upon the best science available at that time. The Russian Federation noted its intent to engage in as much joint research as is possible, although it noted that CITES sample requirements may impose difficulties on what is possible. In this respect, Switzerland drew attention to a Resolution adopted at COP 12 of CITES in Santiago (Chile), aimed at facilitating transboundary movement of sensitive biological samples such as scientific research materials for conservation purposes. It suggested that the CITES Management Authorities should be made aware of this if the need arises.

The Sub-committee endorsed the recommendations of the Scientific Committee.

5.3.1.2 NORTH PACIFIC EASTERN STOCK OF GRAY WHALES

Data on catches and information on calf counts from the northbound migration and the breeding lagoons in Mexico were presented to the Scientific Committee. The Committee was encouraged to hear that calf production remains at the mid-range of pre-1999 levels (after low levels in 1999, 2000, 2001). In 2002, the Scientific Committee had carried out an in-depth assessment of the Eastern North Pacific stock of gray whales and agreed that a take of up to 463 whales per year is sustainable for at least the medium term (~30 years), and is likely to allow the population to remain above MSY. No information was presented this year to change that advice. The Committee was pleased to receive the Gray Whale SLA, which could be used in future for providing management advice.

The Sub-committee endorsed the recommendations of the Scientific Committee.

5.3.1.3 MINKE AND FIN WHALE StockS OFF WEST GREENLAND

The Chair of the SWG had reported that the minke and fin whale stocks off West Greenland was an important issue in the Scientific Committee’s deliberations this year. The Committee has never been able to provide satisfactory management advice for either of these stocks. This reflects the lack of data on stock structure and abundance and is the reason for the Committee to first call for the Greenland Research Programme in 1998. He noted that the Commission’s financial contributions to the programme had been aimed at testing the feasibility of large-scale biopsy sampling and satellite telemetry to try to obtain information on abundance and stock structure but that unfortunately both proved unsuccessful.

The Scientific Committee stressed that its inability to provide advice on safe catch limits is a matter of great concern, particularly in the case of fin whales where the best available abundance estimate dates from 1987/88 and is only 1,096 (95% CI 520-2,100) while that for West Greenland minke whales dates from 1993 and is 8,371 (95% CI 2,400-16,900). Obtaining adequate information for management must be seen as very high priority by both the national authorities and the Commission. The Committee urged the Commission to encourage the Government of Denmark and the Greenland Home Rule authorities to provide the necessary logistical and financial support. Without such adequate information, the
Committee will not be able to provide safe management advice in accord with the Commission’s management objectives, or develop a reliable SLA for many years, with potentially serious consequences for the status of the stocks.

The Scientific Committee recommended that every effort be made to ensure that the number of samples collected from the catch in 2004 is considerably higher than in 2003 and close to 100%. It also recommended strongly that these and all existing samples held in Greenland be analysed as soon as possible in accordance with guidance to be given by the intersessional working group.

The Scientific Committee drew attention to the grace period provision that it had agreed previously in the context of a general aboriginal whaling scheme (although it has not yet been accepted by the Commission) associated with agreed SLAs. Under such a provision, catch limits would begin to be phased out 10-14 years after an abundance estimate was last obtained and catches would revert to zero at the end of the five-year period during which the catch limit would have been half the previous block. The Committee has not previously suggested that such a grace period should have started for fin whales. However, it drew attention to the fact that if it had, such a period would now be nearing completion.

The SWG Chair reported that it was with great concern that the Scientific Committee advised the Commission that in the absence of an agreed abundance estimate for fin whales arising out of the 2004 survey, it will likely recommend that the take of fin whales off West Greenland be reduced or eliminated immediately. If, as hoped, an abundance estimate is obtained, the Committee will review this next year in its formulation of management advice.

In the Sub-committee, Denmark explained that the Greenland Home Rule Government gave financial support for survey projects of between DKK 1.2-1.4 million annually for the years 2002-2004, and reported on the number of samples collected and analysed (see Annex D) and on the publication of the results. It noted what it considered to be a disappointingly short discussion of these results in the SWG, but hoped to receive some guidance from the SWG on the best directions for future analyses. Greenland was therefore looking forward to a project to be undertaken this winter in cooperation with the SWG. On the question of reduction of the current quota of fin whales, Greenland suggested that the Scientific Committee is not the right body to decide such a reduction. The Greenland Home Rule Government stated that it intended to increase its efforts in cooperation with the hunters’ organisation to gain more samples as recommended.

The UK noted that the Scientific Committee recommendations were in the strongest terms it had seen. The UK felt that the Commission would need to agree to take action on the quota if data were not made available. Australia concurred with the UK and suggested that the Scientific Committee concerns should be reinforced by the Sub-committee.

Argentina, New Zealand and the UK expressed concern that the sex ratio of the Greenland’s minke hunt is highly female biased: on average, 72% of all minke whales killed in Greenland since 1986 were female. Denmark explained, as it had on earlier occasions, that sex selection is impossible to enforce in Greenland due to both weather and ocean conditions. New Zealand was concerned that the preferential removal of females could significantly affect the regenerative capacity of the stock and suggested that it would be helpful for Greenland to provide information on the date, location and sex of every whale taken, to show precisely what is going on. New Zealand believed that these issues raise fundamental questions of accountability that go to the centre of the integrity of the legal instrument under which the Commission operates. The UK, supported by Switzerland, remarked that if a degree of sex bias is inevitable, it raised some very important questions about the sustainability of the hunt.

With respect to the female bias in the catch, the SWG Chair clarified that it is common for minke whales to segregate both geographically and temporally by sex in the North Atlantic. The sex bias in the catch is longstanding and earlier attempts to model the animals off West Greenland showed that if the minke whales found there comprised a complete stock they would already have become extinct. The sex bias in the catch probably reflects the sex ratio in the waters there and not any selectivity by whalers (which in any case is not possible). He noted that the Committee was expecting a paper on recent catches (both geographical and temporal by sex) at its next meeting.

Greenland explained that the information on the seasonal distribution of the harvest suggests northward movement in early part of hunting season and a southern movement in the autumn, so that the hunting season, which is in any case short, is even shorter in the northern part of the area of distribution of minke whales in West Greenland. Analysis has not so far shown differential distribution of the two sexes. They suggested that knowledge of this bias is long-standing and not recent. This bias suggests that this is probably a part of a larger stock, whose boundaries are uncertain.

The Sub-committee endorsed the recommendations of the Scientific Committee regarding the minke and fin whale stocks off Greenland.

5.3.1.4 NORTH ATLANTIC HUMPBACK WHALES OFF ST. VINCENT AND THE GRENADINES

The Scientific Committee had agreed that it was most plausible that the animals off St. Vincent and The Grenadines are part of the West Indies breeding population (ca 10,750 animals in 1992), although it acknowledged that further data to confirm this are desirable. It repeated its previous recommendations that every effort be made to obtain photographs and genetic samples from animals taken. The Scientific Committee was disappointed not to receive information on whether or not any catches had been taken last year (no scientists from St. Vincent and The Grenadines had been present and no national progress report had been submitted). However, it noted that the genetic analyses of at least three samples from caught animals is being conducted and it was pleased to hear that sightings cruises are taking place in the region.

The Scientific Committee agreed that if the humpback whales are part of the West Indies breeding population, the block catch limit of 20 for the period 2003-2007 will not harm the stock.

In the Sub-committee, the UK did not dispute the Scientific Committee recommendations, but urged the need for further data, since it believed there could be ramifications if the animals off St. Vincent and The Grenadines are not part of the West Indies population. Australia understood that St. Vincent and The Grenadines passed new whaling regulations in December 2003, and
asked whether a copy of this legislation had been submitted to the Secretariat as is required, and whether it had been found to be consistent with the draft legislation presented to the IWC. The Chair of the SWG indicated that this matter was usually dealt within in the Infractions Sub-committee, but he would investigate this situation.

5.3.2 Commission discussions and action arising
The Commission noted the Sub-committee’s report and endorsed its recommendations. Discussions on specific stocks are summarised in the following sections.

5.3.2.1 BERING-CHUKCHI-BEAUFORT SEAS STOCK OF BOWHEAD WHALES
The USA reported that it had undertaken genetic research in response to the request from the Special Meeting of the Commission in October 2002 that an in-depth assessment of this stock be completed with results available for the 2004 Annual Meeting. The USA noted that the results did reveal genetic differences, but that it is too early to draw conclusions regarding stock identity. It drew attention to the Scientific Committee’s view that for the time being it is reasonable to continue to apply the bowhead SLA, noted the data showing an increase in abundance of this stock and indicated that it saw no need to modify current management approaches. The USA was, however, committed to carrying out further research on stock identity in time for 2007 as requested by the Scientific Committee.

Japan expressed appreciation for the active discussions in the Scientific Committee and believed that the results from work on this stock should be reflected in management advice from this year onwards. As last year it noted what it believed to be double standards in the approach to management of the bowhead stock using the SLA and the Implementation Simulation Trials on western North Pacific minke whales using the CLA. It called for consistency in approach.

5.3.2.2 NORTH PACIFIC EASTERN STOCK OF GRAY WHALES
There were no comments on this stock.

5.3.2.3 MINKE AND FIN WHALE STOCKS OFF WEST GREENLAND
There were no comments on this stock.

5.3.2.4 NORTH ATLANTIC HUMPBACK WHALES OFF ST. VINCENT AND THE GRENADINES
St. Vincent and The Grenadines indicated that it was unfortunate that it had been unable to attend the Scientific Committee and the Aboriginal Subsistence Whaling Subcommittee meetings. It confirmed that it had submitted a copy of its 2003 whaling regulations to the Secretariat, and it reported that on 29 March 2003 one humpback whale, 39ft in length, had been taken.

5.4 Revision of Schedule paragraph 13
5.4.1 Report of the small working group and proposed Schedule amendment
REPORT OF THE SMALL WORKING GROUP
At the 55th Annual Meeting of the IWC, a Small Group comprising the Russian Federation, Denmark, Australia, the USA and the Secretariat was charged with reviewing of the Schedule paragraph 13, that provides for aboriginal subsistence whaling catch limits, to determine how consistency in approach across all such whaling operations could be achieved and to propose some amendments to the Schedule for review and decision-making at the 56th Annual Meeting of the IWC in 2004.

The Small Group worked intersessionally by e-mail and agreed the following.

All provisions governing aboriginal subsistence whaling operations are understood to be, and should be, included in paragraph 13 of the Schedule.

Should the Commission decide to harmonise the Aboriginal Subsistence Whaling Schedule language, the group recommends considering the creation of one option concerning the prohibition on the taking of calves and whales accompanied by calves. The Schedule has such parts in sub-paragraph 13 (b) (1) and 13 (b) (2), but not in the sub-paragraphs 13 (b) (3) and 13 (b) (4). A new sub-paragraph 13 (a) (4) could be inserted in the general principles governing this form of whaling, to read as follows: ‘It is forbidden to strike, take or kill calves or any whale accompanied by a calf.’

The group agreed that nothing in the Russian Federation’s proposals to amend Schedule paragraph 13 was intended to allow for commercialisation of the aboriginal subsistence whaling.

The words ‘when the meat and products of such whales are to be used exclusively for local consumption’ means that some transaction beyond the aboriginal whaling communities under the current Schedule language are acceptable. The definition of aboriginal ‘subsistence use’ was adopted by the Cultural Anthropology panel of the IWC Meeting of Experts on Aboriginal/Subsistence Whaling in February 1979 (reported in IWC Special Issue 4, 1982) and provided that:

(1) The personal consumption of whale products for food, fuel, shelter, clothing, tools or transportation by participants in the whale harvest.

(2) The barter, trade or sharing of whale products in their harvested form with relatives of the participants in the harvest, with others in the local community or with persons in locations other than the local community with whom local residents share familial, social, cultural or economic ties. A generalised currency is involved in this barter and trade, but the predominant portion of the products from such whales are ordinarily directly consumed or utilised in their harvested form within the local community.

(3) The making and selling of handicraft articles from whale products, when the whale is harvested for the purposes defined in (1) and (2) above.

It was agreed by the Small Group that aboriginal communities in Chukotka, which have quota to take gray and bowhead whales, have equal rights to other aboriginal communities that have Aboriginal Subsistence Whaling quota to use the meat and products of these whale species.

The Small Group noted that the proposal to delete the words ‘whose traditional aboriginal subsistence and cultural needs have been recognised’ from Schedule subparagraph 13(b) (2) was intended to reflect this equality of rights. Without prejudice to any Party’s final position and subject to there being no consequential difficulties, it was agreed that should it be necessary to delete the above words to reflect the equality of rights, this would be justified.

PROPOSED SCHEDULE AMENDMENT
After consultation with the Small Group, the Russian Federation proposed the following amendment with a view to improved harmonisation of the Schedule paragraph 13.

---

Amend Schedule paragraph 13 as follows (proposed new text is shown in bold italics; deleted text is in strikethrough mode):

III. Capture

Baleen Whale Catch Limits

13 (a) (4) It is forbidden to strike, take or kill calves or any whale accompanied by a calf.

13 (b) Catch limits for aboriginal subsistence whaling are as follows:

(1) The taking of bowhead whales from the Bering-Chukchi-Beaufort Seas stock by aborigines is permitted, but only when the meat and products of such whales are to be used exclusively for local consumption by the aborigines and further provided that:

(i) For the years 2003, 2004, 2005, 2006 and 2007, the number of bowhead whales struck shall not exceed 280. For each of these years the number of bowhead whales struck shall not exceed 67, except that any unused portion of a strike quota from any year (including 15 unused strikes from the 1998 - 2002 quota) shall be carried forward and added to the strike quotas of any subsequent years, provided that no more than 15 strikes shall be added to the strike quota for any one year.

(ii) It is forbidden to strike, take or kill calves or any bowhead whale accompanied by a calf.

(iii) This provision shall be reviewed annually by the Committee in the light of the advice of the Scientific Committee.

13 (c) The findings and recommendations of the Scientific Committee’s in-depth assessment for 2004 shall be binding on the parties involved and they shall modify the hunt accordingly.

13 (d) The taking of gray whales from the Eastern stock in the North Pacific is permitted, but only by aborigines or Contracting Government on behalf of aborigines, and then only when the meat and products of such whales are to be used exclusively for local consumption by the aborigines whose traditional aboriginal subsistence and cultural needs have been recognised and further provided that:

(i) For the years 2003, 2004, 2005, 2006 and 2007, the number of gray whales taken in accordance with this sub-paragraph shall not exceed 620, provided that number of gray whales taken in any one of the years 2003, 2004, 2005, 2006 and 2007 shall not exceed 140.

(ii) It is forbidden to strike, take or kill calves or any gray whale accompanied by a calf.

(iii) This provision shall be reviewed annually by the Commission in light of the advice of the Scientific Committee.

13 (e) The taking by aborigines of minke whales from the West Greenland and Central stocks and fin whales from the West Greenland stock is permitted and then only when the meat and products are to be used exclusively for local consumption.

(i) The number of fin whales from the West Greenland stock taken in accordance with this sub-paragraph shall not exceed the limits shown in Table 1.

(ii) The number of minke whales from the Central stock taken in accordance with this sub-paragraph shall not exceed 12 in each of the years 2003, 2004, 2005, 2006 and 2007, except that any unused portion of the quota for each year shall be carried forward from that year and added to the quota of any subsequent years, provided that no more than 3 shall be added to the quota for any one year.

(iii) The number of minke whales struck from the West Greenland stock shall not exceed 175 in each of the years 2003, 2004, 2005, 2006 and 2007, except that any unused portion of the strike quota for each year shall be carried forward from that year and added to the strike quota of any subsequent years, provided that no more than 15 strikes shall be added to the strike quota for any one year. This provision will be reviewed if new scientific data become available within the 5-year period and if necessary amended on the basis of the advice of the Scientific Committee.

(4) For the season 2003-2007 the number of humpback whales to be taken by the Bequians of St. Vincent and The Grenadines shall not exceed 20. The meat and products of such whales are to be used exclusively for local consumption in St. Vincent and The Grenadines. Such whaling must be conducted under formal legislation that accords with the submission of the Government of St. Vincent and The Grenadines (IWC/54/AS 8 rev2). The quota for the seasons 2006 and 2007 shall only become operative after the Commission has received advice from the Scientific Committee that the take of 4 humpback whales for each season is unlikely to endanger the stock.

5.4.2 Report of the Aboriginal Subsistence Whaling Sub-committee

In the Sub-committee, while there did not seem to be problems with the report from the Small Group, some concerns were expressed regarding the Schedule amendment proposed by the Russian Federation.

The UK fully accepted that the rights of Chukotka people should be exactly the same as other indigenous peoples but stressed the need to ensure that for aboriginal subsistence whaling operations, the products are, totally or in large measure, used for the people whose needs have been acknowledged. It therefore suggested that rather than simply deleting the text “whose traditional aboriginal subsistence and cultural needs have been recognised” it be moved so as to apply equally to all indigenous whaling operations. New Zealand made a similar point. Austria sought clarification as to whether deleting this phrase would mean that all future new applications for aboriginal quotas would no longer need to demonstrate that they fulfil these criteria. Several members commented that the appropriate tests of need would continue to apply and that it is the Commission itself that recognises need when it approves aboriginal subsistence whaling quotas.

Grenada supported the proposed Schedule amendment in as much as it was aimed at producing a more uniform code for subsistence whaling operations, but questioned why St. Vincent and The Grenadines is the only one of those operations managed by IWC for which explicit text is included to effect that its operations must be conducted according to national legislation. On the understanding that all IWC members must enact national laws in accordance with the Convention, Grenada suggested that this reference in paragraph 13(b)4 either be deleted or inserted into the sub-paragraphs relating to other subsistence whaling operations. Japan considered that the proposed new paragraph 13(a)4 should refer to female whales accompanied by calves and, noting its long-standing cultural needs for whales, questioned how cultural needs are defined.

The Sub-committee endorsed the recommendation of the small group that its report and the proposed Schedule amendment be put forward to the Commission in plenary. The Sub-committee Chair recommended that those countries suggesting modifications to the proposed Schedule amendment consult prior to the Plenary.

5.4.3 Commission discussions and action arising

In the Commission, the Russian Federation introduced the report of the Small Group (see section 5.4.1), drawing particular attention to the definition of ‘subsistence use’, and asked that it be adopted by consensus and included in the Chair’s Report of the meeting. It noted that since the meeting of the Aboriginal Subsistence Whaling Sub-committee it had worked with Denmark, St. Vincent and The Grenadines and the USA to address the Sub-committee’s comments and with them wished to put forward the following slightly revised proposed Schedule amendment:
With the intention to further harmonise Schedule paragraph 13 it is proposed to amend Schedule paragraph 13 as follows (proposed new text is in **bold italics**; deleted text is in **strikeout** mode):

**13.(a) (4) For aboriginal whaling conducted under subparagraphs (b)(1), (b)(2), and (b)(3) of this paragraph, it is forbidden to strike, take or kill calves or any whale accompanied by a calf. For aboriginal whaling conducted under subparagraphs (b)(4) of this paragraph, it is forbidden to strike, take or kill suckling calves or female whales accompanied by calves.**

(5) All aboriginal whaling shall be conducted under national legislation that accords with this paragraph.

(b) Catch limits for aboriginal subsistence whaling are as follows:

(i) The taking of bowhead whales from the Bering-Chukchi-Beaufort Seas stock by aborigines is permitted, but only when the meat and products of such whales are to be used exclusively for local consumption by the aborigines and further provided that:

   (i) For the years 2003, 2004, 2005, 2006 and 2007, the number of bowhead whales landed shall not exceed 280. For each of these years the number of bowhead whales struck shall not exceed 67, except that any unused portion of a strike quota from any year (including 15 unused strikes from the 1998-2002 quota) shall be carried forward and added to the strike quotas of any subsequent years, provided that no more than 15 strikes shall be added to the strike quota for any one year.

   (ii) It is forbidden to strike, take or kill calves or any bowhead whale accompanied by a calf.

   (iii) This provision shall be reviewed annually by the Commission in the light of the advice of the Scientific Committee.

(ii) The findings and recommendations of the Scientific Committee’s in-depth assessment for 2004 shall be binding on the parties involved and they shall modify the hunt accordingly.

(ii) For aboriginal whaling conducted under national legislation and since St. Vincent and The Grenadines are able to distinguish between males and females, the distinction between this hunt and the others regarding the prohibition of taking whales accompanied by calves should be retained.

The Russian Federation believed that a fragile balance had been reached and on behalf of the other co-sponsors asked that in addition to the report of the small group, the revised proposed Schedule amendment could also be adopted by consensus.

The Commission adopted both the report of the small group and the revised proposed Schedule amendment by consensus. The Russian Federation thanked all Commissioners for their understanding and acknowledged the work of the small group in coming to this result. It hoped that the Commission could continue to work in such a friendly atmosphere. St. Vincent and The Grenadines echoed these sentiments.

### 6. REVISED MANAGEMENT SCHEME

#### 6.1 Revised Management Procedure (RMP)\(^8\)

##### 6.1.1 GENERAL RMP ISSUES

**REVIEW OF THE IMPLEMENTATION PROCESS AND LEVELS OF INFORMATION REQUIRED FOR PRE-IMPLEMENTATION ASSESSMENTS AND FOR PROCEEDING TO AN IMPLEMENTATION**

The Scientific Committee reviewed the **Implementation process**\(^9\) in light of its experience with western North Pacific minke whales. The aim was to develop a more streamlined and practical approach that would allow the Committee to provide advice to the Commission in a reasonable timeframe regarding particular implementations of the RMP. The unacceptably long time taken to complete the **Implementation** for western North Pacific common minke whales, particularly in comparison with North Atlantic common minke whales, prompted this work.

The Committee Chair reminded the Commission that unlike the case-specific approach used to develop AWMP Strike Limit Algorithms such as that for the Gray Whale SLA (see section 5.1), it had been decided that the RMP would follow a generic approach that should be applicable to all baleen whales; the RMP’s **Catch Limit Algorithm (CLA)** was thus developed on an assumption of a generic single stock. The most important feature of the

---

8 For details of the Scientific Committee’s deliberation on this Item see J. Cetacean Res. Manage. 7 (Suppl.).

9 i.e. a process by which the Committee makes recommendations to the Commission concerning catch limits (which may be zero or greater than zero) for a particular species in a region.
Implementation Simulation Trials (ISTSs) is to examine RMP performance in a real multi-stock situation and to decide which variant or variants of the RMP can be recommended to the Commission. In all cases it is the CLA that is used to calculate the catch limit. In this respect, the Chair noted that some of the reasons for the lengthy process for western North Pacific whales related to the potential complexity of stock structure and the fact that whaling was taking place in coastal waters during migration. He further noted that it is likely that this type of scenario is one that the Commission will request the Committee to provide management advice on in the future.

The Scientific Committee took considerable time to examine the process in detail. Believing that the RMP represents a major step forward in the provision of safe management advice for natural resources, it wanted to make sure that it had a clear set of guidelines as to how it should be used in real situations. In doing this, the Committee looked at a number of issues surrounding, in particular, questions of plausibility, data requirements and availability, and the balance in the nature of the ISTs. The Committee was also aware that there is almost a paradox in implementing the RMP in that it is a feedback procedure that is designed to learn more as it progresses through time. However, at the beginning of the process (i.e. before feedback starts) there will be the most uncertainty. One of the major discussions of the Committee was to investigate ways to address this issue which do not compromise the appropriate conservative nature of the RMP and the Commission’s objectives.

Given this, the Committee developed technical specifications for the ‘Requirements and Guidelines for Implementations’\textsuperscript{11} The key elements of the Requirements and Guidelines are given below.

(1) The development of a single structure and timetable to avoid the implementation process taking an extended period of time. The important development is that the pre-implementation assessment is the forum for ensuring that sufficient information is available to enter into an Implementation, with the expectation that the latter can be completed within two years.

(2) Practical ways to deal with the issues that have caused significant difficulty in the past, including:
   (i) how to deal with plausibility of alternate hypotheses (on \textit{inter alia} stock structure, historical catch/bycatch,\(g(0)\) for abundance estimates);
   (ii) how to assign weights to simulation trials; and
   (iii) how to interpret trial results.

(3) A way to encourage the provision of information while whaling operations are taking place by giving the Commission an option to initiate the RMP by:
   (i) using a hybrid variant for an initial period whilst ensuring that the objectives of the RMP (particularly with respect to conservation performance) are still met; and
   (ii) linking this specifically to a research programme designed to reduce key uncertainties.

With respect to (3) above, the Committee Chair noted that the general idea, first raised two years ago but not specified in any detail, is that there may be limited circumstances when it is appropriate to give the Commission an option for a hybrid variant, i.e. one that is tested as a combination of a less conservative variant for an initial period of one or two 5-year blocks (whilst data to reduce specific areas of uncertainty are collected), followed by an assumption of a worst case scenario in which it is assumed the associated research programme designed by the Scientific Committee does not result in a reduction of uncertainty and thus the next block reverts to the more conservative variant. The Committee Chair noted that this latter point, although only one aspect of the overall guidelines, had become the focus of some discussion outside the Committee. He therefore provided the following clarifications:

(1) the possibility of using a hybrid variant can only be considered if it has been thoroughly tested in Implementation Simulation Trials and found to have fully acceptable conservation performance under the RMP, both in the short term and the long term;

(2) only RMP variants that perform acceptably or ‘borderline’ on the ‘high’ weight trials would be considered as candidates for the less conservative variant;

(3) this option will only be considered if the Scientific Committee believes that a research programme can be designed that has a good chance of allowing the Committee to answer its questions on the plausibility of the hypotheses under dispute;

(4) the associated research programme that will be developed and guided by the Committee must identify expected progress in a manner that will allow the Committee to review annually whether the programme has been adequately followed;

(5) the option of using a hybrid variant can only be used once - it is not possible for it to be used again at the end of the initial period under the guidelines we have proposed;

(6) if the Committee does put forward a hybrid variant to the Commission, it will simply be one of several options, i.e. all of the variants that perform acceptably will be put before the Commission for its consideration.

The Committee noted that although this differs from the general guidelines used last year for the western North Pacific common minke whale trials (where acceptable variants needed to perform acceptably in all high plausibility trials and at least borderline in medium plausibility trials), any hybrid variant that the Committee might recommend under the requirements developed this year must perform to the same agreed level of acceptability.

The Chair noted that the ‘Requirements and Guidelines for Implementation’ developed by the Committee relate to:

(1) the information needed to initiate the pre-implementation assessment;

(2) the nature and outcomes from a pre-implementation assessment; and

(3) the steps in conducting an Implementation and the expected input and outcomes at each stage.

<tr>
<td>2</td>
<td>The primary objective is to develop an appropriate Implementation Simulation Trials structure and to specify the associated conditioning so that it can be carried out before the First Annual Meeting. Workshop discussions will include: (1) A final review of the plausible hypotheses taking into account the probable management implications to avoid unnecessary work; (2) An examination of more detailed information on expected operations; (3) The determination of the small geographical areas that will be used in specifying the stock structure hypotheses and operational pattern; (4) The development of (options for) potential Small Areas and management variants; (5) The specification of the data and methods for conditioning the trials; (6) Further consideration of experimental ways to distinguish amongst competing stock hypotheses. It is important to note that after this stage: (1) there shall be no changes to the agreed trials structure that implements the agreed plausible hypotheses; (2) no new data will be considered.</td>
<td>The primary objective is to review the results of conditioning and to finalise the ISTs. This review may include new analyses of data but not new data. The Trials may be changed but not the overall structure. Final ISTs based on: (1) final consideration of plausibility, including weighting trials in terms of the overall balance of the ISTs; (2) discussion of what data/research may reduce number of hypotheses; (3) updates to standard data sets (i.e. abundance, catches, bycatches) for use in final trials; (4) specification of operational features and management variants; (5) specification and classification of final trials; (6) develop timetable for remaining work</td>
<td>The primary objective is to review the results of the final trials and develop recommendations for consideration by the full Committee on: (1) management areas; (2) RMP variants (e.g. Catch-coupling, Catch-capping); (3) associated operational constraints (e.g. temporal restrictions); (4) research needs (either within or outside operations) to narrow range of plausible hypotheses; (5) use of 'a less conservative' variant with appropriate research and associated time period.</td>
<td>The primary objective is to review the results of the Second Intersessional Workshop (including any additional trials) and agree recommendations for Implementation. If this includes a recommendation for a 'less conservative' option, integral to this will be an agreed research programme guided and approved by the Committee. A progress report on this programme must be submitted annually to the Scientific Committee.</td>

### Carry out Implementation Review. Make recommendations to Commission.

Determine new trials to account for new information (depending on complexity, this may resemble either stage (2) or stage (3)).

Examine new information and determine if this is inside/outside tested parameter space and/or if it has narrowed hypotheses. If yes, need new trials and at least one workshop. If no, straight to Implementation Review at Annual Meeting (9).

RMP annotation 9 specifies that an Implementation Review should normally be scheduled no later than 5 years since completion of the previous Implementation (Review), but earlier if important new evidence on stock identity, major changes to abundance estimation methodology, etc.
He noted that an Implementation will normally be completed two years after the Committee recommends that the pre-implementation assessment is complete and the assessment can start. The implementation itself will occur during two intersessional workshops and two Annual Meetings. Table 1 summarises the recommended schedule for an Implementation and subsequent Implementation Reviews.

The Scientific Committee recommended the adoption of the ‘Requirements and Guidelines for Implementation’.

OTHER
In response to some questions raised by the Commission in the past concerning the spatial-temporal considerations in the RMP, a possible annotation to the RMP specifications was discussed and drafted by the Committee. It will be discussed and finalised at next year’s meeting, then presented to the Commission.

The Committee’s Requirements and Guidelines for Conducting Surveys and Analysing Data within the RMP were revised and recommended to the Commission for adoption.

The Norwegian representatives to the Committee formally notified it that Norway intended to develop and propose a change to the CLA for minke whales in the North Atlantic, in accordance with the guidelines for such a process given in 1992.12

6.1.1.2 PREPARATIONS FOR IMPLEMENTATION
NORTH PACIFIC BRYDE’S WHALES
The Committee has made relatively slow progress on completing the Implementation for western North Pacific Bryde’s whales inter alia due to its heavy workload. While noting that it was in the pre-implementation assessment stage, the Committee noted the considerable work already undertaken and agreed that it should be possible to move faster towards Implementation than would be the case for new situations. For a number of reasons, the Committee did not make as much progress as it had hoped on this issue in Sorrento. In order to ensure progress during the coming year it therefore agreed to hold an intersessional Workshop before the next annual meeting.

NORTH ATLANTIC FIN WHALES
The Committee reviewed the available information in order to determine whether there was sufficient information to warrant the initiation of a pre-implementation assessment for North Atlantic fin whales. It agreed that there was and recommended that the Committee initiate the pre-implementation assessment, beginning at next year’s annual meeting.

6.1.1.3 BYCATCHES OF LARGE WHALES
The RMP estimates a limit for the number of non-natural removals, not simply a catch limit for commercial whaling. It is therefore important to estimate the numbers of whales removed from the population by indirect means including for example bycatches in fishing gear and ship strikes.

The Scientific Committee began to consider this issue in some detail three years ago. It agreed that priority should be given to those areas where the RMP is likely to be implemented - such as the northwestern Pacific and the northeastern Atlantic. Four steps are required:

(1) identification of the relevant fisheries;
(2) description and categorisation of those fisheries to allow a sampling scheme to be devised;
(3) identification of a suitable sampling strategy or strategies; and
(4) design and implementation of the sampling scheme to enable estimation of the total bycatch.

The Committee has reviewed general methods for estimating bycatches. These fall under two headings:

(1) those based on fisheries data and observer programmes; and
(2) those based on genetic data.

The former have been used successfully for several small cetacean populations.

The Committee agreed that independent observer schemes are generally the most reliable means of estimating bycatch rates in a statistically rigorous manner, but that they may not always be practical and will require careful design.

Genetic approaches potentially represent a new way of estimating bycatches. The Committee has agreed that although genetic methods based on market samples may not be the primary approach to estimating bycatch, they could provide useful supplementary data that could not be obtained in another way. The use of market samples to provide absolute estimates should not be ruled out at this stage. However, for its value to be properly assessed will require further developments in sampling design with input from experts with detailed knowledge of market sampling issues. A proposal for a Workshop on that subject was developed and this Workshop will be held immediately prior to the next annual meeting in Ulsan, Korea. The objectives of the Workshop are:

(1) to review available methods that have been used to provide estimates of large cetacean bycatches via market samples, including a consideration of their associated confidence intervals in the context of the RMP;
(2) to provide advice as to whether market-sampling-based methods can be used to reliably estimate bycatch for use in addressing the Commissions objectives regarding total removals over time and, if so, the requirements for such methods.

It was also noted that the Workshop will be interested in the question of markets only insofar as determining whether or not such data can be used to provide reliable estimates of bycatch.

Work to further explore improved bycatch estimation methods for the two approaches noted above is continuing. Improved data reporting for large whale bycatches was also recommended and a pro-forma developed.

6.1.2 Commission discussions
6.1.2.1 GENERAL ISSUES
With respect to the proposed ‘Requirements and Guidelines for Implementation’, Japan expressed strong appreciation to the authors of these guidelines that it believed would help the effective functioning of the Implementation process and avoid the long delays that have occurred in the past. It sought confirmation from the Scientific Committee Chair that the approach proposed would not increase risk to stocks. Germany also sought clarification on whether a less conservative approach was now being proposed. In response, the Scientific Committee Chair explained that the approach being proposed is appropriately conservative.

---

adequately precautionary and consistent with guidance from the Commission in the past. Australia was of the opinion that there are a range of issues related to the RMP that require clarification, e.g. methods for estimating populations, the spatial determination of stocks, harvesting strategies, the establishment of pre-exploitation levels, and whether population models are capable of dealing with shifts in ecosystem regimes. Given the complexity of the issue, the turnover of Commissioners and adherence of new countries to the Convention, Australia proposed that the Chair of the Scientific Committee be invited to make a comprehensive presentation on the RMP and related aspects to the Commission at its 57th Annual Meeting in Ulsan. The UK, Italy and Germany supported Australia’s proposal. Iceland appreciated the proposal but believed that it should not delay the Scientific Committee’s work. The USA noted that the Committee’s proposals are guidelines and as such define a process rather than changing fundamental aspects of the RMP. It hoped that the proposed presentation would not turn into an opportunity to pick apart the RMP. Norway supported adoption of the guidelines and saw no reason to delay their implementation.

6.1.2.2 PREPARATION FOR IMPLEMENTATION
Japan noted that work on western North Pacific Bryde’s whales began in 1997 but that there had been delays due to other work of the Committee. It regretted that the Implementation Simulation Trials had not been initiated this year.

Iceland expressed concern that limited resources meant that it was not feasible for the Scientific Committee to start two Implementations in the same year resulting in a delay of the completion of the pre-implementation assessment for North Atlantic fin whales at next year’s meeting.

6.1.2.3 ESTIMATION OF BYCATCH
New Zealand welcomed the Scientific Committee’s report on this issue and spoke in support of the proposed workshop, as did the UK, Sweden and Australia. Norway, together with Japan, the Republic of Korea, Dominica and Grenada could not support the Committee’s strong recommendation for the workshop, believing it to be outside the Commission’s mandate and not plausible. The Republic of Korea noted the difficulty in performing market surveys. Instead, it had made efforts to improve bycatch reporting.

6.1.2.4 NORWAY NOTIFICATION
Norway drew attention to its notification to the Scientific Committee, in accordance with existing guidelines, regarding its intention to develop and propose a change to the CLA of the RMP for minke whales in the North Atlantic. It gave two scientific reasons for the proposed changes:

1. the current CLA gives inappropriately small catch limits (compared with, for example, the SLA of the AWMP for eastern North Pacific bowhead and gray whales); and
2. when the RMP was developed in the 1980s, the precautionary principle was interpreted ‘one-sidedly’. It was important to ensure against over exploitation of whale resources. Under a future ecosystem-based management, the precautionary principle must be interpreted ‘two-sidedly’ in the sense that it is important to avoid not only to harvest too many whales, but also not to harvest too few, given the plausible resultant impacts on sustainable fishery yields. The UNWDDS (Johannesburg, 2002) encouraged, with regard to exploitation of living marine resources, the application by 2010 of the ecosystem approach. In this context it is important that the operative management procedure for minke whales is a realistic tool for stabilizing stocks at predetermined levels below carrying capacity.

Japan, noting that it believes the current RMP to be too precautionary, sympathised with Norway and looked forward to hearing of progress in its work. St. Kitts and Nevis and St. Lucia also supported Norway. In contrast, Austria, Germany, Switzerland, Brazil, the UK, New Zealand, Italy, the Netherlands, Mexico and Australia all expressed concern. Some viewed this move by Norway to be shaking the foundations of the RMP and called into question the commitment of members to develop a set of mechanisms to manage exploitation of whale resources. Others believed that with respect to incorporation of an ecosystem approach, Norway would be operating under a speculative hypothesis.

Iceland suggested that the Commission should not be having a political debate on a scientific issue. The USA agreed and clarified that at this point Norway is not asking for an amendment to the RMP but simply notifying their intention to invoke a scientific process. Monaco and Sweden agreed, although Sweden noted that implementation of an ecosystem approach does not necessarily mean that resources should be harvested.

6.1.3 Action arising
The Commission noted the report and endorsed its recommendations, although with respect to the recommended bycatch workshop, the reservations of Norway, Japan, Republic of Korea, Dominica and Grenada were noted. The proposal for a presentation on the RMP at IWC/57 was also noted.

6.2 Revised Management Scheme (RMS)
6.2.1 Report on intersessional work
At IWC/55 in Berlin, the Commission agreed to Henrik Fischer’s proposal to convene a small group of his choosing to explore ways and possibilities of taking the RMS process forward. He subsequently invited Denmark, Iceland, Ireland, Japan, the Netherlands, Spain, Sweden and the USA to take part. All except Ireland were able to accept. Ireland had to decline due to pressures of work associated with the lead-up to Ireland’s presidency of the EU starting in January 2004. The Chair’s small group (CSG) met at the Secretariat’s offices in December 2003 and again in March 2004. Based on these discussions, Henrik Fischer developed his proposals for a way forward on the RMS (see Annex E). This document was circulated in confidence to Commissioners prior to IWC/56 and then presented and discussed at a private meeting of Commissioners in Sorrento on Friday 16 July 2004. A summary of the Chair’s proposed RMS ‘package’ is provided below (note that items indicated with an asterisk require modification of the Schedule).

Elements of a Proposed RMS ‘Package’
1. RMP*: as agreed by the Scientific Committee and endorsed by the Commission.
2. A phased-in approach to the resumption of commercial whaling*: for an initial period (e.g. 5
years after the lifting of the moratorium), commercial whaling would only be allowed in waters under national jurisdiction.

3. **National inspection and observation scheme**: as proposed by the EDG (generally, observers and inspectors on all boats where practical) with VMS on very small vessels with <24hr trips and one observer per catcher attached to a factory ship.

4. **Additional catch verification to combat IUU whaling and/or unreported bycatches (NOT to monitor trade):**
   - National diagnostic DNA registers and market sampling to agreed standards (with outside review) and a procedure to allow checking of samples against the registers*.
   - Resolution urging countries to institute national legislation prohibiting the import of whale products from non-IWC countries as well as from IWC countries that are non-whaling.
   - Documentation up to port of entry if importation from IWC member *.

5. **Compliance**: compliance Review Committee with duties as developed by the RMS Expert Drafting Group and agreed by the Commission, and inclusion of Schedule text as proposed in Berlin: The Compliance Review Committee reports on infringements and the seriousness of these infringements to the Commission and advises the Commission what actions, if any, to be taken’.

6. **Mechanism to apportion RMS costs among Contracting Governments**: costs for national activities should be borne by relevant national governments, while international costs for securing transparency could be allocated in the context of the overall financial contributions scheme.

7. **Measures for the lifting of Paragraph 10(e)**: modify paragraph 10(e) such that it becomes invalid on a specific day whilst ensuring that any whaling operations are undertaken under the full RMS package (N.B. catches other than zero can only be set for species/areas the Scientific Committee provides advice for under the RMS – currently very few).

8. **Whaling under Special Permit**: recognise that it is a Sovereign right under the Convention but develop a Code of Conduct.

9. **Animal welfare considerations:**
   - Explicit recognition of the issue in the Schedule*: 'The hunting of whales shall be undertaken so that the hunted whale does not experience unnecessary suffering and so that people and property are not exposed to danger.'
   - Resolution focussing on improving techniques, voluntary provision of data to regular scientific workshops and possible co-operative research programmes.

In his document, the Chair noted that the above ‘package’ of measures includes, in some way, all but two of the elements that have been discussed recently in the context of the RMS. The exceptions are blanket trade restrictions and sanctuaries. While some form of trade restriction might be appropriate in deterring IUU whaling, he believed that a blanket ban on international trade in whale products would be discriminatory against some countries, against principles of free trade and outside the competence of IWC. With respect to sanctuaries, he considered that each should be reviewed on its own conservation and management merits and would therefore be difficult to build into any RMS ‘package’.

In the absence of Henrik Fischer, the private meeting of Commissioners to discuss his proposals was chaired by Chris O’Grady, Commissioner for Ireland. Henrik Fischer did, however, submit a written statement to Commissioners (see Annex F).

Chris O’Grady reported the outcome of the private meeting of Commissioners to the plenary meeting. He noted that the objective of the meeting was to present and explain the Chair’s proposal and that this had been achieved largely thanks to the presentation of Greg Donovan from the Secretariat. He reported that while some Commissioners expressed difficulties with some elements of the Chair’s proposed package, there was general agreement that (1) a package approach would be a useful way forward and (2) that the Chair’s document formed a good basis for discussion during the Commission plenary. It had also been agreed that the documents circulated to Commissioners in confidence should be made publicly available in response to concerns expressed by some that the intersessional work had lacked transparency. Some criticism had been levelled at the way involvement in the intersessional work had been restricted to certain countries and there was a call from some Commissioners for wider involvement in any future discussions. Finally Chris O’Grady reported that the Commissioners had agreed that substantive discussion on the Chair’s proposed RMS package should be left to the plenary and drew attention to the fact that the Chair’s proposal would require considerable intersessional activity prior to IWC/57 next year.

6.2.2 Commission discussions and action arising
Discussions were structured by first inviting an initial exchange of views on Henrik Fischer’s proposals, then asking for specific comments on the different proposed RMS package elements and then developing a plan for future work.

6.2.2.1 INITIAL COMMENTS
Denmark agreed fully with the sentiments expressed by Henrik Fischer in his statement to Commissioners (Annex F) regarding the RMS process and the need for its early completion and adoption with as broad a support as possible. It agreed that an RMS is needed for both whale conservation and whale management and considered that the Chair’s proposal should be the basis for completing this work, while recognising that obstacles remained to be overcome. However, it stressed that the elements included in the proposed RMS package together represent a delicate balance that had been developed in the spirit of compromise and that this balance should not be compromised. Denmark considered that, as proposed by the Chair, there must be a clear link between the adoption of the RMS and the lifting of the moratorium. It considered that if it is not acknowledged that the objective of an RMS is to conserve whale stocks and to manage whaling in practice, not in theory, using one of the most conservative and precautionary systems ever devised for the setting of quotas of any marine resource (i.e. the RMP), then the rationale for continuing the work would be questionable. Denmark acknowledged that how and when this link is activated is open to discussion, but believed that general opposition to this would de-rail the entire process. It also
believed that for the sake of conservation, the moratorium should be lifted and an agreed mechanism implemented to allow for the international management of whaling. It considered that the alternative would be the continued and likely increased level of whaling around the world without agreed international control. It respectfully requested those Contracting Governments that have expressed a concern about linking adoption of the RMS with lifting of the moratorium to explain the nature of their concerns. Denmark believed that without an RMS in place, the Commission would cease to function according to its own Convention, and that many Contracting Governments would be forced to consider seriously the purpose of their continued membership. It therefore urged delegates, as representatives of responsible governments in an international body, to keep the RMS work at the top of the agenda with Henrik Fischer’s proposal as the window of opportunity and to provide the resources necessary to have an RMS ready for final consideration at IWC/57 in Ulsan next year.

The USA stated that it wished to make clear that it continues to support the moratorium on commercial whaling, but that it nevertheless remains committed to completing the RMS in a timely fashion. It commended the Chair for his efforts in establishing his small group and thus advancing the RMS process. It considered that without his intervention, it is doubtful whether any progress would have been made since IWC/55. The USA noted that it generally agreed with the Chair’s proposal and process and saw the need to develop a plan for inter sessional work on the RMS. It noted that it could not adopt the proposal in its entirety but was willing to use it as a basis for discussions. It expressed some concerns with the Chair’s proposal, particularly with respect to paragraph 10(e) – the moratorium, scientific whaling and cost sharing. It noted the need to include transparency in any future process.

Sweden commented that when it voted in 1982 to introduce the commercial whaling moratorium, it envisaged a 10-year period without whaling in which increased research into the status of whale stocks and the development of an RMS would be carried out. It noted that unfortunately, there had been an increase in whaling outside of IWC control since the moratorium was put into force. Nevertheless, Sweden stressed that it remained committed to completion of the RMS that is now much overdue. It believed that no one, and certainly not the whales, benefit from the present situation and that an RMS is necessary to ensure that whaling will be sustainable and that whale stocks will be restored. Sweden noted that it had therefore accepted gladly the Commission’s decision last year to allow Henrik Fischer to establish a small group to facilitate the process towards a new RMS. It noted that in contrast to discussions within the whole Commission that have not always been constructive, its participation in the small group had been a very positive experience, indicating that progress on the RMS is still possible. It hoped that the spirit of co-operation and willingness to seek compromises that had existed among members of the Chair’s small group could spread among the whole Commission. Sweden was convinced that the formation of the small group had been the only way forward at the time. However, it now believed that the process should be opened up, provided that this is done in a way that will not reduce efficiency. Sweden supported the Chair’s proposal that the RMS should comprise a package, and while his proposals did not fulfill all of Sweden’s requirements, it believed that they contain all the essential elements for an RMS and provide a good framework for further development. Completion of an RMS is a prerequisite to Sweden agreeing to lift the moratorium and it is willing to take an active part in further work. The Netherlands, who stressed that they continued to support the existing commercial whaling moratorium made similar comments.

Japan recalled that when the moratorium on commercial whaling was adopted in 1982, it was adopted on the clear condition that by 1990 at the latest, the Commission would undertake a comprehensive assessment of the effect of this decision on whale stocks and consider modification of the provision and the establishment of catch limits other than zero. It noted that this undertaking, which now includes completion of an RMS, remains unfulfilled. It also noted that it has supported early completion of the RMS and considered that while it has made a number of compromises during discussions, some nations opposed to whaling had made excessive requests regarding certain elements of the RMS thus delaying its completion. In view of this stalemate, Japan had supported and appreciated the establishment of the Chair’s small group, of which it had been a member. Japan accepted that the Chair’s proposed RMS package represents a compromise and noted that because of this, it is not happy will all elements (e.g. the inclusion of special permits). Nevertheless, it remained committed to taking part in future work which public opinion in Japan considered should be concluded by IWC/57 next year. If this was not achieved Japan noted that it would be faced with having to make a difficult decision.

Spain noted that it too remains committed to continuing the process to develop an RMS based on the Chair’s proposal. It did, however, have some concerns especially relating to proposals to lifting the moratorium, scientific whaling and cost sharing.

Iceland considered that the Chair’s document and proposals showed that more progress has been made in the last 10 months than in the last 10 years and that therefore the proposals should not be dismissed lightly. Although having been part of the small group, Iceland noted that it dislikes strongly various elements of the Chair’s proposal, and suggested that this would be the case for all Contracting Governments. However, it stressed that all parties should recognise that there can be no compromise solution on any other basis. Iceland considered that the Chair’s proposal represented the only way forward – beginning again from the status of discussions at IWC/55 would dismantle any chance of reaching a conclusion.

Ireland thanked the Chair and his small group, including the Secretariat, for their work. It regretted that it had been unable to join this group due to pressures of other work. Ireland noted that it supports the early adoption of a robust and effective RMS and the package approach proposed by the Chair. It believed the alternative of addressing the elements of an RMS one by one would be a recipe for confusion and continued division within the Commission. Ireland recalled that since 1995, it has been the author of a compromise proposal aimed at unlocking the paralysis within the Commission regarding adoption of an RMS and that it has consistently called for other Parties within the Commission to come forward with an alternative proposal that would meet with more favour than its own. It noted that the Chair’s proposal is the response for which it has been waiting, and, like others, considered that it is an
important and useful basis for moving forward. Although it supported the package approach, Ireland indicated that it could not, at this stage, accept the package put forward by the Chair, although it was open to further discussions. Its concerns with the package proposed centred on three broad issues:

(1) the link between adoption of an RMS and the lifting of the moratorium;
(2) that whale meat taken within the initial period (e.g. five years) would not be confined to local consumption; and
(3) the proposed handling of whaling under special permit.

Nevertheless, Ireland was optimistic that Henrik Fischer’s proposals could be used as a useful basis for breaking the log-jam within the Commission regarding adoption of an RMS. It concluded that the only way forward is further compromise from all members of the Commission. Ireland was prepared to contribute to this compromise.

Like Sweden, Switzerland believed that a management regime is needed to bring existing activities under IWC control. It considered that while more work is needed to reach a compromise solution, real progress had been made since last year and that the Chair’s proposal provided a good basis for further work. It also considered that the RMS has to be seen as a package of inter-linking elements. Finland, while still supporting the moratorium, commended the work of the Chair and his small group. It too considered the Chair’s proposal as a good basis for further work, although it had difficulties with some of the elements as currently included (e.g. costs and scientific permits). Finland believed that a transparent follow-up is needed with extended participation. Oman associated its position with the view expressed by Ireland and Switzerland.

Dominica considered the work reflected in Henrik Fischer’s proposal as a valuable step in the quest to finalise the RMS. Like others, it recognised that further work is needed but urged Commissioners to consider objectively the merits of the package approach proposed so that the RMS can be completed at IWC/57. It stressed the need for all parties to compromise. Antigua and Barbuda made similar remarks and hoped that the Commission could adopt a similar openness in future discussions as that shown by the Chair’s small group. The Republic of Guinea, St. Lucia, St. Kitts and Nevis, Grenada, Republic of Korea, Morocco and Benin made similar remarks. St. Lucia noted the significant efforts expended in the formation of the Conservation Committee last year, and urged the proponents of that Committee to commit themselves equally to the completion of the RMS along the lines proposed by the Chair.

Monaco believed that a modern and robust RMS is needed as soon as possible in order to restore credibility to the Commission. Like many others, it commended the work of Henrik Fischer and his small group and considered the proposed package of measures to be a useful basis for the construction of a carefully negotiated agreement.

While appreciating the work of the Chair and his small group, Argentina believed the proposal to be unbalanced since the group included neither representatives of countries from the Southern Hemisphere nor representatives from developing countries. It did not consider the Chair’s proposal an appropriate basis for further work.

Germany thanked the Chair, his small group and the Secretariat for their work since the Annual Meeting in Berlin. It noted that it would strive for an RMS based on best practices, drawing on the internationally-accepted high standards in regional fishery organisations. Germany viewed the Chair’s proposal as being helpful, but identified concerns related to lifting of the moratorium, catch verification, compliance, costs, special permit whaling and animal welfare (see next section). It considered that sanctuaries should be included as part of the RMS package. It believed that further work should be done in a fully transparent way according to a framework defined clearly by the Commission.

Italy complemented the Chair for his work. It noted that Italy continues to support the moratorium but at the same time believes it very important to make progress on the RMS. While it agreed that the proposed package was a useful tool for making progress, it saw problems with the proposal, particularly in relation to the proposed handling of scientific permits. Like Germany, Italy called for future work to be done in a more transparent way.

South Africa identified itself as a Southern Hemisphere developing country having concerns regarding the welfare of whales in its Exclusive Economic Zone (EEZ) and adjacent Southern Ocean. It noted that it is no longer a whaling country and that it has no intention of ever returning to this practice. It reported that it has benefited greatly from whalewatching, considering this form of non-consumptive use as the preferable means by which its people, and poor communities in particular, gain from the presence of whales along its coast. Indeed it asserted its right to non-consumptive use and its right to have a stake, through the IWC, in the management and conservation of whales on the high seas and in the Southern Oceans in particular. It described some specific concerns with Henrik Fischer’s proposal which are given in the section below and associated itself with the remarks of Germany. In general terms, South Africa believed that a greater degree of unanimity and convergence is needed among IWC members in relation to scientific advice (e.g. the RMP). It considered that the divergence evident at each Annual Meeting does not bode well for good management.

Brazil noted that it has participated in good faith in the long and difficult discussions on the RMS and had tried to be open and transparent about its two main interests, i.e.

(1) the construction of an adequate foolproof international inspection and observation scheme to prevent reoccurrence of past abuses and damage caused by legal and illegal whaling operations; and
(2) the proper discussion of an agreement to respect the rights of coastal states to appropriate whale resources in a given ocean basin through non-lethally means.

It reiterated its view that there should be no more private/closed door meetings on the RMS, and that Contracting Governments should be able to be represented at meetings with a full delegation as governments see fit. It stressed that transparency, full accountability and due respect to the rights of states that appropriate whale resources non-lethally are, in its view, integral aspects of RMS negotiations.

New Zealand associated itself with the remarks of Germany and South Africa. While recognising the Chair’s efforts to move the RMS process forward, it considered his proposal to be fundamentally flawed and indicated that it
would oppose it strongly in its present form for both general policy and legal reasons. It would not compromise on its fundamental views but it was willing to continue negotiations. New Zealand drew attention to the fact that the Commission has presided over the calamitous decline in whale stocks and believed that the negligence of the organisation in this matter is clear and palpable. It was this decline that had led to the 1982 decision to establish a commercial whaling moratorium, thereby taking steps to rebuild public confidence. New Zealand did not believe that the world’s public was yet ready for the resumption of commercial whaling, and questioned whether the lessons from past mistakes have been adequately learned and heeded. Regarding the future process for RMS discussions, New Zealand proposed that:

(1) the mandate of any groups established should be to develop proposals without preconditions as to their content;
(2) participation in any groups established should be unrestricted; and
(3) meeting schedules and venues should be selected to facilitate the greatest number of participants.

New Zealand considered completion of the RMS to be important, and suggested that this be done prior to the lifting of the moratorium. Furthermore, noting that the Convention is nearly sixty years old and that it is showing signs of weakness that come with age, New Zealand believed it to be badly out of date and in need of revision. Without revision, New Zealand considered that the burdens of administering an RMS would be beyond the capacity of the Commission to handle. In its view, the Convention has serious weaknesses compared with modern treaty instruments. It believed these weaknesses could be remedied, given the collective will to do this, but it was New Zealand’s view that commercial whaling could not resume unless and until there are appropriate international enforcement mechanisms and an appropriate international dispute settlement mechanism in place. It advocated revision of the Convention by way of a diplomatic conference to negotiate a Protocol.

The UK while appreciating the efforts of Henrik Fischer and his small group, considered that while the Chair’s proposal may form the basis for further discussion, like Germany and New Zealand, it doubted whether the proposal, in its present form, is a package that could form the basis of an agreement. The UK accepted however that work should proceed, believed that it should be done an inclusive a manner as possible, and agreed with New Zealand that there should be no preconditions as to its policy content. It also stressed, that if the Commission is to discuss the RMS in Ulsan with a view to reaching a final conclusion, then any draft package should be agreed as early as possible to allow adequate opportunities for public airing.

Australia associated itself with the comments made by South Africa and Germany. While referring to its well-known position that it would not support the resumption of commercial whaling, Australia noted its legitimate interest in ensuring that, in case this should occur, any management scheme developed has been tested against best and improving practice. It asserted its right to be part of an open and transparent process within the Commission regarding development of an RMS.

Kenya noted that it had never been a whaling nation and had no plans to become one. It believed its policy of the non-consumptive use of wildlife is well known, and in this spirit it favoured the continuation of the moratorium and was opposed to the proposed RMS package, despite its progressive intentions. It associated itself with the views expressed by South Africa and New Zealand.

Portugal associated itself with the views expressed by Germany and Ireland. Austria associated itself with the views of Germany, the UK, New Zealand and others. Peru associated itself with Argentina and Brazil. France indicated that while it is opposed to the resumption of commercial whaling, it recognised the work done by the Chair and his small group and awaited the outcome of future work with interest. Mexico supported the statement of South Africa. It also supported the views expressed by Brazil, Argentina and Peru in the sense that the RMS development process has to be more inclusive of geographic diversity, especially countries in the Southern Hemisphere that oppose whaling and are devoted to the conservation of whales. India wanted RMS development to be expedited, but did not support the suggestion that adoption of an RMS should be linked with lifting of the moratorium.

Dominica noted that last year, the Commission gave the Chair the mandate to form a small group of his choosing to work on a way forward. It therefore regretted the remarks made by some delegations regarding what they considered to be a lack of transparency in the intersessional work since the Annual Meeting in Berlin.

6.2.2.2 DISCUSSION OF PROPOSED RMS PACKAGE ELEMENTS

This section collates comments made on specific elements in the Chair’s proposed RMS package. It should be noted that absence of comments by countries neither implies acceptance or rejection of the Chair’s proposals.

RMP

The USA believed that the version of the RMS to be included in the Schedule should be that version adopted by the Commission by consensus in 1994 that incorporated the tuning level of 0.72 and a protection level of 0.54 adopted by the Commission in 1992. This is in line with the Chair’s proposal. Belgium made similar comments.

The UK noted that the Commission had been advised that the RMS linked to the RMP will provide adequate protection to whale stocks and that catch limits would only be set for whale stocks when scientific advice is given on those catch limits. It therefore viewed with concern Norway’s proposal to develop its own version of the RMP (see section 6.1.2).

PHASED-IN APPROACH TO COMMERCIAL WHALING

Brazil viewed this proposal to be one of the most unacceptable provisions within the package. It believed it to be inconsistent with the Convention on the Law of the Sea.

Germany sought clarification as to whether the proposal was to initially restrict whaling to within waters of national jurisdiction (that it understood as being normally a 12 mile limit) or to EEZs (i.e. 200 mile limit). Iceland explained that in fact waters under national jurisdiction extend to 200 miles not 12 miles. The USA confirmed that the Chair’s proposal was intended to restrict whaling to within 200 miles initially.
As indicated above, Ireland was concerned that whale meat taken within the initial period (e.g. 5 years) would not be confined to local consumption. China suggested that domestic legislation needed to be taken into account since its legislation prohibits the taking of whales in national waters.

NATIONAL INSPECTION AND INTERNATIONAL OBSERVATION
Australia, supported by the UK considered that inspection as well as observation should be co-ordinated at the international level by the Commission, and that the proposed provisions for use of vessel monitoring systems (VMS) do not reflect current best practice. Belgium believed that VMS should be compulsory for all whaling vessels.

ADDITIONAL CATCH VERIFICATION MEASURES
Sweden considered additional catch verification measures as a very important part of the RMS, believing it crucial that any systems put in place are transparent and allow for independent checking. It recalled the proposed Schedule amendment it and other countries submitted to the Commission at the Annual Meeting in 2002 and suggested that in the absence of alternative proposals to achieve a similar level of transparency in DNA registers, this remained the best option.

The USA indicated its willingness to support establishment of a DNA register with appropriate IWC oversight and catch documentation based on CITES requirements. It noted its concern regarding the status of current stockpiles of whale meat and other products and how these might be accounted for. Although its preference was that such stockpiles be disposed of by a certain date, it could accept having them entered into a DNA registry.

Belgium considered that the proposed DNA register has to be organised on an international basis for it to be effective. Germany agreed. With respect to catch documentation, Germany considered that it is not satisfactory to simply refer to CITES documentation. It considered that a specific system is needed for IWC and that this would require extensive further work.

Australia did not view the Chair’s proposal as being current best practice and suggested that the provisions of CCAMLR should be examined.

COMPLIANCE
Germany considered that provisions should be developed that would equate to the highest standards in other international organisations. Belgium believed that provisions regarding compliance needed to be carefully drafted. New Zealand believed that enforcement could not be left to national procedures as they would not work. Rather, New Zealand proposed that international enforcement mechanisms are necessary.

APPORTIONING COSTS
Germany, Spain, Netherlands, South Africa, Finland the UK, Monaco and the USA expressed concerns regarding the Chair’s proposals on how to apportion costs of an RMS among Contracting Governments and considered this to be an area where further work is needed. Germany did not believe that there should be cost sharing between all members and those members participating in whaling. It noted that in regional fisheries organisations, it is common practice that the fishing nations have to pay for international oversight (observers). Germany believed this same principle should apply to IWC. Spain made similar remarks. While the UK accepted that there may be certain central costs resulting from the operation of an RMS which might be appropriate to be borne by IWC’s budget as a whole, the UK found it unacceptable that it should be asked to contribute to the costs of enforcement and oversight. The USA, supported by Brazil, believed that the Chair’s proposal would result in certain delegations paying a disproportionate share of the total cost of implementing the RMS and called for a more equitable scheme.

Responding to the comparisons made between IWC and other fisheries management organisations in which costs of observers are borne by the fishing nations (user pays), Denmark drew attention to the fact that other fisheries organisations do not require both a national inspector and an international observer to be present on all vessels and neither do they require DNA analyses of every fish caught. Consequently, Denmark believed that a compromise had to be found and indicated its open-mindedness regarding what the solution might be. Iceland associated itself with these comments and added that the fundamental difference between IWC and other fisheries bodies is that the latter do not have some members that wish to prevent others from fishing. It therefore did not consider such comparisons appropriate. China agreed with the remarks of Denmark and Iceland.

South Africa noted that the likelihood of increasing costs to Contracting Governments associated with the proposal is of concern to a country like itself that cannot be a major contributor.

St. Kitts and Nevis indicated that RMS costs must be shared on the basis of equitable principles.

MEASURES FOR THE LIFTING OF PARAGRAPH 10(E)
Denmark, Japan, Norway, St. Lucia, St. Kitts and Nevis, and Grenada all stressed the need to link adoption of an RMS with the lifting of the commercial whaling moratorium. Norway failed to see the logic of discussing the RMS if there is no intention to use it. Japan, St. Kitts and Nevis and Grenada called for simultaneous lifting of the moratorium with adoption of an RMS. (See also Denmark’s comments in section 6.2.2.1).

Germany, Brazil, New Zealand, the UK, Australia, Belgium, Monaco, India and Argentina were strongly opposed to linking adoption of an RMS with lifting of the moratorium. Spain and Ireland expressed concern with the Chair’s proposal, while the Netherlands called for further elaboration of the phasing in of an RMS package with the phasing out of paragraph 10(e). Brazil believed that discussions on the lifting of paragraph 10(e) should be considered from a geographical as well as time perspective so as to take account of its position on the right of states to use whale resources non-lethally. New Zealand considered that there is no link as a matter of law between adoption of an RMS and lifting of the moratorium - each must be considered on its own merits. It further noted that should the conditions ever be right for lifting the moratorium, this could only happen once an RMS has been adopted. The UK could not see any way in which a package containing both elements will necessarily result in the moratorium only being lifted if an RMS is place without objection. The UK believed that if an objection is raised to the RMS, either at the time of its proposal as a Schedule amendment or subsequently by a government withdrawing from the Convention and re-adhering with a reservation (of which there is a precedent), the RMS should be scrapped and the moratorium immediately put back into force. Australia felt it legitimate for Contracting Governments to have strongly
held views on the nature of a robust management procedure should whaling recommence, while maintaining their opposition to commercial whaling and to the lifting of the moratorium. Australia also questioned whether it would be technically possible to achieve the Chair’s proposal, i.e. that paragraph 10(e) would become invalid on a specific day while ensuring that any whaling operations are undertaken under the full RMS package. It noted in particular that this proposal puts constraints on the rights of Parties to the Convention (i.e. the right to object) and it was not clear how this could be managed. In this respect, the Secretariat noted that it had not yet done any further work on this aspect as suggested in the Chair’s proposal.

WHALING UNDER SPECIAL PERMIT

Several governments believed that Article VIII of the Convention, allowing Contracting Governments to issue permits for the taking of whales for research purposes had been grossly abused in past years and particularly since the moratorium. Germany, Ireland, South Africa, the UK and New Zealand considered that the voluntary code of conduct proposed by the Chair was insufficient. Germany believed that binding rules are needed to regulate whaling under special permits. Ireland’s view was that special permit whaling should cease or at the very least be phased-out, if as proposed, commercial whaling is phased-in. It did not believe that public confidence in IWC’s ability to manage whaling would be achieved if whaling under special permit continued at the same time as commercial whaling was resumed. The UK found it unacceptable that any RMS could be put in place without some real control and preferably cessation of permit whaling. New Zealand suggested that special permit whaling is practised for improper and non-scientific motives and believed that the issue needs to be addressed in its own right regardless of whether or not an RMS is approved. New Zealand considered it inconceivable that special permit whaling could be allowed to continue and considered Article VIII to be one of the most abused provisions of the Convention and the one at which greatest criticism is levelled. New Zealand considered that Article VIII should be included in its proposals to revise the Convention (see earlier comments).

While it viewed the proposed voluntary code of conduct as a good-faith effort to address this issue, the USA did not believe it goes far enough. The USA reported that whaling under special permit is a major issue for them and stressed the need for substantive progress in terms of halting or deferring scientific whaling, irrespective of rights under Article VIII. It did not see an easy solution, but noted its preparedness to review any creative proposals for moving forward. Sweden associated itself with these remarks.

Spain, Italy and Finland also expressed concern regarding the Chair’s proposal. The Netherlands sought further elaboration. Monaco believed that special permit whaling should be brought under full modern control. Belgium considered that quotas for whaling under special permit should be determined by the RMP.

In response to New Zealand’s comments, Japan suggested that if New Zealand considers Japan’s activities on special permit whaling to be an abuse of Article VIII, then it had the option of bringing a case to the International Court of Justice. It therefore did not consider that preparation of a Protocol is necessary, but viewed it as a delaying tactic. Iceland believed it was clear that to change the Convention along the lines suggested by New Zealand would require more of a consensus than Iceland considered politically possible. It suggested that advocating a revision of the Convention as part of the RMS package is, in effect, rejecting an RMS. Norway supported Iceland’s views.

ANIMAL WELFARE CONSIDERATIONS

Noting the importance of animal welfare considerations, Germany indicated that provisions requiring the collection of animal welfare data on a regular basis must be included in the Schedule. It also believed that provisions are needed for killing methods that guarantee instantaneous death or insensibility. Belgium considered that animal welfare considerations should be part of the RMS package. The UK viewed as inadequate the Chair’s proposals in this respect, suggested that they add nothing to what is currently included in various Resolutions and in requests for data that are sometimes honoured and sometimes not. The UK believed that if the Commission as a body is to sanction the killing of whales, then it has an ethical duty and moral responsibility to have input into the way whales are killed, e.g. specifying the types of equipment, specifying the weather conditions and sea state under which whales may be taken, and insisting on the collection of data on the efficiency of hunting methods. It recognised that some of these statistics may be difficult to obtain, but nevertheless believed them to be an essential part of an RMS. Without them, the UK considered that there would be no guarantee that whale welfare would be respected.

6.2.2.3 DEVELOPMENT OF A PLAN FOR FURTHER WORK

Denmark, on behalf of the other co-sponsors (Ireland, Iceland, Republic of Korea, Japan, Netherlands, Spain, Sweden, Switzerland and the USA) introduced a draft Resolution to proceed expeditiously towards the completion of both the drafting of text and technical details of the RMS, with the aim of having the results ready for consideration and adoption at IWC/57 (see Table 2). Denmark explained that the proposed Resolution tried to build on the increasing trust and determination of Contracting Governments to overcome the deadlock on the RMS that has plagued the Commission for so long. It stressed that crucial to the building of trust is the recognition of the dual role of the Commission to both conserve whale stocks and to manage whaling. This recognition had been the point of departure for the Chair’s initiative in developing his proposed RMS package, and Denmark believed that it should be at the heart of the work proposed in the Resolution. Denmark noted that the co-sponsors also recognised the importance of taking account of the key questions and concerns raised in response to the Chair’s proposals (drawing attention to the third preambular paragraph of the Resolution) and in particular the need for full transparency and geographical representation. Assuring delegates that the speedy completion, adoption and implementation of the RMS is an issue on which there is full consensus within the Kingdom of Denmark and noting that the Resolution represented a delicate balance of interest, Denmark urged countries to support the proposed Resolution without amendments.

The USA introduced the proposed intersessional plan of action included with the draft Resolution (see Table 2). It noted that over the course of discussions in Sorrento, a general agreement had emerged that progress on completion of the RMS should be facilitated by intersessional work prior to IWC/57. It also noted the Secretariat’s paper (IWC/56/36) summarising the further work required based on the Chair’s proposal that
demonstrated the need for a mix of activities by some of the Commission’s existing sub-groups, such as the RMS Working Group, Scientific Committee and Contributions Task Force, and some new expert groups to advise on technical matters, e.g. in relation to catch verification.

To balance the need for transparency with the need to be able to work efficiently, the plan of action proposed to (1) address the former by reviving the RMS Working Group (that is open to all Contracting Governments and observers) under the Chairmanship of Henrik Fischer and (2) address the latter by establishing a small drafting group under the RMS Working Group. With respect to size, composition and leadership of the small drafting group, the USA proposed that delegations advise the Chair of their interest in serving and that the Commission leave it to the Chair to decide on the group’s membership and Chair. It was suggested that the Chair of the Commission should also serve on the small drafting group and that the Secretariat be involved in all groups to provide continuity, expertise, oversight and co-ordination. The USA stressed that the process included in the draft Resolution would require a substantial commitment, i.e. involvement of the Secretariat as described, commitment of delegations to attend intersessional meetings or to provide written views and expansion of the duration of the Annual Meeting so this effort could be accorded the highest priority. And finally it noted that these activities would be counter to prevailing attitudes regarding costs, intersessional work and the priority to be accorded to certain issues.

While thanking Denmark and the USA for their introductions, Australia considered that the proposed Resolution had not, unfortunately, been developed in a way as to be fully inclusive of the interests across the Commission. However, it believed that there was scope to revise the Resolution in a way that could meet the requirements of all parties and suggested that further discussion in plenary be postponed to provide an opportunity for interested governments to discuss possible revisions. The Commission agreed to postpone discussions.

On returning to the issue, Australia introduced a revised draft Resolution (see Table 2), explaining where changes had been made. It believed that the revised proposal, which had been developed by a number of countries, represented a delicate balance and suggested that if it could be adopted by consensus, the Commission would have rebuilt its approach to the RMS.

Dominica indicated that with respect to the last operative paragraph it wished to retain the text in the initial draft, i.e. retaining the words ‘with the aim of having the results ready for consideration and adoption at IWC/57’, and accordingly proposed an amendment to this effect. It felt that the revised text would simply encourage further prolongation of discussions. Palau and Iceland spoke in support of Dominica’s proposed amendment and noted that as reference to IWC/57 was included in the intersessional plan of action and in the proposed Terms of Reference for the RMS Working Group, they saw no problem with its inclusion in the Resolution itself. The USA and New Zealand spoke in support of retaining the revised version. The USA expressed concern regarding the inclusion of the term ‘adoption’ since it believed that adoption of an RMS could not be predetermined.

In view of Dominica’s concerns, Australia wondered whether it would be acceptable to include text along the following lines: ‘agrees to proceed expeditiously towards the completion of both the drafting of text and technical details of the RMS according to the attached Intersessional Plan of Work with the aim of having the results ready for consideration at IWC/57’. While Dominica appreciated this suggestion, it could not accept it. As an alternative, Sweden proposed taking text from the Terms of Reference for the RMS Working Group and inserting them in the Resolution, i.e. ‘...ready for consideration including for possible adoption at IWC/57’. Iceland did not believe that Dominica’s proposed amendment pre-empted any action by the Commission, but rather simply set an aim. However, if there could not be consensus on Dominica’s proposal, then Iceland suggested that Sweden’s suggestion provided a way forward. The UK disagreed, believing this to be close to breaching the Commission’s Rule of Procedure E.3(b).

On being put to a vote by a show of hands, Dominica’s proposed amendment was rejected. Sweden’s proposed amendment was accepted by a show of hands. Australia then proposed an amendment to the Resolution as amended by Sweden. It proposed that the third operative paragraph be amended to read ‘...with the aim of having the results ready for consideration, including for possible adoption at IWC/57 and/or to identify any outstanding policy and technical issues’, thus including all the text from the RMS Working Group proposed Terms of Reference. While St. Kitts and Nevis expressed concern that Australia’s latest proposal may be in breach of the Rules of Procedure, the Commission adopted by consensus the Resolution as amended by Australia. The amended Resolution (Resolution 2004–6) is provided in Annex C. While accepting that consensus had been reached, Denmark noted its unhappiness at having to explain the outcome to Henrik Fischer. It stressed that the amended Resolution must not lead to a repetition of returning to a square-brackets exercise, and that only fine-tuning of the Chair’s proposal was needed, nothing more.

7. WHALE KILLING METHODS AND ASSOCIATED WELFARE ISSUES

In introducing this item, the Chair explained that given the limited time available at IWC/56, the number of sub-groups that had needed to meet and the fact that there had been a 3-day workshop on Whale Killing Methods and Associated Animal Welfare Issues at last year’s meeting, the Advisory Committee had agreed not to schedule a meeting of the Working Group in Sorrento. He noted that this agreement was reached on the understanding that:

(a) this issue would be placed early on the plenary agenda and given an adequate time allocation;

(b) Contracting Governments would be asked to provide data and information as requested in a number of Resolutions to the Secretariat for circulation to Contracting Governments well in advance of the plenary;

(c) the Working Group would meet at IWC/57 in 2005.

\[13\] Rule of Procedure E.3(b): Action in pursuance of Article V shall contain the text of the resolutions proposed to amend the Schedule. A proposal that does not contain such regulatory text does not constitute an amendment to the Schedule and therefore requires only a simple majority vote. A proposal that does not contain such regulatory text to revise the Schedule but would commit the Commission to amend the Schedule in the future can neither be put to a vote nor adopted.
Recognising the dual mandate of the IWC for the conservation of whales and the management of whaling according to the 1946 International Convention for the Regulation of Whaling;

Noting that on this basis, considerable progress has been made in identifying the major elements necessary to reach broad agreement on the RMS, as reflected in the Chairman’s Proposal for a Way Forward on the RMS (Doc IWC/56/26);

Taking note of the comments of Contracting Parties on the Chairman’s Proposal at the 56th Annual Meeting of the Commission; and

Concerned that the failure to reach broad agreement on the RMS in the near future may seriously jeopardise the ability of the IWC to fulfil its responsibility of ensuring the effective conservation of whale stocks and the responsible management of whaling;

NOW THEREFORE THE COMMISSION:

Commends the efforts of the Chairman in providing the basis for further work and discussion towards the finalisation of the RMS, as reflected in document IWC/56/26;

Agrees to re-establish the Working Group on the RMS with a view to holding an intersessional meeting prior to IWC/57, as outlined in the attached Intersessional Plan of Work; and

Agrees to proceed expeditiously towards the completion of both the drafting of text and technical details of the RMS according to the attached Intersessional Plan of Work, with the aim of having the results ready for consideration and adoption at IWC/57.

Interessional plan of work

Sufficient material is available from previous efforts, or will have been developed by the end of IWC 56, that the Commission could proceed to develop appropriate draft text for the RMS working on the basis of the Chairman’s proposal (IWC/56/26), his statement (IWC/56/26) and the Secretariat’s document on further work (IWC/56/36). The goal of this effort is to have a finalized text of an RMS package ready for adoption at IWC/57. The following iterative process would occur to develop such a text over the interessional period.

1. Commission formally revives the RMS Working Group and agrees to establish a small drafting group under it (see respective terms of reference in Appendices 1 and 2).

2. Secretariat collates and organises available materials. Technical specialist groups identified in IWC/56/36 are set up.

3. Technical specialist groups meet and finish their work before December 2004.

4. Small drafting group meets (one week) in December 2004.

5. Draft text is circulated to delegations for review and comment. Secretariat circulates comments to all delegations and to members of the small drafting group.

6. RMS Working Group convenes in late February – early March 2005 to consider the draft text and submitted comments, and to develop input to the small drafting group for development of the next iteration.

7. The small drafting group meets immediately afterwards to develop the second draft, which the Secretariat circulates to delegates.

8. The RMS Working Group meets for two days during the week prior to the IWC/57 Plenary session to consider the second draft.

9. The results of the RMS Working Group are presented to the Plenary for its consideration at IWC/57.

Appendix 1. Terms of Reference for RMS Working Group

The RMS Working Group will have the following responsibilities:

1. To complete work on the RMS package, with the goal of having a finalised RMS text ready for adoption at IWC/57.

2. To take account of delegates comments at IWC/56, as well as written submissions from delegates unable to attend the RMS Working Group in person.

3. To provide guidance to, and to review the work of, the Small Drafting Group.

Recognising the dual mandate of the IWC for the conservation of whales and the management of whaling according to the 1946 International Convention for the Regulation of Whaling;

Noting that on this basis, considerable progress has been made in identifying the major elements necessary to reach broad agreement on the RMS, as reflected in the Chairman’s Proposal for a Way Forward on the RMS (Doc IWC/56/26);

Taking note of the comments of Contracting Parties on the Chairman’s Proposal at the 56th Annual Meeting of the Commission; and

Concerned that the failure to reach broad agreement on the RMS in the near future may seriously jeopardise the ability of the IWC to fulfil its responsibilities;

NOW THEREFORE THE COMMISSION:

Commends the efforts of the Chairman in providing a basis for further work and discussion towards finalizing the RMS;

Agrees to re-establish the Working Group on the RMS with a view to holding an intersessional meeting prior to IWC/57, as outlined in the attached Intersessional Plan of Work; and

Agrees to proceed expeditiously towards the completion of both the drafting of text and technical details of the RMS according to the attached Intersessional Plan of Work.

Interessional plan of work

The Chair’s Proposal for a way forward (IWC/56/26), supplemented by his statement (IWC/56/26), other comments made at IWC 56 in relation to the Chair’s proposal and the Secretariat’s document (IWC/56/36), provides a basis for the development of draft text for the RMS, to clarify policy and technical issues and draft text for the RMS. The goal of this effort is to have clarified outstanding policy and technical issues and, as far as possible, have finalized text of an RMS package ready for consideration at IWC/57. The following iterative process would occur to develop such a text over the interessional period.

1. Commission formally revives the RMS Working Group and agrees to establish a small drafting group under it (see respective terms of reference in Appendices 1 and 2).

2. All Contracting Governments are invited to send comments/positions on key issues to the RMS Working Group.

4. RMS Working Group to provide guidance on major policy issues to small drafting group (before December).

5. Small drafting group meets (one week) in December 2004.

6. Draft text is circulated to delegations for review and comment. Secretariat circulates comments to all delegations and to members of the small drafting group.

7. RMS Working Group convenes in early March 2005 to consider the draft text and submitted comments, and to develop input to the small drafting group for development of the next iteration.

8. The small drafting group meets immediately afterwards to develop the second draft, which the Secretariat circulates to delegates.

9. The RMS Working Group meets for two days during the week prior to the IWC/57 Plenary session to consider the second draft.

10. The results of the RMS Working Group are presented to the Plenary for its consideration at IWC/57.

Appendix 1. Terms of Reference for RMS Working Group

The RMS Working Group will have the following responsibilities:

1. To take account of delegates’ comments at IWC/56, as well as written submissions from delegates unable to attend the RMS Working Group in person.

2. To provide guidance to, and to review the work of, the Small Drafting Group.

3. To provide guidance to, and to review the work of, the Small Drafting Group.

RMS WG to be open to observers.
The Chair further noted that a request for information went out to all Contracting Governments, since previous Resolutions call not only for the reporting of data on whales killed and improvements to whaling operations but also for all Contracting Governments to (1) provide appropriate technical assistance to reduce unconsciousness and death in all whaling operations; and (2) to provide relevant data from the killing of other large mammals.

7.1 Reporting on data on whales killed and on improving the humaneness of whaling operations

Denmark and the Russian Federation submitted documents in response to the call for information. These are provided in Annex G. The USA gave an oral report which is summarised in Annex G. Japan did not submit data to the Commission, but did provide information on a bilateral basis. It noted that while it considers this issue to be outside the mandate and scope of the Convention, it has nevertheless worked to improve hunting methods and times to death and has participated in workshops and provided information on a voluntary basis. Japan believed that the data on whales killed should be used by those engaged in whaling to improve the hunts, rather than being used in a non-constructive way by those against whaling. It was disappointed that repeated requests for similar data for terrestrial animals had met with little success.

7.2 Commission discussions and action arising

In the Commission, while appreciation was expressed for the reports submitted there were no specific comments on them.

In response to remarks of Japan, the UK recognised that whale killing data have been used in the past to criticise whaling nations, but stressed that this was not its own intention. The UK sees a need to improve efficiency of the hunts and to reduce times to death. While it is satisfied that efforts are being made by all concerned, the UK believes there is a need for continuous improvement. It did not agree with those who consider animal welfare issues to be outside the mandate of the Convention, and again put forward its view that IWC has a moral obligation to ensure minimum suffering of hunted animals.

Germany noted that animal welfare issues are of vital importance to it, and expressed concern regarding:

(1) that current whaling methods do not guarantee instantaneous insensibility or death;
(2) that the data presently collected and submitted to the Commission are of insufficient quality and completeness to allow a fully-informed assessment of the welfare implications of whaling operations; and
(3) that the criteria used to determine death or irreversible insensibility are inadequate.

It regretted that a meeting of the Working Group had not been scheduled in Sorrento, and stressed the need for the group to meet next year. Australia associated itself with Germany’s remarks.

The Russian Federation suggested that when countries call for more humane hunts, they should also be prepared to provide help. It noted that following its call for assistance at last year’s meeting, only the Netherlands had responded by providing support to a training workshop to be held in Chukotka but also involving the Eskimos of Alaska. It thanked the Netherlands for this support.

Sweden saw the usefulness of comparing data from whaling with data from other hunts, since it believed it important to improve times to death in all hunts. It had therefore tried to gather data on Sweden’s moose hunt in which more than 94,000 animals are shot annually. It noted that while no detailed information on times to death are available (there are no official observers of the hunt), information from a questionnaire organised by the hunters association in 1999 had indicated that 75% of animals fell where they were shot and a further 11% fell nearby. Sweden believed that these data suggest that the instantaneous death rate is in the order of 75-86%, i.e. similar to the instantaneous death rate in the Norwegian minke whale hunt. However, Sweden noted that the main concern is the 3.8% (i.e. approximately 3,500 animals) per year that are not found when searched for.

Resolution on whale killing issues

New Zealand introduced a draft Resolution on Whale Killing Issues on behalf of the other co-sponsors (UK, Italy, Germany, Austria, Mexico, South Africa, the Netherlands, Belgium, Brazil, Portugal, Sweden, Spain, India, Argentina, Finland and the USA). It indicated that its own position is that it does not want any whales to be hunted, but that if this is to be done, then those involved should be encouraged to use more humane methods. New Zealand indicated that this is the purpose of the proposed Resolution. It considered that the many variables associated with hunting whales at sea make it difficult to ensure a swift and humane death, as demonstrated by the data submitted over the years to the Working Group. It believed that Article V of the Convention provides the legal mandate to the Commission to address welfare issues, and that it was time that modern animal welfare science should be
employed to improve whale hunts. The proposed Resolution:

(1) expressed concern that current whaling methods do not guarantee death without pain, stress or distress; that data presently collected and submitted to the Commission are of insufficient quality or completeness for it to make a fully informed assessment of the welfare implications of all whaling operations; and that the criteria currently used to determine the onset of death or irreversible insensibility are inadequate;

(2) requested the Secretariat to update the data collection form so that Contracting Governments may report data for each whale taken, the killing method used and samples taken;

(3) requested that the Working Group on Whale Killing Methods and Associated Welfare Issues reconvene at IWC/57 to examine methods for reducing struck and lost rates and to consider the welfare implications of methods used to kill whales caught in nets; and

(4) requested the Working Group to advise the Commission on: establishing better criteria for determining the onset of irreversible insensibility and death; methods of improving efficiency of whale killing methods; and reducing times to death and other associated welfare issues.

Germany and India spoke in support of the Resolution.

Norway noted that it takes the issue of animal welfare very seriously, agreed that there is a moral responsibility to do the utmost to reduce animal suffering and referred to the work its scientists have done in this area. However, it had problems with the Resolution proposed and considered it unnecessary in view of the outcome of the 3-day workshop held at IWC/55 last year, of which the draft Resolution made no mention. Regarding the operative paragraphs, Norway knew of no situation in which animals are killed (e.g. euthanasia, pets, stunning of livestock, hunting), where it can be guaranteed that every animal will die without pain, stress or distress, since even with the greatest of precautions, mishaps will occur. While noting that in many countries it is considered acceptable that in industrial slaughter houses instant insensibility should be achieved with one shot for 95% of animals killed, Norway indicated that the reality can be very different, reporting that for pigs, this can be 80% and that for bulls it can be as low as 53%.

Referring to Sweden’s earlier comments on its moose hunt, it suggested that an animal falling where it is shot is not unnecessary in view of the outcome of the 3-day workshop held at IWC/55 last year, of which the draft Resolution made no mention. Regarding the operative paragraphs, Norway knew of no situation in which animals are killed (e.g. euthanasia, pets, stunning of livestock, hunting), where it can be guaranteed that every animal will die without pain, stress or distress, since even with the greatest of precautions, mishaps will occur. While noting that in many countries it is considered acceptable that in industrial slaughter houses instant insensibility should be achieved with one shot for 95% of animals killed, Norway indicated that the reality can be very different, reporting that for pigs, this can be 80% and that for bulls it can be as low as 53%.

Referring to Sweden’s earlier comments on its moose hunt, it suggested that an animal falling where it is shot is not necessarily an indication of instantaneous death. Its own studies had indicated a rate of 20%. Norway also objected to the statement that ‘data presently collected and submitted to the Commission are of insufficient quality or completeness for it to make a fully informed assessment of the welfare implications of all whaling operations’. It noted that Norway had collected detailed data for over 20 years, and that its research had led to not only its own hunting methods being safer and more efficient but also those of other hunting nations through transfer of expertise and technology. It further noted that it has presented annual reports to the IWC on welfare issues for many years and published many papers in scientific journals. It therefore did not believe that there is any problem with access to Norwegian data. Regarding the concern expressed in the proposed Resolution to the current criteria used to determine the onset of death or irreversible insensibility, Norway agreed that there are problems with these criteria as they are not sufficient to determine the onset of unconsciousness and death exactly, but that provided the data are being collected by competent individuals using the same methods, the criteria can be used to compare different hunting methods and to evaluate the skills of individual whalers. Norway also reported that from neuropathological research it had done, it is evident that the IWC criteria will result in some animals being classified as alive, when in fact they are dead, thus suggesting some overestimation of times to death. Norway therefore considered that its 80% instantaneous death rate should be regarded as a minimum.

Finally, Norway requested that the Commission should:

(1) take note of the substantial information provided by Contracting Governments at the Workshop on Whale Killing Methods held in Berlin last year;

(2) encourage Contracting Government to continue the cooperative approach agreed to at the Workshop regarding improvements in data collection and reporting, technical developments of killing methods, and criteria and methods to determine death, both operationally and from post-mortem approaches; and

(3) employ the best methods available for killing whales, both for purposes of hunting and euthanasia, including stranded whales and whales taken incidentally in fishing operations.

Denmark noted that it supports all efforts to conduct hunting in as humane a way as possible. However, like Norway it thought the proposed Resolution was redundant in view of last year’s workshop, and was disappointed that neither the workshop nor past work was mentioned. Japan made similar remarks and asked that the Resolution be withdrawn. Monaco indicated that despite its concern for animal welfare issues, it would have problems in supporting the Resolution as currently proposed as it did not adequately recognise the real efforts and progress made on this issue, particularly by Norway, Iceland associated itself with Monaco and appreciated Monaco’s remarks. It believed that in some countries, public concern is being directed away from domestic issues to whaling. The Russian Federation associated itself with Monaco and in addition noted that from its perspective, the issue of struck and lost rates is more an issue related to conservation than to humane killing.

The USA noted its support for IWC’s long-standing commitment to animal welfare issues, that it has held workshops periodically since 1980 and that it is working closely with others on the criteria used to determine the onset of death or irreversible insensibility.

Sweden was disappointed that it appeared that the Resolution could not be adopted by consensus. Recognising the importance of previous workshops, the Netherlands indicated that it would not have a problem if these were referenced in the Resolution. Austria suggested something similar and the addition of some of Norway’s statements. The Chair therefore requested that New Zealand work with Austria, Norway, Sweden and Denmark with a view to revising the proposed Resolution.

On returning to this issue, New Zealand reported that although the cosponsors had consulted widely with others, no agreement had been reached that would enable the Resolution to be passed by consensus. It did, however, propose a minor amendment that would explicitly recognise the significant contribution of Norway in this area.
On being put to a vote, the Resolution was adopted (see Resolution 2004-3, Annex C), there being 29 votes in support of the Resolution and 22 against.

8. SANCTUARIES

8.1 Review of the Southern Ocean Sanctuary

8.1.1 Report of the Scientific Committee

The Committee had been asked by the Commission to review the Southern Ocean Sanctuary (SOS) in 2004 and an intersessional working group had been appointed to develop a proposed framework to carry out the review. In summary, the Committee agreed that:

(1) whales are not effectively protected from whaling in the SOS, because such Sanctuaries apply only to commercial whaling, and because (apart from stocks that migrate to the IOS) whales also migrate outside of the SOS boundaries;
(2) the boundaries of the SOS were appropriately established for some, but not for all stocks; and
(3) it was not possible to completely evaluate the effectiveness of the SOS because the scientific objectives are not clear and are not associated with quantifiable performance measures.

The Committee respectfully requested that the Commission considers clarifying the objective(s) of the SOS in order to allow the Committee to discriminate among designs that would, inter alia: protect whales; protect whale species diversity; and increase whaling yields outside the Sanctuary. The Committee also developed a series of recommendations that, once the overall objectives of the SOS have been refined, will allow these objectives to be evaluated, and will facilitate evaluation in future reviews.

8.1.2 Commission discussions and action arising

Norway recalled that it did not take part in the voting procedure when the Southern Ocean Sanctuary was established as there was no clear advice from the Scientific Committee. It admitted that although initially sceptical over the proposal for an independent review of the Southern Ocean Sanctuary, it was pleased with its outcome and was disappointed that this appeared to have been watered down in the Scientific Committee report. Norway considered the Southern Ocean Sanctuary to do little for conservation, believing that it should be abolished and that IWC should remain a resource management organisation. Japan made similar remarks, believing that the external review had confirmed its well-known views. It too called for the sanctuary to be abolished. Believing that the Commission’s decisions should be based on science, St. Lucia joined the comments of Norway and Japan. Gabon considered that range states should be consulted in the absence of scientific justification.

Australia considered that the Scientific Committee went through a comprehensive and thorough process in the review and respected its outcomes. It believed that the Committee’s conclusions raise issues regarding Marine Protected Areas, scientific concepts and IWC sanctuaries, demonstrating that further work is needed. It accepted the Committee’s suggestions and regarding the Committee’s request for further guidance, volunteered to take the lead in developing a paper for next year’s meeting on this. The UK, Brazil, the USA, Germany, Italy and Belgium associated themselves with Australia’s remarks. The USA and Belgium expressed interest in helping to develop a paper. Brazil supported the ongoing process in the Scientific Committee to review sanctuaries and to bring in external expertise. However it stressed that the work should not be misrepresented. The Scientific Committee had not concluded that the Southern Ocean Sanctuary is invalid. Brazil considered sanctuaries to be valid from both scientific and management standpoints, and supports continuation of the existing sanctuaries and creation of new ones. Argentina agreed.

France, recalled that when it initially introduced the proposal in 1994 to create the Southern Ocean Sanctuary, it had focused on two aspects:

(1) protection of all whale species of the Southern Hemisphere from commercial whaling on their feeding grounds, thus supplementing the protection afforded by the Indian Ocean Sanctuary of whales on their reproductive grounds; and
(2) to supplement the management measures envisaged as part of the RMS with zones where whales would be completely protected.

In addition, France had believed that creation of this sanctuary would contribute to the recovery of species seriously depleted by decades of industrial whaling, noting that when proposed, no Southern Hemisphere country had opposed it. It had also taken into account that no aboriginal subsistence whaling was conducted within the proposed sanctuary area. Now that the sanctuary was under review, France thought it worthwhile to revisit the initial justifications in light of events since 1994. France acknowledged the efforts over the years to improve management regimes (from the ‘blue whale unit’ to the New Management Procedure) but noted that scientific uncertainties remain, and that even with such regimes in place, legal quotas had been set too high and illegal exploitation had not been prevented. It also questioned whether, even if a management procedure could be adopted that took account of past mistakes, successful management could be guaranteed. For this reason, France believed that sanctuaries are needed to ensure long-term conservation, and, even if an RMS were to be adopted, indicated that they would be complementary to exploitation allowed elsewhere.

Addressing the criticism that the Southern Ocean Sanctuary lacked a scientific basis, France recalled that the main reason for its creation was not to meet scientific goals (although it was created on the basis of scientific knowledge) but for conservation purposes. It believed that since 1994, a number of elements had emerged to confirm the need for this long-term measure:

(1) the discovery of new species or sub-species in the sanctuary;
(2) the discovery of important oscillations in population levels creating difficulties in drawing conclusions regarding the capacity of whale populations to recover;
(3) uncertainties regarding the population size of minke whales in the Southern Hemisphere;
(4) other threats to whales, e.g. from pollution, shipping, noise, climate change, incidental catches;

14 For details of the Scientific Committee’s deliberations on this Item see J. Cetacean Res. Manage. 7 (Suppl.).
(5) the difficulty of detecting signs of recovery in whale populations other than humpback and southern right whales;
(6) the development of marine protected areas and of international ocean conservation bodies;
(7) the emergence of whalwatching as a form of non-consumptive use of whale resources; and
(8) a collection of international provisions to safeguard the Antarctic.

France believed these elements also justified the creation of new sanctuaries such as those proposed for the South Atlantic and the South Pacific. It recognised that a sanctuary in which only commercial whaling is prohibited does not correspond to the modern concept of protected areas where all aspects of conservation are included, and believed that evolution of the sanctuary concept within IWC should be one of the Commission’s next concerns, particularly in view of the discussions this year in the Scientific Committee.

The Commission noted the Scientific Committee report and endorsed its recommendations.

**PROPOSED SCHEDULE AMENDMENT**

Japan introduced the following proposed Schedule amendment:

> Delete paragraph 7(b) and to add the following sub-paragraph (h) to existing paragraph 10:

(h) Notwithstanding the over provisions of this paragraph, the taking of 2,914 Antarctic minke whales from the Antarctic sector 40°E-140°W south of 60°S shall be permitted for each of the whaling seasons 2004/05, 2005/06, 2006/07, 2007/08 and 2008/09.

*Explanatory note: Adoption of this schedule amendment will require amendment to Table 1 of the Schedule.*

The effect of deleting paragraph 7(b) would be to abolish the Southern Ocean Sanctuary.

In justifying the proposed Antarctic whaling, Japan noted that a comprehensive assessment of the Antarctic minke whale populations completed in 1990 showed that the population was healthy with numbers of around 761,000 whales. It further noted that the RMP was completed in 1992 and in the following year, the continuation of an annual catch limit of 2,049-4,490 Antarctic minke whales for 100 years was calculated using the RMP. Yet despite this, IWC has not yet permitted the resumption of commercial whaling on the grounds that the RMS has not yet been completed. Japan believed this delay to be due to the deliberate stalling by some Contracting Governments and because a three-quarter majority is required to implement an RMS. It reported that its research under special permit in Areas IV and V from the 1987/88 season reveals that Antarctic minke whales are abundant, and that the population level has remained stable. Japan therefore believed that a larger catch limit could be established. It went on to describe proposed pelagic whaling operations and provisions for monitoring and control.

Australia opposed Japan’s proposed Schedule amendment. It believed that since the proposed takes of minke whales were not based on an agreed abundance estimate (as there is no currently agreed estimate), the credibility of the proposal was brought into question. At the request of Australia, the Scientific Committee Chair clarified that although Japan’s document contained scientific assumptions and calculations based on the RMP and Committee discussions on minke whale abundance, the document had not been submitted to the Scientific Committee as would have been expected. New Zealand’s view was that such a proposal should not be submitted before the introduction of an RMS and asked that it be withdrawn. Sweden believed that the Southern Ocean Sanctuary is fully justified and that the moratorium should remain in place until an RMS is agreed. It expressed concern that the Scientific Committee had been by-passed. The UK, Germany, USA, Mexico, Italy, Monaco, France, India, Kenya, Finland, Spain and Chile also spoke against Japan’s proposal. The Republic of Korea considered that the discussion on whether or not to continue the Southern Ocean Sanctuary should be postponed to await the outcome of further work. With respect to Japan’s proposed takes of whales, the Republic of Korea believed that such a proposal would hinder the development of an RMS and asked that Japan remove this part of its proposal.

St. Kitts and Nevis noted that it had opposed creation of the sanctuary, and that the independent scientific review had discredited it as an effective management tool. Norway supported Japan’s proposal to abolish the Southern Ocean Sanctuary, but stressed that it does not intend to harvest whales in the Southern Ocean. Iceland associated itself with Norway’s remarks. The Republic of Palau suggested that, coupled with a commercial whaling moratorium that has been in place since 1986, the sanctuary had contributed to the recovery of some species. It therefore believed that the sanctuary had fulfilled its purpose and should be abolished. The Republic of Guinea, Benin and St. Lucia also supported Japan’s proposals.

On being put to a vote, the proposed Schedule amendment did not achieve the necessary three-quarter majority for it to be adopted, there being 19 votes in support, 30 against and 2 abstentions.

**8.2 Improvements to the review process**

**8.2.1 Report of the Scientific Committee**

The Committee agreed that the inclusion of outside experts in the review process was beneficial and agreed that this should continue. The major improvement to the review process will arise out of the development by the Commission of clearly identified and quantified objectives. The Committee **agreed** to a series of recommendations that, once overall objectives of the SOS have been refined, will allow these objectives to be realised, and will facilitate evaluation in future reviews.

The Committee agreed to the recommendations listed below.

1. The purpose(s) of the Sanctuaries should be better articulated through a set of refined overall objectives (e.g. preserving species biodiversity; promoting recovery of depleted stocks; increasing whaling yield). In particular, the relationships between the RMP and any Sanctuary programme should be articulated.

2. Appropriate performance measures for Sanctuaries should be developed. These performance measures should link the objectives of a Sanctuary with field monitoring programmes.

3. Systematic inventory and research programmes should be established or further developed so as to build the required information base for a Sanctuary.
management plan and subsequent monitoring programs.

(4) A Sanctuary management plan should clearly outline the broad strategies and specific actions needed to achieve Sanctuary objectives (e.g. how to protect x% of a given feeding area for stock y).

(5) A monitoring strategy that measures progress toward achieving the Sanctuary objectives should be undertaken. A key component of this monitoring strategy should be the development of tangible indicators to monitor progress.

(6) Review criteria that reflect the goals and objectives of the Sanctuary (as described above) should be established.

(7) The Sanctuary management plan should be refined periodically to account for ecological, oceanographic and possible other changes in an adaptive fashion.

8.2.2 Commission discussions and action arising

The Commission noted the report and endorsed its recommendations.

8.3 South Pacific Sanctuary

8.3.1 Proposal to amend the Schedule to establish a sanctuary

For the fifth year\(^\text{15}\), Australia and New Zealand proposed to establish a South Pacific Sanctuary as follows:

In accordance with Article V (1)(c) of the Convention, commercial whaling, whether by pelagic operations or from land stations, is prohibited in a region designated as the South Pacific Sanctuary.

This Sanctuary comprises the waters of the Southern Hemisphere enclosed within the following line: starting from the southern coast of Australia at 130°E; thence due south to 40°S; thence due east to 120°W; thence due north to the equator; thence due west to 141°E; thence generally south along the Papua New Guinea – Indonesian maritime boundary to the northern coast of Papua New Guinea at 141°E; thence generally east, south thence west along the coast of Papua New Guinea to the southern coast of Papua New Guinea at 141°E; thence due south to the northern coast of Australia at 141°E; thence generally east, south thence west along the coast of Australia to the starting point.

This prohibition applies irrespective of the conservation status of baleen or toothed whale stocks in this Sanctuary as may from time to time be determined by the Commission. However, this prohibition shall be reviewed ten years after its initial adoption, and at succeeding ten year intervals and could be revised at such times by the Commission.

New Zealand indicated that it remains convinced that the creation of a South Pacific Sanctuary is vital to ensure the conservation of whales in the region and drew attention to new and continuing efforts of range states and organisations in this regard. It reported that at a national level, New Zealand reported that states and territories of the South Pacific have continued to express support under various auspices including the South Pacific Regional Environment Programme and the Pacific Island’s Forum) for the sanctuary and for whale conservation. It noted that in March 2004, SPREP hosted a workshop to discuss how a regional initiative for marine mammal conservation under the Convention on Migratory Species could enhance existing national measures. The workshop and agreed that a Memorandum of Understanding under CMS should be drawn up with an vision of a Pacific Ocean where populations of marine mammals have recovered to healthy levels of abundance, have recovered to their former distribution, and continue to meet and sustain the cultural aspirations of Pacific peoples’. Stressing that the overwhelming majority of peoples of the region want a sanctuary to be established, New Zealand urged that the proposed Schedule amendment be adopted.

While recognising that some whales in the South Pacific region appear to be recovering well, Australia indicated that scientific information shows that recovery is uneven. For example, Australia noted that despite 30 years of IWC protection, humpback whales have still not reappeared in significant numbers in their former breeding grounds in Fiji, Vanuatu, Samoa or New Zealand. Australia considered that the best way to secure recovery of all populations is to protect them on their breeding grounds and migration routes – which the South Pacific Sanctuary, combined with the Southern Ocean Sanctuary would afford.

8.3.2 Commission discussions and action arising

On a point of order, Iceland indicated that the legality of the proposal should be addressed before any discussion on the proposal itself. It indicated that it did not believe that the proposal met criteria set out in the Convention, specifically in relation to Article V.2 (a), (b) and (d), i.e. that Schedule amendments be: as necessary to carry out the objectives and purposes of the Schedule; based on scientific findings; and take into consideration the interests of consumers of whale products and the whaling industry.

Several countries including Norway, Antigua and Barbuda and Japan took a similar view. Australia and New Zealand noted that the same issue was raised last year and had been settled in favour of the proposal’s sponsors by a ruling of the Chair. They did not wish to rehearse previous discussions. Noting the previous debate, the Chair ruled in favour of the sponsors.

The UK, France, Sweden, Brazil, Italy, Kenya, Germany, Peru, Argentina, Mexico, Chile, USA and Monaco spoke in support of the establishment of a South Pacific Sanctuary. The Republic of Palau, Norway, Iceland, Denmark, Antigua and Barbuda, St. Kitts and Nevis, Republic of Guinea, Japan, Tuvalu and St. Lucia spoke in favour of the sponsors.

For example, Australia noted that despite 30 years of IWC protection, humpback whales have still not reappeared in significant numbers in their former breeding grounds in Fiji, Vanuatu, Samoa or New Zealand. Australia indicated that the best way to secure recovery of all populations is to protect them on their breeding grounds and migration routes – which the South Pacific Sanctuary, combined with the Southern Ocean Sanctuary would afford.

whaling nations. Switzerland had been instructed to abstain if the proposal was not supported by all states bounded by the proposed sanctuary.

8.4 South Atlantic Sanctuary

8.4.1 Proposal to amend the Schedule to establish a sanctuary

For the fourth year, Brazil introduced its proposal, co-sponsored by Argentina and others, to create a South Atlantic Whale Sanctuary. The amendment proposed was the same as in previous years, i.e., the inclusion of a new sub-paragraph in Chapter III of the Schedule as follows:

“In accordance with Article VI(1)(c) of the Convention, commercial whaling, whether by pelagic operations or from land stations, is prohibited in a region designated as the South Atlantic Whale Sanctuary. This Sanctuary comprises the waters of the South Atlantic Ocean enclosed by the following line: starting from the Equator, then generally south following the eastern coastline of South America to the coast of Tierra del Fuego and, starting from a point situated at Lat 55°07,3'S Long 66°25,0'W; thence to the point Lat 55°11,0'S Long 066°04,7'W; thence to the point Lat 55°22,9'S Long 65°43,6'W; thence due South to Parallel 56°22,8'S; thence to the point Lat 56°22,8'S Long 67°16,0'W; thence due South, along the Cape Horn Meridian, to 60°S, where it reaches the boundary of the Southern Ocean Sanctuary; thence due east following the boundaries of this Sanctuary to the point where it reaches the boundary of the Indian Ocean Sanctuary at 40°S; thence due north following the boundary of this Sanctuary until it reaches the coast of South Africa; thence it follows the coastline of Africa to the west and north until it reaches the Equator; thence due west to the coast of Brazil, closing the perimeter at the starting point. This prohibition shall be reviewed twenty years after its initial adoption and at succeeding ten-year intervals, and could be revised at such times by the Commission. Nothing in this subparagraph shall prejudice the sovereign rights of coastal states according to, inter alia, the United Nations Convention on the Law of the Sea.”

Brazil noted that the proposed sanctuary incorporates environmental, social and scientific issues and takes account of the regional interests of its neighbouring nations. It explained that the objective of the sanctuary is to enhance the global effort to establish Marine Protected Areas for marine mammals and to complement existing IWC whale sanctuaries. It believed the initiative is justified by the recognition that after centuries of exploitation, most whale species have had their numbers drastically reduced and are only now showing signs of recovering from the edge of extinction, with many still at less than 10% of the pre-whaling population. On World Biodiversity Day, Brazil re-iterated the importance it attaches to the proposal through a letter from its President to the Heads of State of member nations of the IWC and range states of the South Atlantic requesting support for the sanctuary. The many positive responses encouraged Brazil to resubmit the proposal. Brazil noted that since 1987, it has been proud to be among those countries embracing the principle of non-lethal use of whales as a way to profit sustainably from the species inhabiting its waters and reported that whalewatching has been responsible for an important tourism influx to its coastal regions. It believed that creation of the sanctuary would contribute significantly to fostering international co-operative research among developed and developing countries which would in turn help developing countries to realise the potential of cetacean conservation. It therefore hoped that all developing nations that are range states to the proposed sanctuary would support the proposal. With respect to developed nations, Brazil did not understand how some who take progressive stances on environmental issues in other multilateral fora take a position at the IWC that is in contradiction with the interests of biodiversity conservation, particularly when those developed countries raise the argument of economic difficulties when whaling is of no real significance for their economies. Ten years after the entering into force of the Convention on Biological Diversity, Brazil believed that the establishment of the South Atlantic whale sanctuary is a fundamental step forward in ensuring recognition of the rights of developing countries to protect and use their resources under their own management regime. It urged member countries to support the proposal.

Argentina noted that the proposal for a South Atlantic Sanctuary has broad-based support from its nationals. Like Brazil, it has developed whalewatching as a new brand of ecotourism that has contributed to the welfare of local communities by opening up new livelihoods and to an increased interest in marine mammal conservation among the public. Argentina believed that the proposed sanctuary will provide a useful tool in the protection of whales in their breeding and feeding grounds as well as on their migration routes and contribute to: recovery of whale populations; protection of biodiversity; research on depleted stocks and their habitats; the promotion of modern educational activities; and the development of environmentally friendly tourism in the region. It noted the co-operative activities among countries of the region on other environmental and conservation-related issues that could serve as an example to others and urged their support on this issue.

8.4.2 Commission discussions and action arising

Iceland noted that the content of its point of order raised in relation to the proposed South Pacific Sanctuary was also applicable to the proposal for a South Atlantic Sanctuary. However, discussion of the proposal proceeded.

South Africa, Australia, Germany, New Zealand, India, Peru, Mexico, Monaco, UK, USA, Chile and Portugal spoke in support of the proposed sanctuary. A number of them congratulated Brazil and Argentina on the further work done. Iceland, Norway, Japan, Republic of Guinea, Antigua and Barbuda, Gabon and St. Lucia spoke against the proposal, with several countries indicating that they did not consider that sufficient scientific justification for the sanctuary had been presented and noted that there is no consensus among the Scientific Committee. The Republic of Guinea, speaking as a range state for the proposed sanctuary, indicated that its priority is to complete the RMS and was against vast ocean areas being closed to commercial whaling in principle. With Japan, it made reference to the consumption of fisheries resources by whales that it considered to be a problem. On this matter, Brazil could not agree that whales are the real problem in declining fish stocks given the high level of fisheries activities in the South Atlantic. It noted that the proposal for the sanctuary has been submitted to the Scientific Committee and that it is paying due consideration to the further work of the Committee in this area. It considered that the Commission should be honest and fair to the public by stating clearly that there will never be consensus from the Scientific Committee for the creation of new sanctuaries since on this issue, it is as polarised as the Commission itself.

As there was clearly no consensus on the proposal the Chair proceeded to a vote. There were 26 votes in support, 22 against and 4 abstentions. The proposed Schedule
amendment to create a South Atlantic Sanctuary was therefore not adopted. Ireland and Switzerland (who both abstained) explained their votes by referring to their statements for the South Pacific Sanctuary proposal. Senegal (who voted against the sanctuary) noted that after many years of being unable to participate actively in the Commission, it had made great efforts to regain its voting rights for this meeting. It wished to inform the Commission that it intended to use its vote responsibly and objectively. It wished to make it clear that Senegal is not participating in IWC as a pro- or anti-whaling nation, but as a fishing nation that believes that all marine resources should be used in a sustainable manner.

9. SOCIO-ECONOMIC IMPLICATIONS AND SMALL-TYPE WHALING

Japan reported on the Third Summit of Japanese Traditional Whaling Regions held in Muroto, Kochi prefecture on 30 May 2004. The Summit adopted the ‘Muroto Declaration on Traditional Whaling’, that has been endorsed by the Japanese government.

9.1 Proposed Schedule amendment for the taking of minke whales in the North Pacific

9.1.1 Introduction by Japan

Japan introduced its proposal to add the following sub-paragraph (f) under paragraph 10 of the Schedule:

'(f) Notwithstanding the other provisions of this paragraph, the taking of 150 minke whales from the Okhotsk Sea-West Pacific stock shall be permitted for the whaling season in each of the years 2004, 2005, 2006, 2007 and 2008.'

Explanatory note: Adoption of this Schedule amendment will require amendment to Table 1 of the Schedule.

This provision shall be modified if the Commission, before 2008, adopts other catch limits for this stock based on an agreed management procedure.

This proposal was the same as that introduced last year.

As last year, Japan recalled that it had been sixteen years since the imposition of the moratorium on commercial whaling in Japanese coastal waters and that during this time, it had repeatedly requested an interim relief allocation of 50 minke whales to alleviate the hardships of its small-type coastal whaling communities. It noted that even though the Commission had recognised the severe impacts of the moratorium on the four small-type whaling communities. It noted that even though the Commission had recognised the severe impacts of the moratorium on the four small-type whaling communities and had agreed to work expeditiously to alleviate their distress, the Commission had rejected these requests. In the meantime, Japan believed that whale abundance has increased, while its coastal fisheries have become impoverished, leading to considerable discontent among fishermen over the competition between fisheries and whales.

Japan again noted:

(1) that the Scientific Committee’s Comprehensive Assessment of the Okhotsk Sea-West Pacific stock of the North Pacific minke whales completed in 1991 showed the stock to be robust;
(2) that although the RMP had been adopted in 1994 it had not been implemented; and
(3) that effective monitoring and control measures have been discussed exhaustively for over 10 years and have now turned into unrealistically excessive demands designed to delay completion and implementation of the RMP.

Again as last year, Japan indicated that it wished to resume community-based whaling for the sustainable use of robust whale stocks, the management of fishery resources, and the revitalization of the impoverished community-based coastal whaling communities. It noted that all the edible parts of the harvested whales would be used as food, and a substantive part of them distributed primarily among the four community-based coastal whaling communities and neighbouring areas, as well as Kushiro, where a land station would be built. It considered that the resumption of community-based whaling would promote the local processing industries and stimulate distribution of whale products and tourism, leading to more employment opportunities and a stimulation of the local economy. It also believed that the resumption of community-based whaling would reinstate traditional practices associated with sales of whale meat, and revitalize traditional festivals and rituals of the regions.

Japan gave specifics of the proposed whaling operation (whaling ground, season, catch quota) and monitoring and control provisions.

9.1.2 Commission discussions and action arising

Japan clarified that the proposed takes would be from within its own EEZ.

The UK noted that similar requests from Japan have been discussed over the last several years. In addition to the fact that the proposal undermined the commercial whaling moratorium, the UK was also concerned about the status of the ‘J’ stock. It could not support Japan’s proposal. Monaco expressed concern that the proposed takes would be in addition to those taken under special permit and asked whether the meat from these whales could not be used to satisfy the needs of the four Japanese coastal communities. Like the UK, Sweden viewed the proposal as being inconsistent with the moratorium, considered that it bypassed the Scientific Committee and used a number of incorrect assumptions. The USA, Switzerland, India, New Zealand, Germany, Australia endorsed the remarks of the UK, Monaco and Sweden.

The Republic of Korea expressed sympathy with the Japanese communities involved, but asked whether Japan could delay its request to await progress with the RMS.

St. Vincent and The Grenadines, Dominica, Nicaragua, Republic of Guinea, Russian Federation, Senegal, St. Lucia, Benin, Antigua and Barbuda and China understood and recognised the traditional rights and needs of Japan’s coastal communities and supported Japan’s proposed Schedule amendment. Several of them recognised the proposal’s scientific merits. The Republic of Guinea noted that aboriginal subsistence quotas have been granted for the USA and the Russian Federation with respect to bowhead and gray whales and asked for equal treatment for Japan’s coastal whaling communities. The Russian Federation believed that Monaco’s suggestion to use meat from whales taken under scientific permit to satisfy the needs of the four Japanese coastal communities ignored the 9,000-year cultural tradition of these peoples to harvest their own whales – it is not simply an issue of providing protein. It noted that voting against Japan’s proposal would be voting against a long cultural tradition and urged that the matter not be brought to a vote. The Republic of Palau believed the suggestion of the Russian Federation should be pursued and a compromise found. Monaco indicated that it would be willing to support the proposal if Japan agreed to stop its
scientific permit takes. Denmark and Côte d’Ivoire also did not see why the matter should be rushed. However, as there was clearly no consensus on this, several countries urged the Chair to proceed to a vote.

Japan noted that it was willing to reduce the proposed take of minke whales from 150 to 100 and to reduce the period of the quota to three years. This amended proposal was put to a vote. There were 19 votes in support, 26 against and one abstention. The proposed Schedule amendment was therefore not adopted.

9.2 Proposed Resolution on Japanese Community-Based Whaling  
9.2.1 Introduction by Japan

Stressing that the proposed Resolution was nothing to do with its previous quota request (see section 9.1.1), Japan indicated that it was again seeking the Commission’s commitment to work expeditiously to solve the problems caused by the cessation of minke whaling. It noted that the spirit of the Resolution is very similar to that first adopted at the IWC Annual Meeting in Kyoto in 1993. The draft Resolution did, however, refer to the outcome of recent Summits of Japanese Traditional Whaling Communities and Declarations issued from them. The draft Resolution proposed that the Commission (1) reaffirms its commitment to work expeditiously to alleviate the distress caused by the cessation of minke whaling to the communities of Abashiri, Ayukawa, Wadura and Tajii; and (2) welcomes the initiatives of the Government of Japan to resolve this matter.

The proposed Resolution was co-sponsored by Antigua & Barbuda, Belize, Benin, Cote d’Ivoire, Dominica, Gabon, Grenada, Republic of Guinea, Iceland, Mauritania, Mongolia, Nicaragua, Norway, Republic of Palau, Panama, Russian Federation, St. Kitts and Nevis, St. Lucia, St. Vincent and The Grenadines, Solomon Islands, Suriname, and Tuvalu.

9.2.2 Commission discussions and action arising

The UK noted that in discussions under item 9.1, parallels had been drawn between the requests of Japan for a quota of minke whales and the position of aboriginal subsistence whalers. The UK did not believe that this was appropriate, partly because the peoples of the four Japanese communities are reasonably prosperous, but more particularly because the Commission has never received the kind of ‘needs’ information that could promote discussion on the aboriginal need for these communities. The UK reminded the meeting that after IWC/54 in Shimonoseki, some Contracting Governments suggested that a way forward on Japanese coastal whaling might be for Japan to develop a proposal allowing for non-commercial whaling. No such proposal had been received. Consequently, although the UK was ready to reaffirm sympathy for the position of the communities, it could not endorse the Resolution as Japan had not actually taken the necessary initiatives. New Zealand and Germany endorsed these comments.

The USA indicated that it could not adopt the Resolution as written, and proposed that the operative paragraphs be revised to read: (1) reaffirms its commitment to work expeditiously to alleviate the continued difficulties caused by the cessation of minke whaling to the communities of Abashiri, Ayukawa, Wadura and Tajii; and (2) encourages IWC members to co-operate towards a Resolution of this matter. Japan thanked the USA for its proposal and indicated it could accept the revisions.

The Chair asked if the Resolution could be adopted by consensus. Sweden explained that it could support the Resolution as revised by the USA on the understanding that the intention was ‘to finish the RMS in order to be able to initiate an agreed process for setting possible quotas that might alleviate the continued difficulties caused by the cessation of minke whaling…’. It stressed that it did not seek further revision of the Resolution.

The Resolution, revised as proposed by the USA, was then adopted by consensus (Resolution 2004-2, Annex C).

9.3 Proposed Schedule amendment for the taking of Bryde’s whales from the Western Stock of the North Pacific

9.3.1 Introduction by Japan

As last year, Japan introduced a proposed Schedule amendment to add the following sub-paragraph (g) under paragraph 10:

(g) Notwithstanding the other provisions of this paragraph, the taking of 150 Bryde’s whales from the Western Stock of the North Pacific shall be permitted for the whaling season in each of the years 2004, 2005, 2006, 2007 and 2008.1"

Explanatory note: Adoption of this Schedule amendment will require amendment to Table 2 of the Schedule.

1This provision shall be modified if the Commission, before 2008, adopts other catch limits for this stock based on an agreed management procedure.

Explaning the rationale for its proposal, Japan again noted that the western North Pacific stock of Bryde’s whale was classified as an initial management stock (IMS) or a sustained management stock (SMS) when the moratorium was placed on commercial whaling and that present abundance is estimated at 23,751, according to the Scientific Committee’s Comprehensive Assessment completed in 1996. It considered the stock to be very robust. As with its proposal relating to minke whales discussed under section 9.1, Japan referred to the fact that the RMS has been adopted but not implemented and that an IMS has still not been agreed despite discussions over many years. It again noted that work on the development of Implementation Simulation Trials has made little progress within the Scientific Committee. Nevertheless, by applying the RMP together with an appropriate monitoring and control regime (which it described), Japan believed that sustainable whaling on this stock of Bryde’s whales could be achieved and the impoverished coastal communities revitalised as a result.

9.3.2 Commission discussions and action arising

Nicaragua supported Japan’s proposal. Sweden referred to its remarks made under section 9.1 and indicated that they were also applicable to this request. It further noted that work on the Implementation Simulation Trials for this stock of Bryde’s whales has only just begun. Switzerland agreed with Sweden, emphasising that the moratorium is still in place.

On being put to a vote, Japan’s proposed Schedule amendment failed to achieve the necessary three-quarter majority, there being 22 votes in support, 29 against and 2 abstentions.

10. SCIENTIFIC PERMITS

Japan gave a short PowerPoint presentation on its JARPA and JARPNI II programmes.
10.1 Report of the Scientific Committee

10.1.1 Improvements to review procedures

Last year, the Committee had noted that the existing guidelines, which had developed over a number of years, inevitably include some duplication and overlap within the broad headings used. With the aim of providing a proposal to the Commission on restructuring the guidelines, it agreed to revisit this issue in a year in which there is no major new scientific permit proposal to review. Although the Committee considered a number of options this year, there was no consensus to change the current procedures.

10.1.2 Review results from existing permits

JAPAN: SOUTHERN HEMISPHERE (JARPA)
The Committee received a number of reports of work undertaken as part of the recent field season of JARPA as well as documents using some or all of the JARPA data collected thus far. These were considered where relevant to the main Scientific Committee agenda.

JAPAN: NORTH PACIFIC (JARPNII)
The Committee reviewed the results of the second full year of the JARPN II programme reviewed last year. A total of 150 common minke, 50 Bryde’s, 50 sei and 10 sperm whales were taken. There was considerable disagreement over the value and conclusions that could be drawn over the two-year feasibility study (and see section 10.1.3 below).

ICELAND: NORTH ATLANTIC
Most of the discussion at the 2003 meeting centred on the proposal for a two-year feasibility study in Icelandic waters involving the taking of 100 common minke whales, 100 fin whales and 50 sei whales. The stated goal was to improve understanding of the biology and feeding ecology of important cetacean species in Icelandic waters for better management of living resources based on an ecosystem approach. It includes multiple specific objectives with different priorities for the different species. For common minke whales the primary specific objective is to increase the knowledge of the species’ feeding ecology in Icelandic waters. For fin and sei whales the primary specific objective is the study of biological parameters during the apparent increase in population size in recent decades. These objectives are the basis for the proposed sample sizes. Other research objectives include studies of population structure, pollutants, parasites and pathogens, and the applicability of non-lethal methods. There had been considerable disagreement within the Committee over most aspects of this programme including objectives, methodology, sample sizes, likelihood of success, effect on stocks and the amount and quality of data that could be obtained using non-lethal means.

ICELAND: NORTH ATLANTIC
The Committee noted that the proposal remains the same as last year, except that the schedule for taking 200 minke whales in two years has been revised. The revised schedule implies that the sample of 200 minke whales will be completed in 2006.

The objectives, methodology and arrangements for participation by scientists from other countries remain unchanged from the original proposal. The revised plan for sampling minke whales reduces the numbers of whales sampled per year in 2004 and 2005.

10.2 Commission discussions and action arising

As the meeting was running seriously behind schedule, Australia, with the agreement of other co-sponsors (Argentina, Brazil, Finland, France, Germany, Italy, Mexico, Monaco, the Netherlands, New Zealand, Portugal, San Marino, South Africa, Spain, Sweden, Switzerland, UK and the USA), withdrew a proposed draft Resolution that inter alia called on Japan to halt its research whaling in the Southern Ocean Sanctuary. The co-sponsors stressed that this withdrawal should not be interpreted as a reduction in their concern on this matter and requested that the record refer to a similar Resolution adopted last year (i.e. Resolution 2003-318). Australia went on to note that during the 15 years over which JARPA has taken place, some 6,500 whales had been killed despite the fact that there has been no comprehensive assessment under peer review and no agreed abundance estimate for the stocks targeted. It believed that a full and comprehensive review of the outcome of the JARPA programme is needed before further work is contemplated and that any further research should employ non-lethal techniques. The UK and Germany associated themselves with these remarks.

New Zealand referred to the concern it has expressed for many years over scientific permit whaling, believing that the development of modern techniques such as molecular genetics have rendered lethal whale research redundant.

16 For details of the Scientific Committee’s deliberations on this Item see J. Cetacean Res. Manage. 7 (Suppl.).
17 J. Cetacean Res. Manage. 5 (Suppl.).
Furthermore, it did not believe that the research being done by Japan and Iceland to support fisheries management, rather than whale management, could be justified on moral or ethical grounds and questioned whether the research programmes would meet the ethical requirements of these countries domestic legislation. New Zealand did not dispute the right under Article VIII of the Convention for governments to issue special permits for research whaling, but was of the opinion that this right is being abused. Brazil also acknowledged these rights but considered that the current level of research whaling amounts to commercial-scale operations. It appealed to Japan to reconsider issuing permits to take whales in the Southern Ocean Sanctuary. Argentina associated itself with the remarks of New Zealand and Brazil. Sweden agreed with the moral/ethical argument put forward by New Zealand. It was also opposed to PowerPoint presentations during the plenary, preferring to have documents presented during the plenary with presentations outside the meeting room.

Italy suggested that an overlap between the diet of cetaceans and fish does not necessarily point to competition for food since this depends on the availability of a particular resource. It believed that catching whales to look at stomach contents is a too simplistic way to look at ecosystem trophodynamics. Rather it is necessary to apply complex models, which it did not believe had been done. The USA noted its strong opposition to the scientific permit whaling programmes that it believed had no quantifiable objectives. Like others, Monaco expressed concern regarding the escalation of scientific permit whaling and noted that in the last few years there has been a wealth of information published illustrating that problems with declining fisheries are due to massive over-fishing rather than competition between whales and fish. The UK made similar remarks. Switzerland was against the culling of whales on the assumption that they are in competition for fishery resources and associated itself with the comments of Italy and Monaco. The Netherlands associated itself with earlier remarks, particularly those of Australia, Sweden and Switzerland.

Japan, the Republic of Korea, Norway, St. Kitts and Nevis, Iceland and Dominica spoke in support of research programmes under special permit. Japan noted that it publishes the results from its research programmes in an open manner and that it would welcome scientists from New Zealand and other countries at its own planned JARPA review meeting. Contrary to the view of New Zealand, it did not believe its research under special permit to be either unethical or immoral. The Republic of Korea noted that some of its scientists had taken part in Japan’s JARPN II programme and thanked Japan for this opportunity to co-operate. It believed that the results from the work would improve both fisheries and whale management. Norway stressed the importance of taking an ecosystem-based approach to the management of marine living resources and referred to on-going co-operation in this area with Iceland and Japan. It stressed that this type of research requires some time to yield useful results, noting that sufficient information for use in ecosystem modelling approaches had only been obtained in its own programme after some 10 years. It commended Japanese scientists on the interesting preliminary results from JARPN II. St. Kitts and Nevis suggested that those governments holding the view that alternative approaches to lethal whale research exist should develop their own research programmes to demonstrate this. It supported the work of Japan and urged them to continue. Iceland noted the agreement in various international fora that an ecosystem approach should be applied to the management of marine living resources. As part of the marine ecosystem, it believed that whales must be included in multi-species modelling for ecosystem-based management and that the only way to get information on feeding ecology with the accuracy necessary for such modelling is to look at stomach contents. It therefore considered such research important. Furthermore, Iceland indicated that it does not believe that there is anything wrong or unethical in taking animals from abundant stocks for scientific research. It does not take the view that some animals are more equal than others. Dominica welcomed the debate on this agenda item. It supported the remarks of Norway and Iceland and the continuation of research activities from which countries like itself without the capability for running such programmes could benefit. Referring to Iceland’s comment on ecosystem management, Australia noted that this does not mean ecosystem manipulation which it believed seemed to be the objective of some of the existing research programmes.

Finally, the Chair of the Scientific Committee clarified that the Committee would continue to use existing guidelines to review future scientific permit research proposals and that it would not include work to revise the process as part of its standing agenda.

The Commission noted the Scientific Committee report and endorsed its recommendations.

11. ENVIRONMENTAL AND HEALTH ISSUES

11.1 Integration of environmental concerns with other Scientific Committee work and habitat-related issues

11.1.1 Report of the Scientific Committee

There is an increasing awareness that whales should not be considered in isolation but as part of the marine environment; detrimental changes to their habitat may pose a serious threat to whale stocks. The Committee has examined this issue in the context of the RMP and agreed that the RMP adequately addresses such concerns. However, it has also emphasised that the species most vulnerable to environmental threats might well be those reduced to levels at which the RMP, even if applied, would result in zero catches. Over a period of several years, the Committee has developed two multi-national, multi-disciplinary research proposals. One of these, POLLUTION 2000+ has two aims: to determine whether predictive and quantitative relationships exist between biomarkers (of exposure to and/or effect of PCBs) and PCB levels in certain tissues; and to validate/calibrate sampling and analytical techniques. The other, SOWER 2000 (IWC, 2000) aims to examine the influence of temporal and spatial variability in the physical and biological Antarctic environment on the distribution, abundance and migration of whales. Progress reports on both of these programmes were considered at this year’s meeting.

Given the emergent threat of anthropogenic sound on cetaceans and other elements of marine ecosystems and also the potential for the Committee to assist in the development and interpretation of studies aimed at elucidating the potential impacts of anthropogenic noise on cetaceans, the Committee held a mini-symposium at this year’s meeting, with presentations on the following topics:
(a) the effects of anthropogenic noise on marine animals and the possible synergistic effects between ambient ocean noise levels and other environmental stressors;
(b) physical acoustics and ambient noise in the ocean;
(c) audition and the physiology of hearing in cetaceans and the effects of intense sounds on cetacean hearing; and
(d) whale communication behaviour.

In conclusion, the Committee noted with great concern the impact on large whales in critical habitats of exposure to seismic sound pulses, particularly with respect to severely threatened populations such as the western gray whale. It agreed that there is now compelling evidence implicating that military sonar has a direct impact on beaked whales in particular. It also agreed that evidence of increased sounds from other sources, including ships and seismic activities, were cause for serious concern. The potential for cumulative or synergistic effects of sounds, as found in other taxa, with non-acoustic anthropogenic stressors was noted. A number of detailed recommendations were made concerning beaked whales and military sonar, mitigation and monitoring protocols with respect to seismic operations, and general recommendations on anthropogenic noise.

The Committee was pleased to hear that the intersessional Workshop on Habitat Degradation will take place in November 2004 at the University of Siena, Italy. The Committee also forwarded this year’s SOCER (State of the Cetacean Environment Report) to the Commission.

The Committee also agreed that it was important to integrate work on environmental concerns with that of the other Sub-committees. It noted that next year’s symposium on sea ice would be a joint venture with the IA (in-depth assessments) and BRG (bowhead, right and gray whales) Sub-committees.

11.1.2 Commission discussions and action arising
The UK believed that environmental concerns are paramount in the conservation and management of cetaceans and considered that the greatest threat to cetaceans is the degradation of their environment through chemical pollution, commercial fisheries and global environmental changes. Noting that the effects of noise pollution are a growing concern, the UK endorsed the Scientific Committee’s comprehensive recommendations on this issue. It also applauded the Committee’s work on other habitat degradation issues and looked forward to the outcome of the habitat degradation workshop. It believed the ongoing work on chemical pollution under POLLUTION 2000+ to be important in relation to conservation and consumption of cetaceans and encouraged its continued funding. The UK supported the steps being taken to integrate environmental concerns with other parts of the Scientific Committee’s agenda but noted that the issues of noise and chemical pollution are agreed priority areas for the Standing Working Group on Environmental Concerns. Finally it thanked the editors of the SOCER report. New Zealand, Germany and Australia associated themselves with the remarks of the UK. Referring to the SOCER report, Australia noted the steps it is taking to protect the Great Barrier Reef and was pleased to see that the report next year will include a review of Antarctic cetacean issues.

The Commission noted the Scientific Committee’s report and endorsed its recommendations.

11.2 Reports from Contracting Governments
There were no reports from Contracting Governments on national and regional efforts to monitor and address the impacts of environmental change on cetaceans and other marine mammals.

11.3 Health issues
There were no issues raised under this item.

12. WHALEWATCHING

12.1 Report of the Scientific Committee20
In 2000, the Committee had identified a number of areas for further research on possible long-term effects of whalewatching on whales and a number of possible data types that could be collected from whalewatching operations to assist in assessing their impact. The Committee developed this further at the 2004 meeting. The primary topic considered was a review of the results from the Workshop on the Science for Sustainable Whalewatching held in Cape Town, 6-9 March 2004. The Committee endorsed a number of recommendations from the Workshop concerning:

1. the value of experimental studies to measure the impacts of whalewatching;
2. new approaches and quantitative studies of relevance to the Scientific Committee;
3. further development of a framework for the management of whalewatching similar in concept to those codified in the FAO Code of Conduct for fisheries;
4. use of the precautionary approach in the absence of information of possible damaging effects of whalewatching;
5. use of case studies to promote broad conclusions about assessing impacts of whalewatching on different taxonomic groups at a variety of life history stages;
6. the development of whalewatching guidelines based on criteria that are simple, practical and objectively measurable under field conditions; and
7. further development of the IWC’s 1997 General Principles for the Development of Regulatory Frameworks for Whalewatching (see www.iwc-office.org).

The Committee also reviewed whalewatching guidelines and regulations, and new information on dolphin feeding and ‘swim-with’ programmes.

12.2 Commission discussions and action arising
New Zealand, Brazil, the UK, Australia, Germany, Italy, Argentina, the USA and Spain supported the Scientific Committee’s work in this area and in particular thanked South Africa for hosting the whalewatching management workshop. They endorsed the workshop’s recommendations and expressed regret that there is still disagreement regarding the competency of Commission on this issue which they believed did fall within its mandate. Several

20 For details of the Scientific Committee’s deliberation on this Item see J. Cetacean Res. Manage. 7 (Suppl.).
countries noted that whalewatching is an ideal way to achieve optimal use of whale resources with New Zealand and Australia providing information on the contribution of whalewatching to their economies. Brazil asked the convenors of the Scientific Committee to give due attention to the funding of Invited Participants who could contribute to this debate. South Africa thanked the UK for its financial contribution to the workshop.

Norway noted that it supports whalewatching, has several whalewatching activities in northern Norway and sees no conflict between whalewatching and whaling. Its own experience is that they can benefit from each other. Iceland made similar remarks. Japan also believed that whalewatching and whaling can co-exist, but considered that the collection of data for scientific research from the former has limitations. It believed that whalewatching is outside the scope of the Convention. The Republic of Palau associated itself with the remarks of Norway, Iceland and Japan. The Republic of Korea noted that a recent effort to establish some whalewatching activities had failed because of conflict with fishing grounds.

The Commission noted the report of the Scientific Committee and endorsed its recommendations.

13. CO-OPERATION WITH OTHER ORGANISATIONS

13.1 Report of the Scientific Committee

The Scientific Committee received reports of its co-operation with CMS (Convention on the Conservation of Migratory Species), ASCOBANS (Agreement on Small Cetaceans of the Baltic and North Seas), ACCOBAMS (Agreement on the Conservation of Cetaceans of the Black Sea, Mediterranean Sea and contiguous Atlantic Area), ICES (International Council for the Exploration of the Sea), IATTC (Inter-American Tropical Tuna Commission); ICCAT (International Commission for the Conservation of Atlantic Tuna), CCAMLR (Convention for the Conservation of Antarctic Marine Living Resources), Southern Ocean GLOBEC, NAMMCO (North Atlantic Marine Mammal Commission), FAO - Sub-committee on Fish Trade; PICES (North Pacific Marine Science Organisation); IUCN (International Union for the Conservation of Nature) and ECCO (Eastern Caribbean Cetacean Commission).

The Scientific Committee Chair drew particular attention to the part of its report dealing with co-operation with IUCN. He noted that in response to a request from IUCN, the Committee had reviewed its list of recognised species, including a critique of the status of the new Bryde’s whale species *Balaenoptera omurai*. The Committee agreed that inclusion of the species in the IWC list of recognised species would be premature at present. It recommended that the Bryde’s whale complex continue to be listed under the name *B. edeni* on a provisional basis and that research to resolve the uncertainties be undertaken. In particular, the Scientific Committee recommended that the Government of India be requested to facilitate collection and genetic analysis of a bone sample from the holotype specimen of *B. edeni* in Calcutta so that the taxonomy and nomenclature can be resolved.

13.2 Commission discussions and action arising

The Commission noted the report from the Scientific Committee and endorsed its recommendations. There were no other reports.

The Commission noted that the 13th Conference of the Parties to CITES would be held in Bangkok between 2 and 14 October 2004. It agreed that IWC should be represented at the meeting but left it to the Advisory Committee to decide who the representative should be.

RESOLUTION ON POSSIBLE SYNERGIES WITH THE GLOBAL ENVIRONMENT FACILITY

Mexico, who introduced this draft Resolution on behalf of the other co-sponsors (Argentina, Belize, Brazil, Chile, Nicaragua, Panama, Peru and South Africa), explained that the Global Environment Facility (GEF) is primarily a financial mechanism designed to facilitate and direct financial resources into agreed areas of international environmental concerns. It noted that many international environmental Conventions (like the Convention on Biodiversity) work directly with GEF and was sure that many IWC delegates would be familiar with the GEF and its work. Noting that the Commission has limited resources to fund scientific work and that certain priority areas for some members continue to receive little or no funding, the Resolution’s sponsors believed that it would be worth exploring with the GEF possible synergies, including funding.

After interventions from Dominica, Kenya and Ireland, the operative paragraphs of the draft Resolution were amended to read:

‘NOW THEREFORE THE COMMISSION:

DIRECTS the Secretariat to establish high level contact with the Secretariat of the Global Environment Facility and to:

(i) explore possible synergies and their possible utility of the GEF to the IWC, and investigate, inter alia, possible avenues for the utilisation of GEF funding for IWC related projects, with specific regard to:

(ii) assist for developing countries for scientific research and policies for scientific research, as directed by the IWC.

(iii) an examination of the modalities that the GEF seeks to satisfy and whether IWC projects, now or in the future, could be suitably funded through the Global Environment Facility.

The Secretariat shall report back to the 57th IWC meeting on these matters.’

Switzerland pointed out that GEF’s organisational structure identifies a GEF representative in each country, known as a focal point. It believed that if a country has a particular project for which they seek funding, it should approach GEF through the appropriate focal point. It indicated that it would abstain if the draft Resolution was put to a vote.

Norway sought clarification on the type of projects that might be undertaken in the proposed co-operation with GEF. Mexico stressed that for the moment the sponsors simply wished to begin to explore possibilities, but that from its own perspective, it would be interested in projects on issues such as bycatch and whalewatching. South Africa gave the example of aerial surveys of right whale populations. Norway suggested that perhaps the draft Resolution would best be discussed under agenda Item 15 on the Conservation Committee. The Republic of Korea questioned whether a Resolution is needed if all that is intended at this stage is for the Secretariat to contact GEF and explore possibilities. Japan found the proposal relating...
to joint projects unclear and believed that they probably would refer to areas that Japan did not consider of high priority for the Commission. It did not see any need to explore co-operation with GEF. Australia found the intention of the draft Resolution clear (i.e. to explore possible synergies) and considered that the developing countries sponsoring it deserved the Commission’s support.

Responding to Norway, the Chair indicated that he did not think that it would be appropriate to refer this matter to discussions associated with the Conservation Committee given that that Committee is still in its early stages. The sponsors agreed. On being put to a vote the Resolution was adopted (Resolution 2004-5, Annex C), there being 30 votes in support, 8 against and 14 abstentions.

14. OTHER SCIENTIFIC COMMITTEE ACTIVITIES, ITS FUTURE WORK PLAN AND ADOPTION OF THE SCIENTIFIC COMMITTEE REPORT

14.1 Small cetaceans

14.1.1 Report of the Scientific Committee

Despite disagreement within the Commission over the management responsibilities of the IWC with respect to small cetaceans, it has been agreed that the Scientific Committee can study and provide advice on them. As part of this programme, the Committee has reviewed the biology and status of a number of species and carried out major reviews of significant directed and incidental catches of small cetaceans.

In 2001, the Government of Japan had indicated that it would no longer co-operate with the Committee on small cetacean related matters. In 2002, the Committee referred to the great value of the information provided by the Government of Japan on the status of small cetaceans in previous years and respectfully requested that the Government of Japan reconsider its position on this matter and resume the valuable contribution of Japanese scientists to its work on small cetaceans. Unfortunately, this has not yet happened.

This year, the primary topic considered was the franciscana. The franciscana is found along the Atlantic coasts of Brazil, Uruguay and Argentina, from approximately 18° to 42°S. The Committee reviewed available information on stock structure, abundance, life history, ecology, incidental catches and status. It made a number of research recommendations given the paucity of information for some areas. Bycatch in gillnet fisheries occurs throughout the range of the franciscana. The Committee expressed its concern that in some areas, annual removal rates due to bycatch were between about 1.6 and 3.3% exceeding the 1% removal level determined by the Committee as sufficient to warrant concern regarding the status of small cetaceans.

The Committee referred to its endorsement of the concept of a series of regional Workshops with the general objectives of developing a short- and long-term approach to the successful management and mitigation of the cetacean bycatch problems in a region, building upon work already undertaken by the Committee (see section on Regional Workshops).

The Committee also reviewed progress on previous recommendations it had made, particularly those concerning the critically endangered baïji (Lipotes vexillifer) and vaquita (Phocoena sinus). The Committee received some information from China and welcomed the initiatives being taken, although it noted that the prospects for the baïji remain extremely poor.

The Committee has followed with considerable interest progress on conservation of the highly endangered vaquita; several members of the Committee also serve on the International Committee for the Recovery of the Vaquita (CIRVA). This year the Committee reviewed the report of the third meeting of CIRVA. The Committee reiterated its endorsement of the fundamental conclusions drawn by CIRVA - that the current grave conservation status of this species is due to fisheries bycatch. The Committee noted at least six records of bycatch in the past seven months and, in general, was disheartened by the lack of any substantial progress in reducing bycatches since last year’s meeting. Therefore, the Committee urged the Government of Mexico to implement the previous recommendations of CIRVA and to take immediate action to eliminate the bycatch of this species in the northern Gulf of California.

The Committee has had considerable involvement in the assessment of the harbour porpoise (Phocoena phocoena) in the North Atlantic and has worked closely with ASCOBANS in the formulation of conservation programmes. This year the Committee reviewed and endorsed plans for the project Small Cetaceans of the European Atlantic and North Sea, or SCANS-II, which has three primary objectives: to update estimates of abundance from the original SCANS survey area and to obtain estimates for previously unsurveyed areas; to develop a management framework for assessing the impact of bycatches and setting safe bycatch limits; and to develop methods for monitoring small cetacean populations during periods between major decadal surveys.

The Committee also reiterated previous advice concerning the need to minimise or eliminate anthropogenic direct removals or threats to habitat of the Irrawaddy dolphin and the Ganges river dolphin.

In the light of new evidence, the Committee repeated its concern over the catches and quotas for some stocks of white whales and narwhals, particularly in Greenland, east Hudson Bay and the Russian Arctic. The Committee repeated previous requests for all Governments to submit relevant information on direct and incidental catches of small cetaceans in their national progress reports and for improved information on stock identity and abundance.

14.1.2 Commission discussions and action arising

Switzerland noted that the Scientific Committee had reinforced the recommendations it made last year concerning narwhals and white whales and informed the Commission that the CITES Animals Committee has subjected narwhals to significant trade review. Switzerland also explained that the CITES proposal on Irrawaddy dolphins deals with international trade and not bycatch or direct removals for national use. Germany, the UK and Sweden associated themselves with Switzerland’s remarks. With respect to Irrawaddy dolphins, the UK drew attention to the Scientific Committee recommendation that all direct removals should cease until affected populations have been assessed to which it attached considerable importance. The UK further noted that the Scientific Committee has reviewed some but not all of the actions from past Resolutions on small cetaceans, and that the table of estimates of abundance and catches is incomplete. It was
particularly concerned regarding the absence of information on directed takes of Dall’s porpoise noting that the Scientific Committee in the past has indicated that takes were unsustainable. Australia associated itself with the UK’s remarks on Dall’s porpoise but particularly wished to highlight the Committee’s concerns regarding the West Greenland stock of whale whales and narwhals. It believed that the Commission should also express serious concern given the statement that continued hunting at recent levels “may result in the extinction of West Greenland narwhals in the near future”. New Zealand and Finland associated themselves with the remarks of Switzerland, the UK and Australia.

With respect to the recommendations on the West Greenland narwhal, Denmark referred to its well-known position that small cetaceans are outside the competence of the IWC.

The Commission noted the Scientific Committee report and endorsed its recommendations.

14.2 Other activities
14.2.1 Report of the Scientific Committee

STOCK IDENTITY

Of general concern to the assessment of any cetaceans is the question of stock identity. Examination of this concept in the context of management plays an important role in much of the Committee’s work, whether in the context of the RMP, AWMP or general conservation and management. In recognition of this, the Committee has established a Working Group to review theoretical and practical aspects of the stock concept in a management context. The Committee has noted that it is important in any application of stock structure methods, to examine the sensitivity of conclusions to different a priori decisions about the definition of initial units, to ascertain which population structure hypotheses to examine.

A specialist Workshop to examine the use of simulation testing to assess the performance of methods to identify population structure was held in January 2003 and discussed at the annual meeting later that year. The Workshop developed a suitable simulation framework to allow evaluation of genetic methods used in inferring population structure both in general terms (the issue is of great relevance to conservation and management outside the IWC) and from a specifically IWC viewpoint (particularly in an RMP/AWMP context).

It was recognised that such a complex project must proceed in an iterative fashion and the Workshop concentrated on specifying the various modular tasks needed for Phase I of the process (c.f. Initial Exploration Trials in the AWMP process), for which some results might be expected within a year, while also identifying the types of scenarios that would need to be covered in Phase II and beyond. The Workshop report was published in J. Cetacean Res. Manage. 6(Suppl.). This year the Committee reviewed progress under Phase I of the TOSSM project (Testing Of Spatial Structure Models). It was pleased to see that great progress had been made on the most challenging module, i.e. the development and validation of a program to simulate realistic genetic datasets. Preliminary testing of various methods under certain simple scenarios will begin during the intersessional period.

DNA TESTING

This item is discussed in response to Commission Resolution 1999-822. The Committee considered a report on the public sequence archive GenBank (National Center for Biotechnology Information, http://www.ncbi.nlm.gov/). The Committee recommended that members be urged to deposit sequences to be used in a published report in GenBank and include the GenBank accession numbers in publications, whether or not this is required by the journal (the Guide for Authors for the Journal of Cetacean Research and Management will be modified accordingly). It further recommended that similar practices be established for public archiving of non-sequence genetic data, such as microsatellite loci, primers, alleles, and profiles, where feasible. Such data are not presently accepted by GenBank, and some research may be necessary to identify a suitable archive. One potential provisional venue is the websites maintained by most major journals for supplementary data and information accompanying published papers.

The Committee welcomed the information on the status of the Norwegian minke whale DNA-register covering the years 1997-2002. It was noted that progress has been made toward achieving a fully diagnostic register; no samples were missing for the 625 whales landed in 2002. The number of missing samples in earlier years ranged from 3 to 11. No samples were reported from stranded whales.

No information on collection and archiving of samples in Japan was available to the Committee. It was noted that provision of a progress report on collection and archiving of samples would assist the Committee in meeting its terms of reference as assigned by the Commission.

PUBLICATIONS

The year 2004 was another productive year with respect to the IWC’s scientific publications.

The IWC website now includes a downloadable file containing well over 6,500 references to documents that have been presented to the Committee since 1969. The file lists all of the documents by meeting and includes information on whether and where they have been published. The Committee reiterated the importance of Committee members urging their respective institutes and colleagues to subscribe to the Journal and to submit high quality papers to it. The success of the Journal will be greatly increased as it becomes established in more institutional libraries.

The Committee stressed the vital contribution the Journal makes to the work of the Committee and to the wider issues of the management and conservation of whales.

14.2.2 Commission discussions and action arising

Referring to the Scientific Committee report on (1) progress with the collection and archiving of samples from catches and bycatches and (2) reference databases and standards for a diagnostic register of DNA profiles, Sweden noted that while a report had been received from Norway, no reference was made to information from Japan. It asked whether there was an explanation for this omission. The Scientific Committee Chair noted that a request to Japan for information had been made but that nothing had been received.

14.3 Scientific Committee future work plan

14.3.1 Report of the Scientific Committee
The Chair of the Scientific Committee described the work plan drawn up by the Convenors, with the agreement of the Scientific Committee, after the close of the meeting. The work plan takes account of:

(1) priority items agreed by the Committee last year and endorsed by the Commission and, within them the highest priority items agreed by the Committee on the basis of Sub-committee discussions;
(2) general plenary discussions on this item and in particular the need to reduce the Committee’s workload; and
(3) budget discussions in the full Committee.

14.3.1.1 RMP
As last year, this Sub-committee will concentrate on general issues as well as preparations for Implementation. The priority topics will be in priority order:

General issues

(1) finalise the guidelines and requirements for implementing the RMP;
   (a) develop the thresholds for defining ‘acceptable’, and ‘borderline’ performance for classifying the performance of RMP variants for Implementation Simulation Trials.
   (b) develop a list of agreed stock structure archetypes (in conjunction with SD, as necessary);
(2) further develop the ‘simple model filter’;
(3) finalise the issue of spatio-temporal considerations; and
(4) finalise the issue of the CATCHLIMIT program for running it in a trials situation.

Implementation process

(1) conduct an intersessional workshop to allow the Committee to be in a position to complete the pre-implementation assessment for western North Pacific Bryde’s whales; and
(2) review progress on the development of stock structure hypotheses as part of the pre-implementation assessment for North Atlantic fin whales.

14.3.1.2 AWMP
The priority topics for this Sub-committee are:

(1) Greenland SLA development:
   (a) the 2004 aerial survey;
   (b) genetics simulation studies; and
   (c) SLA exploration and development;
(2) undertake annual review of catch data and management advice for minke and fin whales off Greenland;
(3) undertake annual review of catch data and management advice for humpback whales off St. Vincent and The Grenadines; and
(4) initiate planning for a bowhead whale Implementation Review.

14.3.1.3 BOWHEAD, RIGHT AND GRAY WHALES (BRG)
Given the workload of BRG anticipated during the 2005 meeting, a priority item was agreed concerning southern right whales (see below). The Sub-committee will therefore:

(1) review any new information on bowhead whale stock identity;
(2) undertake annual review of catch data and management advice for ENP gray whales;
(3) undertake annual review of catch data and management advice for BCB bowhead whales;
(4) participate in a joint symposium on the effects of high latitude (Arctic and Antarctic) sea ice on cetaceans;
(5) undertake annual review of the status of the western North Pacific stock of gray whales;
(6) undertake a review of new information on southern right whales; and
(7) if there is time: review new information on small stocks of bowhead and northern right whales.

14.3.1.4 IN-DEPTH ASSESSMENT (IA)
The topics of this Sub-committee, in order of priority, will be:

(1) estimate abundance of Antarctic minke whales;
(2) participate in a joint symposium on the effects of high latitude (Arctic and Antarctic) sea ice on cetaceans;
(3) review workshop report on SOWER cruise plans beyond 2004/05;
(4) begin work on an in-depth assessment of western North Pacific common minke whales, with a focus on J stock, assuming the availability of an abundance estimate for this stock;
(5) continue to examine reasons for differences between minke abundance estimates from CPI and CPII; and
(6) brief review of report from an anticipated non-IWC sponsored workshop on sperm whales.

14.3.1.5 BYCATCHES AND OTHER ANTHROPOGENIC REMOVALS (BC)
This Sub-committee will, as its highest priority:

(1) further review methods to estimate bycatch based on fisheries data and observer programmes;
(2) further review methods to estimate bycatch based on genetic data, especially results from the workshop; and
(3) empirical analysis of the functional relationship of bycatch levels to fishing effort and to population abundance.

It is intended that the following topics will be priority items in 2006 given work expected to be completed by 2006 by other Sub-committees; thus in 2005 if there is time it may also briefly consider:

(4) information and methods on estimates of cetacean mortality caused by vessel strikes; and
(5) information and methods on estimates of cetacean mortality caused by other human activities.

14.3.1.6 SOUTHERN HEMISPHERE WHALES OTHER THAN ANTARCTIC MINKE WHALES (SH)
Priority items in order will be:

(1) complete in-depth assessment of Southern Hemisphere humpback whales with a focus on the C, D and E stocks:
   (a) investigate the distribution and allocation of historic catches to
      (i) proposed sub-areas of breeding grounds and
      (ii) from Antarctic Peninsula to Stocks A and G;
   (b) update the tables summarising the present state of knowledge and work required to continue a
The priority items will be:

14.3.1.11 SCIENTIFIC PERMITS (P)
The priority items will be:

1. review research results from existing permits (including plans for a major review of the JARPA programme); and
2. review plans for new and continuing permit proposals.

14.3.1.12 DNA
The priority items will be:

1. review genetic methods for species, stock and individual identification;
2. collect and archive tissue samples from catches and bycatch; and
3. reference databases and standards for diagnostic DNA registries.

14.3.2 Commission discussions and action arising
The Republic of Korea welcomed the Scientific Committee proposal to look at the status of finless porpoise at next year’s meeting. While it noted that its position is that management of small cetaceans is outside the competence of IWC, it would nevertheless ask its scientists to contribute to this review.

Japan believed that too much of the Scientific Committee’s time is spent on items that Japan believes are lower priority and outside the mandate of the Commission (e.g. whalewatching, small cetaceans, environmental concerns), detracting from more important items such as in-depth assessments, work on the RMP, etc. It requested that if these lower priority items continue to be included on the Scientific Committee’s agenda, that the Committee Chair and Vice-Chair prioritise the time allocated to different items. Japan noted that it shares the concern expressed by the Scientific Committee that the RMP is becoming unworkable, particularly in view of the outcome of the RMP Implementation for North Pacific minke whales. It believed that a significant part of the problem is due to the unnecessarily high tuning level used in the RMP and the fact that the RMP is generic rather than species or case specific. Japan considered that the Commission should give high priority to discussing these issues together with developing a management procedure that included ecosystem considerations. Finally it believed that the Scientific Committee should take a consistent approach to how it deals with uncertainty, e.g. in the RMP and in the AWMP and in determining stock structure. From this intervention, Australia understood Japan to be expressing a fundamental problem with the generic nature of the RMP and noted that this view is of concern.

Germany drew attention to the work on bycatch and in particular to the Committee’s recommendation for a workshop on the use of market sampling to estimate bycatch. It considered it important that steps are taken to develop both short- and long-term approaches to solving or at least mitigating the cetacean bycatch problem. It believed that this should be done through regional workshops under the auspices of IWC in co-operation with regional organisations like ASCOBANS and ACCOBAMS.

Sweden, Australia, Italy, New Zealand, Spain and Finland associated themselves with these remarks. Germany also informed the Commission that the European Union had recently adopted a regulation with measures to minimise cetacean bycatch through:

1. a ban on drift nets;
2. an obligation to use pingers in the gill net fishery; and
3. an obligation to have scientific observers on pelagic trawlers.
PROPOSAL TO REALLOCATE FUNDING

On behalf of the 23 co-sponsors, Grenada introduced a proposal to redistribute the funding allocated to the proposed workshop on the use of market sampling to estimate bycatch across a number of other Scientific Committee activities that the proposers considered to be of higher priority but which were not fully-funded in the F&A Committee recommendations (i.e. the international workshop on North Pacific Byrde’s whales, the AWMP developers fund, the estimation of abundance of Antarctic minke whales and SOWER 2004/05). Grenada explained that the proposal’s sponsors had serious concerns over the utility of using market sampling to provide a better estimate of bycatch than can be gained from onboard observer programmes and by monitoring animals taken in set nets and traps that enter the market. They believed that the precision of the DNA mark/recapture method is quite low, meaning that it could not be used to account for total catches over time for purposes of the RMP. Furthermore, these countries considered that the market-based genetic methodology cannot be used in any case for estimating bycatch in countries where bycaught animals do not enter the market, even though these represent the majority of countries who have fisheries that are likely to take whales as bycatch. The proposers believed that the bycatch workshop could be put off without ill effect, while the other high priority items deserve to be completed as expeditiously as possible.

Austria, Australia, the UK and New Zealand spoke against this proposal, noting in particular that the Scientific Committee’s recommendation for the bycatch workshop had already been discussed on two earlier occasions (in the F&A Committee and see section 6.1). Austria noted that should the proposal be adopted, it would feel obliged to revisit allocation across all projects, particularly those which currently have attracted no funding.

On a point of order, Sweden supported by Kenya, moved to adjourn the debate on this item. This motion was carried by a show of hands. On being put to a vote, the proposal to reallocate funding was not adopted, there being 19 votes in favour, 26 against and 2 abstentions.

14.4 Adoption of the Report

The Commission adopted the Scientific Committee report and its recommendations, including the future work plan.

15. CONSERVATION COMMITTEE

The meeting of the Conservation Committee took place on the afternoon of Wednesday 14 July and the morning of Thursday 15 July 2004. It was chaired by Horst Kleinschmidt (South Africa and Vice-Chair of the Commission). Delegates from 26 Contracting Governments participated. A summary of the Committee’s discussions is included below. The full Sub-committee report is available as Annex H.

15.1 Report of the Conservation Committee

15.1.1 General discussion

As this was the inaugural meeting of the Conservation Committee, the Chair had invited members to address general issues relating to the establishment and purpose of the new Committee before turning to specific agenda items. There was consensus that all members of the IWC should be and were committed to conservation, and that the new Committee should not supervise or duplicate the work of any other bodies of the Commission. However, a range of views were expressed about the appropriateness or otherwise of the steps taken to establish the Conservation Committee and it was agreed that efforts since IWC/55 to improve the level of communication between members in disagreement were important.

Many of the co-sponsors of Resolution 2003-1, by which the Committee was established, stated that the new body should be viewed as pro-conservation, not anti-whaling. These members recognised that the Convention provides for both conservation and management of whale stocks, and believed that the establishment of the Conservation Committee did not prevent the fulfilment of either of these objectives. The conservation of whale stocks was in the common interest.

These members held the view that the establishment of the Committee would not alter or in any way impinge upon the attributions or work of any of the Commission’s active bodies, nor would it change any of the functions or terms of reference of such bodies, or of the Commission itself. Rather, the primary objective in setting up the Conservation Committee in their view was to rationalise the Commission’s work on that part of its agenda that deals with conservation issues, as well as to institutionalise and better distribute the Commission’s workload. They emphasised that the Conservation Committee would not have any supervisory function over the work of the Scientific Committee, which has its agenda and terms of reference clearly established by the Commission.

Those who had supported the establishment of the Committee looked forward to the Committee improving the way the IWC met its responsibility for managing whales by addressing issues not only from the perspective of whaling. To date, conservation issues had been typically addressed late in the plenary, and the Committee would allow such issues to be discussed in detail several days before the plenary. The Committee could provide advice and guidelines on conservation-related functions that were currently dispersed, and serve as a central node to identify and prioritise topics. This might prevent overload on other bodies of the Commission.

Other members, who had opposed Resolution 2003-1, indicated that they still had reservations about the establishment of the Committee, especially because in their view it took the objective of the ‘conservation of whale stocks’ out of the context of the objective of making possible ‘the orderly development of the whaling industry’. They were committed to the sustainable use of natural resources, and viewed completion of a Revised Management Scheme to prevent over-exploitation as a higher priority conservation measure than items that might be addressed under a Conservation Committee. Their participation in the first meeting should not be construed as change of position on the Resolution. These members stated that the process used at IWC/55 to create a new body made no attempt to bring the members of the IWC together.
a mechanism to address those conservation issues which are capable of attracting widespread support ought not to have been promoted in a manner which did not effectively consult nearly half of the members of the IWC. Some efforts to discuss alternative language had been rejected out of hand, which was not conducive to open and fair dealings.

Those who had opposed the establishment of the Committee noted that, even if nothing in Resolution 2003-1 defined conservation narrowly, the wording of the Resolution and its appendix of past decisions of the Commission made it clear that the initiative would alienate nearly half of the members of the IWC. Nonetheless, members present who had opposed the process had decided to attend the first meeting, expecting a change to the name of the Committee and amendment of the original Resolution, in order to reciprocate their goodwill.

The Committee discussed the question of how to define ‘conservation’, and particularly whether that should be construed as including ‘sustainable use’. It was noted that various definitions were available, both from dictionaries (though there was no equivalent term in some languages), and in the texts and agreements of other treaties. While it was agreed that conservation was of interest to all members, and that further discussion on its definition would be worthwhile, a definitive answer was beyond the capacity of the Committee’s first meeting. Some indicated that they had envisaged the Committee addressing issues that did not fit the remit of ‘sustainable use’, while others would welcome further discussion on this.

It was noted that many members of the Commission were absent. This could be viewed as an indication of dissatisfaction with the process by which the Committee was established. Supporters of the Committee indicated that they were engaged in a constructive dialogue with some of the absent members, in the interest of seeking broad participation, and hoped that the Committee’s report might demonstrate to them the value of the Committee.

15.1.2 Relationship between the Conservation Committee and other bodies within the Commission

It was recognised that relationships between the Conservation Committee and other bodies within the Commission will be vital to the success and effectiveness of the new Committee and that relationships should be based on the principle of complementarity, not duplication.

The Committee agreed that interactions with the Scientific Committee would occur in the same way that the Scientific Committee interacts with other subsidiary bodies already established by the Commission. As with the Aboriginal Subsistence Whaling Sub-committee and the first meeting of the Conservation Committee, the Chair of the Scientific Committee would attend and provide information on scientific matters that are germane to that body’s work.

Relationships with the Technical Committee were also addressed. Some members viewed the reference to ‘conservation’ in the Rules of Procedure that relate to the Technical Committee as evidence of potential overlap with the Conservation Committee. It was noted that Rule of Procedure M7 might need to be changed to avoid duplication of functions. The alternative view was that appropriate delegation of responsibility could ensure complementarity: the Commission could refer to the Technical Committee the development of proposed management measures that the Commission considered for adoption into the Schedule (i.e. matters pertaining to Article V), while referring to the Conservation Committee the development of the conservation agenda and related proposed recommendations (i.e. matters pertaining to Article VI).

15.1.3 Proposed Terms of Reference, working methods and funding considerations

Resolution 2003-1 contained three terms of reference for the Conservation Committee:

1. the preparation and recommendation to the Commission of its future Conservation Agenda;
2. the implementation of those items in the Agenda that the Commission may refer to it;
3. making recommendations to the Commission in order to maintain and update the Conservation Agenda on a continuing basis.

Many felt that these should guide the initial work of the Committee and that additional terms should be developed if and when required. Further drafting work should proceed in an open process under the auspices of the Commission as a whole or its Chair. Others who would prefer alternative terms of reference or who had not commented were encouraged to make specific proposals.

In light of the concerns raised by those who had opposed Resolution 2003-1, a small group was formed to examine the language of the Resolution and further discuss terms of reference, outside of the Committee meeting. The group discussed concepts of conservation, ways to move forward after Resolution 2003-1, and terms of reference. It agreed to the importance of addressing conservation in the IWC and to respect different views on whaling. Furthermore the group offered for discussion a collection of possible ways forward, including different ways of defining the concept of conservation, and various alternatives, including Resolutions, that could clarify the work of the new Committee (see Annex H, Appendix 3).

The Committee agreed to hold annual meetings, in line with the practice of other committees and working groups. The Conservation Committee would not normally ‘meet’ intersessionally, other than by e-mail correspondence when necessary.

Paragraph 8 of Resolution 2003-1 charged the Committee with beginning to explore the possibility of a trust fund to make resources available both to the Commission and to Contracting Governments to implement research related to the Conservation Agenda. Discussion indicated it was premature to discuss this in detail and that in any case it would be up to the Commission to decide whether to establish such a fund.

15.1.4 Consideration of items to fall under the auspices of the Conservation Committee

The Committee recognised the value of establishing a list of items to address as part of the ‘extensive conservation agenda’ mentioned in its founding Resolution. The following were proposed as initial items of common interest: endangered species and populations; human impacts (e.g. noise, vessel strike, bycatch, entanglements, strandings); habitat protection for cetacean conservation; whalewatching best practice guidelines; reporting systems for strandings, entanglements and bycatch; legal and regulatory arrangements for cetacean conservation.
Some countries argued that the list is too general and too extensive. These countries argued that conservation issues are very important, but only for a small number of species and stocks of large whales. Many species and stocks of large whales are either quite numerous or rapidly growing, and for these, in their opinion, the items on the list above are not important for conservation.

Of the conservation-related items currently addressed by the Scientific Committee, the following were identified as most germane to the work of the Conservation Committee: highly endangered species and populations; scientific research related to development of techniques for improved assessment of status and mitigation measures to potential threats where identified; incidental takes of cetaceans including assessment of problems at the population level and development and evaluation of mitigation measures; non-consumptive utilisation of cetaceans; whales and their environment, with an emphasis on population level effects and interaction with interpreting abundance estimates; sanctuaries, in particular their value to the monitoring and recovery of depleted populations; scientific advice relevant to enforcement and compliance with conservation measures; collaboration with other organisations; voluntary submission of national reports on cetacean conservation.

15.1.5 Collaboration with other organisations
Through Resolution 2003-1, the Conservation Committee was directed ‘to explore how the Commission can coordinate its conservation agenda through greater collaboration with a wider range of other organisations and conventions’. It was noted that the Committee could centralise collaboration, maintain an overview of those who serve as ambassadors for the IWC, and identify opportunities for new and improved collaborations. The Memorandum of Understanding between CMS and IWC was noted and a member of the CMS Secretariat indicated that CMS looks forward to continuing to work closely with IWC.

15.1.6 Development of a Conservation Agenda
The Committee viewed its discussion of terms of reference, relationships with other bodies, and items to fall under its auspices as the first steps towards the development of a conservation agenda. Some delegations considered it premature to enter into substantive discussions until a conclusion has been reached regarding the nature of the Conservation Committee. Other delegations disagreed with this and felt it was appropriate to start substantive discussions at this time.

15.2 Commission discussions and action arising
Austria, The Netherlands, Sweden, France, Australia, Mexico, Germany, New Zealand, the USA, Peru, Spain, the UK, Monaco, Oman and Finland all welcomed the report from the Conservation Committee, indicated their continued support for the Committee and looked forward to further intersessional work. Many congratulated the Chair on his preparation and management of the meeting and many stressed the need for wider participation from IWC members. Austria expressed the hope that constructive work could be done to save some of the most endangered species. The Netherlands drew attention to the report from the small group established within the Conservation Committee (see Appendix C, Annex H) and suggested that the Commission endorse the proposed way forward, i.e. that further discussions on the expectations of the work of the Conservation Committee should be continued under the responsibility of the IWC or its Chair to ensure that all views will be taken into account. Sweden was of the opinion that the Conservation Committee should start work on substantive matters at IWC/57 next year and indicated that it would work with others to ensure that concrete work does take place.

Iceland welcomed the apparent new-found willingness to discuss the nature of the Conservation Committee and expressed the hope that the preparatory work that should have been done last year to engage all members of the Commission would now be done. It believed this is necessary before the Committee enters into any substantive discussions.

Japan drew attention to the controversy surrounding the establishment of the Conservation Committee at the meeting in Berlin last year and continued to be against it. Along with many other Commission members, Japan believed that the current objectives of the Conservation Committee are not in line with the dual objectives of the Convention, i.e. the conservation and management of whale resources. It further noted that it will not attend any meetings of the Committee unless its name and objectives are changed to include sustainable use of whale stocks. Dominica reaffirmed its position of last year and reserved its rights not to participate in the work of the Conservation Committee.

The Commission adopted the report of the Conservation Committee noting the reservations of Japan and Dominica.

16. CATCHES BY NON-MEMBER NATIONS
There were no contributions or discussion under this item.

17. FUTURE SUSTAINABLE WHALING
This new item had been included on the agenda at the request of Japan.

17.1 Introduction by Japan
Japan introduced, using a PowerPoint presentation, a document entitled ‘The centennial of Antarctic whaling – from the history of over-harvesting to the creation of new sustainable whaling’. The paper addressed:

(1) lessons from the past as a guide to the future;
(2) the status of Antarctic whaling;
(3) an overview of Antarctic whaling from 1904 to 2004;
(4) Japanese whaling in the Antarctic – its characteristics as compared to the whaling by other nationals – including sections on the importance of whale meat in Japanese Antarctic whaling (which compared how Norway, the UK, the USSR, the Netherlands and Japan used whale products, i.e. for oil, animal food, human consumption and other), and continuity of Japan’s whaling culture from its traditional whaling to Antarctic whaling;
(5) failures of the past to manage large whales in the Antarctic – a meaningful lesson to make whaling successful in future;
(6) how international legal instruments prescribe the need for full utilisation of whales; and
(7) some aspects of future whaling.

Japan gave the following as the main points regarding how whaling should be conducted in the future.

(1) Setting of the catch limits with which the sustainability and the optimum utilisation of whale stocks are to be achieved is critical. The RMP must be structured to meet the original objectives. It is a management tool that is intended to achieve three objectives:

(a) assurance to maintain the whale population at a safe level;
(b) long term sustainability of whaling;
(c) all possible risks are to be avoided. It might be necessary to improve the RMP to enhance these three factors in order to achieve optimum utilisation of whale resources.

Further, research effort needs be strengthened with a view to implementing multi-species management, through which all the components of marine ecosystem, including large whale stocks, can be rationally used in a well-balanced manner.

(2) Scientific research as an integral part of whaling operations: As the realisation and pursuit of sustainable whaling is dependent and based on healthy whale populations, it is imperative that reliable scientific data should be made available. With this as a basis for the new sustainable whaling in future, unbiased scientific data collection must accompany whaling operations. For the purpose of achieving the sustainability of whale stocks and whaling activities at the same time, scientific research aspects should be incorporated as a part of whaling operations even if it is more burdensome to the efficiency of commercial operations or the pursuit of maximum profit. The successful results from the JARPA demonstrate that such research activities would make a significant contribution to our understanding and monitoring of the marine ecosystem and environment. Using whale management as a core to the ecosystem approach to the management of ocean resources, the potential for optimum utilisation of whales and other marine living resources can be enhanced.

(3) A full utilisation of catches made possible by human consumption of whales as food: A prime characteristic of Japanese whaling is that whales are regarded as a valuable food resource that must be fully used, not be wasted. This characteristic has been evidenced throughout the history of whaling in Japan, from the pre-modern whaling in the Edo Era to Antarctic whaling and the current research take of whales under the JARPA. The full utilisation of whales taken and the thought that whales are gifts bestowed by heaven to sustain humans are two sides of the same coin. The fact that respect to the whales’ souls has been religiously manifested in many areas and in various periods of history in Japan gives a special feature to whaling culture in Japan. In considering the future of whaling activities, it seems quite beneficial to re-evaluate these aspects of full utilisation in Japanese whaling culture as a moral bulwark against the over-harvesting of resources, such as whales. This is ethically legitimate in the Japanese culture, and should be promoted in environmentally friendly societies.

(4) International contribution: Only abundant and robust whale stocks distributed in the Antarctic Ocean including Antarctic minke whales, estimated by the Scientific Committee of the IWC at 760,000 animals, will be harvested under the operation of new sustainable whaling. Sustainable utilisation of such rich resources is open to all nations subject to their rights and obligations under international law. However, at least at present, it seems that only Japan has the will and capacity to harvest the abundant whale stocks in the Antarctic. Therefore, it is our strong suggestion that, when Japan will commence this new whaling in the Antarctic Ocean, Japan should consider voluntarily using a part of any profit from the whaling activities to benefit the world’s interests. This would provide other members of international community, especially developing countries, with the opportunity to benefit from the rich whale resources in the Antarctic. We hope that other countries will participate in new sustainable whaling and thus promote the noble purpose and objective of the ICRW.

Japan expressed the hope that this renewed approach to whaling would be welcomed.

17.2 Commission discussions and action arising

Norway noted that the information presented by Japan on Norway’s use of whale products (i.e. mainly for oil) was correct but that it applied only to products from whales caught in the Antarctic. During the period 1945 to 1972, Norway was not using whales caught in the Antarctic for human consumption. However this was not the case with whales caught elsewhere. Norway stressed its long tradition of using whale meat for human consumption extending back to Medieval times using minke whales and some other species along Norway’s coast. This tradition continues to this day, although of course the technology for taking whales has changed.

Referring to item (4) above, Australia stressed that there is no currently agreed Scientific Committee abundance estimate for Antarctic minke whales.

Regarding Japan’s request that this item be kept on the agenda and anticipating future PowerPoint presentations, the UK respectfully suggested that in view of the already crowded agenda, this item be dealt with as a side event, e.g. during a coffee or lunch break. The Chair responded that the Secretary and Advisory Committee would consider, before the next Annual Meeting, how best to handle PowerPoint presentations.

18. INFRACTIONS, 2003 SEASON

The Infractions Sub-committee met on 14 July with delegates from 30 Contracting Governments. The Sub-committee’s Chair, Sung Kwon Soh (Korea), summarised the group’s discussions. The full report is given in Annex I.

As in previous years, despite differences of opinion as to whether the item concerning stockpiles of whale products and trade questions is within the scope of the Convention, the Sub-committee agreed that an exchange of views was useful.

The summary of catches by IWC member nations in the 2003 and 2003/2004 seasons is available as Annex J.

18.1 Report of the Infractions Sub-committee

18.1.1 Infractions reports from Contracting Governments

Infractions reports for 2003 were received from Denmark, St. Vincent and The Grenadines, the USA, the Russian Federation and the Republic of Korea. Only the USA and the Republic of Korea reported infractions.
The USA reported two infractions in 2003, which occurred during an aboriginal subsistence hunt, when a female bowhead whale accompanied by a calf was taken. The female was landed whilst the status of the calf was unknown. The taking of cow-calf pairs is prohibited in Eskimo hunting tradition, and also under the regulations both of this Commission and of the AEWC (Alaska Eskimo Whaling Commission) Management plan. The AEWC has primary enforcement responsibility under a cooperative agreement with the Government of the USA. Following a hearing, the AEWC Commissioners concluded that the crew had not acted with proper caution and rescinded the bowhead subsistence captain’s registration for two years.

The Republic of Korea reported that the Ministry of Maritime Affairs and Fisheries and the marine police of Korea had exposed five illegal catches of minke whales in 2003 and had taken judicial and administrative measures (see Annex I, Appendix 3). Four of the cases were deliberate, the catches being taken covertly with a spear by small fishing vessels. The fifth case was that of a dead whale found floating with spearheads stuck into it. The Korean authorities perceive these incidents to be a result of poachers trying to make money. The Government of Korea does not think poaching to be a major problem since all suspect poachers are listed and their movements watched by the police. The bycatch reporting system has proved useful in discriminating between illegal catches and bycatches. In addition, the authorities have continued to strengthen public awareness of poaching activities through the mass media. The Government of Korea will continue its efforts to bring an end to these illegal activities. The Republic of Korea clarified that it is not permitted to carry harpoons on fishing vessels.

18.1.2 Surveillance of whaling operations
Information submitted by the USA, the Russian Federation and St. Vincent and The Grenadines indicated that 100% of their catches were under direct national inspection. Denmark (Greenland) reported on quota monitoring. Following questions from New Zealand and the UK concerning internal legal requirements in Denmark for collection of DNA samples and actions in the event of the samples not being provided, Denmark reported that it was mandatory to supply samples, and that it had written to all municipal authorities in Greenland to inform them of this fact.

New Zealand considered that failure to collect samples should be reported as an Infraction since Article IX of the Convention requires each Contracting Government to ‘take appropriate measures to ensure the application of the provisions of this Convention and the punishment of infractions against the said provisions in operations carried out by persons or by vessels under its jurisdiction’ and Paragraph 29(b) of the Schedule requires samples to be collected.

Denmark did not agree with New Zealand’s interpretation, as Paragraph 29(b) refers to small type whaling and not to aboriginal subsistence whaling. Denmark will try to take appropriate measures to ensure samples are collected in the future, but it considered that missing samples are not infractions in the sense of Article IX of the Convention. In addition, it would help if the hunters knew the samples would be put to good use, as at present many samples seem to be stored in freezers but not analysed. The Department of Fishing and Hunting will continue its efforts to collect samples.

New Zealand reiterated its opinion that collection of samples is obligatory under Para 29(b) of the Schedule and that failure to do so is an offence that should be reported as an infraction, particularly in view of the definition of ‘small type whaling’ in the Schedule and the strong language used by the Scientific Committee to express its concerns on this matter.

Following a suggestion from the Chair, New Zealand and Denmark agreed to discuss this matter further on a bilateral basis.

The UK noted that a bowhead whale was reported to have been killed in Greenland on 25 April 2004.25 Australia expressed concern that since a new law had been enacted by Japan in 2001 allowing whales caught in nets to be killed, that the numbers of bycatch in Japan had increased dramatically, from 29 in 2000 to 79 in 2001, 109 in 2002 and to 125 in 2003. They cautioned that this could be considered an active hunt. Japan considered the question was not relevant to the Infractions Sub-committee. Rather, the Scientific Committee is the right forum for such discussions and Japan had provided information on bycatch to that Committee. It would respond directly to Australia on this issue if asked.

The UK noted that other countries e.g. Iceland and Korea also have significant levels of bycatch. It recognised that some other countries have a different opinion as to whether bycatch should be regarded as an infraction. However, the UK believed that everyone should agree that numbers of bycaught whales should be taken off any quota and, since the quota was zero, bycatch constituted an infraction.

18.1.3 Checklist of information required or requested under section VI of the Schedule
The following information was provided:

Denmark: Information on date, position, species, length and sex is collected for between 83-100% of the catch, depending on the item. Other biological data and information on killing methods and struck and lost animals are also collected.

USA: Information on date, species, position, length, sex, whether a foetus is present, killing method and numbers struck and lost is collected for between 97-100% of the catch depending on the item. Biological samples are collected for about 50% of animals.

Russian Federation: Information on date, species, position, length, sex, whether a foetus is present, killing method and numbers struck and lost is collected for 100% of the catch.

St. Vincent and The Grenadines: Information on date, species, position, length, sex, killing method and numbers struck and lost is collected for 100% of the catch.

Norway: the required information has been submitted to the Secretariat as noted in the Scientific Committee report26.

25 Denmark responded to a first question, which related to 2003, and said that no bowhead had been killed in 2003. It did not respond to the question of 2004 during the meeting, but subsequently reported that a bowhead whale had been seen in fishing nets in 2004 but that it had not been killed.

26 J. Cetacean Res. Manage. 7 (Suppl.).
18.1.4 Submission of national laws and regulations
A summary of national legislation supplied to the Commission was prepared by the Secretariat. The UK and the USA applauded St. Vincent and The Grenadines for adopting domestic legislation that governs the aboriginal take of humpback whales. Australia expressed similar sentiments and enquired whether the regulations met the requirements of Schedule Para 13b(4). The Secretariat believed that they do and noted that the regulations were available if Australia wished to confirm this.

18.1.5 Other matters
The Secretariat had received no reports from Contracting Governments on availability, sources and trade in whale products and no comments were made during the meeting.

The UK referred to six northern bottlenose whales killed in the Faroe Islands in 2002 and noted that the Scientific Committee had expressed concern over the status of this stock in the 1970s. The UK asked a series of questions requesting details of the incidents. It noted that this species is included in Schedule Table 3 with a zero catch limit, and believed that the killing of these whales constituted an infraction.

Denmark responded that six whales had died as a result of stranding and that such events were not infractions. Denmark has provided information on similar events on a bilateral basis on many occasions in the past and would be happy to do so again.

The UK repeated that, because the species is in the Schedule, the reasons for the kills need to be documented.

Australia notified the Sub-committee of an alleged incident that occurred in 2004 in which a whale of unknown species was caught by an Australian fishing vessel, and the vessel returned to port with whale meat on board. The allegation has been referred to the Australian Federal Police for investigation. Australia will inform the IWC of the outcome of this matter once further details are available.

18.2 Commission discussions and action arising
The UK noted that in the Sub-committee it had raised the issue of the killing of six Northern bottlenose dolphins in the Faroe Islands and asked for details of these incidents. It had been informed by the representative of the Faroese government that (a) the matter was no concern to the UK and (b) that the whales had stranded. The UK expressed concern with this response since it had heard from another source in the Faroes that stranded animals are normally successfully and relatively easily returned to the sea. It questioned why this had not been done in this case and why the kills were authorised. Germany associated itself with these remarks. Denmark did not respond. Japan considered the matter to be outside the competence of IWC. New Zealand disagreed.

The Commission took note of and adopted the Sub-committee’s report.

19. LEGAL ADVICE IN RELATION TO THE IWC

19.1 Proposal regarding legal advice in relation to the IWC
As a first step in exploring how legal advice should be sought in the future, last year the Commission agreed that the Secretariat should investigate how other Conventions deal with legal issues and the sort of legal issues they have faced. This paper was provided as background information.

In addition, the Netherlands (who had first brought this matter to the attention of the Commission at the 5th Special Meeting of the Commission in October 200227) introduced a paper that set out options on how to address future legal issues that may arise within IWC. It had prepared the paper to help to maintain momentum on this issue and to facilitate discussions. The options included:

1. appointment of a legal officer;
2. establishment of a legal committee;
3. putting together a roster of legal experts;
4. recourse to external legal advice on an ad hoc basis; and
5. access to existing international judicial institutions.

The Netherlands noted that the options were not mutually exclusive and that an optimal legal function may require the selection of a mix of options. The paper did not include options for the settlement of disputes that may arise between Parties to the Convention or in connection with compliance with the Convention by Parties.

The Netherlands invited comments on the proposed options and the formulation of alternatives with the aim of the Commission taking an informed decision that would assist future deliberations. However, recognising that time remaining at this 56th Annual Meeting was short, the Netherlands proposed that its paper be referred to the F&A Committee at its meeting next year. The Netherlands remained convinced that establishing a mechanism for dealing with legal issues would help to depolarise and depoliticise debate and contribute to confidence building among countries.

19.2 Commission discussions and action arising
New Zealand welcomed the papers from the Secretariat and the Netherlands which reflected careful research and thought. New Zealand re-iterated its view that the 1946 Convention is deficient in its legal mechanisms and that legal issues would continue to cause difficulties with the work of the Commission. Its preferred approach in resolving the situation would be through a diplomatic conference that would have the goal of bringing the Convention’s legal instrument up to date through the adoption of a Protocol covering a range of matters as raised under item 6.2 on the RMS. It accepted that consensus on such an approach would be illusive at present, and in the mean time noted the sovereign right of member states to determine their views on legal issues. That being said, New Zealand took the view, and would support, the Commission seeking legal advice, although the source of such advice would have to be carefully determined. Australia associated itself with these remarks.

Noting that FAO has a fairly substantial legal section, India suggested that early consultation with them may be helpful. Sweden, the USA, Argentina, Antigua and Barbuda also welcomed the paper from the Netherlands and supported the proposal to explore the matter further in the F&A Committee. Sweden found the options put forward in the paper interesting and believed that Option 1, appointment of a legal officer within the Secretariat, might be a good way to proceed. Argentina and Antigua and Barbuda expressed concern about the potential costs of this option, with Antigua and Barbuda suggesting that Option 2, establishment of a legal committee might be the best

approach at least in the first instance. Argentina stressed that the role of any legal adviser(s) or committee should be simply to provide advice, since it is the Commission that takes decisions. In view of the discussions on the RMS, the USA suggested that the F&A Committee also consider the need and role of a parliamentarian. Norway also welcomed the papers but was of the view that unless and until a new arbitration clause is included in the Convention (through a diplomatic conference), it is the sovereign right of member states to regulate their own obligations within the Convention. It therefore saw no need to investigate the matter further at this stage.

Noting Norway’s comments, the Chair proposed that the issue be referred to the F&A Committee at IWC/57 as proposed by the Netherlands. The Commission agreed.

20. ADMINISTRATIVE MATTERS

Agenda items 20-22 covering administrative and financial matters were considered first by the Finance and Administration (F&A) Committee that met on Friday 16 June 2004 under the chairmanship of Halvard Johansen (Norway). Delegates from 35 Contracting Governments attended the meeting. The F&A Committee report is attached as Annex K.

20.1 Annual Meeting arrangements and procedures

20.1.1 Need for a Technical Committee

The Technical Committee (TC) has not met since in IWC/51 in 1999. However, the F&A Committee recommended that the need for the TC be kept under review and remain on the agenda since it may have a role to play when the RMS is completed and catch limits set.

The Commission agreed.

20.1.2 Use of simultaneous translation

Through Resolution 2003-4 adopted at IWC/55, the Commission had decided to establish a Working Group to explore the implications for the provision of technical components for simultaneous interpretation and to make recommendations on how provision of technical components for simultaneous interpretation may be provided at the IWC to accommodate the needs of contracting parties for whom English is a second language. Members of the Working Group comprised Antigua and Barbuda, Benin, France, Gabon, Republic of Guinea, Japan, Senegal, Spain and the Secretariat.

The Working Group proposed the following.

- Initially facilities for three languages would be provided (French, Spanish and Japanese). Japanese was proposed since most Japanese delegates speak in their mother tongue at the meetings. French and Spanish were proposed since, out of IWC’s membership as of 2 July 2004, 15 countries are French-speaking and 16 countries are Spanish-speaking. In addition, requests have been made in the past for interpretation into these languages. It was further proposed that provision for additional languages could be considered at a later date (e.g. after two years).
- Initially, to help reduce costs, the technical set-up used would be that where headsets would be provided only for those national delegations using simultaneous interpretation, but with a view to moving toward the usual set up where headsets are provided to all delegates.
- Initially simultaneous interpretation would be provided only for the Commission plenary. Provision at other meetings (i.e. Commission sub-groups and private Commissioners’ meetings) could be considered at a later date (e.g. after two years). It would seem prudent, both financially and technically to have a phased approach to provision of simultaneous interpretation.
- The Commission would meet most of the costs through an increase in the budget provision for the Annual Meeting (approx. 2% initially). If costs are in excess of this, then the host government would cover additional expenses. In the case where the Annual Meeting is arranged by the Secretariat in the UK (in the absence of an offer from a Contracting Government), the Working Group proposed that any additional costs to provide simultaneous interpretation equipment be met by drawing on the Commission’s reserves.

The F&A Committee welcomed the Working Group report, recognised the importance of this issue and agreed that some action should be taken to facilitate the participation of delegates for whom English is not their first language so as to put all member countries on the same footing. There was general agreement that the costs of providing the technical facilities for simultaneous interpretation should be met by the Commission, although a suggestion was made that the Commission may also wish to seek voluntary contributions to support this provision.

Some F&A Committee members supported the approach proposed by the Working Group, although the view was expressed that if possible (e.g. by restricting the number of languages for which interpretation facilities would be provided to two rather than three), it would be desirable to extend provision of simultaneous interpretation facilities to the Commissions sub-groups (not including the Scientific Committee) and to the private Commissioners’ meetings. Others felt that, with the increasing membership and increasing number of languages spoken by members, it would be appropriate for the Commission to take broader steps, allocating a higher percentage of the budget so as to provide, for example (and perhaps even in time for IWC/57 in Ulsan), interpretation for a greater number of languages and the translation of documents - as is the case in some other intergovernmental organisations. A number of members, however, expressed concern regarding the proposal to include translation of documents before the implications, particularly of cost, could be properly assessed. They did not believe there was sufficient time to make this assessment during IWC/56.

After a further exchange of views, the Committee agreed to recommend the following compromise to the Commission:

(1) That the Committee acknowledges the importance of facilitating the effective participation of all Contracting Governments in the work of the Commission and that no government should be disadvantaged by language:

(a) That the Working Group propose language facilities for the Commission plenary and private Commissioners’ meetings.

(b) That in the first instance, equipment facilities for the provision of simultaneous interpretation be provided for French and Spanish for the Commission’s sub-groups (but not the Scientific Committee), the Commission plenary and private Commissioners’ meetings. This would come into effect in time for IWC/57 in Ulsan next year.
(3) That the budget provision for the Annual Meeting would be increased by 2%, as recommended by the Working Group.
(4) That the Secretariat should work inter sessionally, with a small Task Force (composition to be decided), to develop cost estimates and implications for the provision of document translation at Annual Meetings and to report to the F&A Committee at IWC/57 in Ulsan for possible decision-making.

The Commission agreed to this approach.

20.2 Amendments to the Rules of Procedure and Financial Regulations

20.2.1 Election of the Chair and Vice-Chair of the Commission

Japan had introduced to the F&A Committee the following proposals concerning Rules of Procedure F.1 and G.1:

Amendment of Rule F.1: that the text be amended such that the Chair may be elected from among the Commissioners and Alternate Commissioners. The specific text of this proposal is that line 1 of rule F. 1. be amended to read: The Chair of the Commission shall be elected from time to time from among the Commissioners and Alternate Commissioners and shall…

Amendment of Rule G.1: that the text be amended such that the Vice-Chair may be elected from among the Commissioners and Alternate Commissioners. The specific text of this proposal is that line 1 of rule G. 1 be amended to read: The Vice-Chair of the Commission shall be elected from time to time from among Commissioners and Alternate Commissioners and…

In the Committee, a number of governments indicated that while they appreciated and understood the motivation behind the proposed amendments, they considered – as pointed out when this same matter was raised at IWC/54 in Shimonoseki – that the proposal was contrary to Article III.2 of the Convention and therefore illegal.

Japan noted this position. It indicated that it did not wish to pursue the matter any further with the Committee but noted that it may raise it in the Plenary. Japan subsequently withdrew the proposal and there was no discussion in Plenary.

20.2.2 Appointment of the Chair and Vice-Chair of the Scientific Committee

At the 2002 Scientific Committee meeting, the Scientific Committee developed a proposed procedure and amendment to the Rules of Procedure for the Scientific Committee regarding the appointment of its Chair and Vice-Chair. At its meeting this year, the Scientific Committee proposed that a second paragraph be added to Rule of Procedure C.5 of the Scientific Committee Rules of Procedure as follows (proposed new text in bold italics):

C. Organisation

5. The Committee shall elect from its members a Chair and Vice-Chair who will normally serve for a period of three years. They shall take office at the conclusion of the annual meeting at which they are elected. The Vice-Chair shall act for the Chair in its/her absence.

The election process shall be undertaken by the heads of national delegations who shall consult widely before nominating candidates. Under normal circumstances, the Vice-Chair will become Chair at the end of his/her term unless he/she declines. A new Chair must also be elected. If the election of the Chair or Vice-Chair is not by consensus, a vote shall be conducted by the Secretary and verified by the current Chair. A simple majority shall be decisive. In cases where a vote is tied, the Chair shall have the casting vote. If requested by a head of delegation, the vote shall proceed by secret ballot. In these circumstances, the results shall only be reported in terms of which nominee received the most votes, and the vote counts shall not be reported or retained.

The Scientific Committee proposal was reviewed by the Heads of Delegation to the Scientific Committee. They reconfirmed by consensus the Committee’s support for its earlier position regarding secret ballots and agreed that the proposed Rule of Procedure should be revised to indicate that it was expected that the Vice-Chair would become Chair at the end of his/her term unless he/she declined. They therefore recommended that the following amended text be put forward to the Commission via the F&A Committee for adoption (proposed new text bold italics):

The election process shall be undertaken by the heads of national delegations who shall consult widely before nominating candidates. Under normal circumstances, the Vice-Chair will become Chair at the end of his/her term (unless he/she declines), and a new Vice-Chair will then be elected. If the Vice-Chair declines to become Chair, then a new Chair must also be elected. If the election of the Chair or Vice-Chair is not by consensus, a vote shall be conducted by the Secretary and verified by the current Chair. A simple majority shall be decisive. In cases where a vote is tied, the Chair shall have the casting vote. If requested by a head of delegation, the vote shall proceed by secret ballot. In these circumstances, the results shall only be reported in terms of which nominee received the most votes, and the vote counts shall not be reported or retained.

The Commission adopted the proposal.

20.3 NGO participation

20.3.1 NGO participation and Rules of Procedure

In September last year, the Secretariat had been approached by a representative of one of the large environmental NGOs regarding changes that a number of NGOs would like to rules of NGO accreditation in particular but also in their level of participation in Commission affairs. The Secretariat had brought this matter to the attention of the Advisory Committee to seek advice on the best way to proceed. The Advisory Committee agreed that this issue should be brought to the attention of the F&A Committee via a paper outlining the issues raised and the potential implications of these. The focus of the paper was on NGO participation in the Commission and its sub-groups excluding the Scientific Committee. The Advisory Committee had suggested that the F&A Committee have a general discussion on the matter this year and that if changes were suggested, decisions could be taken at IWC/57 next year, as appropriate.

The Advisory Committee’s discussion document addressed the four following issues:

(1) removal of the requirement that non-governmental organisations maintain offices in more than three countries;
(2) allowing accredited NGOs to send up to [five?] representatives to IWC meetings as observers with the possibility of all observers being in the meeting room at any one time;
(3) revising the fee structure for NGOs, such that the effect of the changes listed above is fee-neutral (cost-neutral?) in the year of its introduction and that thereafter, fees should not in general increase by more than such an amount as is necessary to keep pace with inflation in the UK (as host country to the IWC);
(4) formally confirming the right of NGO representatives to speak at IWC meetings, but with some limitation on the number of interventions that could be made.

The document stressed that, should the Commission decide to consider whether, and if so how, its Rules of Procedure might be amended to accommodate the wishes of some
NGOs for more active participation, certain requirements are paramount, i.e. that changes in the rules should not:
- impede the orderly and timely conduct of business in meetings of the Commission or its subsidiary bodies;
- result in an increase in the IWC’s costs or a diminution in its income;
- significantly increase either the number of NGO observers present at meetings, nor the volume of documentation which the IWC Secretariat is required to produce to accommodate them.

Given the discussions in the F&A Committee, its Chair concluded that IWC is already transparent since it is open to observers from non-member governments, other intergovernmental organisations, NGOs and in the case of the plenary, also to the media. He noted that some members had serious concerns regarding the granting of speaking rights to NGOs, but suggested that further consideration might be given to items (1) to (3) above. The F&A Committee agreed to his proposal that the Secretariat work with the Advisory Committee interessionally to explore how items (1)-(3) might be implemented and to report to the F&A Committee next year, together with any recommendations as appropriate. It was understood that it will be necessary for the Secretariat to consult with NGOs on this issue and it was agreed that the issue of speaking rights be set aside for the time being. The Committee also supported the suggestion that if Contracting Governments do not consider the pre-conditions listed under the three bullet points above cover all of their concerns, they should be invited to contribute proposals for further pre-conditions that would help in limiting/better defining NGO attendance.

The Commission endorsed the approach proposed by the F&A Committee.

20.3.2 NGO code of conduct

On Wednesday 21 July, the Chair reported to Plenary that a number of Commissioners had brought to his attention press releases and media interviews in which certain NGOs had made allegations regarding voting buying within IWC. One such press release had been made available to participants via the tables provided for the distribution of non-official documents. The Chair noted that a number of private meetings of Commissioners had been held to discuss this matter and to consider what, if any, action might be appropriate. While he noted that the Commission has traditionally welcomed the contributions of NGOs at its meetings, it considered that attendance carries certain responsibilities. On behalf of the Commission, the Chair expressed extreme concern regarding the circulation of unsubstantiated allegations that had caused offence to many Contracting Governments and urged all NGOs to behave with due and proper respect to all member Governments. He also noted the disruption to the Commission meeting caused by such allegations both in Sorrento and at IWC/55 in Berlin. As a result, the Chair reported that the Commission intends to develop a Code of Conduct for NGOs that would focus on NGO activities during the Annual Meeting and that could, if appropriate, include provisions related to the loss of accreditation. A working group convened by Iceland (members: Dominica; Japan; the Netherlands; New Zealand; St. Kitts and Nevis; Sweden; and the USA) had been established to develop this Code of Conduct that would hopefully be ready for review by the whole Commission at IWC/57 next year.

21. FORMULA FOR CALCULATING CONTRIBUTIONS

At its meeting last year, the Commission agreed that the Contributions Task Force should meet again prior to IWC/56 to try to finalise a proposal for a revised contributions formula. A meeting had been scheduled for May 2004. However, given the intersessional work of the Commission and its potential implications for any revised contributions formula, Henrik Fischer believed that it would be prudent to delay further work of the Task Force until these implications could be assessed. Consequently, while continuing to recognise the high priority the Commission gives to the development of a revised contributions formula, it was decided, after consultation with the Task Force members and with the Advisory Committee, to postpone the Task Force meeting.

In the F&A Committee, while recognising the sense of postponing the May 2004 Task Force meeting, a number of delegations stressed the importance of completing expeditiously the work on a revised financial contributions formula. There was also some discussion regarding Chair of the Task Force, given that Daven Joseph (Antigua and Barbuda) was no longer Commissioner or representing Antigua and Barbuda. There was some debate as to whether Chairs are appointed as individuals or as countries and whether Task Force Chairs should be appointed by the Commission or elected by the group itself. Noting these different views, the new Commissioner for Antigua and Barbuda was invited to convene a meeting of Task Force members to elect a Chair. Following a short meeting, the convener was able to report that by consensus, the Task Force recommended that, if the Commission so wishes, the Task Force continue with the Commissioner for Antigua and Barbuda (Anthony Liverpool) as Chair and with the Commissioner for Argentina (Eduardo Iglesias) as Vice-Chair.

The Commission noted the F&A Committee report and endorsed its recommendations regarding the Chair and Vice-Chair of the Contributions Task Force. St. Vincent and The Grenadines expressed appreciation for the work that the Contributions Task Force had done and urged expeditious completion of its work. It fully supported retaining the Interim Measure adopted at IWC/54 in Shimoseki for calculating financial contributions until a replacement is available. The new Task Force Chair noted his commitment to ensuring the Task Force completes its work in a timely manner and hoped that significant progress will be made by the Annual Meeting next year. St. Lucia associated itself with the remarks of St. Vincent and The Grenadines and the Task Force Chair.

Resolution to take into account the special position of very small countries in calculating financial contributions

Monaco and San Marino introduced a proposal to transfer their two countries from capacity-to-pay Group 3 to Group 2 under the Interim Measure. It was also proposed that this transfer have no effect on the contribution of Contracting Governments belonging to capacity-to-pay Group 1. Under the Interim Measure, Contracting Governments are allocated into one of four ‘capacity-to-pay’ groups depending on their GNI and GNI per capita as follows:

---

28 This was not a matter discussed by the F&A Committee.
Group 1 – countries with GNI < US $10 billion and GNI/capita < US $10,000;
Group 2 – countries with GNI > US $10 billion and GNI/capita < US $10,000;
Group 3 – countries with GNI < US $1,000 billion and GNI/capita > US $1,000;
Group 4 – countries with GNI > US $1,000 billion and GNI/capita > US $10,000.

Financial contributions are initially calculated using the ‘old’ formula. Group 1 and 2 countries were then given a 50% and 25% discount for the years 2002/03 and 2003/04 which was further reduced in 2004/05 by 25% and 10% respectively. The shortfall is distributed according to the following proportions: whaling countries 10%, Group 3 countries 30%, Group 4 countries 60%.

Monaco explained that the aim of the proposal was to correct an anomaly in the Interim Measure caused by an overestimation of the capacity-to-pay of very small countries. It suggested that Monaco qualified for this status as it has an area of only two square kilometres and a population of only 32,000. Most of the population are expatriates who, because no tax is levied, contribute nothing to the GNI of Monaco. It also noted that Monaco’s GNI (some 1.3 billion US$) is one of the lowest of those countries that are members of IWC. With such a GNI, Monaco is not able to sustain a military force or a navy, has only seven embassies around the world and can participate in only a limited number of international organisations of which the IWC is obviously one. Since adhering to the Convention in 1982, Monaco felt that it has contributed its fair share to resources and to debate and had hosted a number of meetings. However, it noted that since the introduction of the Interim Measure, Monaco’s financial contributions had increased from around £15,000 to over £25,000 putting a strain on the extent to which it has been able to participate in meetings. Monaco did not believe that it should be placed in Group 3 simply because it has many wealthy expatriates and suggested that it and San Marino (for the same reasons) be transferred to Group 2. Monaco added that if the Commission rejected the proposal, it would likely not be able to participate for much longer. It called for adoption of the proposal by consensus.

San Marino associated itself with the statements of Monaco.

France, Iceland, UK, Australia and New Zealand indicated that they could support the proposal. Argentina was sympathetic with the proposal but expressed concern that this would lead to other countries requesting reallocation to a different capacity-to-pay group. It indicated, however, that it would not block a consensus. Norway expressed similar concerns and believed that the groupings should not be changed at this time. It suggested that the proposal be postponed to await the outcome of the work of the Task Force. Dominica also did not see the need to set such a precedent in view of the work of the Task Force. Dominica did not believe that the Task Force could complete its work until an agreement had been reached regarding apportioning of costs associated with a future

RMS. Japan associated itself with the remarks of the USA and others and asked the sponsors if they would withdraw their proposal and await the outcome of the work of the Task Force. Monaco declined as there is no guarantee that the Task Force would complete its work as early as suggested.

The proposal was adopted on being put to a vote (Resolution 2004-4, Annex C). There were 20 votes in support, 15 against and 17 abstentions. The Chair suggested that the Task Force give some consideration to defining what is meant by ‘very small countries’. Monaco suggested that Group 2 countries be those with GNI < 5 billion US$.

While congratulating Monaco and San Marino on the outcome, Ireland explained that it had abstained as it was concerned that such a move would set a precedent, with other countries making different cases for re-allocation of capacity-to-pay group. It urged the Task Force to complete its work. The USA associated itself with Ireland, and again called for the necessary mandate to be given to the Task Force. There was no further discussion on this matter. Switzerland who had abstained, associated itself with Ireland and the USA.

22. FINANCIAL STATEMENTS AND BUDGETS
The F&A Committee had received the report of the Budgetary Sub-committee that had worked intersessionally and had met during IWC/56 with Jean-Pierre Plé (USA) as Chair. The Budgetary Sub-committee had reviewed the provisional statement for 2003/2004 and proposed budgets for 2004/2005 and 2005/2006.

At the recommendation of the F&A Committee, the Commission approved the Provisional Financial Statements subject to audit.

During the F&A Committee, the Secretariat had reported that approximately 90% of financial contributions for the Financial Year 2003/04 had been received by the due date for settlement (28 February 2004). It had noted that the charging of penalty interest of 10% for late payments and the loss of voting rights provided a strong incentive for members to pay on time. In the Committee, concern was expressed by some that the 10% penalty interest charge presented difficulties to developing countries. The fixed rate of 10% interest was questioned at a time when market rates of interest are much lower. Dominica raised this issue during the Commission meeting and indicated that it planned to propose amendments to the Rules of Procedure next year.

As recommended by the F&A Committee, the Commission:
(1) adopted the proposed budget for the 2004/2005 financial year (Annex L), including a 2% increase in provision for the Annual Meeting to take account of costs associated with simultaneous interpretation (see section 20.1.2) and the provision for research expenditure (Annex M); the reservations of Norway, Japan and Germany were noted (see Annex K);
(2) agreed that for the 2005 Annual Meeting the registration fee for non-government observers be set at £590 and that the media fee at £35; and
(3) noted the forecast budget for 2005/2006.
The USA noted that the outcome of discussions on the RMS and the intersessional plan of activity agreed as part of Resolution 2004–6 (Annex C), had cost implications that needed to be considered in relation to the budget for the next financial year (2004/05). The Secretary noted that the budget proposed had anticipated a certain level of intersessional activity of the RMS, and that apart from the RMS Working Group meeting scheduled to take place before December 2004, all other activities should be covered. She suggested that a Contracting Government may wish to host the first meeting of the RMS Working Group.

22.3 Secretariat offices

Last year, the Commission had agreed to the Budgetary Sub-committee’s recommendation that the Secretariat explore a range of alternatives to its existing premises including:

1. continuing to rent the Red House;
2. purchasing the Red House or another suitable property in Cambridge or elsewhere in the UK; or
3. relocation of the Secretariat to another member country.

The background to these recommendations is that the cost of the Secretariat represents a significant percentage of the IWC’s budget (i.e. £958k out of £1,623k of operating expenditure - as per the 2002-03 audited accounts). The rental of Red House (i.e. £69k) represents 4.3% of the £1,623k of operating expenditure, while salaries, and allowances (i.e. £622k) represent 38% of the £1,623k of expenditure.

The Secretariat’s report examined the criteria for relocation within the UK and overseas and the associated variables (rents, wind-up costs, set-up costs, transition costs, loss of expertise and effects on organisational effectiveness etc). It reached the conclusions given below.

- Currently there are savings to be made from relocating the IWC abroad, both in terms of lower rental costs and local salaries. The savings however may be sensitive to currency/economic fluctuations. Savings in expenditure in the early years of relocation could easily revert to additions to expenditure in later years.
- Over the transition period it is possible that transition costs (e.g. paying rent on two properties – if relocation occurred before the current lease expired) would equal or even exceed cost savings.
- If the current lease is continued until 2009, the rent will be capped at around £73,700 per annum from June 2005. This will give stability to costs and still provide a competitive rent in relation to alternative sites in the Cambridge area.
- The renewal of the lease in 2009 offers the chance to re-negotiate the current terms. The current lease only allows increases in rent. The chance to reduce the rent and allow rent decreases at each 5-yearly rent review could be explored.
- The focus of much of this paper has been on the relative costs of property and the relative costs of operating in various parts of the world. The costs associated with losing staff with the operational expertise and relationships that have been developed over many years should also be taken into consideration.
- The volatility of international markets make budgeting over a long time frame problematic. An effective Secretariat needs stability to function effectively and so its location should be considered within a long-term perspective. A country that can offer a stable cost base allied to operational effectiveness should give an acceptable balance between value and performance in the face of fluctuations in the world economy.

Recognising that:

1. rent of the Red House is not an excessive cost;
2. expertise within the Secretariat would be lost if the Secretariat were moved away from the Cambridge area; and
3. that there is still over five years until the current lease expires

the F&A Committee endorsed the Sub-committee’s recommendations that the Secretariat explore alternatives within the Cambridge area, including those listed below.

- Ask the NASCO (North Atlantic Salmon Conservation Organisation) Secretariat in Edinburgh, Scotland how it managed to purchase its Headquarters building in terms of funding and what effect their status as an International Organisation had in buying property. (Financing any purchase would have to be carefully considered in the context of minimising the effects on Financial Contributions).
- Near the date of renewal of the lease, examine whether there might be any scope for the owners of Red House to ‘gift’ the property to the IWC. This might be an option if the inheritance tax status of the owner made this option advantageous.
- Keep the property market in Cambridge under active review to allow the early assessment of rental or purchase alternatives.
- If new property was acquired, to assess the possibility to renting part of that property as a means of minimising total property costs.

The Commission endorsed these recommendations.

22.4 Budgetary Sub-committee rota

At IWC/54 in Shimonoseki, 2002, the Commission adopted a rota for membership of the Budgetary Sub-committee. In summary:

- using the same country groupings as the Interim Measure for Financial Contributions, membership comprises:
  - 2 members from Group 1;
  - 2 members from Group 2;
  - 2 members from Group 3; and
  - Japan, USA + one other from Group 4;

- membership is for 2 years (except for Japan and the USA who have a ‘permanent’ place since they are likely to be the two highest paying contributors under almost any formula for the calculation of financial contributions for the foreseeable future being the highest payers now and probably in the future);
- any member that declines to serve to be replaced by the next member in alphabetical sequence within its Group;

29 It is recognised that these country groupings were developed solely for the purposes of the Interim Measure for calculating financial contributions and may need revision when a new formula is adopted.
• new members of the Commission to be fitted into the cycle at the nearest alphabetical point after they have had a period in which to familiarise themselves with the organisation;
• the appointment of the Sub-committee Chair should be handled by the Chair of the Commission and the Advisory Committee.

At IWC/55 last year, the Commission agreed that the Secretariat review the current rota system with a view to:
(1) making it more attractive for countries to serve on the Sub-committee;
(2) providing greater continuity;
(3) improving the process for selection of the Sub-committee Chair; and
(4) reporting back to the Budgetary Sub-committee for further action as appropriate.

At its meeting this year, the Sub-committee reviewed a variety of options put forward by the Secretariat for consideration regarding items (1) to (3) above and recommended to the F&A Committee that the following be incorporated into the membership rota system:

To encourage participation in the Sub-committee:
A. When inviting countries to serve, stress not only the importance of the work of the Sub-committee (it really does make the job of the F&A Committee much easier and more efficient), but also that the workload is not high - either intersessionally or at Annual Meetings. The Sub-committee is only active during the period from March to when the annual meeting is held – and this only involves responding to documents/proposals from the Secretariat. All intersessional work is done by email/fax and no meetings are involved. At annual meetings, the Sub-committee generally meets for only 1-2 sessions.
B. Undertake to schedule meetings of the Budgetary Sub-committee when other Commission sub-groups are not meeting and try to avoid scheduling the Budgetary Sub-committee at the beginning of the series of Commission sub-group meetings (because not all delegations arrive in time to otherwise participate).
C. Keep the four economic groups, but add two ‘open seats’ (i.e. for any interested countries) as a fifth category. Countries filling the two open seats would need to be identified and agreed at the meeting of the Finance and Administration Committee. Formalise the current informal arrangement allowing Contracting Governments not members of the Budgetary Sub-committee to attend meetings as observers.

To provide greater continuity:
D. Extend the term of members from 2 to 3 years.
E. Appoint not only a Sub-committee Chair but also a Vice-Chair. Under normal circumstances, the Vice-Chair would replace the outgoing Chair. This would have the effect of two Sub-committee members serving for either four years (under the current system) or six years if the term of all members was extended as proposed in D above.

Improving the process for the selection of the Sub-committee Chair and Vice-Chair
F. That the Sub-committee elects its own Chair (as is the case in other Commission sub-groups – and indeed the Commission itself);

The Commission endorsed these recommendations. It also agreed that:
• Germany and Norway be invited to take the ‘open seats’ commencing immediately following IWC/56;
• the Budgetary Sub-committee provide clearer guidelines for its operation (i.e. term for the ‘open seats’ and status of observers from Contracting Governments not on the Sub-committee) and to report back its conclusions to the F&A Committee next year.

The proposed rota for the budgetary Sub-committee for 2004/05 onwards is given in the F&A Committee report (Annex K).

22.5 Other matters
In the F&A Committee, Brazil briefly drew attention to its concern regarding the costs incurred to Contracting Governments, especially those of developing countries, of sending delegations to Annual Meetings, particularly given the length of the meeting series. It hoped that host governments and the Secretariat would take account of these concerns when determining the timing and location of Annual Meetings. This was supported by a number of other governments. The Committee took note of this concern and drew it to the attention of the Commission.

23. ADOPTION OF THE REPORT OF THE FINANCE AND ADMINISTRATION COMMITTEE
The Commission adopted the report of the F&A Committee.

Resolution on the frequency of meetings of IWC
On behalf of the other sponsors (Australia, Belgium, France, Germany, Italy, Kenya, Monaco, Norway, San Marino, Spain, South Africa and Switzerland), Ireland introduced a draft Resolution to, inter alia:
(1) accept the principle of IWC meetings being held less frequently than regular Annual Meetings, coupled with ensuring that intersessional meetings do not increase as a counter balance;
(2) create a working group to investigate (by correspondence) and make recommendations to IWC/57 on the implications of less frequent meetings;
(3) use the working group recommendations as a basis for a detailed Resolution at IWC/57 and a change in the Rules of Procedure of the Commission at IWC/58; and
(4) apply the principle of less frequent meetings after IWC/58 in 2006.

Ireland noted that that the increasing burden of Annual Meetings in terms of costs and personnel has been discussed on previous occasions and that the suggestion of less frequent meetings is not a new one. It drew attention to other Conventions dealing with fisheries, biodiversity and the environment who organise their affairs effectively on the basis of biennial or triennial meetings and hoped that the draft Resolution could be adopted by consensus.

The UK expressed its willingness to consider the proposal for less frequent meetings in principle, but noted that less than annual meetings might cause difficulties if the Commission adopts an RMS and starts to set catch limits. It noted that other Conventions with biennial or triennial meetings are set-up rather differently than IWC, with, in many cases, Sub-committees being established to do the bulk of the work. By contrast, the ICRW requires actions to
be taken by the Commission. It therefore was not generally in favour of the proposal. South Africa appreciated these remarks but urged that the issue be pursued fully.

The USA was not opposed to considering less frequent meetings, but suggested a number of amendments to the draft Resolution to: (1) propose that the principle of less frequent meetings be ‘explored’ rather than ‘accepted’; and (2) delete reference to the draft Resolution and changes to Rules of Procedure. Ireland indicated that it could accept these amendments and suggested that as a result, reference to implementation of less frequent meetings be applied after IWC/58 be deleted. The other co-sponsors agreed to these changes.

Denmark could agree to explore the issue, but like others, suggested that less frequent meetings might not be practical if an RMS was adopted and catch limits had to be set.

Dominica welcomed the proposal but suggested that a clause be inserted to urge that work on the RMS proceed expeditiously during the intersessional period leading up to IWC/57 next year.

Iceland and Japan indicated that they could not support the proposal at present, believing it to be premature. Iceland considered that it might delay adoption and implementation of an RMS. Japan believed that work on the RMS should be completed first and that for the time being, it is necessary for the Commission to meet annually. Kenya saw no connection with the RMS and urged that the proposal be adopted by consensus. Chile was against the proposal for more practical reasons. It believed: (1) that intersessional activity would increase and that it would have difficulties in finding the funds necessary to enable it to be involved; and (2) that its Government would force a reduction in annual contributions (since meetings would no longer be held annually). In response to Chile’s second remark, Ireland suggested that less frequent meetings should lead in any case to either a freezing or a reduction in financial contributions.

Although Iceland, Japan, Chile and Argentina were not in favour of the proposal, they indicated that they would not block consensus. The Resolution, amended as described above, was then adopted, noting the concerns of these countries (see Resolution 2004-7, Annex C).

24. DATE AND PLACE OF ANNUAL AND INTERSESSIONAL MEETINGS

24.1 57th Annual Meeting, 2005
The Republic of Korea reported that IWC/57 will be held at the Lotte Hotel in Ulsan during the period 30 May to 24 June 2005 – the exact timing to be decided by the Commission.

The Secretary introduced a provisional schedule for the meeting, noting in particular that given Resolution 2004-6 on Completion of the RMS, two days had been allocated for a meeting of the RMS Working Group, and the meeting of the Commission had been extended from four days to five. The Commission agreed with the timing proposed, i.e. that the Scientific Committee meet from 30 May to 10 June (with a pre-meeting on sea ice and whale habitat and a workshop on the use of market sampling to estimate bycatch taking place in the period 27-29 May), the Commission sub-groups in the period from 13 to 17 June, and the Commission from Monday 20 to Friday 24 June 2005.

24.2 58th Annual Meeting, 2006
The Commission had received two offers to host the Annual Meeting in 2006; one from France, the other from St. Kitts and Nevis. As neither country was able to offer to host a meeting in a subsequent year, the location of IWC/58 was put to a vote by secret ballot. There were 27 votes for St. Kitts and Nevis, 25 for France and 1 abstention. The 2006 meeting will therefore be held in St. Kitts and Nevis.

24.3 Other
Spain indicated its willingness to host the Annual Meeting in 2007 but indicated its flexibility regarding the year. Kenya indicated that it intended to offer to host the meeting in 2008, but like Spain, was willing to be flexible.

25. ELECTION OF THE CHAIR AND VICE-CHAIR
At last year’s meeting, Henrik Fischer (Denmark) and Carlos Dominguez Diaz (Spain) were elected as Chair and Vice-Chair respectively for a 3-year term. However, as Carlos Dominguez Diaz was unable to continue as Vice-Chair a replacement had to be elected. Horst Kleinschmidt (Commissioner for South Africa) and Minoru Morimoto (Commissioner for Japan) were proposed. On being put to a vote by secret ballot, Mr Kleinschmidt was elected. He received 26 votes. Mr Morimoto received 25 and there were two abstentions. It was agreed that Mr Kleinschmidt’s appointment would be for three years.

26. ADVISORY COMMITTEE
At last year’s meeting, the Commissioners from Dominica and the UK were elected onto the Advisory Committee to replace the Commissioners from St. Lucia and the USA respectively. Since St. Lucia had remained on the Advisory Committee for three years (instead of the usual two years as stipulated in Rule of Procedure M.9), the Commission agreed that Dominica should serve on the Advisory Committee for one year only – its term ending at IWC/56. At IWC/56, the Commission reappointed Dominica to serve on the Advisory Committee for a further two years.

27. SUMMARY OF DECISIONS AND REQUIRED ACTIONS
A summary of decisions and actions required is provided at the beginning of this report.

28. OTHER MATTERS
On behalf of the Commission, the Chair warmly thanked the Government of Italy for hosting the 56th Annual Meeting and for providing such a magnificent location and venue. He also extended his thanks to Mr Morimoto for his support as Vice-Chair, the Secretariat, the interpreters and the staff of Studio Ega who had helped in meeting organisation.

Several countries expressed deep appreciation to both the Chair and Vice-Chair for managing in an extremely efficient and accommodating way what they considered to be a very good meeting.

The meeting was closed at 17.10 on Thursday 22 July 2004.

29. AMENDMENTS TO THE SCHEDULE
The amendments to the Schedule adopted at the meeting are provided in Annex N.
## Annex A

### Delegates and Observers Attending the 56th Annual Meeting

Agenda

1. INTRODUCTORY ITEMS
   1.1 Welcome Address
   1.2 Opening Statements (IWC/56/OS)
   1.3 Secretary’s Report on Credentials and Voting Rights
   1.4 Meeting Arrangements
   1.5 Review of Documents (IWC/56/1)

2. ADOPTION OF THE AGENDA (IWC/56/2)

3. SECRET BALLOTS
   (Chair’s Report of the 55th Annual Meeting, Section 3)
   3.1 Proposal to amend Rule of Procedure E.3 (d)
   3.2 Commission discussions and action arising

4. WHALE STOCKS
   (Chair’s Report of the 55th Annual Meeting, Section 6)
   4.1 In-depth assessment of western North Pacific common minke whales
      4.1.1 Report of the Scientific Committee (IWC/56/Rep 1)
      4.1.2 Commission discussions and action arising
      4.2 Antarctic minke whales
      4.2.1 Report of the Scientific Committee (IWC/56/Rep 1)
      4.2.2 Commission discussions and action arising
      4.3 Southern Hemisphere whales other than minke whales
      4.3.1 Report of the Scientific Committee (IWC/56/Rep 1)
      4.3.2 Commission discussion and action arising
   4.4 Other small stocks – bowhead, right and gray whales
      4.4.1 Report of the Scientific Committee (IWC/56/Rep 1)
      4.4.2 Commission discussion and action arising
   4.5 Other

5. ABORIGINAL SUBSISTENCE WHALING
   (Chair’s Report of the 55th Annual Meeting, Section 7)
   5.1 Aboriginal subsistence whaling scheme
      5.1.1 Report of the Aboriginal Subsistence Whaling Sub-committee (IWC/56/Rep 3)
      5.1.2 Commission discussions and action arising
   5.2 Aboriginal subsistence whaling catch limits
      5.2.1 Report of the Aboriginal Subsistence Whaling Sub-committee (IWC/56/Rep 3)
      5.2.2 Commission discussions and action arising
   5.3 Revision of Schedule paragraph 13 (IWC/56/4)
      5.3.1 Report of the Aboriginal Subsistence Whaling Sub-committee (IWC/56/Rep 3)
      5.3.2 Commission discussions and action arising
   5.4 Other

6. REVISED MANAGEMENT SCHEME (RMS)
   (Chair’s Report of the 55th Annual Meeting, Section 9)
   6.1 Revised Management Procedure (RMP)
      6.1.1 Report of the Scientific Committee (IWC/56/Rep 1)
      • general issues
      • preparation for implementation (western North Pacific Bryde’s whales, North Atlantic fin whales)
      • bycatch
      6.1.2 Commission discussions and action arising
   6.2 Revised Management Scheme
      6.2.1 Chair’s report on intersessional work
      6.2.2 Commission discussions and action arising
   6.3 Other

7. WHALE KILLING METHODS AND ASSOCIATED WELFARE ISSUES
   (Chair’s Report of the 55th Annual Meeting, Section 8)
   7.1 Reporting on data on whales killed and on improving the humaneness of whaling operations (IWC/56/5-8)
   7.2 Commission discussions and action arising

8. SANCTUARIES
   (Chair’s Report of the 55th Annual Meeting, Section 10)
   8.1 Review of the Southern Ocean Sanctuary
      8.1.1 Report of the Scientific Committee (IWC/56/Rep 1)
      8.1.2 Commission discussions and action arising and possible Schedule amendment proposal
   8.2 Improvements to the sanctuary review process
      8.2.1 Report of the Scientific Committee (IWC/56/Rep 1)
      8.2.2 Commission discussions and action arising
   8.3 South Pacific Sanctuary
      8.3.1 Proposal to amend the Schedule to establish a sanctuary (IWC/56/9)
      8.3.2 Commission discussions and action arising
   8.4 South Atlantic Sanctuary
      8.4.1 Proposal to amend the Schedule to establish a sanctuary (IWC/56/10)
      8.4.2 Commission discussions and action arising
   8.5 Other

9. SOCIO-ECONOMIC IMPLICATIONS AND SMALL-TYPE WHALING
   (Chair’s Report of the 55th Annual Meeting, Section 11)
   9.1 Proposal to amend the Schedule
   9.2 Commission discussions and action arising

10. SCIENTIFIC PERMITS
    (Chair’s Report of the 55th Annual Meeting, Section 12)
    10.1 Report of the Scientific Committee (IWC/56/Rep 1)
        10.1.1 Improvements to review procedures
        10.1.2 Review of results from existing permits
        10.1.3 Review of new or continuing proposals
        10.1.4 Other
    10.2 Commission discussions and action arising

11. ENVIRONMENTAL AND HEALTH ISSUES
    (Chair’s Report of the 55th Annual Meeting, Section 13)
    11.1 Integration of environmental concerns with other Scientific Committee work
        11.1.1 Report of the Scientific Committee (IWC/56/Rep 1)
11.1.2 Commission discussions and action arising

11.2 Habitat-related issues

11.2.1 Report of the Scientific Committee
   (IWC/56/Rep 1)
   • POLLUTION 2000
   • SO-GLOBEC/CCAMLR
   • State of the Cetacean Environment
     (SOCER)
   • Arctic issues
   • Anthropogenic noise
   • Habitat degradation workshop

11.2.2 Commission discussions and action arising

11.3 Reports from Contracting Governments on national and regional efforts to monitor and address the impacts of environmental change on cetaceans and other marine mammals

11.4 Health Issues - Commission discussions and action arising

11.5 Other

12. WHALEWATCHING
   (Chair’s Report of the 55th Annual Meeting, Section 5)

12.1 Report of the Scientific Committee
   (IWC/56/Rep 1)

12.2 Commission discussions and action arising

13. CO-OPERATION WITH OTHER ORGANISATIONS
   (IWC/56/11)
   (Chair’s Report of the 55th Annual Meeting, Section 14)

13.1 Report of the Scientific Committee
   (IWC/56/Rep 1)

13.2 Other reports

13.3 Commission discussions and action arising

14. OTHER SCIENTIFIC COMMITTEE ACTIVITIES, ITS FUTURE WORK PLAN AND ADOPTION OF THE SCIENTIFIC COMMITTEE REPORT
   (Chair’s Report of the 55th Annual Meeting, Section 15)

14.1 Small cetaceans
   14.1.1 Report of the Scientific Committee
     (IWC/56/Rep 1)

14.1.2 Commission discussions and action arising

14.2 Other activities
   14.2.1 Report of the Scientific Committee
     (IWC/56/Rep 1)

14.2.2 Commission discussions and action arising

14.3 Scientific Committee Future Work Plan
   14.3.1 Report of the Scientific Committee
     (IWC/56/Rep 1)

14.3.2 Commission discussions and action arising

14.4 Adoption of the Report

15. CONSERVATION COMMITTEE
   (Chair’s Report of the 55th Annual Meeting, Section 4 and Resolution 2003-1)

15.1 Report of the Conservation Committee
   (IWC/56/Rep 5 and IWC/56/12)

15.2 Commission discussions and action arising

16. CATCHES BY NON-MEMBER NATIONS
   (Chair’s Report of the 55th Annual Meeting, Section 16)

16.1 Commission discussions and action arising

17. FUTURE SUSTAINABLE WHALING – FULL UTILISATION OF HARVESTED WHALES

17.1 Introduction by Japan

17.2 Commission discussions and action arising

18. INFRACTIONS, 2003 SEASON
   (Chair’s Report of the 55th Annual Meeting, Section 17)

18.1 Report of the Infractions Sub-committee
   (IWC/56/Rep 4)

18.2 Commission discussions and action arising

19. LEGAL ADVICE IN RELATION TO THE IWC
   (Chair’s Report of the 55th Annual Meeting, Section 18)

19.1 Secretary’s report on how other Conventions deal with legal issues (IWC/56/13)

19.2 Commission discussions and action arising

20. ADMINISTRATIVE MATTERS
   (Chair’s Report of the 55th Annual Meeting, Section 19)

20.1 Annual Meeting arrangements and procedures

20.1.1 Report of the Finance and Administration Committee (IWC/56/Rep 2)
   • Need for a Technical Committee
   • Use of simultaneous translation

20.1.2 Commission discussions and action arising

   20.2.1 Report of the Finance and Administration Committee (IWC/56/Rep 2)

20.2.2 Commission discussions and action arising

21. FORMULA FOR CALCULATING CONTRIBUTIONS
   (Chair’s Report of the 55th Annual Meeting, Section 20)

21.1 Report of the Finance and Administration Committee (IWC/56/Rep 2)

21.2 Commission discussions and action arising

22. FINANCIAL STATEMENTS AND BUDGETS
   (IWC/56/14)
   (Chair’s Report of the 55th Annual Meeting, Section 21)

22.1.1 Report of the Finance and Administration Committee (IWC/56/Rep 2)

22.1.2 Commission discussions and action arising

22.2.1 Report of the Finance and Administration Committee (IWC/56/Rep 2)

22.2.2 Commission discussions and action arising

22.3 Other

22.3.1 Report of the Finance and Administration Committee (IWC/56/Rep 2)

22.3.2 Commission discussions and action arising

23. ADOPTION OF THE REPORT OF THE FINANCE AND ADMINISTRATION COMMITTEE (IWC/56/Rep 2)

24. DATE AND PLACE OF ANNUAL AND INTERSESSIONAL MEETINGS

24.1 57th Annual Meeting, 2005 (IWC/56/15)

24.2 58th Annual Meeting, 2006

24.3 Other

25. ADVISORY COMMITTEE

26. SUMMARY OF DECISIONS AND REQUIRED ACTIONS

27. OTHER MATTERS
Annex C

Resolutions Adopted during the 56th Annual Meeting

Resolution 2004-1

RESOLUTION ON THE WESTERN NORTH PACIFIC GRAY WHALE

CONCERNED that the IUCN listed the western gray whale as ‘critically endangered’ in 2000 because of its geographic and genetic isolation combined with the small population size of about 100;

FURTHER CONCERNED that the Scientific Committee has noted that only 23 reproductive females are known;

NOTING that the Scientific Committee in 2004 strongly agreed that the evidence that this population is in serious danger of extinction is compelling;

RECALLING that in 2001 the Commission passed a Resolution (Resolution 2001-3) calling on range states and others to actively pursue all practicable solutions to eliminate anthropogenic mortality in the western North Pacific gray whale stock and to minimise anthropogenic disturbances in the migration corridor and on their breeding and feeding grounds;

DEEPLY CONCERNED by the report of the 2004 Scientific Committee that states that the recovery and growth of the population appear to be hindered by a variety of biological difficulties and that the onset of oil and gas development programs is of particular concern with regard to the survival of this population;

NOTING the management recommendations of the 2004 Scientific Committee that as a matter of absolute urgency measures are taken to protect this population and its habitat off Sakhalin Island;

NOTING that although there already was independent scientific advice, there is, nevertheless, a continued need for expert and independent scientific advice on the effects that oil and gas development projects might have on the western North Pacific gray whale stock;

NOTING that in recent years significant resources and effort in studying the western North Pacific gray whale stock near Sakhalin Island, and that in view of the uncertainty over the possible negative impacts on the population and its habitat by current oil and gas activities, this kind of research and monitoring must be continued in greater detail as oil and gas activities increase in scale; and

FURTHER NOTING that the International Whaling Commission is internationally recognised as having competence for the management and conservation of whale stocks, has a wealth of scientific knowledge and expertise and has been reviewing research on the western gray whale population off Sakhalin Island since 1995;

NOW THEREFORE THE COMMISSION:

CALLS UPON range states and others to be mindful of Resolution 2001-3 when contemplating exploration projects in and around Sakhalin Island and to continue to observe the recommendations to actively pursue all practicable actions to eliminate anthropogenic mortality in this stock and to minimise anthropogenic disturbances in the migration corridor and on breeding and feeding grounds;

ENDORSES all conclusions and recommendations of the 2004 Scientific Committee concerning western gray whales including that:

(1) ‘as a matter of absolute urgency that measures be taken to protect this population and its habitat off Sakhalin Island’;

(2) ‘strongly recommends that the ongoing Russian-US and Russian and Republic of Korea national programmes on western gray whale research and monitoring continues and expands into the future’;

(3) ‘strongly recommends that all range states develop or expand national monitoring and research programmes on western gray whales’;

(4) ‘strongly recommends that in situations when displacement of whales could have significant demographic consequences, seismic surveys should be stopped.’

REQUESTS that the Secretariat urgently offers its services and scientific expertise to the organisations concerned with oil and gas development projects and potential exploration projects in the Sakhalin area, and provides them with the findings of any relevant research and Scientific Committee reports;

FURTHER REQUESTS that the Secretariat makes every effort to actively participate and provide advice and expertise at any international expert panels convened to consider the impacts on the western gray whale of oil and gas development projects in and around Sakhalin Island; and

FURTHER REQUESTS that the Commission request all the range states to develop, begin or continue scientific research programmes on the migration, distribution, breeding, population assessment and other research of the entire range of the western gray whale.
Resolution 2004-2

RESOLUTION ON JAPANESE COMMUNITY-BASED WHALING

WHEREAS, since 1986, the International Whaling Commission has repeatedly discussed in-depth the importance of the history and culture of Japanese traditional whaling at its various working groups and the Commission itself;

WHEREAS the International Whaling Commission, recognising the socio-economic and cultural needs of the four community-based whaling communities in Japan (Abashiri, Ayukawa, Wadaura and Taiji), has repeatedly resolved to work expeditiously to alleviate the distress to the communities which has resulted from the cessation of minke whaling (first, IWC/45/51; most recently, IWC Resolution 2001-6);

WHEREAS, more recently, the Summits of Japanese Traditional Whaling Communities were held in three consecutive years in Japan (Nagato, Yamaguchi in 2002, Ikitsuki, Nagasaki in 2003, and Muroto, Kochi in 2004) and they have further examined the long-lasting whaling history and culture which are deeply rooted in various places of Japan, not only in four community-based whaling communities but also throughout Japan;

WHEREAS the Summits acknowledged that archaeological findings have shown that the ancient Japanese could have started to utilise beached whales at least 9,000 years ago, could have begun active hunting of dolphins and porpoises at least 5,000 years ago, and could have launched grand-scale active hunting of large whales at least 2,000 years ago;

WHEREAS the Summits emphasised that, among others, holding the philosophy and having skills to utilise whales fully was and is the core essence of the Japanese whaling culture;

WHEREAS the Declarations adopted at the Summits (the 2002 Nagato Declaration, the 2003 Ikitsuki Declaration, and the 2004 Muroto Declaration) pledged that Japanese time-honoured whaling traditions and culture are to be passed onto the future generations; and

WHEREAS various UN conventions, treaties, and other documents upheld the importance of sustainable use of natural resources in general and the significance of continued customary resource use for communities;

NOW THEREFORE BE IT RESOLVED THAT THE COMMISSION:

REAFFIRMS the Commission’s commitment to work expeditiously to alleviate the continued difficulties caused by the cessation of minke whaling to the communities of Abashiri, Ayukawa, Wadaura and Taiji, and

ENCOURAGES IWC members to co-operate towards a resolution of this matter.

Resolution 2004-3

RESOLUTION ON WHALE KILLING ISSUES

RECOGNISING that welfare considerations for cetaceans killed for food is of international concern;

NOTING that Article V.1.f of the International Convention for the Regulation of Whaling empowers the Commission to amend the Schedule ‘to adopt regulations with respect to the conservation and utilisation of whale resources by fixing … types and specifications of gear and apparatus and appliances which may be used’, and that the Commission has exercised this welfare mandate through modification of the schedule and adopting 15 resolutions on welfare aspects of whaling which have established several technical fora for addressing welfare issues;

RECALLING that the IWC has defined ‘Humane Killing’ as ‘Death brought about without pain, stress, or distress perceptible to the animal. That is the ideal. Any humane killing technique aims first to render an animal insensitive to pain as swiftly as technically possible. In practice this cannot be instantaneous in the scientific sense’ (IWC/33/15 & IWC/51/12) and that, in order to determine whether these criteria are met, various data must be collected from whaling operations;

FURTHER RECOGNISING that the IWC criteria used to determine death or irreversible insensitivity are inadequate; while also recognising that the IWC Working Group and Workshops on Whale Killing Methods are attempting to develop criteria to more adequately determine death or irreversible insensitivity both operationally and from post-mortem approaches;

NOTING that the efficiency of killing methods is influenced by many factors including the calibre of the weapon used, the nature of the ammunition, the target area of the whale, the angle of the shot, the proximity of the whale to the vessel, the accuracy of the gunner, prevailing weather conditions and sea state, including sea ice, and the size and species of the whale targeted;

NOTING FURTHER that data collection requirements are not being met in some hunts, while appreciating that efforts have been made by some member nations to provide available data;

RECALLING that Contracting Parties should make reasonable attempts to release alive, with the minimum harm possible, whales that have been incidentally captured (IWC Resolution 2001-4), but that the Commission has not considered the welfare implications of this practice nor the killing methods that might be employed if the whale cannot be released;

NOTING WITH CONCERN that the number of whales struck in some hunts can have significant welfare implications, while appreciating the efforts of certain member nations, especially Norway, to improve the
FIFTY-SIXTH ANNUAL MEETING, ANNEX C

humaneness of their hunts through weapons improvement programs and increased hunt efficiency;
NOW THEREFORE THE COMMISSION:

EXPRESSES CONCERN, in light of its mandate and long-standing commitment to address welfare issues, that current whaling methods do not guarantee death without pain, stress or distress; that data presently collected and submitted to the Commission are of insufficient quality or completeness for it to make a fully informed assessment of the welfare implications of all whaling operations; and that the criteria currently used to determine the onset of death or irreversible insensibility are inadequate;
REQUESTS THE SECRETARIAT to update the data collection form for the reporting of data in order that contracting governments may report data for each whale taken, the killing method used and samples taken;
REQUESTS the IWC/57 annual meeting to reconvene the Working Group on Whale Killing Methods and Associated Welfare issues, to examine methods for reducing struck and lost rates in whaling operations and to consider the welfare implications of methods used to kill whales caught in nets;
REQUESTS the Working Group on Whale Killing Methods and Associated Welfare Issues to advise the Commission on:
• establishing better criteria for determining the onset of irreversible insensibility and death;
• methods of improving the efficiency of whale killing methods; and
• reducing times to death and other associated welfare issues.

Resolution 2004-4

PROPOSAL TO TAKE INTO ACCOUNT THE SPECIAL POSITION OF VERY SMALL COUNTRIES IN CALCULATING FINANCIAL CONTRIBUTIONS

NOTING that contracting parties should contribute financially to the Commission in a fair and equitable manner;
RECOGNISING that two contracting parties that currently belong to capacity-to-pay Group 3, according to the Interim Measure for calculating contributions, are very small countries with a very small population, and thus a much smaller Gross National Income than the other countries that belong to that Group;
ALSO RECOGNISING that in all other international organisations the special position of these two countries is properly taken into account in the calculation of financial contributions; and
RECOGNISING further that taking account of the special position of these countries within the IWC should not affect the financial contributions of those contracting parties that have the least capacity to pay, and thus belong to Group 1 according to the Interim Measure for calculating contributions;
NOW THEREFORE THE COMMISSION:
DECIDES that, under the Interim Measure for calculating contributions, Monaco and San Marino are transferred from capacity-to-pay Group 3 to Group 2; and
FURTHER DECIDES that this transfer shall have no effect on the contribution of contracting parties that belong to capacity-to-pay Group 1.

Resolution 2004-5

RESOLUTION ON POSSIBLE SYNERGIES WITH THE GLOBAL ENVIRONMENT FACILITY

COGNIZANT of the need to have strong supporting relationships with other international bodies that deal with subject matter with a strong overlapping interest;

RECOGNISING Paragraph 121 of the 2002 Plan of Implementation from the World Summit on Sustainable Development which called for an ‘Institutional Framework for Sustainable Development’ which would be strengthened by:

- Increasing effectiveness and efficiency through limiting overlap and duplication of activities of international organizations, within and outside of the United Nations system, based on their mandates and comparative advantages.

- APPRECIATIVE of the International Whaling Commissions long standing interactions with, inter alia, CITES, CMS & CCAMLR;

- DESIROUS to support synergies between overlapping conventions so as to improve mutually reinforcing scientific, administrative, policy and financial assistance objectives;

- CONSCIOUS of the need to fully support the respective primacy of each organisation;

NOW THEREFORE THE COMMISSION:

DIRECTS the Secretariat to establish high level contact with the Secretariat of the Global Environment Facility and to:

- explore possible synergies and their possible utility of the GEF to the IWC, and investigate, inter alia, possible avenues for the utilization of GEF funding for IWC related projects, with specific regard to:
  
  (i) assistance for developing countries for scientific research and policies for scientific research, as directed by the IWC;

  (ii) the utility in joint projects seeking funding with other international organizations, such as, inter alia, the Convention on Biological Diversity, the Convention on Migratory Species, the World Heritage Convention, and the Ramsar Convention on Wetlands;

  (iii) an examination of the modalities that the GEF seeks to satisfy and whether IWC projects, now or in the future, could be made to fit such objectives.

The Secretariat shall report back to the 57th IWC meeting on these matters.

Resolution 2004-6

RESOLUTION ON COMPLETION OF THE REVISED MANAGEMENT SCHEME (RMS)

RECOGNISING the dual mandate of the IWC for the conservation of whales and the management of whaling according to the 1946 International Convention for the Regulation of Whaling;

NOTING that on this basis, considerable progress has been made in identifying major elements necessary to reach broad agreement on the RMS, as reflected in the Chairman’s Proposal for a Way Forward on the RMS (Doc IWC/56/26);

TAKING NOTE of the comments of Contracting Parties on the Chairman’s Proposal at the 56th Annual Meeting of the Commission; and

CONCERNED that the failure to reach broad agreement on the RMS in the near future may seriously jeopardise the ability of the IWC to fulfil its responsibilities;

NOW THEREFORE THE COMMISSION:

COMMENDS the efforts of the Chairman in providing a basis for further work and discussion towards finalising the RMS;

AGREES to re-establish the Working Group on the RMS with a view to holding an intersessional meeting prior to IWC/57, as outlined in the attached Intersessional Plan of Work; and

AGREES to proceed expeditiously towards the completion of both the drafting of text and technical details of the RMS according to the attached Intersessional Plan of Work with the aim of having the results ready for consideration, including for possible adoption, at IWC/57, and/or to identify any outstanding policy and technical issues.
INTERSESSIONAL PLAN OF WORK

The Chair’s Proposal for a way forward (IWC/56/26), supplemented by his statement (IWC/56/28), other comments made at IWC/56 in relation to the Chair’s proposal and the Secretariat’s document (IWC/56/36), provides a basis for the development of draft text for the RMS, to clarify policy and technical issues and draft text for the RMS. The goal of this effort is to have clarified outstanding policy and technical issues and, as far as possible, have finalised text of an RMS package ready for consideration at IWC/57. The following iterative process would occur to develop such a text over the intersessional period:

1. Commission formally revives the RMS Working Group and agrees to establish a small drafting group under it (see respective terms of reference in Appendices 1 and 2).
2. All Contracting Governments are invited to send comments/positions on key issues to the RMS Working Group.
4. RMS Working Group to provide guidance on major policy issues to small drafting group (before December 2004).
5. Small drafting group meets (one week) in December 2004.
6. Draft text is circulated to delegations for review and comment. Secretariat circulates comments to all delegations and to members of the small drafting group.
7. RMS Working Group convenes in early March 2005 to consider the draft text and submitted comments and to develop input to the small drafting group for development of the next iteration.
8. The small drafting group meets immediately afterwards to develop the second draft, which the Secretariat circulates to delegates.
9. The RMS Working Group meets for two days during the week prior to the IWC/57 Plenary session to consider the second draft. The results of the RMS Working Group are presented to the Plenary for its consideration at IWC/57.

Appendix 1

Terms of Reference for RMS Working Group

The RMS Working Group will have the following responsibilities:

1. To complete work on the RMS package, with the goal of having a finalised RMS text ready for consideration, including for possible adoption, at IWC/57, and/or to identify any outstanding policy and technical issues.
2. To take account of delegates’ comments at IWC/56, as well as written submissions from delegates.
3. To provide guidance to, and to review the work of, the Small Drafting Group.

RMS Working Group to be open to observers.

Appendix 2

Terms of Reference for the Small Drafting Group (SDG)

Under the auspices of the RMS Working Group the SDG will have the following responsibilities:

1. To prepare a consolidated draft text for the replacement of parts of Chapters V and VI of the current Schedule.
2. To prepare consolidated draft text on other related issues in the RMS package.
3. To utilise the Chair’s proposal (IWC/56/26) and his statement (IWC/56/28), as a framework for this work.
4. To rearrange, revise and renumber paragraphs in the draft text for Chapters V and VI as appropriate but not to attempt to merge them with other parts of the Schedule.

Representation on SDG and Technical Specialist Groups (TSGs): Chair to seek expressions of interest to ensure regional and policy diversity in the groups. The SDG and TSGs should include Governments with adequate regional coverage, and adequate coverage of those For/Against/Neutral on the key issues.
Resolution 2004-7

RESOLUTION ON THE FREQUENCY OF MEETINGS OF THE INTERNATIONAL WHALING COMMISSION

AWARE that the Rules of Procedure of the International Whaling Commission (IWC) provide for a regular Annual Meeting of the Commission, and that the positions of Chair and Vice-Chair of the IWC shall serve for a period of three years;

NOTING that other international Conventions dealing with fisheries, species, biodiversity and the environment organise their affairs very effectively on the basis of biennial or triennial meetings;

CONCERNED that the costs of the annual meetings of the IWC are increasing from year to year;

NOTING that many Contracting Parties, especially from developing countries, have difficulty in meeting the high costs of attending annual meetings of the Commission;

NOW THEREFORE THE COMMISSION HEREBY DECIDES:

That the principle of meetings of the IWC being held less frequently than regular Annual Meetings be explored;

That, in applying this principle, the intention should be to avoid holding more frequent inter-sessionary meetings as a counter-balancing measure;

That a working group be established by the Commission to investigate and make recommendations on the implications of less frequent meetings of the IWC;

That, in its deliberations, the working group should have particular regard to the implications of less frequent meetings for the term of office of the Chair and Vice-Chair of the Commission; for the work of the other Committees of the IWC; and, with specific regard to the deliberations of the Scientific Committee, that the group should examine whether the current pattern of holding annual meetings should be maintained in the initial years of the new arrangements at least;

That the working group should report to IWC/57 in Ulsan, Republic of Korea.
Annex D

Report of the Sub-Committee on Aboriginal Subsistence Whaling

Wednesday 14 July 2004, Sorrento, Italy

1. INTRODUCTORY ITEMS

The meeting took place at the Hilton Sorrento Palace Hotel, Sorrento, Italy on 14 July 2004. A list of participants is given in Appendix 1. The terms of reference of the Aboriginal Subsistence Whaling Sub-committee are to consider relevant information and documentation from the Scientific Committee, and to consider nutritional, subsistence and cultural needs relating to aboriginal subsistence whaling and the use of whales taken for such purposes, and to provide advice on the dependence of aboriginal communities on specific whale stocks to the Commission for its consideration and determination of appropriate management measures (Rep. int. Whal. Commn. 48: 31).

1.1 Election of Chair

Andrea Nouak (Austria) was elected Chair.

1.2 Appointment of Rapporteur

Alexander Gillespie (New Zealand) was appointed as rapporteur.

1.3 Review of documents

The documents for discussion included:

- IWC/56/AS1 Revised Draft Agenda.

2. ADOPTION OF THE AGENDA

The adopted agenda is given as Appendix 2.

3. ABORIGINAL SUBSISTENCE WHALING SCHEME

3.1 Aboriginal Whaling Management Procedure (AWMP)

3.1.1 Report of the Scientific Committee

3.1.1.1 GRAY WHALES (IWC/56/REP 1, ITEM 8.2)

The Chair of the Scientific Committee’s Standing Working Group on the Development of an Aboriginal Whaling Management Procedure, Greg Donovan (hereafter Chair of the SWG), reported on the Scientific Committee’s work in this regard. Last year, he had informed the Sub-committee that the Scientific Committee expected to be able to recommend a Strike Limit Algorithm (SLA) for eastern North Pacific gray whales to the Commission at the present meeting. This will be the second SLA that the Scientific Committee has recommended in the development process. Because the Committee were making a major recommendation, the Chair of the SWG gave a thorough presentation of the work of the Committee on this issue over the whole development process. The full presentation is available upon request to interested delegations as an electronic file or as a printout of the slides used. He also noted that as in previous years, he is happy to discuss any issues raised with interested parties. What follows is a very short summary of the key points made in the presentation.

Full details of the Scientific Committee’s work can be found in IWC/56/Rep 1, Item 8 and Annex E.

The Scientific Committee began addressing aboriginal subsistence management procedures in the early 1990s after completion of the RMP. In 1994, the Commission formally instructed the Scientific Committee to work on the development of an aboriginal whaling management procedure (Resolution 1994-4). The Commission had reiterated the objectives of such a scheme as to:

1. ensure risks of extinction are not seriously increased (highest priority);
2. enable harvests in perpetuity appropriate to cultural and nutritional requirements; and
3. maintain stocks at highest net recruitment level and if below that ensure they move towards it.

The advantages (to both the management body and the users) of a management procedure over ‘ad hoc’ management were stressed, as was the value of computer simulations to try out potential candidate procedures. The simulation trial structure is designed to test procedures against the inevitable uncertainty in scientific knowledge about the whales and their environment.

The Commission agreed in 1998 that the eventual aboriginal whaling scheme (which includes both the scientific and non-scientific aspects of management) would include both generic and case-specific elements. In particular, it was agreed that SLAs (the way in which the need requests forwarded by the Commission to the Scientific Committee are evaluated to determine whether they are acceptable from the point of view of the risk-related objectives given above - it is assumed for the purposes of trials that all strikes result in death) could be case-specific and introduced to the AWS as they became available. The Scientific Committee had agreed that it would proceed with the data-rich fisheries first, i.e. the bowhead and gray whale hunts. In 2002 it proposed the Bowhead SLA. Throughout the process, the Scientific Committee placed great emphasis on feedback from the Commission and hunters via the Commission’s Aboriginal Whaling Sub-committee, and each year the Chair of the SWG has made a detailed presentation of the development process, requested advice on various matters and been available for consultation with interested delegations and individuals.
The candidate procedures for the gray whale case were tested for a broad range of uncertainty in a variety of factors, including: changes in \textit{MSYR} and \textit{MSYL}; model uncertainty; time dependent changes in carrying capacity, natural mortality and productivity; episodic events; stochasticity; survey bias and variability; survey frequency and errors in the historic catch series. The overall performance of candidate \textit{SLAs} was judged by a combination of an examination of the detailed conservation and need satisfaction statistics for each of the \textit{Evaluation Trials} and \textit{Robustness Trials} and human integration of these results in the context of the relative plausibility each member assigns to the individual trials.

Two procedures performed equally well in the trials, one was the J-B2 and the other was the GUP2\textsuperscript{a} based on J-B2 and D-M2 procedures. The Scientific Committee therefore had examined other features that may be used to separate the two \textit{SLAs}. Recalling the discussions about the value or otherwise of the ‘unified’ (averaging) approach when recommending the \textit{Bowhead SLA}, the Committee noted that the GUP approach includes a built-in check and balance system in that if one of the component \textit{SLAs} behaves poorly for a particular scenario, this effect may be balanced by the other \textit{SLA} and vice versa. Averaging has also been recommended by MCDM\textsuperscript{b} experts as an appropriate method. It again followed this philosophical approach and agreed that the GUP2 \textit{SLA} fully met the Commission’s management objectives. It also noted that it might be possible to ‘polish’ the GUP2 \textit{SLA} and its two constituent \textit{SLAs} further. However, the Committee agreed that it should not expend resources unnecessarily in further attempting to achieve some hypothetical level of ‘perfection’. It strongly believed that these resources should be dedicated to addressing the serious issue of the Greenland fisheries for fin and minke whales, for which the Committee has never been able to provide management advice.

In conclusion, the Scientific Committee unanimously recommended that the GUP2 \textit{SLA} (hereafter the ‘Gray whale \textit{SLA}’) be forwarded to the Commission. It believes that this \textit{SLA} meets the objectives of the Commission set out in 1994 (IWC, 1995) and represents the best scientific advice that the Committee can offer the Commission with respect to the management of the Eastern North Pacific stock of gray whales.

In making this recommendation, the Scientific Committee noted the integral importance of \textit{Implementation Reviews} to the whole process. Regular \textit{Implementation Reviews} would occur every five years and normally involve at least reviews of information:

1. required for the \textit{SLA} (i.e. catch data, abundance estimates); and
2. to ascertain if the present situation is as expected and within tested parameter space.

In addition, to enable swift reaction to new information that gives rise to serious concern, \textit{Unscheduled \textit{Implementation Reviews}} can be called. He provided a number of examples as to possible ‘triggers’ for such early reviews. There are a variety of possible outcomes of \textit{Implementation Reviews}, including:

(a) the continuation of use of the \textit{SLA};
(b) the setting of a zero strike limit;
(c) the running of further simulation trials;
(d) the undertaking of a new census immediately; or
(e) a combination of some of the above.

The Chair of the SWG thanked Eva Dereksdóttir, Kjartan Magnússon, Sue Holloway (née Johnston) and Doug Butterworth (incidentally all Invited Participants) for the enormous amount of work and thought they had put into the development process. He also specifically thanked Cherry Allison and André Punt for the tremendous support they provided. He noted that this was the second \textit{SLA} that had been developed by the SWG under the auspices of the Scientific Committee and he thanked them as a whole for the atmosphere of co-operation was always present, even when there are genuine scientific differences of opinion at the various stages of the development process. He believed that a continuation of this mode of working will be essential if the SWG is to address successfully the most difficult case it has faced, that of the Greenland fisheries.

DISCUSSION AND RECOMMENDATIONS

In response to a question from Sweden about what might happen if no surveys occur for longer than a 10-year period, the Chair of the SWG referred to the discussions on the AWS that had been presented two years ago and are available in \textit{Ann. Rep. Int. Whal. Commn.} 2002: 74-75. In summary, the ‘grace period’ process would be evoked whereby, unless an agreed abundance estimate was forthcoming, then the block limit for the following block would be half that for the present block, after which it would revert to zero. In response to a question from the UK about the appropriateness of the GUP2 approach, the Chair of the SWG reiterated that, as in the case of the \textit{Bowhead SLA}, the Scientific Committee noted that from an MCDM perspective the \textit{Gray Whale SLA} is a perfectly valid approach and it noted the benefits of the inbuilt check-balance by merging two quite different procedures.

In conclusion the Sub-committee endorsed the report and recommendations of the Scientific Committee.

3.1.1.2 GREENLANDIC FISHERIES (IWC/56/REP 1, ITEMS 8.3, 8.4)

The Chair of the SWG reminded the meeting that an urgent need for a Greenland Research Programme had been first identified in 1998. This is primarily due to the lack of recent abundance estimates and the poor knowledge of stock structure. It will be extremely difficult, if not impossible, to develop an \textit{SLA} for the Greenlandic fisheries that will satisfy all of the Commission’s objectives without such information. This is particularly important in the light of the Scientific Committee’s grave concern at its inability to provide management advice for these fisheries.

He separated out this item into four main issues: stock structure; abundance estimates; biological data and \textit{SLA} development. With respect to the former, the problem was that although the available information suggested that the animals found off West Greenland did not comprise either separate fin or common minke whale stocks, the identity and size of the complete stocks is unknown. The Committee has agreed to follow a two-step process to further the essential work needed to provide information suitable for management; namely an initial simulation study to focus appropriate genetic analyses.

\textsuperscript{1} Grand Unified Procedure
\textsuperscript{2} Multiple criteria decision-making.
In this regard, he noted that the Scientific Committee has previously strongly recommended that genetic samples be taken for all of the catch. However, the numbers for 2003 were very low (12 minke whale and 1 fin whale), even though it is mandatory under local regulations to return a sample from each whale that is caught. The Committee expressed disappointment at the lack of progress in obtaining genetic samples, although it noted new procedures were in place. It repeated its strong recommendation that samples for genetic analysis be collected from the catch as a matter of very high priority. It urged the Commission to encourage the Government of Denmark and the Greenland Home Rule authorities to assist with logistical and, if necessary, financial support. Finally, it encourages Greenlandic scientists to investigate other potential sources of samples. It also welcomed the news that some 50 samples are available from the eastern USA and Canada and it urged that these be analysed.

With respect to abundance estimates, the Chair of the SWG noted that, last year, the Committee had strongly recommended that a traditional aerial cue-counting survey be carried out in summer 2003 in Greenland. For logistical and financial reasons it had not been possible to undertake such a survey, but some valuable experimental work had been carried out in 2003 that had been fully discussed. Greenlandic scientists presented a plan for a full aerial photographic (not cue-counting) survey this summer. The Committee had noted the great need for new abundance estimates and, in order to facilitate presentation of appropriate analyses as quickly as possible, had established an intersessional advisory group. The Chair of the SWG noted that the difficult environmental conditions (notably fog and high winds) in Greenland made the undertaking of successful surveys problematic.

The catch data for 2003 were: 6 landed fin whales (2M and 4F), with 3 struck and lost; 178 landed West Greenland common minke whales (58M, 117F, 3 unknown sex) and 7 struck and lost; and 13 landed East Greenland common minke whales (1M, 11F, and 1 unknown sex). An analysis of recent catch data will be provided to the next Committee meeting.

In terms of developing an SLA, the Chair of the SWG was pleased to report that three papers, albeit preliminary, had been presented and that these will help to provide a framework for future work. The differences between the relatively ‘easy’ data-rich cases of the bowhead and gray whales and the data-poor Greenlandic cases, may warrant a different approach to the examination of the trade-off between risk and need satisfaction and the Committee will develop such a statistic to add to the list of those it normally considers. The issues will be considered in depth at the next SWG meeting.

The SWG had also considered how best to proceed with the development of one or more SLAs for Greenlandic aboriginal whaling, given the continuing uncertainties about stock structure, abundance, and mixing in the region. One approach would be to postpone SLA development until more and better data become available. The SWG rejected this approach, instead believing that SLA development was a matter of considerable urgency. The SWG intended to develop the best SLA(s) it could given the data available, and noting the potential of the simulation approach to help identify appropriate data collection programmes, it recognised that it might become necessary to improve the SLA(s) at future Implementation Reviews when more information is available. The Committee had endorsed this approach. The Chair of the SWG advised that issues related to management advice would be presented under later Agenda Items (4.3 and 4.4).

3.1.2 Discussion and Recommendations

After this exchange of views, the Chair summarised that the Sub-committee endorsed all recommendations of the Scientific Committee on these items.

New Zealand stated that what has occurred with regard to data provision by Greenland is unsatisfactory. New Zealand suggested that the Commission has an obligation to probe what has caused this situation and what can be done about it. The annual take of fin and minke whales has created serious difficulties, and Scientific Committee has been unable to provide scientific advice. Despite the Scientific Committee’s efforts, very little has been achieved to improve the knowledge of the Greenland stocks. New Zealand was concerned that this year, Greenland reported to the Scientific Committee that they had only provided one genetic sample from six fin whales taken. New Zealand questioned whether it is now time to impose restrictions on the catch quota for Greenland. They then asked Denmark what explanations they had and how they intended to remedy this situation, which given the Scientific Committee advice, is a very urgent one.

Denmark responded that information on the importance of returning samples has been given to the hunters. Only one sample from a fin whale, and 12 from minke whales have been returned in 2003. The Home Rule Government regrets the low number of samples collected. For the 2004 season, letters and phials have been sent to the municipalities, and when issuing licenses, the municipal officers hand out phials to the hunters. The Home Rule Government also works to improve the collection of samples in cooperation with the hunters association and by making a press release, so that the information is conveyed. The UK expressed its concern with this response. The UK recognised that the policing of the hunt was difficult, but stated that the conditions under which ASW is enabled to take place in Greenland are known to the hunters, and were included in licences. The UK felt that non-compliance with conditions required more than a slap on the wrist.

3.2 Aboriginal Whaling Scheme (AWS)

3.2.1 Report of the Scientific Committee (IWC/56/Rep 1, Item 8.2.6)

The Chair of the SWG noted that at the 2002 meeting, the Committee had developed generic scientific aspects of an aboriginal whaling management scheme that would be used in conjunction with the case specific SLAs. (These had been reported in detail to this Sub-committee but no agreement had been reached on these by the Commission.) This year, as last, the Committee again recommends these to the Commission. They are specified in Ann. Rep. Int. Whal. Commn. 2002: 74-75. The Chair of the SWG will be happy to spend time explaining these further with interested delegations at any time.

3.2.2 Discussion and recommendations

Australia recognised that the focus of discussion was on science, but sought to register its concern over whaling management regimes. This Sub-committee should give equal attention to management considerations as to the scientific considerations. The USA stated that they have previously expressed concerns over certain provisions of
the AWS and that their reservations should continue to be noted.

After this exchange of views, the Sub-committee endorsed the recommendations of the Scientific Committee on these items.

4. ABORIGINAL SUBSISTENCE WHALING CATCH LIMITS

4.1 Bering-Chukchi-Beaufort (B-C-B) Seas stock of bowhead whales

4.1.1 Report of the Scientific Committee (IWC/56/Rep 1, Item 9.1)

The Chair of the SWG noted that this year, the Scientific Committee had undertaken an in-depth assessment of the B-C-B bowhead whales. Considerable focus had been given to the question of stock structure and a number of papers were presented that were facilitated by the provision of data under the Committee’s new data availability agreement. The Committee agreed that substantial progress has been made in investigating possible stock or population structure among B-C-B bowheads but that there is insufficient information at this stage to fully support or fully refute the hypothesis of a single stock; in fact it is premature to reject any of the hypotheses, or even to draw conclusions about their relative plausibility. The Committee was pleased to receive information on an extensive research programme to address this issue further.

The Scientific Committee also received information on traditional assessment methods, not to provide management advice per se but as a way of examining whether ‘reality’ was still within the parameter space tested in the trial structure of the Bowhead SLA. It was noted that stock structure issues applied equally to these methods as to the use of the Bowhead SLA.

Catch information was provided for 2003 by the USA: a total of 41 bowhead whales were struck resulting in 35 animals landed. The efficiency (the ratio of the number landed to the number struck) of the hunt was 85%, which is higher than the average efficiency over the past 10 years (77%). Of the 35 landed whales, 17 were females and the sex was not determined for one whale. Of the 17 females, 5 were presumably mature (>13.4m in length). Three of these large females were closely examined; two had recently given birth and the other was not pregnant.

In addition, there was a Russian harvest of three male bowhead whales in Chukotka waters.

In terms of management advice, the Scientific Committee agreed that the future Implementation Review of bowhead whales will include stock structure issues as a major component. This Implementation Review will examine the robustness of the Bowhead SLA with respect to plausible stock hypotheses via simulation trials. If shown to be necessary, this may result in changes to the Bowhead SLA. Such an Implementation Review will begin at the 2006 Annual Meeting, with a view to ensuring that management advice at the 2007 meeting is based on the best science then available. The Committee also recommended that a report on the progress of the research programme should be provided each year to the Scientific Committee and it encourages cooperative research amongst the various interested research groups.

The Scientific Committee also noted:

1. the continuing increase in the abundance estimates derived from the census under the recent catch limits and record high calf counts;
2. the spatio-temporal distribution and opportunistic nature of the hunt and the low numbers of whales struck annually in St. Lawrence Island and Chukotka; and
3. the development of an extensive research programme that will address questions of stock structure and allow the formulation of one or more plausible stock structure hypotheses.

Given these factors, the Committee agreed that the Bowhead SLA remains the most appropriate tool for providing management advice for this harvest, at least in the short-term, and consequently the results from the Bowhead SLA (see IWC/56/Rep 1, Item 9.1.4) indicate that no change is needed to the current block quota for 2003-2007.

4.1.2 Discussion and recommendation

The USA noted the collaborative efforts of US scientists with scientists of other countries, particularly Russia, Norway and Japan. They also noted the recommendation of the Scientific Committee on the need for additional research on the bowhead stock identity issue. The USA is committed to undertaking this research so that by 2007, when the bowhead quota is next reviewed, its management will be based upon the best science available at that time.

Japan asked the USA if it could provide Japan with the baleen plates of bowhead whales caught by the Alaskan hunters. In response, the USA agreed to discuss this issue with Japan outside of the Sub-committee. The Russian Federation stated that during this IWC meeting the USA and Russia intend to sign a Memorandum of Understanding and also intend to start work in 2004 on genetic research, as well as biological research. Russia intends to engage in as much joint research as is possible, although it noted that CITES requirements may impose difficulties on what is possible. Switzerland drew the attention of the Sub-committee to the fact that at COP 12 of CITES in Santiago (Chile), a resolution was adopted aiming at facilitating transboundary movement of sensitive biological samples such as scientific research materials for conservation purposes, and that the CITES Management Authorities should be made aware of IWC transboundary issues if the need arises.

After this exchange of views, the Sub-committee endorsed the recommendations of the Scientific Committee on these items.

4.2 North Pacific Eastern stock of gray whales

4.2.1 Report of the Scientific Committee (IWC/56/Rep 1, Item 9.2)

Twenty-two Chukotka aboriginal whaling organisations submitted requests for harvesting a total of 167 gray whales. However, according to permit regulations of the Russian Federation Ministry of Natural Resources, only 135 permits for gray whales were distributed among aboriginal whaling organisations and native settlements. A total of 126 gray whales (70 males and 56 females) were taken in 2003 and two gray whales were struck and lost.

New information on calf counts from the northbound migration and the breeding lagoons in Mexico was presented. The Committee was encouraged to hear that calf production remains at the mid-range of pre-1999 levels.
of a general aboriginal whaling scheme (although it has not yet been accepted by the Commission) associated with agreed SLAs. As shown in IWC/54/5 Appendix 4, under such a provision, catch limits would begin to be phased out 10-14 years after an abundance estimate was last obtained and catchers would revert to zero at the end of the five-year period during which the catch limit would have been half the previous block. The Committee has not previously suggested that such a grace-period should have started for fin whales. However, it drew attention to the fact that if it had, such a period would now be nearing completion.

It is with great concern that the Scientific Committee advised the Commission that in the absence of an agreed abundance estimate for fin whales arising out of the 2004 survey, it will likely recommend immediately that the take of fin whales off West Greenland be reduced or eliminated. If, as hoped, an abundance estimate is obtained, the Committee will review this next year in its formulation of management advice.

4.3.1 and 4.4.1 Report of the Scientific Committee

The Scientific Committee recommended that every effort be made to ensure that the number of samples collected from the catch in 2004 will be very considerably higher than in 2003 and close to 100%. It also strongly recommended that these and all existing samples held in Greenland be analysed as soon as possible in accordance with guidance to be given by the intersessional working group.

The Scientific Committee drew attention to the grace-period provision that it had agreed previously in the context of the Home Rule Government has given financial support for survey projects between DKK 1.2-1.4 million annually for the years 2002-2004. Between 1998-2003, a total of 301 samples have been collected making it about 50 per year. 166 samples have been analysed in 2003. In 2002-2004, about 50 per year. 166 samples have been analysed in 2003. There are 200 samples in the freezers to be analysed. Results from the samples have been published in the Marine Ecology Progress Series. There has been disappointingly little discussion of these results in the SWG, but Greenland hopes to receive some guidance from the SWG on the best directions for future analyses. Greenland is therefore looking forward to a project to be undertaken this winter, in cooperation with the SWG. A simulation study of possible connections between minke whale stocks will provide guidelines that will guide the analysis of the samples in the freezers and the coming samples. On the question of reduction of the current quota of fin whales, Greenland suggested that the Scientific Committee is not the right body to decide such a reduction. Greenland suggested it would be strange if quotas would be reduced due to bad weather this August and expressed their hope that the weather was with them in August. In conclusion, the Greenland Home Rule Government stated that it intended to increase its efforts to gain more samples as recommended in cooperation with the hunters organisation. The UK noted Denmark’s remarks with interest but stated that this was not the first time this problem had arisen. The Scientific Committee recommendations were in the strongest terms the UK had seen. The UK felt that the Commission would need to agree to take action on the quota if data were not made available. Australia concurred with the UK in noting that the Scientific Committee wording was unprecedented, and suggested that the Scientific Committee concerns should be reinforced by this Sub-Committee.

Argentina expressed concern because the sex ratio of the Greenland’s minke hunt is highly female biased: on average, 72% of all minke whales killed in Greenland since 1986 were female. Argentina asked Greenland why it believes the bias occurs and what might be the solution to
this problem? Denmark answered that this kind of question has been raised before. Nevertheless, they explained again that sex selection is impossible to enforce in Greenland due to both weather and ocean conditions.

New Zealand questioned whether the answer given by Denmark was sufficient. They noted that the information given showed a high female sex bias (72% for all minke whales caught in Greenland and 92% for East Greenland minke whales since 1996). New Zealand was concerned that the preferential removal of females could significantly affect the regenerative capacity of the stock. It would be helpful for Greenland to provide information on the date, location and sex of every whale taken, to show precisely what is going on. These issues raise fundamental questions of accountability that go to the centre of the integrity of the legal instrument under which the Commission operates. The time for accountability has arrived.

Germany stated that more information about what was going on was required, and were appreciative that this matter will be followed up next year. They also appreciated the strong recommendations given by the Scientific Committee relating to the failure of abundance estimates. Germany suggested that this is clearly a matter which the Commission has to follow up on.

The UK expressed its concern about sex bias, and remarked that if a degree of sex bias was inevitable, it raised some very important questions about the sustainability of the hunt. Switzerland agreed with the UK, suggesting that if the harvest is overtly biased on females, questions of sustainability must arise.

With respect to the female bias in the catch, the Chair of the SWG clarified that it is common for minke whales to segregate both geographically and temporally by sex in the North Atlantic. The sex bias in the catch is longstanding and earlier attempts to model the animals off West Greenland showed that if the minke whales found there comprised a complete stock they would already have become extinct. The sex bias in the catch probably reflects the sex ratio in the waters there and not any selectivity by whalers (which in any case is not possible). He noted that the Committee was expecting a paper on recent catches (both geographical and temporal by sex) at its next meeting.

Greenland explained that the information on the seasonal distribution of the harvest suggests northward movement in early part of hunting season and a southern movement in the autumn, so that the hunting season, which is in any case short, is even shorter in the northern part of the area of distribution of minke whales in West Greenland. Analysis has not so far shown differential distribution of the two sexes. They suggested that knowledge of this bias is long standing and not recent. This bias suggests that this is probably a part of a larger stock, whose boundaries are uncertain.

After this exchange of views, the Sub-Committee endorsed the recommendations of the Scientific Committee on these items.

4.5 North Atlantic humpback whales off St. Vincent and The Grenadines
4.5.1 Report of the Scientific Committee (IWC/56/Rep 1, Item 8.6)
The Chair of the SWG reported that in recent years, the Scientific Committee has examined the stock structure of humpback whales in the North Atlantic. It is most plausible that the animals from St. Vincent and the Grenadines are part of the West Indies breeding population (ca. 10,750 in 1992). However, further data to confirm this are desirable and the Committee repeated previous recommendations that every effort be made to obtain photographs and genetic samples from St. Vincent and the Grenadines. The Scientific Committee was disappointed not to receive information on whether or not any catches had been taken last year. There were no scientists from St. Vincent and the Grenadines present at the meeting and no national progress report had been submitted. However, it noted that the genetic analyses of at least three samples from caught animals is being conducted. It was also pleased to hear that sightings cruises are taking place in the region and looked forward to receiving a report in the future.

The Commission has adopted a total block catch limit of 20 for the period 2003-2007. The Scientific Committee agreed that if the humpback whales are part of the West Indies breeding population, this catch limit will not harm the stock.

4.5.2 Discussion and recommendations
The UK did not dispute the Scientific Committee recommendations, but urged the need for further data. The UK suggested that if not identified as part of the West Indies stock, there could be ramifications on the stock. Australia understood that St. Vincent and the Grenadines passed new whaling regulations in December 2003, and asked whether a copy of this legislation had been submitted to the Secretariat as is required, and whether it had been found to be consistent with the draft legislation presented to the IWC. The Chair of the SWG indicated that this matter was usually dealt with in the Infractions Sub-committee, but he would investigate this situation. The Chair noted that St. Vincent and the Grenadines were not present.

5. SCHEDULE PARAGRAPH 13
The Chair drew attention to Document IWC/56/4 and asked the Russian Federation to introduce the item. The Russian Federation explained that at IWC/55 in Berlin last year, they had drawn attention to what it considered anomalies in the way that the Chukotka peoples are treated compared with other aboriginal groups and proposed changes to the Schedule to address these inconsistencies. However, after discussions within the Aboriginal Subsistence Whaling Sub-committee and in the Commission, the Russian Federation agreed to withdraw its proposed Schedule amendments and to work intersessionally on this issue. To this end, the Commission agreed that a small group (comprising of the Russian Federation, Denmark, Australia and the USA, working with the Secretariat) should work intersessionally by email to review Schedule paragraph 13 to determine how consistency in approach to ASW operations could be achieved and to propose a Schedule amendment for review and decision-making at IWC/56. A report from this group, together with proposed Schedule revisions is available as IWC/56/4.

The SWG agreed that all the provisions governing aboriginal subsistence whaling operations are understood to be, and should be, included in paragraph 13 of the Schedule. Should the Commission decide to harmonise the ASW Schedule language, the group recommends considering the creation of one option concerning the prohibition on the taking of calves and whales accompanied by calves. A new sub-paragraph could be inserted in the
general principles governing this form of whaling to read as follows:

‘13. (a) (4) It is forbidden to strike, take or kill calves or any whale accompanied by a calf.’

The Small Group agreed that nothing in the Russian Federation’s proposal to amend Schedule paragraph 13 was intended to allow for commercialisation of aboriginal subsistence whaling. The native peoples never harvested whales for commerce. The native peoples use the predominant portion of the products for their own needs and only an insignificant part is exchanged or used for transactions with other communities.

The words ‘when the meat and products of such whales are to be used exclusively for local consumption’ in subparagraphs 13(b)1, 13(b)2, 13(b)3 and 13(b)4 means that some transaction beyond the aboriginal whaling communities under the current Schedule language are acceptable. The definition of aboriginal ‘subsistence use’ was adopted by the Cultural Anthropology panel of the IWC Meeting of Experts on Aboriginal/Subsistence Whaling in February 1979 (IWC Special Issue 4, 1982) and provided that:

(1) the personal consumption of whale products for food, fuel, shelter, clothing, tools or transportation by participants in the whale harvest;
(2) the barter, trade or sharing of whale products in their harvested form with relatives of the participants in the harvest, with others in the local community or with persons in locations other than the local community with whom local residents share familial, social, cultural or economic ties. A generalised currency is involved in this barter and trade, by the predominant portion of the products from such whales are ordinarily directly consumed or utilised in their harvested form within the local community; and
(3) the making and selling of handicraft articles from whale products, when the whale is harvested for the purposes defined in (1) and (2) above.

The Russian Federation indicated that the words ‘…the aborigines whose traditional aboriginal subsistence and cultural needs have been recognised,’ in sub-paragraph 13(b)2 is not related to the right of native peoples in taking gray whales, but, rather, to the right of native peoples in using harvested gray whales. These kind of limitations in the use of meat and products of whales do not exist in the other sub-paragraphs of Paragraph 13. A representative of the Chukotka native peoples explained that the existing condition leads to paradoxical situations where in different villages, even in the same village, and even for the same person, people have different rights in using legally harvested gray and bowhead whales. This situation violates human rights and discriminates against native peoples of Chukotka.

It was agreed by the Small Group that aboriginal communities in Chukotka, which have a quota to take gray whales and bowhead whales, have equal rights to other aboriginal communities that have Aboriginal Subsistence Whaling quotas to use the meat and products of these whale species.

The Small Group noted that the proposal to delete the words – ‘whose traditional aboriginal subsistence and cultural needs have been recognised’ – from Schedule sub-

paragraph 13(b)(2) was intended to reflect this equality of rights.

The Russian Federation noted that any limitations of human rights of entire peoples, especially minority native peoples, are an extremely delicate question, with great ethical and political implications. In relation to these issues, the Russian Federation asked the delegations of Contracting Governments to be politically correct in their discussion, and expressed a preference that the ASW Subcommittee recommend that the Commission include an item on its agenda to adopt the Report of the Small Group and adopt the proposal to amend the Schedule paragraph 13 by consensus.

5.1 Discussion and recommendations

The Chair summarised that the proposal suggests a new Para 13(a)4, a deletion of the relevant sentences in Para 13(b) as well as the deletion of the phrase ‘whose traditional aboriginal subsistence and cultural needs have been recognised’.

The USA thanked the Russian Federation for their leadership of the small group. They noted that although the group represented different views, they had reached consensus on the report, and encouraged the Subcommittee to accept the report in the same spirit. The UK congratulated the Small Group on its work. Although the UK generally had no difficulty with the report it was uneasy about the suggested solution. The UK fully accepted that the rights of Chukotka people should be exactly the same as other indigenous peoples, regardless of the whales taken, but stressed the obligation to ensure that for ASW operations the products are in large measure, or totally, used for the people whose needs have been acknowledged. As such, the UK would be inclined to delete the ‘objectionable’ part from the end of the paragraph, and put it at the top of the section, so as to apply equally to all indigenous whaling operations. Australia also pointed out that recommending adoption of the report, is not the same as accepting the Schedule amendments.

Grenada expressed support for the proposal by the Russian Federation in as much as it is aimed at producing a more uniform code for ASW, thereby qualifying equality and respecting human rights for each of the four ASW operations. However, with regard to the stated aim of providing equality of rights the wording of the proposed Amendment of the paragraph 13 of the Schedule, Grenada wondered why only St. Vincent and the Grenadines of the four ASW operations is required to conduct whaling according to national legislation. Does this mean that the other three ASW schemes are not required to follow national laws? The Chair of the SWG replied that it was his understanding that all nations have to enact national laws, in accordance with the Convention. Grenada then stated that in the interests of uniformity, fairness and human rights either the sentence singling out of St. Vincent and the Grenadines should be deleted, or the requirement to whale according to national legislation should be inserted into the appropriate subsections of paragraph 13 (b)(1),(2) and (3) for each of the four ASW schemes.
Austria raised a question of clarification on the striking of the phrase ‘whose traditional aboriginal subsistence and cultural needs have been recognised.’ Whilst it may be correct to strike that here, where does this sentiment remain anchored in the International Convention for the Regulation of Whaling (ICRW)? Does striking it mean that all future, new applications for aboriginal quotas no longer need to demonstrate that they fulfil these criteria? New Zealand agreed with Austria and felt that Russia had made a compelling case, and that Russia ought not to be subject to the problems outlined here. The issue, however, is whether the current proposed drafting will provide the required results. New Zealand suggested that a possible solution would be to place the phrase on the recognition of need at the top of paragraph 13, as an over-riding principle for all IWC-approved ASW operations. New Zealand stated that the recognition of cultural need was at the heart of the aboriginal whaling, and that the language that it was proposed to delete had been included as a result of the Makah quota request and was needlessly confused by the allocation of a block quota.

The USA responded to the intervention from the UK by stating that the phrase in question is not necessary, and the position of the USA is that the Commission itself recognizes needs when it approves a quota request. The USA noted, in response to the intervention by New Zealand, that the Commission recognised the needs of the Makah Tribe in both 1997 and 2002 when it approved requests for quotas put forth on their behalf.

The Republic of Guinea expressed their support for the Russian Federation’s proposal. Australia explained that it was their understanding that appropriate tests of need should continue be applied. Japan stated that it could support the sentiments contained in the proposal but had some questions on it. The first question was why the proposed 13(a)(4) states ‘any whale accompanied by a calf’. It should, in the Japan’s view, be ‘female’ whale. The second question was how to define the cultural needs. It stated that Japan has long-standing cultural needs for whales dating back to 9,000 BC and that those needs had been satisfied through commercial whaling and are being satisfied to some extent by the byproducts from research whaling activities which is perfectly legal under the ICRW. Australia noted the fine balance of this report, and the need to treat this matter with some delicacy. Australia suggested that the proposals by Japan could upset this balance. Benin expressed their support for the Russian Federation and invited the Committee to review the proposals of the Russian Federation.

The Chair concluded that the Sub-Committee takes note of the report IWC/56/4 and records that the issue had not been fully resolved. She reminded the Sub-Committee that the Russian Federation’s new proposal is a Schedule Amendment and has to be officially proposed in the Plenary to be either adopted by consensus or, if this is not possible, a three quarters majority vote.

The Russian Federation did not agree with the Chair’s conclusion and qualified that the issue was resolved in the Sub-Committee.

The Small Group recommended that the report and the proposal to amend the Schedule be put forward to the Plenary. The Sub-Committee supported this recommendation.

While there may not have been consensus in the Sub-Committee, the Russian Federation pointed out that based on the interventions there seemed to be agreement that there exists a problem of unequal rights among native people and that this problem should be resolved. The Russian Federation noted that since this is an aboriginal subsistence issue it should be resolved by consensus and that no one should provoke voting on an aboriginal question. The UK stated that it had not proposed the additional sentence(s), merely that between now and Plenary, it would need to reflect on whether they were necessary or not.

Australia pointed out that despite these discussions, there is no disagreement with the report. Australia further noted that no alternative text has been put forward for the report itself. Nonetheless, it was still an open question whether members should support a Schedule amendment text.

Japan raised the question why St. Vincent and the Grenadines were not represented on the Small Working Group. Australia explained this was because it was a small volunteer group, and St. Vincent and the Grenadines had not volunteered.

The Chair repeated that the issue will have to be brought forward to the Plenary and recommended that the respective countries meet to discuss some of the proposed modifications before the Plenary.

6. OTHER MATTERS

There were no other matters raised.

The Chair thanked the Sub-committee for its constructive and efficient work.

7. ADOPTION OF REPORT

The Report was adopted at 17:00 on Friday 16 July 2004 by correspondence.

Chair’s Proposals for a Way Forward on the RMS

SUMMARY OF CHAIR’S PROPOSAL FOR AN RMS ‘PACKAGE’

A small group comprising myself [Henrik Fischer], Denmark, Iceland, Japan, the Netherlands, Spain, Sweden, the USA and the Secretariat met twice in Cambridge. Based on the very constructive discussions held, I would like to bring a proposal forward for consideration by the whole Commission on how to take us forward towards an RMS. I believe that an effective RMS is essential both for the wise management and conservation of whale stocks; the present stalemate is not conducive to either.

The proposal included in this document and summarised below is based on the principle of compromise and respect of the various viewpoints held by Commission members within a framework that ensures that the rules and regulations of the Commission are obeyed and seen to be obeyed in an efficient and cost-effective manner. This will involve use of both the Schedule and voluntary measures such Resolutions and codes of conduct (issues requiring Schedule text are shown with an asterisk below).

ELEMENTS OF A PROPOSED RMS ‘PACKAGE’

1. **RMP**: as agreed by the Scientific Committee and endorsed by the Commission.

2. **A phased-in approach to the resumption of commercial whaling**: for an initial period (e.g. 5 years after the lifting of the moratorium), commercial whaling would only be allowed in waters under national jurisdiction.

3. **National inspection and observation scheme**: as proposed by the EDG (generally, observers and inspectors on all boats where practical) with VMS on very small vessels with < 24hr trips and one observer per catcher attached to a factory ship.

4. **Additional catch verification to combat IUU whaling and/or unreported bycatches (NOT to monitor trade)**:
   - national diagnostic DNA registers and market sampling to agreed standards (with outside review) and a procedure to allow checking of samples against the registers,*
   - resolution urging countries to institute national legislation prohibiting the import of whale products from non-IWC countries as well as from IWC countries that are non-whaling; and
   - documentation up to port of entry if importation from IWC member *

5. **Compliance**: Compliance Review Committee with duties as developed by the RMS EDG and agreed by the Commission, and inclusion of Schedule text as proposed in Berlin:

   ‘The Compliance Review Committee reports on infringements and the seriousness of these infringements to the Commission and advises the Commission what actions, if any, to be taken’.

6. **Mechanism to apportion RMS costs among Contracting Governments**: costs for national activities should be borne by relevant national governments, while international costs for securing transparency could be allocated in the context of the overall financial contributions scheme.

7. **Measures for the lifting of Paragraph 10(e)**: modify paragraph 10(e) such that it becomes invalid on a specific day whilst ensuring that any whaling operations are undertaken under the full RMS package (N.B. catches other than zero can only be set for species/areas the Scientific Committee provides advice for under the RMP – currently very few).

8. **Whaling under Special Permit**: recognise that it is a Sovereign right under the Convention but develop a Code of Conduct.

9. **Animal welfare considerations**:
   - Explicit recognition of the issue in the Schedule*

   ‘The hunting of whales shall be undertaken so that the hunted whale does not experience unnecessary suffering and so that people and property are not exposed to danger.’

   - Resolution focusing on improving techniques, voluntary provision of data to regular scientific workshops and possible co-operative research programmes.

This ‘package’ of measures includes, in some way, all but two of the elements that have been discussed recently in the context of the RMS. The exceptions are blanket trade restrictions and sanctuaries. While some form of trade restriction might be appropriate in deterring IUU whaling, I believe that a blanket ban on international trade in whale products would be discriminatory against some countries, against principles of free trade, and outside the competence of IWC. With respect to sanctuaries, each should be reviewed on its own conservation and management merits and would therefore be difficult to build into any RMS ‘package’.

If the Commission reacts favourably to my proposals in Sorrento, recognising that they are of course open to discussion, then I believe it should be possible to have firm proposals ready for adoption at the meeting in 2005. This will however require substantial intersessional activity of both a technical and policy nature.
The 1946 International Convention for the Regulation of Whaling clearly gives IWC a dual mandate, i.e. both the conservation and the management of whaling and whale stocks; these are not mutually exclusive but directly inter-related. It is for the following reasons that I believe that an RMS is essential for the credibility of the IWC.

It is a fact that whales are being caught by some IWC members. While recognising and respecting the different views on whaling held by member nations, from the point of view of conservation and wise management, it is best that whaling is managed using a scientific, consistent and fair approach. The highly migratory behaviour of the large whales makes international co-operation on management essential and the IWC is best placed to fulfil this management role. However, at present our organisation is not generally seen to be working effectively and indeed the present polarised views and actions are, I believe, detrimental to conservation.

The IWC Scientific Committee spent several years developing the RMP - the most advanced method for the conservation and management of a natural resource. This procedure was developed specifically for baleen whales with the aim of maintaining all whale stocks at healthy levels and avoiding the problems identified with past scientific management approaches, particularly by taking scientific uncertainty specifically into account in accordance with the Precautionary Principle. As already mentioned, this approach was agreed by the Commission in 1994 but has not yet been implemented. If implemented today, the RMP would only allow catches of some stocks of minke whales. It would not result, contrary to popular opinion in some countries, in a ‘free for all’ on all stocks of all whale species.

As has been recognised since at least 1992, effective conservation and management measures developed using the RMP must be accompanied by a modern supervision and control system (i.e. the RMS) that ensures that those measures are not only obeyed, but are seen to be obeyed. However, despite some nine years of discussions, agreement on the RMS has still not been reached.

I strongly believe that if the IWC is to fulfil its role in the conservation and management of whale stocks and to avoid past errors, real effort must be made to complete the RMS expeditiously. To do this parties must respect the views of others, and in that light, develop a package of measures that is as broadly acceptable as possible whilst meeting the agreed objectives in the most practical and cost effective manner. Building on the progress made in a number of important areas and working in good faith, it should be possible to rapidly complete this work, thereby ensuring the conservation and management of whale stocks for the future, restoring the credibility of the IWC as an effective organisation and providing an example of how modern natural resource management should be carried out. Failure to put an RMS in place will jeopardise the future of the IWC and serves neither the interests of whale conservation nor management.

CHAIR’S PROPOSALS FOR A WAY FORWARD ON THE RMS

1. INTRODUCTION

Following the adoption of the ‘moratorium’ on commercial whaling in 1982, that came into effect in 1986, the Scientific Committee spent several years developing the Revised Management Procedure (RMP). The RMP is a conservative scientific method for determining safe catch limits that explicitly takes scientific uncertainty into account. The Commission adopted the RMP in 1994, but agreed that it would not be implemented until a Revised Management Scheme (RMS) was completed. In addition to the RMP, the RMS was to include measures to ensure that regulations were obeyed, primarily via an updated and revised national inspection and International Observer Scheme (IOS). Subsequent discussions of what the RMS should contain have included the need for catch verification measures in addition to those within an IOS and the collection of animal welfare data. Additionally, related issues such as limiting catches to waters under national jurisdiction, trade restrictions, scientific permits, sanctuaries and the relationship between completion of the RMS with Schedule paragraph 10(e) have also been discussed – many of these having been introduced as part of the ‘Irish Proposal’ brought forward in 1997 as a way to help overcome the impasse that developed within IWC following adoption of the moratorium.

Many Contracting Governments have spent considerable time and effort over the years on RMS discussions. Despite the fact that progress has been made in some areas, particularly with the inspection and observation scheme, there has been no progress in others and hence no overall agreement. This has led to increasing frustration among Contracting Governments and accusations as to who was responsible for the delay. At last year’s Annual Meeting in Berlin, a private meeting of Commissioners was neither able to make recommendations regarding possible components of an RMS or on how to take the RMS process further.

During the plenary meeting, the Commission did, however, agree to my proposal to convene a small group of my choosing to explore ways and possibilities of taking the RMS process forward. I subsequently invited Denmark, Iceland, Ireland, Japan, the Netherlands, Spain, Sweden and the USA to take part. All except Ireland were able to accept. Ireland had to decline due to pressures of work and the USA to take part. All except Ireland were able to accept. Ireland had to decline due to pressures of work associated with the lead-up to Ireland’s presidency of the EU starting January 2004.

The ‘Chair’s Small Group’ (CSG) met at the Secretariat’s offices in December 2003 and again in March 2004. The discussions were very productive and based on their outcome, I would like to bring some thoughts and
proposals forward for consideration by the whole Commission. I was heartened that the CSG operated in a spirit of openness with a desire to understand the differing points of view on RMS-related issues, without assigning dishonest or underhand motives where there was disagreement. All recognised the current problems within the Commission stemming from a lack of mutual trust and agreed that it was vital that these are overcome if the Commission is to fulfil its mandate. Similarly, there was widespread recognition that all must be willing to compromise to reach an agreement that is broadly acceptable; any compromises must of course still enable the objectives of the RMS (see below) to be met.
