Pygmy killer whales are found in tropical and subtropical waters throughout the world (Ross and Leatherwood 1994). They are poorly known in most parts of their range. Small numbers have been taken directly and incidentally in both the western and eastern Pacific. Most knowledge of this species is from stranded or live-captured specimens. Pryor et al. (1965) stated that pygmy killer whales have been observed several times off the lee shore of Oahu, and that "they seem to be regular residents of the Hawaiian area." More recently, pygmy killer whales have also been seen off the islands of Niihau and Lanai (McSweeney et al. 2009). Summer/fall shipboard surveys of the waters within the U.S. Exclusive Economic Zone (EEZ) of the Hawaiian Islands, resulted in three sightings of pygmy killer whales in 2002 and five in 2010 (Figure 1; Barlow 2006, Bradford et al. 2013).

Several recent studies suggest that while pygmy killer whales are relatively rare in Hawaiian waters, a small resident population occurs in the main Hawaiian Islands (MHI). A 22-year study off the Hawaii Island indicates that pygmy killer whales occur there year-round and in stable social groups. Over 80% of pygmy killer whales seen off Hawaii Island have been resighted and 92% have been linked into a single social network (McSweeney et al. 2009). Movements have also been documented between Hawaii Island and Oahu and between Oahu and Lanai (Baird et al. 2011a). Satellite telemetry data from four tagged pygmy killer whales suggest this resident group remains within 20km of shore (Baird et al. 2011a,b). Encounter rates for pygmy killer whales during near shore surveys are rare, representing less only 1.7% of all cetacean encounters to since 2000 (Baird et al. 2013). Division of this population into a separate island-associated stock may be warranted in the future.

For the Marine Mammal Protection Act (MMPA) stock assessment reports, there is a single Pacific management stock including animals found both within the Hawaiian Islands EEZ and in adjacent high seas waters. Because data on abundance, distribution, and human-caused impacts are largely lacking for high seas waters, the status of this stock is evaluated based on data from U.S. EEZ waters of the Hawaiian Islands (NMFS 2005).

POPULATION SIZE

A population estimate is available from the eastern tropical Pacific (Wade and Gerrodette 1993), but it is not known whether any of these animals are part of the same population that occurs around the Hawaiian Islands. A 2002 shipboard line-transect survey of the entire Hawaiian Islands EEZ resulted in an abundance estimate of 956 (CV=0.83) pygmy killer whales (Barlow 2006). The recent 2010 shipboard line-transect survey of the Hawaiian Islands EEZ resulted in an abundance estimate of 3,433 (CV=0.52) pygmy killer whales (Bradford et al. 2013). This is currently the best available abundance estimate for this stock.

Minimum Population Estimate

The minimum population size is calculated as the lower 20th percentile of the log-normal distribution (Barlow et al. 1995) of the 2010 abundance estimate or 2,274 pygmy killer whales within the Hawaiian EEZ.

Current Population Trend
The broad and overlapping confidence intervals around the 2002 and 2010 estimates preclude assessment of pygmy killer whales trends with the available data.

**CURRENT AND MAXIMUM NET PRODUCTIVITY RATES**
No data are available on current or maximum net productivity rate.

**POTENTIAL BIOLOGICAL REMOVAL**
The potential biological removal (PBR) level for pygmy killer whales stock is calculated as the minimum population estimate for the U.S. EEZ of the Hawaiian Islands (2,274) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.50 (for a stock of unknown status with no known fishery mortality or serious injury within the Hawaiian Islands EEZ; Wade and Angliss 1997), resulting in a PBR of 23 pygmy killer whales per year.

**HUMAN-CAUSED MORTALITY AND SERIOUS INJURY**

**New Serious Injury Guidelines**
NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an “injury that is more likely than not to result in mortality”. Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

**Fishery Information**
Information on fishery-related mortality and serious injury of cetaceans in Hawaiian waters is limited, but the gear types used in Hawaii fisheries are responsible for marine mammal mortality and serious injury in other fisheries throughout U.S. waters. Entanglement in gillnets and hooking or entanglement in various hook and line fisheries have been reported for small cetaceans in Hawaii (Nitta & Henderson, 1993). A stranded pygmy killer whale from Oahu showed signs of hooking injury (Schofield 2007) and mouthline injuries have also been noted in some individuals (Baird unpublished data), though it is not known if these interactions result in serious injury or mortality. No estimates of human-caused mortality or serious injury are currently available for nearshore hook and line or gillnet fisheries because these fisheries are not observed or monitored for protected species bycatch.

There are currently two distinct longline fisheries based in Hawaii: a deep-set longline (DSLL) fishery that targets primarily tunas, and a shallow-set longline fishery (SSLL) that targets swordfish. Both fisheries operate within U.S. waters and on the high seas. Between 2007 and 2011, no pygmy killer whales were observed hooked or entangled in the SSLL fishery (100% observer coverage) or the DSLL fishery (20-22% observer coverage) (Bradford & Forney 2013, McCracken 2013). However, eight unidentified cetaceans were taken in the DSLL fishery, and two unidentified cetaceans were taken in the SSLL fishery, some of which may have been pygmy killer whales.

**Other Mortality**
In recent years, there has been increasing concern that loud underwater sounds, such as active sonar and seismic operations, may be harmful to beaked whales (Cox et al. 2006) and other cetaceans, including melon-headed whales (Southall et al. 2006, 2013, Brownell et al. 2009) and pygmy killer whales (Wang and Yang 2006). The use of active sonar from military vessels has been implicated in mass strandings of beaked whales, and recent mass-stranding reports suggest some delphinids may be impacted as well. Two mass-strandings of pygmy killer whales occurred in the coastal areas of southwest Taiwan in February 2005, possibly associated with offshore naval training exercises (Wang and Yang 2006). A necropsy of one of the pygmy killer whales revealed hemorrhaging in the cranial tissues of the animal. Additional research on the behavioral response of delphinids in the presence of sonar transmissions is needed in order to understand the level of impact. No estimates of potential mortality or serious injury are available for U.S. waters.

**STATUS OF STOCK**
The Hawaii stock of pygmy killer whales is not considered strategic under the 1994 amendments to the MMPA. The status of pygmy killer whales in Hawaiian waters relative to OSP is unknown, and there are insufficient data to evaluate trends in abundance. Pygmy killer whales are not listed as “threatened” or “endangered” under the Endangered Species Act (1973), nor designated as “depleted” under the MMPA. Given the absence of
recent recorded fishery-related mortality or serious injuries, the total fishery mortality and serious injury can be considered to be insignificant and approaching zero.

REFERENCES

FALSE KILLER WHALE (Pseudorca crassidens):
Hawaiian Islands Stock Complex – Main Hawaiian Islands Insular, Northwestern Hawaiian Islands, and Hawaii Pelagic Stocks

STOCK DEFINITION AND GEOGRAPHIC RANGE

False killer whales are found worldwide in tropical and warm-temperate waters (Stacey et al. 1994). In the North Pacific, this species is well known from southern Japan, Hawaii, and the eastern tropical Pacific. False killer whales were encountered during two shipboard line-transect surveys of the U.S. Exclusive Economic Zone (EEZ) around the Hawaiian Islands in 2002 and 2010 (Figure 1; Barlow 2006, Bradford et al. 2014) and focused studies near the main and Northwestern Hawaiian Islands indicate that false killer whales occur in near shore waters throughout the Hawaiian archipelago (Baird et al. 2008, 2013). This species also occurs in U.S. EEZ waters around Palmyra and Johnston Atolls (e.g., Barlow et al. 2008, Bradford & Forney 2013) and American Samoa (Johnston et al. 2008, Oleson 2009).

Genetic, photo-identification, and telemetry studies indicate there are three demographically-independent populations of false killer whales in Hawaiian waters. Genetic analyses indicate restricted gene flow between false killer whales sampled near the main Hawaiian Islands (MHI), the Northwestern Hawaiian Islands (NWHI), and in pelagic waters of the Eastern (ENP) and Central North Pacific (CNP) (Chivers et al. 2010; Martien et al. 2011, 2014). Martien et al. (2014) analyzed mitochondrial DNA (mtDNA) control region sequences and genotypes from 16 nuclear DNA (nuDNA) microsatellite loci from 206 individuals from the MHI, NWHI, and offshore waters of the CNP and ENP and showed highly significant differentiation between populations confirming limited gene flow in both sexes. Their analysis using mtDNA reveals strong phylogeographic patterns consistent with local evolution of haplotypes unique to false killer whales occurring nearshore within the Hawaiian Archipelago and their assessment of nuDNA suggests that NWHI false killer whales are at least as differentiated from MHI animals as they are from offshore animals. Photographic-identification and social network analyses of individuals seen near the MHI indicate a tight social network with no connections to false killer whales seen near the NWHI or in offshore waters, and assessment of satellite telemetry collected from 27 tagged MHI false killer whales shows movements restricted to the MHI (Baird et al. 2010, 2012). Further evaluation of photographic and genetic data from individuals seen near the MHI suggests the occurrence of three separate social clusters (Baird et al. 2012, Martien et al. 2011), where mating occurs primarily, though not exclusively within clusters (Martien et al. 2011). Additional details on data and analyses supporting the separation of false killer whales in Hawaiian waters into three separate stocks are summarized within Oleson et al. (2010, 2012).

Figure 1. False killer whale on-effort sighting locations during standardized shipboard surveys of the Hawaiian Islands U.S. EEZ (2002, gray diamond, Barlow 2006; 2010, black triangles, Bradford et al. 2014, pelagic waters of the central Pacific south of the Hawaiian Islands (2005, gray crosses, Barlow and Rankin 2007) and the Johnston Atoll EEZ. Outer dashed lines represent approximate boundary of U.S. EEZs; light shaded gray area is the main Hawaiian Islands insular false killer whale stock area, including overlap zone between MHI insular and pelagic false killer whale stocks; dark shaded gray area is the Northwestern Hawaiian Islands stock area, which overlaps the pelagic false killer whale stock area and part of the MHI insular false killer whale stock area. Detail of stock boundaries shown in Figure 2.
Fishery observers have collected tissue samples for genetic analysis from cetaceans incidentally caught in the Hawaii-based longline fishery since 2003. Between 2003 and 2010, eight false killer whale samples, four collected outside the Hawaiian EEZ and four collected within the EEZ but more than 100 nautical miles (185km) from the main Hawaiian Islands were determined to have Pacific pelagic haplotypes (Chivers et al. 2010). At the broadest scale, significant differences in both mtDNA and nDNA are evident between pelagic false killer whales in the ENP and CNP strata (Chivers et al. 2010), although the sample distribution to the east and west of Hawaii is insufficient to determine whether the sampled strata represent one or more stocks, and where pelagic stock boundaries would be drawn.

The stock range and boundaries of the three Hawaiian stocks of false killer whales were recently reevaluated, given significant new information on the occurrence and movements of each stock and are reviewed in detail in Bradford et al. (2015) and shown in Figure 2. The stocks have partially overlapping ranges. MHI insular false killer whales have been satellite tracked as far as 115 km from the main Hawaiian Islands, while pelagic stock animals have been tracked to within 11 km of the main Hawaiian Islands and throughout the NWHI. NWHI false killer whales have been seen as far as 93 km from the NWHI and near-shore around Kauai and Oahu (Baird et al. 2012, Bradford et al. 2015). Stock boundary descriptions are complex, but can be summarized as follows. The MHI stock boundary is derived from a Minimum Convex Polygon (MCP) of a 72-km radius extending around the main Hawaiian Islands, with the offshore extent of the radii connected on the leeward sides of Hawaii Island and Niihau to encompass the offshore movements of MHI individuals within that region. The NWHI stock boundary is defined by a 93-km radius around the NWHI, or the boundary of the Papahānaumokuākea Marine National Monument, with this radial boundary extended to the southeast to encompass Kauai and Niihau. The NWHI boundary is latitudinally expanded at the eastern end of the NWHI to encompass animal movements observed outside of the 93-km radius (see Figure 2). The pelagic stock has no outer boundary. Throughout the MHI the pelagic stock inner boundary is placed at 11 km from shore. There is no inner boundary within the NWHI. The construction of these stock boundaries results in a number of stock overlap zones. The waters outside of 11km from shore from Oahu to Hawaii Island out to the MHI insular stock boundary are an overlap zone between the MHI insular and pelagic stocks. The entirety of the NWHI stock range, with the exception of the area within 11km around
Kauai and Niihau is an overlap zone between NWHI and pelagic false killer whales. All three stocks overlap between 11 km from shore around Kauai and Niihau out to the MHI insular stock boundary between Kauai and Nihoa and to the NWHI stock boundary between Kauai and Oahu (see Figure 2).

The pelagic stock includes animals found within the Hawaiian Islands EEZ and in adjacent international waters; however, because data on false killer whale abundance, distribution, and human-caused impacts are largely lacking for international waters, the status of this stock is evaluated based on data from U.S. EEZ waters of the Hawaiian Islands (NMFS 2005). The Palmyra Atoll stock of false killer whales is still considered to be a separate stock because comparisons amongst false killer whales sampled at Palmyra Atoll and those sampled from the MHI insular stock and the pelagic ENP reveal restricted gene flow, although the sample size remains too low for robust comparisons (Chivers et al. 2010). NMFS will obtain and analyze additional samples for genetic studies of Hawaii pelagic and Palmyra stock structure, and will evaluate new information on stock ranges as it becomes available.

For the Marine Mammal Protection Act (MMPA) stock assessment reports, there are currently five Pacific Islands Region management stocks: 1) the Main Hawaiian Islands insular stock, which includes animals inhabiting waters within a modified 72km radius around the main Hawaiian Islands, 2) the Northwestern Hawaiian Islands stock, which includes animals inhabiting waters within the 93-km radius of the Papahānaumokuākea Marine National Monument and around Kauai, with a slight latitudinal expansion of this area at the eastern end of the range, 3) the Hawaii pelagic stock, which includes false killer whales inhabiting waters greater than 11 km from the main Hawaiian Islands, including adjacent high seas waters, 4) the Palmyra Atoll stock, which includes animals found within the U.S. EEZ of Palmyra Atoll, and 5) the American Samoa stock, which includes animals found within the U.S. EEZ of American Samoa. Estimates of abundance, potential biological removal, and status determinations for the first three stocks are presented below; the Palmyra Atoll and American Samoa stocks are covered in separate reports.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fishery Information

Interactions with false killer whales, including depredation of catch of a variety of pelagic fishes, have been identified in logbooks and NMFS observer records from Hawaii pelagic longline fishing trips (Nitta and Henderson 1993, Oleson et al. 2010, PIRO 2015). False killer whales have been observed feeding on mahi mahi, Coryphaena hippurus, and yellowfin tuna, Thunnus albacares (Baird 2009), and they have been reported to take large fish from the trolling lines of commercial and recreational fishermen (Shallenberger 1981). There are anecdotal reports of marine mammal interactions in the commercial Hawaii shortline fishery which sets gear at Cross Seamount and possibly around the main Hawaiian Islands. The commercial shortline fishery is licensed to sell their catch through the State of Hawaii Commercial Marine License program, and until recently, no reporting systems existed to document marine mammal interactions. Baird and Gorgone (2005) documented high rates of dorsal fin disfigurements consistent with injuries from unidentified fishing line for false killer whales belonging to the MHI insular stock. A recent report included evaluation of additional individuals with dorsal fin injuries and suggested that the rate of interaction between false killer whales and various forms of hook and line gear may vary by population and social cluster, with the MHI insular stock showing the highest rate of dorsal fin disfigurements (Baird et al. 2014). The commercial or recreational fishery or fisheries responsible for these injuries is unknown. Examination of a stranded MHI insular false killer whale in October 2013 revealed that this individual had five fishing hooks and fishing line in its stomach (NMFS PIR Marine Mammal Response Network). Although the fishing gear is not believed to have caused the death of the whale, the finding confirms that MHI insular false killer whales are consuming previously hooked fish or are interacting with hook and line fisheries in the MHI. Many of the hooks within the whale’s stomach were not consistent with those currently allowed for use within the commercial longline fisheries and could have come from a variety of near-shore fisheries. No estimates of human-caused mortality or serious injury are currently available for near-shore hook and line or other fisheries because these fisheries are not observed or monitored for protected species bycatch.
Because of high rates of false killer whale mortality and serious injury in Hawaii-based longline fisheries, a Take Reduction Team was established in January 2010 (75 FR 2853, 19 January, 2010). The Team was charged with developing recommendations to reduce incidental mortality and serious injury of the Hawaii pelagic, MHI insular and Palmyra stocks of false killer whales in Hawaii-based longline fisheries. The Team submitted a draft Take Reduction Plan (TRP) to NMFS (http://www.nmfs.noaa.gov/pr/pdfs/interactions/fkwtrp_draft.pdf), and NMFS published a final TRP based on the Team’s recommendations (77 FR 71 260, 29 November, 2012). Take reduction measures include gear requirements, time-area closures, and measures to improve captain and crew response to hooked and entangled false killer whales. The seasonal contraction of the Longline Exclusion Zone (LLEZ) around the MHI was also eliminated. The TRP became effective December 31, 2012, with gear requirements effective February 27, 2013. These measures were not in effect during 2008-2012, the majority of the period for which bycatch was estimated in this report. Adjustments to bycatch estimation methods are implemented for 2013 to account for changes in fishing gear and captain training intended to reduce the false killer whale serious injury rate (see below, McCracken 2015).

There are two distinct longline fisheries based in Hawaii: a deep-set longline (DSLL) fishery that targets primarily tunas, and a shallow-set longline fishery (SSLL) that targets swordfish. Both fisheries operate within U.S. waters and on the high seas, but are prohibited from operating within the Papahānaumokuākea Marine National Monument and within the LLEZ around the main Hawaiian Islands. Stock Assessment Reports generally describe fishery interaction details for the most recent five years, and as such, only years 2010 through 2014 are described here. Years 2008 and 2009 are also included in Table 1 to allow for computation of a 5-yr annual bycatch estimate for the period prior to the implementation of the TRP. Between 2010 and 2014, three false killer whales were observed hooked or entangled in the SSLL fishery (100% observer coverage) within the U.S. EEZ of the Hawaiian Islands, and 25 false killer whales were observed taken in the DSLL fishery (20-22% observer coverage) within Hawaiian waters or adjacent high-seas waters (excluding Palmyra Atoll EEZ waters) (Bradford & Forney 2016). The severity of injuries resulting from interactions with longline gear is determined based on an evaluation of the observer’s description of each interaction and following the most recently developed criteria for assessing serious injury in marine mammals (NMFS 2012). Of the three animals taken in the SSLL fishery, two were considered not seriously injured and one could not be determined based on the information provided by the observer. In the DSLL fishery, 12 false killer whales were observed taken in the DSLL fishery (20-22% observer coverage) within Hawaiian waters or adjacent high-seas waters (excluding Palmyra Atoll EEZ waters) (Bradford & Forney 2016). The severity of injuries resulting from interactions with longline gear is determined based on an evaluation of the observer’s description of each interaction and following the most recently developed criteria for assessing serious injury in marine mammals (NMFS 2012). Of the three animals taken in the SSLL fishery, two were considered not seriously injured and one could not be determined based on the information provided by the observer. In the DSLL fishery, 12 false killer whales were observed taken in the Hawaiian EEZ. Two of those takes occurred in 2012 within the pelagic-NWHI overlap zone north of Kauai before this area was closed to longline fishing. Both animals were considered to be seriously injured. Of the remaining 10 interactions within the Hawaiian EEZ, all were within the range of the pelagic stock, with six considered seriously injured, one not considered seriously injured, and three could not be determined based on the information provided by the observer. Outside of the Hawaiian EEZ, ten were considered seriously injured, and three were considered not seriously injured. Five additional unidentified “blackfish” (unidentified cetaceans known to be either false killer whales or short-finned pilot whales) were also taken, one within the SSLL fishery and four in the DSLL fishery. The single SSL interaction occurred outside the Hawaiian EEZ and the animal was considered seriously injured. Of the four DSLL interactions, two occurred inside Figure 3. Locations of observed false killer whale takes (black symbols) and possible takes (blackfish) of this species (open symbols) in the Hawaii-based longline fisheries, 2009-2013. Takes occurring prior to the implementation of Take-Reduction Plan (2010-2012) regulations are shown as diamonds, and those since the TRP regulations (2013-2014) are shown as stars. Some take locations overlap. Solid gray lines represent the U.S. EEZ; the dotted line is the MHI insular stock area; the dashed line is the NWHI stock area; both MHI and NWHI stocks overlap with the pelagic stock. The gray shaded area represents the longline exclusion zone, implemented year-round since December 31, 2012, and Papahānaumokuākea Marine National Monument. Both areas are currently closed to longline fishing.
the Hawaii EEZ, with both considered seriously injured, and two occurred outside the Hawaii EEZ, with one considered seriously injured and one considered not seriously injured.

Table 1. Summary of available information on incidental mortality and serious injury (MSI) of false killer whales and unidentified blackfish (false killer whale or short-finned pilot whale) in commercial longline fisheries, by stock and EEZ area, as applicable (McCracken 2016). 5-yr mean annual takes are presented for 2008-2012, prior to the implementation of the TRP, for 2013-2014 due to changes in fishing gear under the TRP intended to reduce serious injury rate, and for 2010-2014, ignoring any change in mortality rate. Information on all observed takes (T) and combined mortality & serious injury is included. Unidentified blackfish are pro-rated as either false killer whales or short-finned pilot whales according to their distance from shore (McCracken 2010). CVs are estimated based on the combined variances of annual false killer whale and blackfish take estimates and the relative density estimates for each stock within the overlap zones. Values of ‘0’ presented with no further precision are based on observation at 100% coverage and are not estimates.

</table>
The injury status of estimated takes is prorated to serious versus non-serious using the historic rate of serious injury within the observed takes. For the period 2008 to 2012, the rate of serious injury for false killer whales was 93% (McCracken 2014). Because the implementation of weak hooks under the TRP was intended to reduce the serious injury rate, these historic averages were not used for 2013-2014. The allocation of estimated serious versus non-serious injuries in 2013-2014 takes was based on the proportion of serious versus non-serious injuries of observed takes in those years (McCracken 2016). The proration of serious injury status will be updated as additional data become available to better estimate serious versus non-serious injury proportion under TRP measures.

Takes of false killer whales of unknown stock within the stock overlap zones must be prorated to MHI insular, pelagic, or NWHI stocks. No genetic samples are available to establish stock identity for the two takes inside the NWHI-pelagic overlap zone north of Kauai, but both stocks are considered at risk of interacting with longline gear. The pelagic stock is known to interact with longline fisheries in waters offshore of the overlap zone, based on two genetic samples obtained by fishery observers (Chivers et al. 2010). MHI insular and NWHI false killer whales have been documented via telemetry to move far enough offshore to reach longline fishing areas (Bradford et al. 2015), and animals from the MHI insular stock have a high rate of dorsal fin disfigurements consistent with injuries from unidentified fishing line (Baird and Gorgone 2005, Baird et al. 2014). Annual bycatch estimates are prorated to stock using the following process. Takes of unidentified blackfish are prorated to false killer whale and short-finned pilot whale based on distance from shore (McCracken 2010). The distance-from-shore model was chosen following consultation with the Pacific Scientific Review Group, based on the model’s logic and performance relative to a number of other models with similar output (McCracken 2010). Following proration of unidentified blackfish takes to species, Hawaii EEZ and high-seas estimates of false killer whale take are calculated by summing the annual false killer whale take and the annual blackfish take prorated as false killer whale within each region (McCracken 2016). For the deep-set fishery within the Hawaii EEZ, annual takes are apportioned to each stock overlap zone and the pelagic-only stock area based on relative annual fishing effort in each zone. The total annual EEZ bycatch estimate is multiplied by the proportion of total fishing effort (by set) within each zone to estimate the bycatch within that zone. Because the shallow-set longline fishery is fully observed, takes are assigned to the zone in which they were observed and there is no further apportionment based on fishing effort. For each longline fishery, the zonal bycatch estimates are then multiplied by the relative density of each stock in the respective zone to prorate bycatch to stock. For the deep-set fishery, if bycatch was observed within a specific overlap zone, the observed takes were assigned to that zone and the remaining estimated bycatch was assigned among zones and stocks according to the described process. Following proration by fishing effort and stock density within each zone, stock-specific bycatch estimates are summed across zones to yield the total stock-specific annual bycatch by fishery. Uncertainty in stock-specific bycatch estimates combines variances of total annual false killer whale bycatch and the fractional variance of false killer whale density according to which stock is being estimated. Enumeration of fishing effort within stock overlap zones is assumed to be known without error.

Based on this approach, estimates of annual mortality and serious injury of false killer whales, by stock and EEZ area, are shown in Table 1. Three mortality and serious injury estimates are provided (Table 1): a 5-yr average for the period prior to TRP-implementation (2008-2012), a 2-yr average for the period following TRP implementation (2013-2014), and a 5-yr average for the most recent 5 years assuming no significant change in mortality rate within the fishery (2010-2014). The bycatch rate (per 1000 sets) and of the proportion of non-serious injuries prior to and following TRP implementation were examined as part of the FKW TRT monitoring strategy. Proration of false killer whale takes within the overlap zones and of unidentified blackfish takes introduces unquantified uncertainty into the bycatch estimates, but until methods of determining stock identity for animals observed taken within the overlap zone are available, and all animals taken can be identified to species (e.g., photos, tissue samples), these proration approaches are needed ensure that potential impacts to all stocks are assessed in the overlap zones.

* Two observed takes occurred within the NWHI-pelagic overlap zone and are therefore allocated for proration between NWHI and pelagic stocks. Remaining estimated takes are prorated among stocks as described for each overlap zone.
† Injury status could not be determined based on information collected by the observer. Injury status is prorated (see text).
POPULATION SIZE

A Status Review for the MHI insular stock in 2010 (Oleson et al. 2010) used recent, unpublished estimates of abundance for two time periods, 2000-2004 and 2006-2009 in a Population Viability Analysis (PVA). These estimates were based on open population models, for the two time periods. The abundance estimate for the 2000-2004 period is 162 (CV=0.23) animals. Two separate estimates for 2006-2009 were presented in the Status Review; 151 (CV=0.20) and 170 (CV=0.21), depending on whether animals photographed near Kauai are included in the estimate. The animals seen near Kauai included in the higher estimate have now been associated with the NWHI stock (Baird et al. 2013), such that the best estimate of population size for the MHI insular stock is the smaller estimate of 151 animals. Half the data used in the derivation of this population estimate are more than 8 years old and are now considered outdated under NMFS Guidelines for Assessing Marine Mammal Stocks (NMFS 2005).

Minimum Population Estimate

The minimum population estimate for the MHI insular stock of false killer whales is the number of distinctive individuals identified during 2011 to 2014 photo-identification studies, or 92 false killer whales (Baird et al. 2015). A portion of the data used in 2006-2009 mark-recapture estimates (Oleson et al. 2010) of abundance are considered outdated, and therefore are not suitable for deriving a minimum abundance estimate.

Current Population Trend

Reeves et al. (2009) suggested that the MHI insular stock of false killer whales may have declined during the last two decades, based on sightings data collected near Hawaii using various methods between 1989 and 2007. Baird (2009) reviewed trends in sighting rates of false killer whales from aerial surveys conducted using consistent methodology around the main Hawaiian Islands between 1994 and 2003 (Mobley et al. 2000). Sighting rates during these surveys showed a statistically significant decline that could not be attributed to any weather or methodological changes. The Status Review of MHI insular false killer whales (Oleson et al. 2010) presented a quantitative analysis of extinction risk using a Population Viability Analysis (PVA). The modeling exercise was conducted to evaluate the probability of actual or near extinction, defined as a population reduced to fewer than 20 animals, given measured, estimated, or inferred information on population size and trends, and varying impacts of catastrophes, environmental stochasticity and Allee effects. All plausible models indicated the probability of decline to fewer than 20 animals within 75 years was greater than 20%. Though causation was not evaluated, all plausible models indicated the population has declined since 1989, at an average rate of -9% per year (95% probability intervals -5% to -12.5%), though some two-stage models suggested a lower rate of decline over the past decade (Oleson et al. 2010).

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

No data are available on current or maximum net productivity rate for this species in Hawaiian waters.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for the MHI insular false killer whale stock is calculated as the minimum population estimate (92) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.1 (for a stock listed as Endangered under the ESA and with minimum population size less than 1500 individuals; Taylor et al. 2000) resulting in a PBR of 0.18 false killer whales per year, or approximately one animal every 5.5 years.

STATUS OF STOCK

The status of MHI insular stock false killer whales relative to OSP is unknown, although this stock appears to have declined during the past two decades (Oleson et al. 2010, Reeves et al. 2009; Baird 2009). MHI insular false killer whales are listed as “endangered” under the Endangered Species Act (1973) (77 FR 70915, 28 November, 2012). The Status Review report produced by the Biological Review Team (BRT) (Oleson et al. 2010) found that Hawaiian insular false killer whales are a Distinct Population Segment (DPS) of the global false killer whale taxon. Of the 29 identified threats to the population, the BRT considered the effects of small population size, including inbreeding depression and Allee effects, exposure to environmental contaminants (Ylitalo et al. 2009), competition for food with commercial fisheries (Boggs & Ito, 1993, Reeves et al. 2009), and hooking, entanglement, or intentional harm by fishermen to be the most substantial threats to the population. The BRT concluded that Main Hawaiian Islands insular false killer whales were at high risk of extinction. Following additional information on the occurrence of another island-associated stock in the NWHI, the BRT reevaluated the DPS decision and concluded that the population still met the standard to be listed as a DPS (Oleson et al. 2012). Because MHI insular false killer whales are formally listed as "endangered" under the ESA, they are automatically considered as a "depleted" and
"strategic" stock under the MMPA. For the 5-yr period prior to the implementation of the TRP, the average estimated mortality and serious injury to MHI insular stock false killer whales (0.21 animals per year) exceeded the PBR (0.18 animals per year). For years 2013-2014, the estimate of mortality and serious injury (0) is below the PBR (0.18), and ignoring any change in mortality rates is assumed under the TRP, the mortality and serious injury to MHI insular false killer whales for the most recent 5-yr period, 2010-2014 (0.1) is less than PBR (0.18). The total fishery mortality and serious injury for the MHI insular stock of false killer whales cannot be considered to be insignificant and approaching zero, as it is greater than 10% of PBR. Following implementation of the TRP a significant portion of the recognized stock range is inside of the expanded year-round LLEZ around the MHI, providing significant protection for this stock from longline fishing. Prior to that time, a seasonal contraction to the LLEZ potentially exposed a significant portion of the offshore range of the stock to longline fishing. Additional monitoring of bycatch rates for this stock will be required before assessing whether the expansion of the LLEZ and other take-reduction measures have reduced fishery takes below PBR. Effects of other threats have yet to be assessed, e.g., nearshore hook and line fishing and environmental contamination. There is significant geographic overlap between various nearshore fisheries and evidence of interactions with hook-and-line gear (e.g. Baird et al. 2015), such that these fisheries may pose a threat to the stock. Recent research has indicated that concentrations of polychlorinated biphenyls (PCBs) exceeded proposed threshold levels for health effects in 84% of sampled MHI insular false killer whales (Foltz et al. 2014).

HAWAII PELAGIC STOCK POPULATION SIZE

Analyses of a 2002 shipboard line-transect survey of the Hawaiian Islands EEZ resulted in an abundance estimate of 484 (CV = 0.93) false killer whales within the Hawaiian Islands EEZ outside of about 75 nmi of the main Hawaiian Islands (Barlow & Rankin 2007). A new abundance survey was completed in 2010 within the Hawaiian Islands EEZ and resulted in five on-effort detections of false killer whales attributed to the Hawaii pelagic stock. Analysis of the 2010 HICEAS shipboard line-transect data resulted in an abundance estimate of 1,540 (CV=0.66) false killer whales outside of 11 km of the main Hawaiian Islands (Bradford et al. 2014, 2015). Bradford et al. (2014) reported that most (64%) false killer whale groups seen during the 2010 HICEAS survey were moving toward the vessel when detected by the visual observers. Together with an increase in sightings close to the trackline, these behavioral data suggest vessel attraction is likely occurring and may be significant. Although Bradford et al. (2014, 2015) employed a half-normal model to minimize the effect of vessel attraction, the abundance estimate may still be positively biased as a result of vessel attraction because groups originally outside of the survey strip, and therefore unavailable for observation by the visual survey team, may have moved within the survey strip and been sighted. There is some suggestion of such attractive movement within the acoustic data and visual data (Bradford et al. 2014), though the extent of any bias created by this movement is unknown. A 2005 survey (Barlow and Rankin 2007) resulted in a separate abundance estimate of 906 (CV=0.68) false killer whales in international waters south of the Hawaiian Islands EEZ and within the EEZ of Johnston Atoll, but it is unknown how many of these animals might belong to the Hawaii pelagic stock.

Minimum Population Estimate

The minimum population size is calculated as the lower 20th percentile of the log-normal distribution (Barlow et al. 1995) of the 2010 abundance estimate for the Hawaiian Islands EEZ outside of 11 km from the main Hawaiian Islands (Bradford et al. 2014, 2015) or 928 false killer whales. The minimum abundance estimate has not been corrected for vessel attraction and may be positively-biased.

Current Population Trend

No data are available on current population trend. It is incorrect to conclude that the increase in the abundance estimate from 2002 to 2010 represents an increase in population size, given changes to the survey design in 2010 and the analytical framework specifically intended to better enumerate and account for overall group size (Bradford et al. 2014), the low precision of each estimate, and a lack of understanding of the oceanographic processes that may drive the distribution of this stock over time. Further, estimation of the detection function for the 2002 and 2010 estimates relied on shared data, such that the resulting abundance estimates are not statistically independent and cannot be compared in standard statistical tests. Only a portion of the overall range of this population has been surveyed, precluding evaluation of abundance of the entire stock.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

No data are available on current or maximum net productivity rate for this species in Hawaiian waters.
POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for the Hawaii pelagic stock of false killer whales is calculated as the minimum population estimate for the U.S. EEZ of the Hawaiian Islands (928) times (Bradford et al. 2014, 2015). This is the best available abundance estimate for false killer whales within the Northwestern Hawaiian Islands. Bradford et al. (2014) reported that most (64%) false killer whale groups seen during the 2010 HICEAS survey were seen moving toward the vessel when detected by the visual observers. Together with an increase in sightings close to the trackline, these behavioral data suggest vessel attraction is likely occurring and may be significant. Bradford et al. (2014, 2015) employed a half-normal model to minimize the effect of vessel attraction, because groups originally outside of the survey strip, and therefore unavailable for observation by the visual survey team, may have moved within the survey strip and been sighted. There is some suggestion of such attractive movement within the acoustic and visual data (Bradford et al. 2014) though the extent of any bias created by this movement is unknown.

Minimum Population Estimate

The minimum population size is calculated as the lower 20th percentile of the log-normal distribution (Barlow et al. 1995) of the 2010 abundance estimate for the Northwestern Hawaiian Islands stock (Bradford et al. 2015) or 290 false killer whales. This estimate has not been corrected for vessel attraction and may be positively-
Current Population Trend

No data are available on current population trend because there is only one estimate of abundance from 2010.

Current and Maximum Net Productivity Rates

No data are available on current or maximum net productivity rate for this species in the waters surrounding the Northwestern Hawaiian Islands.

Potential Biological Removal

The potential biological removal (PBR) level for the Northwestern Hawaiian Islands false killer whale stock is calculated as the minimum population estimate (290) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.40 (for a stock of unknown status, with a Hawaiian Islands EEZ mortality and serious injury rate CV > 0.8; Wade and Angliss 1997), resulting in a PBR of 2.3 false killer whales per year.

Status of Stock

The status of false killer whales in Northwestern Hawaiian Islands waters relative to OSP is unknown, and there are insufficient data to evaluate trends in abundance. Concentrations of polychlorinated biphenyls (PCBs) exceeded proposed threshold levels for health effects in 84% of sampled MHI insular false killer whales (Foltz et al 2014), and elevated concentrations are also expected in NWHI false killer whales given the amplification of these contaminants through the food chain and likely similarity in false killer whale diet across the region. Biomass of some false killer whale prey species may have declined around the Northwestern Hawaiian Islands (Oleson et al. 2010, Boggs & Ito 1993, Reeves et al. 2009), though waters within the Papahanaumokuakea Marine National Monument have been closed to commercial longlining since 1991 and to other fishing since 2006. This stock is not listed as “threatened” or “endangered” under the Endangered Species Act (1973), nor as “depleted” under the MMPA. The rate of mortality and serious injury to NWHI false killer whales, (0.6 for 2008-2012, 0 for 2013-2014, 0.4 for 2010-2014) is less than the PBR (2.3 animals per year), but is not approaching zero mortality and serious injury rate because it exceeds 10% of PBR (NMFS 2004). A significant portion of the recognized stock range is within the Marine National Monument and the expanded LLEZ, such that this stock is likely not exposed to high levels of fishing effort because commercial and recreational fishing is prohibited within Monument waters and longlines are excluded from the majority of the stock range. Additional monitoring of bycatch rates for this stock will be required before assessing whether TRP measures have reduced fishery takes to below 10% of PBR.

FALSE KILLER WHALE (*Pseudorca crassidens*):
Palmyra Atoll Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

False killer whales are found worldwide mainly in tropical and warm-temperate waters (Stacey et al. 1994). In the North Pacific, this species is known from southern Japan, Hawaii, and the eastern tropical Pacific. Four on-effort sightings of false killer whales were recorded during a 2005 shipboard survey of the U.S. Exclusive Economic Zone (EEZ) of Palmyra Atoll (Figure 1; Barlow & Rankin 2007). This species also occurs in U.S. EEZ waters around Hawaii (Barlow 2006, Bradford et al. 2012), Johnston Atoll (NMFS/PIR/PSD unpublished data), and American Samoa (Johnston et al. 2008, Oleson 2009).

Genetic analyses indicate restricted gene flow between false killer whales sampled near the main Hawaiian Islands (MHI), the Northwestern Hawaiian Islands (NWHI), and in pelagic waters of the Eastern (ENP) and Central North Pacific (CNP) (Chivers et al. 2007, 2010, Martien et al. 2011). The Palmyra Atoll stock of false killer whales remains a separate stock, because comparisons amongst false killer whales sampled at Palmyra Atoll and those sampled from the insular stock of Hawaii and the pelagic ENP revealed restricted gene flow, although the sample size remains low for robust comparisons (Chivers et al. 2007, 2010). NMFS will obtain and analyze additional tissue samples from Palmyra and the broader tropical Pacific for genetic studies of stock structure, and will evaluate new information on stock ranges as it becomes available.

For the Marine Mammal Protection Act (MMPA) stock assessment reports, there are currently five Pacific Islands Region management stocks (Chivers et al. 2008, Martien et al. 2011): 1) the Hawaii insular stock, which includes animals inhabiting waters within 140 km (approx. 75 nmi) of the main Hawaiian Islands, 2) the Northwestern Hawaiian Islands stock, which includes false killer whales inhabiting waters within 93 km (50 nmi) of the NWHI and Kauai, 3) the Hawaii pelagic stock, which includes false killer whales inhabiting waters greater than 40 km (22 nmi) from the main Hawaiian Islands, 4) the Palmyra Atoll stock, which includes false killer whales found within the U.S. EEZ of Palmyra Atoll, and 5) the American Samoa stock, which includes false killer whales found within the U.S. EEZ of American Samoa. Estimates of abundance, potential biological removal, and status determinations for the Palmyra Atoll stock are presented below; the Hawaii Stock Complex and American Samoa Stocks are presented in separate reports.

POPULATION SIZE

A 2005 line transect survey in the U.S. EEZ waters of Palmyra Atoll produced an estimate of 1,329 (CV = 0.65) false killer whales (Barlow & Rankin 2007). This is the best available abundance estimate for false killer whales within the Palmyra Atoll EEZ.

Minimum Population Estimate

The log-normal 20th percentile of the 2005 abundance estimate for the Palmyra Atoll EEZ (Barlow & Rankin 2007) is 806 false killer whales.

Figure 1. False killer whale on-effort sighting locations during a 2005 standardized shipboard survey of the Palmyra U.S. EEZ and pelagic waters of the central Pacific south of the Hawaiian Islands (gray crosses, Barlow and Rankin 2007). Solid lines represent approximate boundary of U.S. EEZs.
Current Population Trend
No data are available on current population trend.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES
No data are available on current or maximum net productivity rate for this species in Palmyra Atoll waters.

POTENTIAL BIOLOGICAL REMOVAL
The potential biological removal (PBR) level for the Palmyra Atoll false killer whale stock is calculated as the minimum population size (806) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.40 (for a stock of unknown status with a mortality and serious injury rate CV >0.80; Wade and Angliss 1997), resulting in a PBR of 6.4 false killer whales per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY
Fishery Information
Interactions with false killer whales, including depredation of catch, have been identified in logbooks and NMFS observer records from Hawaii pelagic longlines (Nitta and Henderson 1993, NMFS/PIR unpublished data). False killer whales have also been observed feeding on mahi mahi, Coryphaena hippurus, and yellowfin tuna, Thunnus albacares, and they have been reported to take large fish from the trolling lines of both commercial and recreational fishermen (Shallenberger 1981).

The Hawaii-based deep-set longline (DSLL) fishery targets primarily tunas and operate within U.S. waters and on the high seas near Palmyra Atoll. Between 2006 and 2010, one false killer whale was observed taken in the DSLL fishery within the Palmyra EEZ (&#ge;20% observer coverage) (Forney 2011). Based on an evaluation of the observer’s description of each interaction and following the most recently developed criteria for assessing serious injury in marine mammals (Andersen et al. 2008), the single false killer whale taken in the Palmyra EEZ was considered seriously injured (Forney 2011). The total estimated annual and 5-yr average mortality and serious injury of cetaceans in the DSLL fishery operating around Palmyra (with approximately 20% coverage) are reported by McCracken (2011) (Table 1). Although M&SI estimates are shown as whole numbers of animals, the 5-yr average M&SI is calculated based on the unrounded annual estimates.

Because of high rates of false killer whale mortality and serious injury in Hawaii-based longline fisheries, a Take-Reduction Team (TRT) was established in January 2010 (75 FR 2853, 19 January 2010). The scope of the TRT was to reduce mortality and serious injury in the Hawaii pelagic, main Hawaiian Islands insular, and Palmyra stocks of false killer whales and across the DSLL and SSLL fisheries. The Team submitted a Draft Take-Reduction Plan to NMFS for consideration (Available at: http://www.nmfs.noaa.gov/pr/pdfs/interactions/fkwtrp_draft.pdf), and NMFS has recently published regulations based on this TRP (77 FR 71260, 29 November, 2012). The Team chose to exclude the Palmyra Atoll stock in the final implementation of the Plan due to low levels of M&SI of this stock for the past 5 years.
Table 1. Summary of available information on incidental mortality and serious injury of false killer whales (Palmyra Atoll stock) in the Hawaii-based longline fishery (McCracken 2011). Mean annual takes are based on 2006-2010 estimates unless otherwise indicated. Information on all observed takes (T) and combined mortality events & serious injuries (MSI) is included. Total takes were prorated to deaths, serious injuries, and non-serious injuries based on the observed proportions of each outcome.

Minimum total annual takes within U.S. EEZ: 0.3 (1.7)

STATUS OF STOCK
The status of false killer whales in Palmyra Atoll EEZ waters relative to OSP is unknown, and there are insufficient data to evaluate trends in abundance. No habitat issues are known to be of concern for this stock. They are not listed as “threatened” or “endangered” under the Endangered Species Act (1973), nor as “depleted” under the MMPA. The rate of mortality and serious injury to false killer whales within the Palmyra Atoll EEZ in the Hawaii-based longline fishery (0.3 animals per year) does not exceed the PBR (6.4) for this stock and thus, this stock is not considered “strategic” under the MMPA. The total fishery mortality and serious injury for Palmyra Atoll false killer whales is less than 10% of the PBR and, therefore, can be considered to be insignificant and approaching zero. Additional injury and mortality of false killer whales is known to occur in U.S and international longline fishing operations in international waters, and the potential effect on the Palmyra stock is unknown.

REFERENCES

FALSE KILLER WHALE (*Pseudorca crassidens*):
American Samoa Stock

**STOCK DEFINITION AND GEOGRAPHIC RANGE**

False killer whales are found worldwide mainly in tropical and warm-temperate waters (Stacey et al. 1994). The species is well-documented throughout the tropical and sub-tropical south Pacific, from Papua New Guinea and Australia to the line islands (Reeves et al. 1999). The species has been taken in the drive hunt in the Solomon Islands (Reeves et al. 1999). During small-boat surveys from 2003 to 2006 in the waters surrounding the island of Tutuila, American Samoa, false killer whales were observed during summer surveys on five occasions (Johnston et al. 2008). During a shipboard survey in 2006 false killer whales were also encountered just north of the island of Ta’u, in the Manu’a Group within American Samoa (Johnston et al. 2008). Two false killer whales were entangled near 40-Fathom Bank south of the islands by the American Samoa-based longline fishery in 2008 (Oleson 2009), indicating some false killer whales maintain a more pelagic distribution. Five genetic samples collected near Tutuila are available for comparison to other false killer whale populations throughout the Pacific (Johnston et al 2008). For the Marine Mammal Protection Act (MMPA) stock assessment reports, there are four Pacific management stocks: 1) The Hawaii Insular Stock, which includes animals found within the 25-75 nmi longline exclusion boundary surrounding the main Hawaiian Islands, 2) The Hawaii Pelagic Stock, which includes animals found within the U.S. EEZ of the Hawaiian Islands but outside the 25-75 nmi longline exclusion zone, 3) The Palmyra Stock, which includes animals found within the U.S. EEZ of the Palmyra Atoll, and 4) The American Samoa Stock, which includes animals found within the U.S. EEZ American Samoa (this report).

**POPULATION SIZE**

No abundance estimates are currently available for false killer whales in U.S. EEZ waters of American Samoa; however, density estimates for false killer whales in other tropical Pacific regions can provide a range of likely abundance estimates in this unsurveyed region. Published estimates of false killer whales (animals per km²) in the Pacific are: 0.0002 (CV= 0.93) for the U.S. EEZ of the Hawaiian Islands (Barlow and Rankin 2007); 0.0038 (CV=0.65) for the U.S. EEZ around Palmyra, (Barlow and Rankin 2007), 0.0021 (CV=0.64) and 0.0016 (CV=0.31) for the eastern tropical Pacific Ocean (Wade and Gerrodette 1993; Ferguson and Barlow 2003). Applying the lowest and highest of these density estimates to U.S. EEZ waters surrounding American Samoa (area size = 404,578 km²) yields a range of plausible abundance estimates of 87 – 1,538 false killer whales.

Figure 1. False killer whale sightings during visual surveys from 2003-2006 (Johnston et al. 2008).
Minimum Population Estimate

No minimum population estimate is currently available for waters surrounding American Samoa, but the false killer whale density estimates from other tropical Pacific regions (Barlow and Rankin 2007, Wade and Gerrodette 1993, Ferguson and Barlow 2003, see above) can provide a range of likely values. The lognormal 20th percentiles of plausible abundance estimates for the American Samoa EEZ, based on the densities observed elsewhere, range from 45 – 936 false killer whales.

Current Population Trend

No data are available on current population trend.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

No data are available on current or maximum net productivity rate.

POTENTIAL BIOLOGICAL REMOVAL

No PBR can presently be calculated for false killer whales within the American Samoa EEZ, but based on the range of plausible minimum abundance estimates (45 - 936), a recovery factor of 0.40 (for a species of unknown status with a fishery mortality and serious injury rate CV > 0.80 within the American Samoa EEZ; Wade and Angliss 1997), and the default growth rate (½ of 4%), the PBR would likely fall between 0.4 and 7.5 false killer whales per year.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Information on fishery-related mortality of cetaceans in American Samoa waters is limited, but the gear types used in American Samoa fisheries are responsible for marine mammal mortality and serious injury in other fisheries throughout U.S. waters. Gillnets appear to capture marine mammals wherever they are used, and float lines from lobster traps and longlines can be expected to occasionally entangle cetaceans (Perrin et al. 1994). The primary fishery in American Samoa is the commercial pelagic longline fishery that targets tunas, which was introduced in 1995 (Levine and Allen 2009). In 2008, there were 28 federally permitted vessels within the longline fishery in American Samoa. The fishery has been monitored since March 2006 under a mandatory observer program, which records all interactions with protected species (Pacific Islands Regional Office 2009). Two false killer whales were killed or seriously injured by the fishery in 2008 (Oleson 2009). The average annual serious injury and mortality in commercial fisheries for false killer whales in American Samoa waters is 7.8 (CV=1.7) animals per year (Table 1).

Prior to 1995, bottomfishing and trolling were the primary fisheries in American Samoa but became less prominent after longlining was introduced (Levine and Allen 2009). Nearshore subsistence fisheries include spear fishing, rod and reel, collecting, gill netting, and throw netting (Craig 1993, Levine and Allen 2009). Information on fishery-related mortality of cetaceans in the nearshore fisheries is unknown, but the gear types used in American Samoa fisheries are responsible for marine mammal mortality and serious injury in other fisheries throughout U.S. waters. Gillnets appear to capture marine mammals wherever they are used. Although boat-based nearshore fisheries have been randomly monitored since 1991, by the American Samoa Department of Marine and Wildlife Sources (DMWR), no estimates of annual human-caused mortality and serious injury of cetaceans are available.

Figure 2. Locations of observed false killer whale takes (filled diamonds) in the American Samoa longline fishery, 2006-2008. Solid line represents the U.S. EEZ. Set locations in this fishery are summarized in Appendix 1.
STATUS OF STOCK
The status of false killer whales in American Samoan waters relative to OSP is unknown, and there are insufficient data to evaluate trends in abundance. No habitat issues are known to be of concern for this stock. False killer whales are not listed as “threatened” or “endangered” under the Endangered Species Act (1973), nor as “depleted” under the MMPA. The status of the American Samoa stock of false killer whales under the 1994 amendments to the MMPA cannot be determined at this time because no abundance estimates are available and PBR cannot be calculated. However, the estimated rate of fisheries related mortality and serious injury within the American Samoa EEZ (7.8 animals per year) exceeds the range of likely PBRs (0.4 – 7.5) for this region, suggesting that this stock would probably be strategic if abundance estimates were available. Additional research on the abundance of false killer whales in American Samoa is required to resolve this stock's status. Insufficient information is available to determine whether the total fishery mortality and serious injury for false killer whales is insignificant and approaching zero, but this appears unlikely given the estimated takes and likely PBR range.

Table 1. Summary of available information on incidental mortality and serious injury of false killer whales (American Samoa stock) in commercial fisheries operating within the U.S. EEZs (Oleson 2009). Longline fishery take estimates represent only those trips with at least 10 sets/trip (Oleson 2009). Mean annual takes are based on 2006-2008 data unless otherwise indicated.

KILLER WHALE (*Orcinus orca*): Hawaii Stock

**STOCK DEFINITION AND GEOGRAPHIC RANGE**

Killer whales have been observed in all oceans and seas of the world (Leatherwood and Dahlheim 1978). Although reported from tropical and offshore waters (Heyning and Dahlheim 1988), killer whales prefer the colder waters of both hemispheres, with greatest abundances found within 800 km of major continents (Mitchell 1975). They are considered rare in Hawaiian waters. No killer whales were seen during 1993-98 aerial surveys within about 25 nmi of the main Hawaiian Islands, but one sighting was reported during subsequent surveys (Mobley et al. 2000, 2001). Baird et al. (2006) reported 21 sighting records in Hawaiian waters between 1994 and 2004. Summer/fall shipboard surveys of U.S. Exclusive Economic Zone (EEZ) Hawaiian waters resulted in two sightings in 2002 and one in 2010 (Figure 1; Barlow 2006; Bradford et al. 2013). Three strandings have been reported since 1950 (Richards 1952, NMFS PIR Marine Mammal Respones Network database), including one since 2007. Eighteen additional sightings were reported around the main Hawaiian Islands, French Frigate Shoals, and offshore of the Hawaiian islands (Baird et al. 2006). Except in the northeastern Pacific where "resident", "transient", and “offshore” stocks have been described for coastal waters of Alaska, British Columbia, and Washington to California (Bigg 1982; Leatherwood et al. 1990, Bigg et al. 1990, Ford et al. 1994), little is known about stock structure of killer whales in the North Pacific. A global-scale analysis of killer whale phylogeographic structure clustered one animal sampled near Hawaii with eastern and western North Pacific transients. The other Hawaii sample within that analysis did not cluster with any known ecotype, but had divergence time between that of transient and offshore forms (Morin et al 2010).

For the Marine Mammal Protection Act (MMPA) stock assessment reports, eight killer whale stocks are recognized within the Pacific U.S. EEZ: 1) the Eastern North Pacific Alaska Resident stock - occurring from southeastern Alaska to the Aleutian Islands and Bering Sea, 2) the Eastern North Pacific Northern Resident stock - occurring from British Columbia through part of southeastern Alaska, 3) the Eastern North Pacific Southern Resident stock – occurring mainly within the inland waters of Washington State and southern British Columbia, but also in coastal waters from British Columbia through California, 4) the Eastern North Pacific Gulf of Alaska, Aleutian Islands, and Bering Sea Transient stock - occurring mainly from Prince William Sound through the Aleutian Islands and Bering Sea, 5) the AT1 Transient stock - occurring in Alaska from Prince William Sound through the Kenai Fjords, 6) the West Coast Transient stock - occurring from California through southeastern Alaska, 7) the Eastern North Pacific Offshore stock - occurring from California through Alaska, and 8) the Hawaiian stock (this report). The Hawaii stock includes animals found both within the Hawaiian Islands EEZ and in adjacent high seas waters. Because data on abundance, distribution, and human-caused impacts are largely lacking for high seas waters, the status of this stock is evaluated based on data from U.S. EEZ waters of the Hawaiian Islands (NMFS 2005). Stock assessment reports for the Southern Resident, Eastern North Pacific Offshore, and Hawaiian stocks can be found in the Pacific Region stock assessment reports; all other killer whale stock assessments are included in the Alaska Region stock assessments.

**POPULATION SIZE**

A 2002 shipboard line-transect survey of the entire Hawaiian Islands EEZ resulted in an abundance estimate of 349 (CV=0.98) killer whales (Barlow 2006). The recent 2010 shipboard line-transect survey of the
Hawaiian Islands EEZ resulted in an abundance estimate of 101 (CV = 1.0) killer whales (Bradford et al 2013). This is currently the best available abundance estimate for this stock.

**Minimum Population Estimate**

The minimum population size is calculated as the lower 20th percentile of the log-normal distribution (Barlow et al 1995) of the 2010 abundance estimate or 50 killer whales within the Hawaiian Islands EEZ.

**Current Population Trend**

No data are available on current population trend. The broad and overlapping confidence intervals around the 2002 and 2010 estimates preclude assessment of trend with the available data.

**CURRENT AND MAXIMUM NET PRODUCTIVITY RATES**

No data are available on current and maximum net productivity rate in Hawaiian waters.

**POTENTIAL BIOLOGICAL REMOVAL**

The potential biological removal (PBR) level for this stock is calculated as the minimum population size within the U.S. EEZ of the Hawaiian Islands (50) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.50 (for a stock of unknown status with no known fishery mortality or serious injury within the Hawaiian Islands EEZ; Wade and Angliss 1997), resulting in a PBR of 1.0 killer whales per year.

**HUMAN-CAUSED MORTALITY AND SERIOUS INJURY**

**New Serious Injury Guidelines**

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an “injury that is more likely than not to result in mortality”. Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

**Fishery Information**

Information on fishery-related mortality and serious injury of cetaceans in Hawaiian waters is limited, but the gear types used in Hawaiian fisheries are responsible for marine mammal mortality and serious injury in other fisheries throughout U.S. waters. No interactions between nearshore fisheries and killer whales have been reported in Hawaiian waters. No estimates of human-caused mortality or serious injury are currently available for nearshore hook and line or gillnet fisheries because these fisheries are not observed or monitored for protected species bycatch. Killer whale interactions with Hawaii fisheries appear to be rare. In 1990, a solitary killer whale was reported to have removed the catch from a longline in Hawaii (Dollar 1991). There are currently two distinct longline fisheries based in Hawaii: a deep-set longline (DSLL) fishery that targets primarily tunas, and a shallow-set longline fishery (SSL) that targets swordfish. Both fisheries operate within U.S. waters and on the high seas. Between 2007 and 2011, no killer whales were observed hooked or entangled in the SSL fishery (100% observer coverage) or the DSLL fishery (20-22% observer coverage) (McCracken 2013, Bradford & Forney 2013).

**STATUS OF STOCK**

The Hawaii stock of killer whales is not considered strategic under the 1994 amendments to the MMPA. The status of killer whales in Hawaiian waters relative to OSP is unknown, and there are insufficient data to evaluate trends in abundance. No habitat issues are known to be of concern for this stock. Killer whales are not listed as “threatened” or “endangered” under the Endangered Species Act (1973), nor designated as “depleted” under the MMPA. Given the absence of recent recorded fishery-related mortality or serious injuries the total fishery mortality and serious injury can be considered to be insignificant and approaching zero.

**REFERENCES**

SHORT-FINNED PILOT WHALE (*Globicephala macrorhynchus*): Hawaii Stock

**STOCK DEFINITION AND GEOGRAPHIC RANGE**

Short-finned pilot whales are found in all oceans, primarily in tropical and warm-temperate waters. They are commonly observed around the main Hawaiian Islands and are also present around the Northwestern Hawaiian Islands (Shallenberger 1981, Baird et al. 2013, Bradford et al. 2013). Summer/fall shipboard surveys of the waters within the U.S. Exclusive Economic Zone (EEZ) of the Hawaiian Islands resulted in 25 sightings in 2002 and 36 in 2010, including more encounters near shore within the Northwestern Hawaiian Islands (Figure 1; Barlow 2006, Bradford et al. 2013). Twenty-three strandings of short-finned pilot whales have been documented from the Hawaiian Islands since 1957, including five mass strandings in May and October of 1958 and 1959 (Tomich 1986; Nitta 1991; Maldini et al. 2005, NMFS-PIR Marine Mammal Response Network database). There have been four strandings since 2007. Two forms of short-finned pilot whales have been identified in Japanese waters based on pigmentation patterns and differences in the shape of the heads of adult males (Kasuya et al. 1988). The pilot whales in Hawaiian waters are similar morphologically to the Japanese "southern form." Phylogeographic analysis of short-finned pilot whale samples off Hawaii versus those in the eastern tropical Pacific and western Pacific suggest long-term isolation of those animals found in Hawaiian waters (Chivers et al. 2003).

Photo-identification and telemetry studies suggest there may be inshore and pelagic populations of short-finned pilot whales in Hawaiian waters. Resighting and social network analyses of individuals photographed off Hawaii Island suggest the occurrence of one large and several smaller social clusters that use those waters, with some individuals within the smaller social clusters commonly resighted off Hawaii Island (Mahaffy 2012). Further, two groups of 14 individuals have been seen at Hawaii and elsewhere in the main Hawaiian Islands, one off Oahu and the other off Kauai. Satellite telemetry data from over 60 individuals tagged throughout the main Hawaiian Islands also support the occurrence of at least two populations (Oleson et al. 2013). Genetic analyses are underway to evaluate differentiation between island-associated versus pelagic short-finned pilot whales. Oleson et al. (2013) suggested formal stock division would be more robust following conclusion of genetics analyses and updating of the social network with more recent sightings data.

Fishery interactions with short-finned pilot whales demonstrate that this species also occurs in U.S. EEZ waters of Palmyra Atoll and Johnston Atoll, but it is not known whether these animals are part of the Hawaii stock or whether they represent separate stocks of short-finned pilot whales. For the Marine Mammal Protection Act (MMPA) stock assessment reports, short-finned pilot whales within the Pacific U.S. EEZ are divided into two discrete areas: 1) Hawaiian waters (this report), and 2) waters off California, Oregon and Washington. The Hawaii stock includes animals found both within the Hawaiian Islands EEZ and in adjacent high seas waters. The status of the Hawaii stock is evaluated based on abundance, distribution, and human-caused impacts within the Hawaiian Islands EEZ, as such datasets are largely lacking for high seas waters (NMFS 2005).

**POPULATION SIZE**

A 2002 shipboard line-transect survey of the entire Hawaiian Islands EEZ resulted in an abundance...
estimate of 8,846 (CV=0.49) short-finned pilot whales (Barlow 2006). The recent 2010 shipboard line-transect survey of the Hawaiian Islands EEZ resulted in an abundance estimate of 12,422 (CV = 0.43) short-finned pilot whales (Bradford et al. 2013). This is currently the best available abundance estimate for short-finned pilot whales within the Hawaiian Islands EEZ.

**Minimum Population Estimate**

The minimum population size is calculated as the lower 20th percentile of the log-normal distribution (Barlow et al. 1995) of the 2010 abundance estimate for the Hawaiian Islands EEZ or 8,782 short-finned pilot whales.

**Current Population Trend**

The broad and overlapping confidence intervals around the 2002 and 2010 estimates preclude assessment of trend with the available data.

**CURRENT AND MAXIMUM NET PRODUCTIVITY RATES**

No data are available on current or maximum net productivity rate.

**POTENTIAL BIOLOGICAL REMOVAL**

The potential biological removal (PBR) level for the Hawaii short-finned pilot whale stock is calculated as the minimum population estimate (8,782) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.40 (for a stock of unknown status with a Hawaiian Islands EEZ fishery mortality and serious injury rate CV> 0.80; Wade and Angliss 1997), resulting in a PBR of 70 short-finned pilot whales.

**HUMAN- CAUSED MORTALITY AND SERIOUS INJURY**

**New Serious Injury Guidelines**

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NMFS 2012). NMFS defines serious injury as an “injury that is more likely than not to result in mortality”. Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

**Fishery Information**

Information on fishery-related mortality of cetaceans in Hawaiian waters is limited, but the gear types used in Hawaiian fisheries are responsible for marine mammal mortality and serious injury in other fisheries throughout U.S. waters. Entanglement in gillnets and hooking or entanglement in various hook and line fisheries have been reported for small cetaceans in Hawaii (Nitta & Henderson, 1993). No estimates of human-caused mortality or serious injury are currently available for nearshore hook and line or gillnet fisheries because these
fisheries are not observed or monitored for protected species bycatch.

There are currently two distinct longline fisheries based in Hawaii: a deep-set longline (DSLL) fishery that targets primarily tunas, and a shallow-set longline fishery (SSLL) that targets swordfish. Both fisheries operate within U.S. waters and on the high seas, but are prohibited from operating within the Papahanaumokuakea Marine National Monument, a region that extends 50 nmi from shore around the Northwestern Hawaiian Islands, and within the Longline Exclusion Area, a region extending 25-75 nmi from shore around the main Hawaiian Islands. Between 2007 and 2011, no short-finned pilot whales were observed hooked or entangled in the SSLL fishery (100% observer coverage), and four short-finned pilot whales were observed taken in the DSLL fishery (20-22% observer coverage) (Bradford & Forney 2013, McCracken 2013), all in high-seas waters. Based on an evaluation of the observer’s description of the interaction and following the most recently developed criteria for assessing serious injury in marine mammals (NMFS 2012), two short-finned pilot whales were considered not seriously injured, and the other two were considered seriously injured (Bradford & Forney 2013). Seven additional unidentified “blackfish” (unidentified cetaceans known to be either false killer whales or short-finned pilot whales) that may have been pilot whales were also seriously injured during 2007-2011 (Bradford & Forney 2013). Additionally, one

Table 1. Summary of available information on incidental mortality and serious injury of short-finned pilot whales (Hawaii stock) and including those presumed to be short-finned pilot whales based on assignment of unidentified blackfish to this species in commercial longline fisheries, within and outside of the U.S. EEZs (McCracken 2013). Mean annual takes are based on 2007-2011 data unless otherwise indicated. Information on all observed takes (T) and combined mortality events & serious injuries (MSI) is included. Total takes were prorated to deaths, serious injuries, and non-serious injuries based on the observed proportions of each outcome. Unidentified blackfish are prorated as either false killer whales or short-finned pilot whales according to their distance from shore (McCracken 2010). CVs are estimated based on the combination of annual short-finned pilot whale and blackfish variances and do not yet incorporate additional uncertainty introduced by prorating the unidentified blackfish.

</table>
unidentified blackfish was taken on the high seas in the deep set longline fishery in 2011, but was not seriously injured (Table 1). Five of the seven serious injuries were taken in the DSLL fishery within U.S. EEZ waters and the remaining two serious injuries were taken the SSLL fishery on the high seas (Table 1 and Figure 3). Unidentified blackfish are prorated to each stock based on distance from shore (McCracken 2010). The distance-from-shore model was chosen following consultation with the Pacific Scientific Review Group, based on the model’s performance and simplicity relative to a number of other more complicated models with similar output (McCracken 2010). Proration of unidentified blackfish takes introduces unquantified uncertainty into the bycatch estimates, but until all animals taken can be identified to species (e.g., photos, tissue samples), this approach ensures that potential impacts to all stocks are assessed. Average 5-yr estimates of annual mortality and serious injury for 2007-2011 are 0.7 (CV = 2.1) short-finned pilot whales outside of U.S. EEZs and 0.1 (CV = 7.2) within the Hawaiian Islands EEZ. Although M&SI estimates are shown as whole numbers of animals, the 5-yr average M&SI is calculated based on the unrounded annual estimates. Eight unidentified cetaceans were taken in the DSLL fishery, and two unidentified cetaceans were taken in the SSLL fishery, some of which may have been short-finned pilot whales.

**STATUS OF STOCK**

The Hawaii stock of short-finned pilot whales is not considered strategic under the 1994 amendments to the MMPA. The status of short-finned pilot whales in Hawaiian waters relative to OSP is unknown, and there are insufficient data to evaluate trends in abundance. No habitat issues are known to be of concern for this stock. Short-finned pilot whales are not listed as “threatened” or “endangered” under the Endangered Species Act (1973), nor designated as “depleted” under the MMPA. The estimated rate of mortality and serious injury within the Hawaiian Islands EEZ (0.1 animals per year) is less than the PBR (70). Based on the available data, which indicate total fishery-related takes are less than 10% of PBR, the total fishery mortality and serious injury for short-finned pilot whales can be considered to be insignificant and approaching zero.

**REFERENCES**

BLAINVILLE'S BEAKED WHALE (*Mesoplodon densirostris*):
Hawaii Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE
Blainville's beaked whale has a cosmopolitan distribution in tropical and temperate waters, apparently the most extensive known distribution of any *Mesoplodon* species (Mead 1989). Forty-five sightings over 13 years were reported from the main islands by Baird et al (2013), who indicated that Blainville’s beaked whale represent a small proportion (2-3%) of all odontocete sightings in the main Hawaiian Islands. Shallenberger (1981) suggested that Blainville's beaked whales were present off the Waianae Coast of Oahu for prolonged periods annually. Summer/fall shipboard surveys of the waters within the U.S. Exclusive Economic Zone (EEZ) of the Hawaiian Islands, resulted in three sightings in 2002 and one in 2010; however, several sightings of unidentified *Mesoplodon* whales may have also been Blainville’s beaked whale (Figure 1; Barlow 2006, Bradford et al. 2013).

Recent analysis of Blainville’s beaked whale resightings and movements near the main Hawaiian Islands (MHI) suggest the existence of insular and offshore (pelagic) populations of this species in Hawaiian waters (McSweeney et al. 2007, Schorr et al., 2009, Baird et al. 2013). Photo-identification of individual Blainville’s beaked whales from Hawaii Island since 1986 reveal repeated use of this area by individuals for over 17 years (Baird et al. 2011) and 75% of individuals seen off Hawaii Island link by association into a single social network (Baird et al. 2013). Those individuals seen farthest from shore and in deep water (>2100m) have not been resighted, suggesting they may be part of an offshore, pelagic population (Baird et al. 2011). Eleven Blainville’s beaked whales linked to the social network have been satellite tagged off Hawaii Island. All 11 individuals had movements restricted to the MHI, extending to nearshore waters of Oahu, with average distance from shore of 21.6 km (Baird et al. 2013). One individual tagged 32km from Hawaii Island did not link to the social network and had movements extending far from shore, moving over 900km from the tagging location in 20 days, approaching the edge of the Hawaiian EEZ west of Nihoa (Baird et al. 2011). Division of this population into a separate island-associated stock may be warranted in the future.

For the Marine Mammal Protection Act (MMPA) stock assessment reports, three *Mesoplodon* stocks are defined within the Pacific U.S. EEZ: 1) *M. densirostris* in Hawaiian waters (this report), 2) *M. stejnegeri* in Alaskan waters, and 3) all *Mesoplodon* species off California, Oregon and Washington. The Hawaii stock of Blainville’s beaked whales includes animals found both within the Hawaiian Islands EEZ and in adjacent high seas waters. Because data on abundance, distribution, and human-caused impacts are largely lacking for high seas waters, the status of this stock is evaluated based on data from U.S. EEZ waters of the Hawaiian Islands (NMFS 2005).

POPULATION SIZE
A 2002 shipboard line-transect survey of the entire Hawaiian Islands EEZ resulted in an abundance estimate of 2,872 (CV=1.17) Blainville’s beaked whales (Barlow 2006). The recent 2010 shipboard line-transect survey of the Hawaiian Islands EEZ resulted in an abundance estimate of 2,338 (CV = 1.13) Blainville’s beaked whales (Bradford et al. 2013) in the Hawaii stock. This is currently the best available abundance estimate for this stock.
Minimum Population Estimate
The minimum population size is calculated as the lower 20th percentile of the log-normal distribution (Barlow et al. 1995) of the 2010 abundance estimate or 1,088 Blainville’s beaked whales within the Hawaiian Islands EEZ.

Current Population Trend
The broad and overlapping confidence intervals around the 2002 and 2010 estimates preclude assessment of population trend for the Hawaii stock with the available data.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES
No data are available on current or maximum net productivity rate.

POTENTIAL BIOLOGICAL REMOVAL
The potential biological removal (PBR) level for this stock is calculated as the minimum population estimate for the U.S. EEZ of the Hawaiian Islands (1,088 ) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.50 (for a species of unknown status with no recent fishery mortality or serious injury within the Hawaiian Islands EEZ; Wade and Angliss 1997), resulting in a PBR of 11 Hawaii Blainville’s beaked whales per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY
New Serious Injury Guidelines
NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an “injury that is more likely than not to result in mortality”. Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

Fishery Information
Information on fishery-related mortality of cetaceans in Hawaiian waters is limited, but the gear types used in Hawaii fisheries are responsible for marine mammal mortality and serious injury in other fisheries throughout U.S. waters. No interactions between nearshore fisheries and Blainville’s beaked whales have been reported in Hawaiian waters. No estimates of human-caused mortality or serious injury are currently available for nearshore hook and line fisheries because these fisheries are not observed or monitored for protected species bycatch.

There are currently two distinct longline fisheries based in Hawaii: a deep-set longline (DSLL) fishery that targets primarily tunas, and a shallow-set longline fishery (SSLL) that targets swordfish. Both fisheries operate within U.S. waters and on the high seas. Between 2007 and 2011, no Blainville’s beaked whale was observed killed or seriously injured in the SSLL fishery (100% observer coverage) or the DSLL

Figure 2. Location of the Blainville’s beaked whale take (filled diamond) and the possible takes of this species (cross) in Hawaii-based longline fisheries, 2007-2011. Solid lines represent the U.S. EEZ. Fishery descriptions are provided in Appendix 1.
fishery (20-22% observer coverage) (Bradford & Forney 2013, McCracken 2013) within the Hawaiian EEZ. One Blainville’s beaked whale was observed taken, but not seriously injured, on the high seas in the SSLL fishery (Bradford & Forney 2013). One unidentified *Mesoplodon* whale and one unidentified beaked whale were taken in the SSLL fishery and both were considered to be seriously injured based on an evaluation of the observer’s description of the interaction and following the most recently developed criteria for assessing serious injury in marine mammals (NMFS 2012). Average 5-yr estimates of annual mortality and serious injury for 2007-2011 are zero Blainville’s beaked whales within or outside of the U.S. EEZs, and 0.4 (CV = 0) *Mesoplodon* or unidentified beaked whales outside the U.S. EEZs (Table 1). Eight unidentified cetaceans were taken in the DSLL fishery, and two unidentified cetaceans were taken in the SSLL fishery, some of which may have been Blainville’s beaked whales.

Table 1. Summary of available information on incidental mortality and serious injury of Blainville’s beaked whales (Hawaii stock) in commercial longline fisheries, within and outside of the Hawaiian Islands EEZ (McCracken 2013). Mean annual takes are based on 2007-2011 data unless otherwise indicated. Information on all observed takes (T) and combined mortality events & serious injuries (MSI) is included. Total takes were prorated to deaths, serious injuries, and non-serious injuries based on the observed proportions of each outcome.

Other Mortality

Anthropogenic sound sources, such as military sonar and seismic testing have been implicated in the mass strandings of beaked whales, including atypical events involving multiple beaked whale species (Simmonds and Lopez-Jurado 1991, Frantiz 1998, Anon. 2001, Jepson et al. 2003, Cox et al. 2006). While D’Amico et al. (2009) note that most mass strandings of beaked whales are unassociated with documented sonar activities, lethal or sub-lethal effects of such activities would rarely be documented, due to the remote nature of such activities and the low probability that an injured or dead beaked whale would strand. Filadelfho et al. (2009) reported statistically significant correlations between military sonar use and mass strandings of beaked whales in the Mediterranean and Caribbean Seas, but not in Japanese and Southern California waters, and hypothesized that regions with steep bathymetry adjacent to coastlines are more conducive to stranding events in the presence of sonar use. In Hawaiian waters, Faerber & Baird (2010) suggest that the probability of stranding is lower than in some other regions due to nearshore currents carrying animals away from beaches, and that stranded animals are less likely to be detected due...
to low human population density near many of Hawaii’s beaches. Actual and simulated sonar are known to interrupt the foraging dives and echolocation activities of tagged beaked whales (Tyack et al. 2011, DeRuiter et al. 2013). Cuvier’s beaked whales tagged and tracked during simulated mid-frequency sonar exposure showed avoidance reactions, including prolonged diving, cessation of echolocation click production associated with foraging, and directional travel away from the simulated sonar source (DeRuiter et al. 2013). Blainville’s beaked whale presence was monitored on hydrophone arrays before, during, and after sonar activities on a Caribbean military range, with evidence of avoidance behavior: whales were detected throughout the range prior to sonar exposure, not detected in the center of the range coincident with highest sonar use, and gradually returned to the range center after the cessation of sonar activity (Tyack et al. 2011). Fernández et al. (2013) report that there have been no mass strandings of beaked whales in the Canary Islands following a 2004 ban on sonar activities in that region. The absence of beaked whale bycatch in California drift gillnets following the introduction of acoustic pingers into the fishery implies additional sensitivity of beaked whales to anthropogenic sound (Carretta et al. 2008, Carretta and Barlow 2011). The impact of sonar exercises on resident versus offshore beaked whales may be significantly different with offshore animals less frequently exposed, and possibly subject to more extreme reactions (Baird et al. 2009). No estimates of potential mortality or serious injury are available for U.S. waters.

STATUS OF STOCK
The Hawaii stock of Blainville’s beaked whales is not considered strategic under the 1994 amendments to the MMPA. The status of Blainville’s beaked whales in Hawaiian waters relative to OSP is unknown, and there are insufficient data to evaluate trends in abundance. Blainville’s beaked whales are not listed as “threatened” or “endangered” under the Endangered Species Act (1973), nor designated as “depleted” under the MMPA. Given the absence of recorded recent fishery-related mortality or serious injuries within U.S. EEZs, the total fishery mortality and serious injury can be considered to be insignificant and approaching zero. The impacts of anthropogenic sound on beaked whales remain a concern (Barlow and Gisiner 2006, Cox et al. 2006, Hildebrand et al. 2005, Weilgart 2007). One Blainville’s beaked whale found stranded on the main Hawaiian Islands has tested positive for Morbillivirus (Jacob 2012). Although morbillivirus is known to trigger lethal disease in cetaceans (Van Bressem et al. 2009), its impact on the health of the stranded animal is not known as it was found in only a few tested tissues (Jacob 2012). The presence of morbillivirus in 10 species of cetacean in Hawaiian waters, including all 3 known species of beaked whales (Jacob 2012), raises concerns about the history and prevalence of this disease in Hawaii and the potential population impacts on Hawaiian cetaceans.

CUVIER'S BEAKED WHALE (Ziphius cavirostris): Hawaii Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Cuvier's beaked whales occur in all oceans and major seas (Heyning 1989). Summer/fall shipboard surveys of the waters within the U.S. Exclusive Economic Zone (EEZ) of the Hawaiian Islands, resulted in four sightings in 2002 and 22 in 2010, including markedly higher sighting rates during nearshore surveys in the Northwestern Hawaiian Islands. (Figure 1; Barlow 2006, Bradford et al. 2013).

Resighting and movement data of individual Cuvier’s beaked whales suggest the existence of insular and offshore populations of this species in Hawaiian waters. A 21-yr study off Hawaii Island suggests long-term site fidelity and year-round occurrence (McSweeney et al 2007). Eight Cuvier’s beaked whales have been tagged off Hawaii Island since 2006, with all remaining close to the island of Hawaii for the duration of tag data received (Baird et al 2013). Approximately 95% of all locations were within 45 km of shore and the farthest offshore an individual was documented was 67 km (Baird et al. 2013). The satellite data suggest that a resident population may occur near Hawaii Island, distinct from offshore, pelagic Cuvier’s beaked whales. This conclusion is further supported by the long-term site fidelity evident from photo-identification data (McSweeney et al. 2007). Division of this population into a separate island-associated stock may be warranted in the future.

For the Marine Mammal Protection Act (MMPA) stock assessment reports, Cuvier's beaked whales within the Pacific U.S. EEZ are divided into three discrete, non-contiguous areas: 1) Hawaiian waters (this report), 2) Alaskan waters, and 3) waters off California, Oregon and Washington. The Hawaii stock includes animals found both within the Hawaiian Islands EEZ and in adjacent high seas waters. Because data on abundance, distribution, and human-caused impacts are largely lacking for high seas waters, the status of this stock is evaluated based on data from U.S. EEZ waters of the Hawaiian Islands (NMFS 2005).

POPULATION SIZE

Wade and Gerrodette (1993) estimated population size for Cuvier's beaked whales in the eastern tropical Pacific, but it is not known whether any of these animals are part of the same population that occurs around the Hawaiian Islands. A 2002 shipboard line-transect survey of the entire Hawaiian Islands EEZ resulted in an abundance estimate of 15,242 (CV=1.43) Cuvier’s beaked whales (Barlow 2006). The recent 2010 shipboard line-transect survey of the Hawaiian Islands EEZ resulted in an abundance estimate of 1,941 (CV = 0.70) Cuvier’s beaked whales (Bradford et al 2013), including a correction factor for missed diving animals. This is currently the best available abundance estimate for the Hawaii stock.

Minimum Population Estimate

Minimum population size is calculated as the lower 20th percentile of the log-normal distribution (Barlow et al. 1995) of the 2010 abundance estimate, or 1,142 Cuvier’s beaked whales.
Current Population Trend

The significant decrease in abundance estimates between the 2002 and 2010 surveys is attributed to the use of higher sea states (beaufort 0–5) in estimating the trackline detection probability for the 2010 survey, compared to the 2002 survey, which utilized only beaufort sea state data 0 through 2 (Bradford et al. 2013). This change in analysis methodology resulted in far less extrapolation over the survey area, resulting in a more representative estimate of abundance. The 2002 survey data have not been reanalyzed using this method. This change precludes evaluation of population trends at this time.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

No data are available on current or maximum net productivity rate.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for the pelagic stock of Cuvier’s beaked whales is calculated as the minimum population estimate for the U.S. EEZ of the Hawaiian Islands (1,142) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.50 (for a species of unknown status with no known fishery mortality within the Hawaiian Islands EEZ; Wade and Angliss 1997), resulting in a PBR of 11.4 Cuvier’s beaked whales per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

New Serious Injury Guidelines

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an “injury that is more likely than not to result in mortality”. Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

Fishery Information

Information on fishery-related mortality of cetaceans in Hawaiian waters is limited, but the gear types used in Hawaiian fisheries are responsible for marine mammal mortality and serious injury in other fisheries throughout U.S. waters. In 1998, a Cuvier’s beaked whale stranded possibly entangled, with scars and cuts from fishing gear along its body (Bradford & Lyman 2013). The gear was not described. No other interactions between nearshore fisheries and Cuvier’s beaked whales have been reported in Hawaiian waters. No estimates of human-caused mortality or serious injury are currently available for nearshore hook and line fisheries because these fisheries are not observed or monitored for protected species bycatch.

There are currently two distinct longline fisheries based in Hawaii: a deep-set longline (DSLL) fishery that targets primarily tunas, and a shallow-set longline fishery (SSLL) that targets swordfish. Both fisheries operate within U.S. waters and on the high seas. Between 2007 and 2011, no Cuvier’s beaked whales were observed hooked or entangled in the SSL fishery (100% observer coverage) or the DSLL fishery (20-22% observer coverage) (Bradford and Forney 2013, McCracken 2013).

Figure 2. Location of the possible take of Cuvier’s beaked whale (cross) in Hawaii-based longline fisheries, 2007-2011. Solid lines represent the U.S. EEZ. Fishery descriptions are provided in Appendix 1.
One unidentified beaked whale was taken in the SSLL fishery and considered seriously injured based on an evaluation of the observer’s description of the interaction and following the most recently developed criteria for assessing serious injury in marine mammals (NMFS 2012). Average 5-yr estimates of annual mortality and serious injury for 2007-2011 are zero Cuvier’s beaked whales within or outside of the U.S. EEZs, and 0.2 unidentified beaked whales outside the U.S. EEZs (Table 1). Eight unidentified cetaceans were taken in the DSLLL fishery, and two unidentified cetaceans were taken in the SSLL fishery, some of which could have been Cuvier’s beaked whales.

### Table 1. Summary of available information on incidental mortality and serious injury of Cuvier’s beaked whales (Hawaii pelagic stock) and unidentified beaked whales (ZU) in commercial longline fisheries, within and outside of the Hawaiian Islands EEZ (McCracken 2013). Mean annual takes are based on 2007-2011 data unless otherwise indicated. Information on all observed takes (T) and combined mortality events & serious injuries (MSI) is included. Total takes were prorated to deaths, serious injuries, and non-serious injuries based on the observed proportions of each outcome.

LONGMAN’S BEAKED WHALE (Indopacetus pacificus):
Hawaii Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE
Longman’s beaked whale is considered one of the least known cetacean species (Jefferson et al. 1993; Rice 1998; Dalebout et al. 2003). Until recently, it was known only from two skulls found in Australia and Somalia (Longman 1926; Azzaroli 1968). Recent genetic studies (Dalebout et al. 2003) have revealed that sightings of ‘tropical bottlenose whales’ (Hyperoodon sp.; Pitman et al. 1999) in the Indo-Pacific region were in fact Longman’s beaked whales, providing the first description of the external appearance of this species. Although originally described as Mesoplodon pacificus (Longman 1926), it has been proposed that this species is sufficiently unique to be placed within its own genus, Indopacetus (Moore 1968; Dalebout et al. 2003). The distribution of Longman’s beaked whale, as determined from stranded specimens and sighting records of ‘tropical bottlenose whales’, includes tropical waters from the eastern Pacific westward through the Indian Ocean to the eastern coast of Africa. A single stranding of Longman’s beaked whale has been reported in Hawaii, in 2010 near Hana, Maui (West et al. 2012), and there was a single sighting off Kona over 13 years of nearshore surveys off the leeward waters of the main Hawaiian Islands (Baird et al. 2013). Summer/fall shipboard surveys of the waters within the U.S. Exclusive Economic Zone (EEZ) of the Hawaiian Islands, resulted in one sighting in 2002 and three in 2010 (Barlow 2006, Bradford et al. 2013; Figure 1).

For the Marine Mammal Protection Act (MMPA) stock assessment reports, there is one Pacific stock of Longman’s beaked whales, found within waters of the Hawaiian Islands EEZ. This stock includes animals found both within the Hawaiian Islands EEZ and in adjacent high seas waters; however, because data on abundance, distribution, and human-caused impacts are largely lacking for high seas waters, the status of this stock is evaluated based on data from U.S. EEZ waters of the Hawaiian Islands (NMFS 2005).

POPULATION SIZE
A 2002 shipboard line-transect survey of the entire Hawaiian Islands EEZ resulted in an abundance estimate of 1,007 (CV=1.25) Longman’s beaked whales (Barlow 2006). The recent 2010 shipboard line-transect survey of the Hawaiian Islands EEZ resulted in an abundance estimate of 4,571 (CV = 0.65) Longman’s beaked whales (Bradford et al 2013). This is currently the best available abundance estimate for this stock.

Minimum Population Estimate
The minimum population size is calculated as the lower 20th percentile of the log-normal distribution (Barlow et al 1995) around the 2010 abundance estimate, or 2,773 Longman’s beaked whales within the Hawaiian Islands EEZ.

Current Population Trend
The increase in the abundance estimate for the 2010 survey versus the 2002 survey is attributed primarily to
use of beaufort sea states 0-5 in 2010 versus 0-2 in the 2002 when estimating the trackline detection probability, resulting in significantly less extrapolation to unsurveyed areas in 2010 (Bradford et al. 2013). This change in analysis methodology precludes evaluation of population trend at this time.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES
No data are available on current or maximum net productivity rate for Longman’s beaked whales.

POTENTIAL BIOLOGICAL REMOVAL
The potential biological removal (PBR) level for this stock is calculated as the minimum population size within the U.S. EEZ of the Hawaiian Islands (2,773) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.50 (for a stock of unknown status with no known fishery mortality or serious injury within the Hawaiian Islands EEZ; Wade and Angliss 1997), resulting in a PBR of 28 Longman’s beaked whales per year.

HUMAN CAUSED MORTALITY AND SERIOUS INJURY
New Serious Injury Guidelines
NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an “injury that is more likely than not to result in mortality”. Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

Fishery Information
Information on fishery-related mortality and serious injury of cetaceans in Hawaiian waters is limited, but the gear types used in Hawaiian fisheries are responsible for marine mammal mortality and serious injury in other fisheries throughout U.S. waters. No interactions between nearshore fisheries and Longman’s beaked whales have been reported in Hawaiian waters. No estimates of human-caused mortality or serious injury are currently available for nearshore hook and line fisheries because these fisheries are not observed or monitored for protected species bycatch. There are currently two distinct longline fisheries based in Hawaii: a deep-set longline (DSLL) fishery that targets primarily tunas, and a shallow-set longline fishery (SSL) that targets swordfish. Both fisheries operate within U.S. waters and on the high seas. Between 2007 and 2011, no Longman’s beaked whales were observed hooked or entangled in the SSL fishery (100% observer coverage) or the DSLL fishery (20-22% observer coverage) (McCracken 2013, Bradford & Forney 2013). However, eight unidentified cetaceans, which may have included Longman’s beaked whales, were taken in the DSLL fishery, and two unidentified cetaceans, one unidentified Mesoplodon, and one unidentified beaked whale, which may have included Longman’s beaked whales, were taken in the SSL fishery.

Other Mortality
Anthropogenic sound sources, such as military sonar and seismic testing have been implicated in the mass strandings of beaked whales, including atypical events involving multiple beaked whale species (Simmonds and Lopez-Jurado 1991, Frantz 1998, Anon. 2001, Jepson et al. 2003, Cox et al. 2006). While D’Amico et al. (2009) note that most mass strandings of beaked whales are unassociated with documented sonar activities, lethal or sub-lethal effects of such activities would rarely be documented, due to the remote nature of such activities and the low probability that an injured or dead beaked whale would strand. Filadelphia et al. (2009) reported statistically significant correlations between military sonar use and mass strandings of beaked whales in the Mediterranean and Caribbean Seas, but not in Japanese and Southern California waters, and hypothesized that regions with steep bathymetry adjacent to coastlines are more conducive to stranding events in the presence of sonar use. In Hawaiian waters, Faerber & Baird (2010) suggest that the probability of stranding is lower than in some other regions due to nearshore currents carrying animals away from beaches, and that stranded animals are less likely to be detected due to low human population density near many of Hawaii’s beaches. Actual and simulated sonar are known to interrupt the foraging dives and echolocation activities of tagged beaked whales (Tyack et al. 2011, DeRuiter et al. 2013). Cuvier’s beaked whales tagged and tracked during simulated mid-frequency sonar exposure showed avoidance reactions, including prolonged diving, cessation of echolocation click production associated with foraging, and directional travel away from the simulated sonar source (DeRuiter et al. 2013). Blainville’s beaked whale presence was monitored on hydrophone arrays before, during, and after sonar activities on a Caribbean military range, with
evidence of avoidance behavior: whales were detected throughout the range prior to sonar exposure, not detected in the center of the range coincident with highest sonar use, and gradually returned to the range center after the cessation of sonar activity (Tyack et al. 2011). Fernández et al. (2013) report that there have been no mass strandings of beaked whales in the Canary Islands following a 2004 ban on sonar activities in that region. The absence of beaked whale bycatch in California drift gillnets following the introduction of acoustic pingers into the fishery implies additional sensitivity of beaked whales to anthropogenic sound (Carretta et al. 2008, Carretta and Barlow 2011). No estimates of potential mortality or serious injury are available for U.S. waters.

STATUS OF STOCK

The Hawaii stock of Longman’s beaked whales is not considered strategic under the 1994 amendments to the MMPA. The status of Longman’s beaked whales in Hawaiian waters relative to OSP is unknown, and there are insufficient data to evaluate trends in abundance. Longmans’ beaked whales are not listed as “threatened” or “endangered” under the Endangered Species Act (1973), nor designated as “depleted” under the MMPA. Given the absence of recent recorded fishery-related mortality or serious injuries, the total fishery mortality and serious injury can be considered to be insignificant and approaching zero. The impacts of anthropogenic sound on beaked whales remain a concern (Barlow and Gisiner 2006, Cox et al. 2006, Hildebrand et al. 2005, Weilgart 2007). The first confirmed case of morbillivirus in a Hawaiian cetacean was found in a subadult Longman’s beaked whale stranded on Maui in 2010 (West et al. 2012). The presence of morbillivirus in 10 species of cetacean in Hawaiian waters, including all 3 known species of beaked whales (Jacob 2012), raises concerns about the history and prevalence of this disease in Hawaii and the potential population impacts on Hawaii cetaceans.

PYGMY SPERM WHALE (*Kogia breviceps*): Hawaii Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Pygmy sperm whales are found throughout the world in tropical and warm-temperate waters (Caldwell and Caldwell 1989). Pygmy sperm whales have been observed in nearshore waters off Oahu, Maui, Niihau, and Hawaii Island (Shallenberger 1981, Mobley et al. 2000, Baird 2005, Baird et al. 2013). Two sightings were made during a 2002 shipboard survey of waters within the U.S. Exclusive Economic Zone (EEZ) of the Hawaiian Islands (Figure 1; Barlow 2006). A freshly dead pygmy sperm whale was picked up approximately 100 nmi north of French Frigate Shoals on a similar 2010 survey (NMFS, unpublished data). Nothing is known about stock structure for this species.

For the Marine Mammal Protection Act (MMPA) stock assessment reports, pygmy sperm whales within the Pacific U.S. EEZ are divided into two discrete areas: 1) Hawaiian waters (this report), and 2) waters off California, Oregon and Washington. The Hawaii stock includes animals found both within the Hawaiian Islands EEZ and in adjacent high seas waters; however, because data on abundance, distribution, and human-caused impacts are largely lacking for high seas waters, the status of this stock is evaluated based on data from U.S. EEZ waters of the Hawaiian Islands (NMFS 2005).

POPULATION SIZE

A 2002 shipboard line-transect survey of the entire Hawaiian Islands EEZ resulted in an abundance estimate of 7,138 (CV=1.12) pygmy sperm whales (Barlow 2006), including a correction factor for missed diving animals. This estimate for the Hawaiian EEZ is more than 8 years old and therefore will no longer be used based on NMFS Guidelines for Assessing Marine Mammal Stocks (NMFS 2005). A 2010 shipboard line-transect survey within the Hawaiian EEZ did not result in any sightings of pygmy sperm whales (Bradford et al. 2013).

Minimum Population Estimate

No minimum estimate of abundance is available for pygmy sperm whales, as there were no on-effort sightings during a 2010 shipboard line-transect survey of the Hawaiian EEZ.

Current Population Trend

No data are available on current population abundance or trend.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

No data are available on current or maximum net productivity rate.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for this stock is calculated as the minimum population size within the U.S EEZ of the Hawaiian Islands times one half the default maximum net growth rate for cetaceans (½ of
4%) times a recovery factor of 0.50 (for a stock of unknown status with no known fishery mortality or serious injury within the Hawaiian Islands EEZ; Wade and Angliss 1997). Because there is no minimum population size estimate for pygmy sperm whales in Hawaii, the PBR is undetermined.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

New Serious Injury Guidelines

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an “injury that is more likely than not to result in mortality”. Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

Fishery Information

Information on fishery-related mortality of cetaceans in Hawaiian waters is limited, but the gear types used in Hawaiian fisheries are responsible for marine mammal mortality and serious injury in other fisheries throughout U.S. waters. One pygmy sperm whale was found entangled in fishing gear off Oahu in 1994 (Bradford & Lyman 2013), but the gear was not described and the fishery not identified. No estimates of human-caused mortality or serious injury are currently available for nearshore hook and line fisheries because these fisheries are not observed or monitored for protected species bycatch.

There are currently two distinct longline fisheries based in Hawaii: a deep-set longline (DSLL) fishery that targets primarily tunas, and a shallow-set longline fishery (SSLL) that targets swordfish. Both fisheries operate within U.S. waters and on the high seas. Between 2007 and 2011, one pygmy or dwarf sperm whale was observed hooked in the SSLL fishery (100% observer coverage) (Figure 2, Bradford & Forney 2013, McCracken 2013). Based on an evaluation of the observer’s description of the interaction and following the most recently developed criteria for assessing serious injury in marine mammals (NMFS 2012), this animal was considered not seriously injured (Bradford & Forney 2013). No pygmy sperm whales were observed hooked or entangled in the DSLL fishery (20-22% observer coverage). Eight unidentified cetaceans were taken in the DSLL fishery, and two unidentified cetaceans were taken in the SSLL fishery, some of which may have been pygmy sperm whales.

STATUS OF STOCK

The Hawaii stock of pygmy sperm whales is not considered strategic under the 1994 amendments to the MMPA. The status of pygmy sperm whales in Hawaiian waters relative to OSP is unknown, and there are insufficient data to evaluate trends in abundance. Pygmy sperm whales are not listed as “threatened” or “endangered” under the Endangered Species Act (1973), nor designated as “depleted” under the MMPA. Given the

Figure 2. Location of pygmy or dwarf sperm whale takes (filled diamond) in Hawaii-based longline fisheries, 2007-2011. Solid lines represent the U.S. EEZs. Fishery descriptions are provided in Appendix 1.
absence of recent recorded fishery-related mortality or serious injuries within the Hawaiian Islands EEZ, the total fishery mortality and serious injury can be considered to be insignificant and approaching zero. The increasing level of anthropogenic noise in the world’s oceans has been suggested to be a habitat concern for whales (Richardson et al. 1995), particularly for deep-diving whales like pygmy sperm whales that feed in the oceans’ “sound channel”. One pygmy sperm whale found stranded in the main Hawaiian Islands tested positive for *Morbillivirus* (Jacob 2012). Although *morbillivirus* is known to trigger lethal disease in cetaceans (Van Bressem et al. 2009), its impact on the health of the stranded animal is unknown (Jacob 2012). The presence of *morbillivirus* in 10 species of cetacean in Hawaiian waters (Jacob 2012) raises concerns about the history and prevalence of this disease in Hawaii and the potential population impacts on Hawaiian cetaceans.

**Table 1.** Summary of available information on incidental mortality and serious injury of pygmy sperm whales (Hawaiian stock) in commercial longline fisheries within and outside of the Hawaiian Islands EEZ (McCracken 2013). Mean annual takes are based on 2007-2011 data unless otherwise indicated. Information on all observed takes (T) and combined mortality events & serious injuries (MSI) is included. Total takes were prorated to deaths, serious injuries, and non-serious injuries based on the observed proportions of each outcome.

DWARF SPERM WHALE (*Kogia sima*): Hawaii Stock

**STOCK DEFINITION AND GEOGRAPHIC RANGE**

Dwarf sperm whales are found throughout the world in tropical to warm-temperate waters (Nagorsen 1985). At least eight strandings of dwarf sperm whales have been documented in Hawaii since 1985 (Tomich 1986; Nitta 1991; Maldini et al. 2005, NMFS PIR Marine Mammal Response Network database), including two since 2007. From 2002 and 2012, dwarf sperm whales have been seen near Niihau, Kauai, Oahu, Lanai, and Hawaii during small boat surveys (Baird et al 2005, Baird et al 2013). Summer/fall shipboard surveys of the waters within the U.S. Exclusive Economic Zone (EEZ) of the Hawaiian Islands resulted in five sightings of dwarf sperm whales during 2002 and one during 2010 (Figure 1; Barlow 2006, Bradford et al. 2013).

Small boat surveys within the main Hawaiian Islands (MHI) since 2002 have documented dwarf sperm whales on 73 occasions, most commonly in water depths between 500m and 1,000m (Baird et al. 2013). Long-term site-fidelity is evident off Hawaii Island, with one third of the distinctive individuals seen there encountered in more than one year. Resighting data from 25 individuals documented at Hawaii Island suggest an island-resident population with restricted range, with all encounters in less than 1,600m water depth and less than 20 km from shore (Baird et al. 2013). Division of this population into a separate island-associated stock may be warranted in the future. For the Marine Mammal Protection Act (MMPA) stock assessment reports, dwarf sperm whales within the Pacific U.S. EEZ are divided into two discrete, non-contiguous areas: 1) Hawaiian waters (this report), and 2) waters off California, Oregon and Washington. The Hawaii stock includes animals found within the Hawaiian Islands EEZ and in adjacent high seas waters; however, because data on abundance, distribution, and human-caused impacts are largely lacking for high seas waters, the status of this stock is evaluated based on data from U.S. EEZ waters of the Hawaiian Islands (NMFS 2005).

**POPULATION SIZE**

Wade and Gerrodette (1993) provided an estimate for the eastern tropical Pacific, but it is not known whether these animals are part of the same population that occurs in the central North Pacific. This species’ small size, tendency to avoid vessels, and deep-diving habits, combined with the high proportion of *Kogia* sightings that are not identified to species, may result in negatively biased estimates of relative abundance in this region. A 2002 shipboard line-transect survey of the entire Hawaiian Islands EEZ resulted in an abundance estimate of 17,519 (CV=0.74) dwarf sperm whales (Barlow 2006), including a correction factor for missed diving animals. There were no on-effort sightings of dwarf sperm whales during the 2010 shipboard survey of the Hawaiian EEZ (Bradford et al 2013), such that there is no current abundance estimate for this stock.

**Minimum Population Estimate**

The log-normal 20th percentile of the 2002 abundance estimate (Barlow 2006) is 10,043 dwarf sperm whales within the Hawaiian Islands EEZ; however, the minimum abundance estimate for the entire Hawaiian EEZ is ≥ 8 years old and will no longer be used (NMFS 2005). No minimum estimate of abundance is available for this
stock, as there were no sightings of dwarf sperm whales during a 2010 shipboard line-transect survey of the Hawaiian EEZ.

**Current Population Trend**

No data are available on current population abundance or trend.

**CURRENT AND MAXIMUM NET PRODUCTIVITY RATES**

No data are available on current or maximum net productivity rate.

**POTENTIAL BIOLOGICAL REMOVAL**

The potential biological removal (PBR) level for this stock is calculated as the minimum population size within the U.S. EEZ of the Hawaiian Islands times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.50 (for a stock of unknown status with no known fishery mortality or serious injury within the Hawaiian Islands EEZ; Wade and Angliss 1997). Because there is no minimum population size estimate for Hawaii pelagic dwarf sperm whales, the PBR is undetermined.

**HUMAN-CAUSED MORTALITY AND SERIOUS INJURY**

**New Serious Injury Guidelines**

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an “injury that is more likely than not to result in mortality”. Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

**Fishery Information**

Information on fishery-related mortality of cetaceans in Hawaiian waters is limited, but the gear types used in Hawaiian fisheries are responsible for marine mammal mortality and serious injury in other fisheries throughout U.S. waters. No interactions between nearshore fisheries and dwarf sperm whales have been reported in Hawaiian waters. No estimates of human-caused mortality or serious injury are currently available for nearshore hook and line fisheries because these fisheries are not observed or monitored for protected species bycatch.

There are currently two distinct longline fisheries based in Hawaii: a deep-set longline (DSLL) fishery that targets primarily tunas, and a shallow-set longline fishery (SSLL) that targets swordfish. Both fisheries operate within U.S. waters and on the high seas. Between 2007 and 2011, one pygmy or dwarf sperm whale was observed hooked in the SSLL fishery (100% observer coverage) (Figure 2, McCracken 2013, Bradford & Forney 2013). Based on an evaluation of the observer’s description of the interaction and following the most recently developed criteria for assessing serious injury in marine mammals (NMFS 2012), this

![Figure 2](image_url)

STATUS OF STOCK

The Hawaii stock of dwarf sperm whales is not considered strategic under the 1994 amendments to the MMPA. The status of dwarf sperm whales in Hawaiian waters relative to OSP is unknown, and there are insufficient data to evaluate trends in abundance. Dwarf sperm whales are not listed as “threatened” or “endangered” under the Endangered Species Act (1973), nor designated as “depleted” under the MMPA. There have been no reported fishery related mortality or injuries within the Hawaiian Islands EEZ, such that the total mortality and serious injury can be considered to be insignificant and approaching zero. The increasing levels of anthropogenic noise in the world’s oceans has been suggested to be a habitat concern for whales (Richardson et al. 1995), particularly for deep-diving whales like dwarf sperm whales that feed in the oceans’ “sound channel”.

REFERENCES

SPERM WHALE (*Physeter macrocephalus*): Hawaii Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Sperm whales are widely distributed across the entire North Pacific and into the southern Bering Sea in summer but the majority are thought to be south of 40°N in winter (Rice 1974, 1989; Gosho et al. 1984; Miyashita et al. 1995). For management, the International Whaling Commission (IWC) had divided the North Pacific into two management regions (Donovan 1991) defined by a zig-zag line which starts at 150°W at the equator to 160°W between 40-50°N, and ending at 180°W north of 50°N; however, the IWC has not reviewed this stock boundary in many years (Donovan 1991). Summer/fall surveys in the eastern tropical Pacific (Wade and Gerrodette 1993) show that although sperm whales are widely distributed in the tropics, their relative abundance tapers off markedly westward towards the middle of the tropical Pacific (near the IWC stock boundary at 150°W) and tapers off northward towards the tip of Baja California. The Hawaiian Islands marked the center of a major nineteenth century whaling ground for sperm whales (Gilmore 1959; Townsend 1935). Since 1936, at least 28 strandings have been reported from the Hawaiian Islands (Woodward 1972; Nitta 1991; Maldini et al. 2005, NMFS PIR Marine Mammal Response Network database), including 7 since 2007. Sperm whales have also been sighted throughout the Hawaiian EEZ, including nearshore waters of the main and Northwestern Hawaiian Islands (Rice 1960; Barlow 2006; Lee 1993; Mobley et al. 2000; Shallenberger 1981). In addition, sperm whale sounds have been recorded throughout the year off Oahu (Thompson and Friedl 1982). Summer/fall shipboard surveys of waters within the U.S. Exclusive Economic Zone (EEZ) of the Hawaiian Islands resulted in 43 sperm whale sightings in 2002 and 46 in 2010 throughout the study area (Figure 1; Barlow 2006, Bradford et al. 2013).

The stock identity of sperm whales in the North Pacific has been inferred from historical catch records (Bannister and Mitchell 1980) and from trends in CPUE and tag-recapture data (Ohsumi and Masaki 1977). A 1997 survey designed specifically to investigate stock structure and abundance of sperm whales in the northeastern temperate Pacific revealed no apparent hiatus in distribution between the U.S. EEZ off California and areas farther west, out to Hawaii (Barlow and Taylor 2005). Recent genetic analyses revealed significant differences in mitochondrial and nuclear DNA and in single-nucleotide polymorphisms between sperm whales sampled off the coast of California, Oregon and Washington and those sampled near Hawaii and in the eastern tropical Pacific (ETP) (Mesnick et al. 2011). These results suggest demographic independence between matrilineal groups found California, Oregon, and Washington, and those found elsewhere in the central and eastern tropical Pacific. Further, assignment tests identified male sperm whales sampled in the sub-Arctic with each of the three regions, suggesting mixing of males from potentially several populations during the summer (Mesnick et al. 2011).

For the Marine Mammal Protection Act (MMPA) stock assessment reports, sperm whales within the Pacific U.S. EEZ are divided into three discrete, non-contiguous stocks: 1) waters around Hawaii (this report), 2) California, Oregon and Washington waters, and 3) Alaskan waters. The Hawaii stock includes animals found both within the Hawaiian Islands EEZ and in adjacent high seas waters; however, because data on abundance, distribution, and human-caused impacts are largely lacking for high seas waters, the status of the Hawaii stock is evaluated based on data from U.S. EEZ waters of the Hawaiian Islands (NMFS 2005).

![Figure 1. Sperm whale sighting locations during the 2002 (open diamonds) and 2010 (black diamonds) shipboard surveys of U.S. EEZ waters surrounding the Hawaiian Islands (Barlow 2006, Bradford et al. 2013; see Appendix 2 for details on timing and location of survey effort). Outer line represents approximate boundary of survey area and U.S. EEZ. Gray shading indicates area of Papahanaumokuakea Marine National Monument.](image-url)
POPULATION SIZE

A large 1982 abundance estimate for the entire eastern North Pacific (Gosho et al. 1984) was based on a CPUE method which is no longer accepted as valid by the International Whaling Commission. A spring 1997 combined visual and acoustic line-transect survey conducted in the eastern temperate North Pacific resulted in estimates of 26,300 (CV=0.81) sperm whales based on visual sightings, and 32,100 (CV=0.36) based on acoustic detections and visual group size estimates (Barlow and Taylor 2005). Sperm whales appear to be a good candidate for acoustic surveys due to the increased range of detection; however, visual estimates of group size are still required (Barlow and Taylor 2005). In the eastern tropical Pacific, the abundance of sperm whales has been estimated as 22,700 (95% C.I.=14,800-34,600; Wade and Gerrodette 1993). However, it is not known whether any or all of these animals routinely enter the U.S. EEZ of the Hawaiian Islands. A 2002 shipboard line-transect survey of the entire Hawaiian Islands EEZ resulted in an abundance estimate of 6,919 (CV=0.81) sperm whales (Barlow 2006). The recent 2010 shipboard line-transect survey of the Hawaiian Islands EEZ resulted in an abundance estimate of 3,354 (CV = 0.34) sperm whales (Bradford et al. 2013), including a correction factor for missed diving animals. This is currently the best available abundance estimate for this stock.

Minimum Population Estimate

The minimum population size is calculated as the lower 20th percentile of the log-normal distribution (Barlow et al. 1995) around the 2010 abundance estimate or 2,539 sperm whales within the Hawaiian Islands EEZ.

Current Population Trend

The broad and overlapping confidence intervals around the 2002 and 2010 estimates preclude assessment of trend with the available data.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

No data on current or maximum net productivity rate are available.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for the Hawaii stock of sperm whales is calculated as the minimum population size (2,539) within the U.S. EEZ of the Hawaiian Islands times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.2 (for an endangered species with \( N_{\text{min}} > 1,500 \) and \( CV_{N_{\text{min}}} > 0.50 \), with low vulnerability to extinction; (Taylor et al. 2003), resulting in a PBR of 10.2 sperm whales per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

New Serious Injury Guidelines

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NMFS 2012). NMFS defines serious injury as an “injury that is more likely than not to result in mortality”. Injury determinations for stock assessments...
revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

**Fishery Information**

Information on fishery-related mortality of cetaceans in Hawaiian waters is limited, but the gear types used in Hawaiian fisheries are responsible for marine mammal mortality and serious injury in other fisheries throughout U.S. waters. One stranded sperm whale was found with fishing line and netting its stomach, though it is unclear whether the gear caused its death, nor what fisheries the gear came from (NMFS PIR MMRN). No estimates of human-caused mortality or serious injury are currently available for nearshore hook and line fisheries because these fisheries are not observed or monitored for protected species bycatch.

There are currently two distinct longline fisheries based in Hawaii: a deep-set longline (DSLL) fishery that targets primarily tunas, and a shallow-set longline fishery (SSLL) that targets swordfish. Both fisheries operate within U.S. waters and on the high seas. Between 2007 and 2011, no sperm whales were observed hooked or entangled in the SSLL fishery (100% observer coverage) and one was observed either hooked or entangled in the DSLL fishery (20-22% observer coverage) (Bradford & Forney 2013). The observer could not determine whether the whale was hooked or entangled; however, the mainline came under tension when the animal surfaced. The whale was cut free with the hook, 0.5m wire leader, 45g weight, 12m of branchline, and 25-30 ft of mainline possibly attached. This interaction was prorated as 75% probability of serious injury because the whale was hooked or entangled but the exact nature of the injury could not be determined (Bradford & Forney 2013). This determination is based on an evaluation of the observer’s description of the interaction and following the most recently developed criteria for assessing serious injury in marine mammals (NMFS 2012). The prorating of serious injury is based on the proportion of known outcomes for whales with similar fisheries interactions in other regions. Average 5-yr estimates of annual mortality and serious injury for sperm whales during 2007-2011 are zero sperm whales outside of U.S. EEZs, and 0.7 (CV = 0.6) within the Hawaiian Islands EEZ (Table 1, McCracken 2013).

**Table 1.** Summary of available information on incidental mortality and serious injury of sperm whales in commercial longline fisheries, within and outside of the U.S. EEZs (McCracken 2013). Mean annual takes are based on 2007-2011 data. Information on all observed takes (T) and combined mortality events & serious injuries (MSI) is included. Total takes were prorated to deaths, serious injuries, and non-serious injuries based on the observed proportions of each outcome.

*This injury was prorated 75% probability of being a serious injury based on known outcomes from other whales with this injury type (NOAA 2012).

**Historical Mortality**

Between 1800 and 1909, about 60,842 sperm whales were estimated taken in the North Pacific (Best 1976). The reported take of North Pacific sperm whales by commercial whalers between 1947 and 1987 totaled 258,000 (C.
Allen, pers. comm.). Factory ships operated as far south as 20°N (Ohsumi 1980). Ohsumi (1980) lists an additional 28,198 sperm whales taken mainly in coastal whaling operations from 1910 to 1946. Based on the massive under-reporting of Soviet catches, Brownell et al. (1998) estimated that about 89,000 whales were additionally taken by the Soviet pelagic whaling fleet between 1949 and 1979. Japanese coastal operations apparently also under-reported catches by an unknown amount (Kasuya 1998). Thus a total of at least 436,000 sperm whales were taken between 1800 and the end of commercial whaling for this species in 1987. Of this grand total, an estimated 33,842 were taken by Soviet and Japanese pelagic whaling operations in the eastern North Pacific from the longitude of Hawaii to the U.S. West coast, between 1961 and 1976 (Allen 1980, IWC statistical Areas II and III), and 965 were reported taken in land-based U.S. West coast whaling operations between 1947 and 1971 (Ohsumi 1980). In addition, 13 sperm whales were taken by shore whaling stations in California between 1919 and 1926 (Clapham et al. 1997). There has been a prohibition on taking sperm whales in the North Pacific since 1988, but large-scale pelagic whaling stopped earlier, in 1980. Some of the whales taken during the whaling era were certainly from a population or populations that occur within Hawaiian waters.

**STATUS OF STOCK**

The only estimate of the status of North Pacific sperm whales in relation to carrying capacity (Gosho et al. 1984) is based on a CPUE method which is no longer accepted as valid. The status of sperm whales in Hawaiian waters relative to OSP is unknown, and there are insufficient data to evaluate trends in abundance. Sperm whales are formally listed as "endangered" under the Endangered Species Act (ESA), and consequently the Hawaiian stock is automatically considered as a "depleted" and "strategic" stock under the MMPA. The estimated rate of fisheries related mortality or serious injury within the Hawaiian Islands EEZ (0.7 animals per year) is less than the PBR (10.2). Insufficient information is available to determine whether the total fishery mortality and serious injury for sperm whales is insignificant and approaching zero mortality and serious injury rate. The increasing level of anthropogenic noise in the world’s oceans has been suggested to be a habitat concern for whales (Richardson et al. 1995), particularly for deep-diving whales like sperm whales that feed in the oceans' “sound channel”. One sperm whale stranded in the main Hawaiian Islands tested positive for both Brucella and Morbillivirus (Jacob 2012, West, unpublished data). Brucella is a bacterial infection that may limit recruitment by compromising male and female reproductive systems if it is common in the population, and it can also cause neurological disorders that may result in death (Van Bressem et al. 2009). Morbillivirus is known to trigger lethal disease in cetaceans (Van Bressem et al. 2009); however, investigation of the pathology of the stranded sperm whale suggests that Brucella was more likely the cause of death in this sperm whale (West, unpublished data). The presence of Morbillivirus in 10 species (Jacob 2012) and Brucella in 3 species (Cherbov 2010, West unpublished data) raises concerns about the history and prevalence of these diseases in Hawaii and the potential population impacts on Hawaiian cetaceans. It is not known if Brucella or Morbillivirus are common in the Hawaii stock.

BLUE WHALE (*Balaenoptera musculus musculus*): Central North Pacific Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

The International Whaling Commission (IWC) has formally considered only one management stock for blue whales in the North Pacific (Donovan 1991), but up to five populations have been proposed (Reeves et al. 1998). Rice (1974) hypothesized that blue whales from Baja California migrated far offshore to feed in the eastern Aleutians or Gulf of Alaska and returned to feed in California waters; though more recently concluded that the California population is separate from the Gulf of Alaska population (Rice 1992). Length frequency analyses (Gilpatrick et al. 1996) and photo-identification studies (Calambokidis et al. 1995) through the 1990s supported separate populations for blue whales feeding off California and those feeding in Alaskan waters. Whaling catch data indicated that whales feeding along the Aleutian Islands were probably part of a central Pacific stock (Reeves et al. 1998), which was thought to migrate to offshore waters north of Hawaii in winter (Berzin and Rovnin 1966). Blue whale feeding aggregations have not been found in Alaska despite several surveys (Leatherwood et al. 1982; Stewart et al. 1987; Forney and Brownell 1996). More recently, analyses of acoustic data obtained throughout the North Pacific (Stafford et al. 2001; Stafford 2003) have revealed two distinct blue whale call types, suggesting two North Pacific stocks: eastern and central (formerly western). The regional occurrence patterns suggest that blue whales from the eastern North Pacific stock winter off Mexico, Central America, and as far south as 8° S (Stafford et al. 1999), and feed during summer off the U. S. West Coast and to a lesser extent in the Gulf of Alaska. This stock has previously been observed to feed in waters off California (and occasionally as far north as British Columbia; Calambokidis et al. 1998) in summer/fall (from June to November) migrating south to productive areas off Mexico (Calambokidis et al. 1990) and as far south as the Costa Rica Dome (10° N) in winter/spring (Mate et al. 1999, Stafford et al. 1999).

Blue whales belonging to the central Pacific stock appear to feed in summer southwest of Kamchatka, south of the Aleutians, and in the Gulf of Alaska (Stafford 2003; Watkins et al. 2000), and in winter migrate to lower latitudes in the western and central Pacific, including Hawaii (Stafford et al. 2001).

The first published sighting record of blue whales near Hawaii is that of Berzin and Rovnin (1966), though recently, two blue whales were seen with fin whales and an unidentified rorqual in November 2010 during a survey of Hawaiian U.S. EEZ waters (Bradford et al. 2013). Four sightings have been made by observers on Hawaii-based longline vessels (Figure 1; NMFS/PIR, unpublished data). Additional evidence that blue whales occur in this area comes from acoustic recordings made off Oahu and Midway Islands (Northrop et al. 1971; Thompson and Friedl 1982), which likely included at least some whales within the EEZ. The recordings made off Hawaii showed bimodal peaks throughout the year (Stafford et al. 2001), with central Pacific call types heard during winter and eastern Pacific calls heard during summer. For the Marine Mammal Protection Act (MMPA) stock assessment reports, there are two blue whale stocks within the Pacific U.S. EEZ: 1) the central North Pacific stock (this report), which includes whales found around the Hawaiian Islands during winter and 2) the eastern North Pacific stock, which feeds primarily off California.

![Figure 1. Locations of blue whale sightings made by observers aboard Hawaii-based longline fishing vessels between July 1994 and December 2009 (crosses, NMFS/PIR unpublished data), and location of a single blue whale sighting during a 2010 (black diamond) shipboard cetacean survey of U.S. EEZ waters surrounding the Hawaiian Islands (Bradford et al. 2013; see Appendix 2 for details on timing and location of survey effort). Outer line indicates approximate boundary of survey area and U.S. EEZ. Gray shading indicates area of Papahanaumoakua Marine National Monument. Dotted line represents the 1000m isobath.](image-url)
POPULATION SIZE
From ship line-transect surveys, Wade and Gerrodette (1993) estimated 1,400 blue whales for the eastern tropical Pacific. No blue whale sightings were made during summer/fall 2002 shipboard surveys of the entire Hawaiian Islands EEZ (Barlow 2006). A 2010 shipboard line-transect survey of the entire Hawaiian Islands EEZ resulted in a summer/fall abundance estimate of 81 (CV = 1.14) blue whales (Bradford et al. 2013). This is currently the best available abundance estimate for this stock within the Hawaii EEZ, but the majority of blue whales would be expected to be at higher latitudes feeding grounds at this time of year.

Minimum Population Estimate
The minimum population size is calculated as the lower 20th percentile of the log-normal distribution (Barlow et al. 1995) of the 2010 abundance estimate, or 38 blue whales within the Hawaiian Islands EEZ.

Current Population Trend
The first sightings of blue whales during systematic surveys occurred in 2010, and there is currently insufficient data to assess population trends.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES
No data are available on current or maximum net productivity rate.

POTENTIAL BIOLOGICAL REMOVAL
The potential biological removal (PBR) level for the Central North Pacific stock of blue whales is calculated as the minimum population size within the U.S. EEZ of the Hawaiian Islands (38) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.1 (the default value for an endangered species with $N_{min} < 1500$; Taylor et al. 2003), resulting in a PBR of 0.1 Central Pacific blue whales per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY
New Serious Injury Guidelines
NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an “injury that is more likely than not to result in mortality”. Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

Fishery Information
There are currently two distinct longline fisheries based in Hawaii: a deep-set longline (DSLL) fishery that targets primarily tunas, and a shallow-set longline fishery (SSLL) that targets swordfish. Both fisheries operate within U.S. waters and on the high seas. Between 2007 and 2011, no blue whales were observed hooked or entangled in the SSLL fishery (100% observer coverage) or the DSLL fishery (20-22% observer coverage) (McCracken 2013, Bradford & Forney 2013).

Historical Mortality
At least 9,500 blue whales were taken by commercial whalers throughout the North Pacific between 1910 and 1965 (Ohsumi and Wada 1972). Some proportion of this total may have been from a population or populations that migrate seasonally into the Hawaiian EEZ. The species has been protected in the North Pacific by the IWC since 1966.

STATUS OF STOCK
The status of blue whales in Hawaiian waters relative to OSP is unknown, and there are insufficient data to evaluate trends in abundance. Blue whales are formally listed as "endangered" under the Endangered Species Act (ESA), and consequently the central Pacific stock is automatically considered as a "depleted" and "strategic" stock under the MMPA. Because there have been no reported fishery related mortality or serious injuries of blue whales within the Hawaiian Islands EEZ, the total fishery-related mortality and serious injury of this stock can be considered to be insignificant and approaching zero. Increasing levels of anthropogenic noise in the world’s oceans has been suggested to be a habitat concern for blue whales (Reeves et al. 1998). Tagged blue whales exposed to
simulated mid-frequency sonar and pseudo-random noise demonstrated a variety of behavioral responses, including no change in behavior, termination of deep dives, directed travel away from sound sources, and cessation of feeding (Goldbogen et al. 2013). Behavioral responses were highly dependent upon the type of sound source and the behavioral state of the animal at the time of exposure. Deep-feeding and non-feeding whales reacted more strongly to experimental sound sources than surface-feeding whales that typically showed no change in behavior. The authors stated that behavioral responses to such sounds are influenced by a complex interaction of behavioral state, environmental context, and prior exposure of individuals to such sound sources. One concern expressed by the authors is if blue whales did not habituate to such sounds near feeding areas that “repeated exposures could negatively impact individual feeding performance, body condition and ultimately fitness and potentially population health.” Currently, no evidence indicates that such reduced population health exists, but such evidence would be difficult to differentiate from natural sources of reduced fitness or mortality in the population.

REFERENCES
FIN WHALE (*Balaenoptera physalus physalus*):

**Hawaii Stock**

**STOCK DEFINITION AND GEOGRAPHIC RANGE**

Fin whales are found throughout all oceans from tropical to polar latitudes. They have been considered rare in Hawaiian waters and are absent to rare in eastern tropical Pacific waters (Hamilton et al. 2009). Balcomb (1987) observed 8-12 fin whales in a multispecies feeding assemblage on 20 May 1966 approx. 250 mi. south of Honolulu. Additional sightings were reported north of Oahu in May 1976, in the Kauai Channel in February 1979 (Shallenberger 1981), north of Kauai in February 1994 (Mobley et al. 1996), and off Lanai in 2012 (Baird unpublished data).

Summer/fall shipboard surveys of the waters within the U.S. Exclusive Economic Zone (EEZ) of the Hawaiian Islands resulted in five sightings in 2002 and two sightings in 2010 (Barlow 2003, Bradford et al 2013; Figure 1). A single stranding was reported on Maui in 1954 (Shallenberger 1981). Thompson and Friedl (1982; and see Northrop et al. 1968) suggested that fin whales migrate into Hawaiian waters mainly in fall and winter, based on acoustic recordings off Oahu and Midway Islands. Although the exact positions of the whales producing the sounds could not be determined, at least some of them were almost certainly within the U.S. EEZ. More recently, McDonald and Fox (1999) reported an average of 0.027 calling fin whales per 1000 km² (grouped by 8-hr periods) based on passive acoustic recordings within about 16 km of the north shore of Oahu.

The International Whaling Commission (IWC) recognized two stocks of fin whales in the North Pacific: the East China Sea and the rest of the North Pacific (Donovan 1991). Mizroch et al. (1984) cite evidence for additional fin whale subpopulations in the North Pacific. There is still insufficient information to accurately determine population structure, but from a conservation perspective it may be risky to assume panmixia in the entire North Pacific. In the North Atlantic, fin whales were locally depleted in some feeding areas by commercial whaling (Mizroch et al. 1984), in part because subpopulations were not recognized. The Marine Mammal Protection Act (MMPA) stock assessment reports recognize three stocks of fin whales in the North Pacific: 1) the Hawaii stock (this report), 2) the California/Oregon/Washington stock, and 3) the Alaska stock. The Hawaiian stock includes animals found both within the Hawaiian Islands EEZ and in adjacent high seas waters; however, because data on abundance, distribution, and human-caused impacts are largely lacking for high seas waters, the status of this stock is evaluated based on data from U.S. EEZ waters of the Hawaiian Islands (NMFS 2005).

**POPULATION SIZE**

Using passive acoustic detections from a hydrophone north of Oahu, MacDonald and Fox (1999) estimated an average density of 0.027 calling fin whales per 1000 km² within about 16 km from shore. However, the relationship between the number of whales present and the number of calls detected is not known, and therefore this acoustic method does not provide an estimate of absolute abundance for fin whales. A 2002 shipboard line-transect survey of the entire Hawaiian Islands EEZ resulted in an abundance estimate of 174 (CV=0.72) fin whales (Barlow 2003). The recent 2010 shipboard line-transect survey of the Hawaiian Islands EEZ resulted in an abundance estimate of 58 (CV = 1.12) fin whales (Bradford et al 2013). This is currently the best available abundance estimate.
for this stock within the Hawaii EEZ, but the majority of fin whales would be expected to be at higher latitudes feeding grounds at this time of year.

**Minimum Population Estimate**

The minimum population size is calculated as the lower 20th percentile of the log-normal distribution (Barlow et al 1995) around the 2010 abundance estimate or 27 fin whales within the Hawaiian Islands EEZ.

**Current Population Trend**

No data are available on current population trend. The broad and overlapping confidence intervals around the 2002 and 2010 estimates preclude assessment of trend with the available data.

**CURRENT AND MAXIMUM NET PRODUCTIVITY RATES**

No data are available on current or maximum net productivity rate.

**POTENTIAL BIOLOGICAL REMOVAL**

The potential biological removal (PBR) level for the Hawaii stock of fin whales is calculated as the minimum population size within the U.S EEZ of the Hawaiian Islands (27) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.1 (the default value for an endangered species with Nmin <1500; Taylor et al 2003), resulting in a PBR of 0.1 fin whales per year.

**HUMAN-CAUSED MORTALITY AND SERIOUS INJURY**

**New Serious Injury Guidelines**

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an “injury that is more likely than not to result in mortality”. Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

**Fishery Information**

There are currently two distinct longline fisheries based in Hawaii: a deep-set longline (DSLL) fishery that targets primarily tunas, and a shallow-set longline fishery (SSLL) that targets swordfish. Both fisheries operate within U.S. waters and on the high seas. Between 2007 and 2011, no fin whales were observed hooked or entangled in the SSLL fishery (100% observer coverage) or the DSLL fishery (20-22% observer coverage) (McCracken 2013, Bradford & Forney 2013).

**Historical Mortality**

Large numbers of fin whales were taken by commercial whalers throughout the North Pacific from the early 20th century until the 1970s (Tønnessen and Johnsen 1982). Approximately 46,000 fin whales were taken from the North Pacific by commercial whalers between 1947 and 1987 (C. Allison, IWC, pers. comm.). Some of the whales taken may have been from a population or populations that migrate seasonally into the Hawaiian EEZ. The species has been protected in the North Pacific by the IWC since 1976.

**STATUS OF STOCK**

The status of fin whales in Hawaiian waters relative to OSP is unknown, and there are insufficient data to evaluate trends in abundance. Fin whales are formally listed as "endangered" under the Endangered Species Act (ESA), and consequently the Hawaiian stock is automatically considered as a "depleted" and "strategic" stock under the MMPA. Because there have been no reported fishery related mortality or serious injuries within the Hawaiian Islands EEZ, the total fishery-related mortality and serious injury of this stock can be considered to be insignificant and approaching zero. Increasing levels of anthropogenic sound in the world’s oceans has been suggested to be a habitat concern for whales, particularly for baleen whales that may communicate using low-frequency sound (Croll et al. 2002). Behavioral changes associated with exposure to simulated mid-frequency sonar, including no change in behavior, cessation of feeding, increased swimming speeds, and movement away from simulated sound sources has been documented in tagged blue whales (Goldbogen et al. 2013), but it is unknown if fin whales respond in the same manner to such sounds.

BRYDE'S WHALE (*Balaenoptera edeni*): Hawaii Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Bryde's whales occur in tropical and warm temperate waters throughout the world. Leatherwood et al. (1982) described the species as relatively abundant in summer and fall on the Mellish and Miluoki banks northeast of Hawaii and around Midway Islands. Ohsumi and Masaki (1975) reported the tagging of "many" Bryde's whales between the Bonin and Hawaiian Islands in the winters of 1971 and 1972 (Ohsumi 1977). Summer/fall shipboard surveys of the waters within the U.S. Exclusive Economic Zone (EEZ) of the Hawaiian Islands resulted in 13 Bryde's whale sightings throughout the study area in 2002 and 30 in 2010 (Figure 1; Barlow 2006; Bradford et al 2013). There is currently no biological basis for defining separate stocks of Bryde's whales in the central North Pacific. Bryde's whales were seen occasionally off southern California (Morejohn and Rice 1973) in the 1960s, but their seasonal occurrence has increased since at least 2000 based on detection of their distinctive calls (Kerosky et al. 2012).

For the MMPA stock assessment reports, Bryde's whales within the Pacific U.S. EEZ are divided into two areas: 1) Hawaiian waters (this report), and 2) the eastern Pacific (east of 150°W and including the Gulf of California and waters off California). The Hawaiian stock includes animals found both within the Hawaiian Islands EEZ and in adjacent high seas waters; however, because data on abundance, distribution, and human-caused impacts are largely lacking for high seas waters, the status of this stock is evaluated based on data from U.S. EEZ waters of the Hawaiian Islands (NMFS 2005).

POPULATION SIZE

Tillman (1978) concluded from Japanese and Soviet CPUE data that the stock size in the North Pacific pelagic whaling grounds, mostly to the west of the Hawaiian Islands, declined from approximately 22,500 in 1971 to 17,800 in 1977. An estimate of 13,000 (CV=0.20) Bryde's whales was made from vessel surveys in the eastern tropical Pacific between 1986 and 1990 (Wade and Gerrodette 1993). The area to which this estimate applies is mainly southeast of the Hawaiian Islands, and it is not known whether these animals are part of the same population that occurs around the Hawaiian Islands. A 2002 shipboard line-transect survey of the entire Hawaiian Islands EEZ resulted in an abundance estimate of 469 (CV=0.45) Bryde’s whales (Barlow 2006). A more recent estimate from a similar 2010 EEZ-wide survey resulted in an abundance estimate of 798 (CV = 0.28) Bryde’s whales (Bradford et al. 2013). This is currently the best available abundance estimate for this stock.

Minimum Population Estimate

Minimum population size is calculated as the lower 20th percentile of the log-normal distribution (Barlow et al. 1995) of the 2010 abundance estimate, or 633 Bryde’s whales.

Current Population Trend

No data are available on current population trends. The broad and overlapping confidence intervals around
the 2002 and 2010 estimates preclude assessment of trends with the available data.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

No data are available on current or maximum net productivity rate.

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) level for the Hawaii stock of Bryde’s whales is calculated as the minimum population size within the U.S EEZ of the Hawaiian Islands (633) times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.50 (for a stock of unknown status with no known fishery mortality or serious injury within the Hawaiian Islands EEZ; Wade and Angliss 1997), resulting in a PBR of 6.3 Bryde’s whales per year.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

New Serious Injury Guidelines

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an “injury that is more likely than not to result in mortality”. Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

Fishery Information

There are currently two distinct longline fisheries based in Hawaii: a deep-set longline (DSLL) fishery that targets primarily tunas, and a shallow-set longline fishery (SSLL) that targets swordfish. Both fisheries operate within U.S. waters and on the high seas. Between 2007 and 2011, no Bryde’s whales were observed hooked or entangled in the SSLL fishery (100% observer coverage) or the DSLL fishery (20-22% observer coverage) (McCracken 2013, Bradford & Forney 2013). One Bryde’s whale was observed entangled in shallow-set longline gear off the Hawaiian Islands in 2005 (Forney 2010).

Historical Mortality

Small numbers of Bryde's whales were taken near the Northwestern Hawaiian Islands by Japanese and Soviet whaling fleets in the early 1970s (Ohsumi 1977). Pelagic whaling for Bryde's whales in the North Pacific ended after the 1979 season (IWC 1981), and coastal whaling for this species ended in the western Pacific in 1987 (IWC 1989).

STATUS OF STOCK

The Hawaii stock of Bryde’s whales is not considered strategic under the 1994 amendments to the MMPA. The status of Bryde's whales in Hawaiian waters relative to OSP is unknown, and there are insufficient data to evaluate trends in abundance. Bryde’s whales are not listed as “threatened” or “endangered” under the Endangered Species Act (1973), nor designated as “depleted” under the MMPA. Given the absence of recent recorded fishery-related mortality or serious injuries within the Hawaiian Islands EEZ, the total fishery mortality and serious injury can be considered to be insignificant and approaching zero. The increasing level of anthropogenic noise in the world’s oceans has been suggested to be a habitat concern for whales (Richardson et al. 1995, Weilgart 2007).

SEI WHALE (*Balaenoptera borealis borealis*): Hawaii Stock

**STOCK DEFINITION AND GEOGRAPHIC RANGE**

The International Whaling Commission (IWC) recognizes one stock of sei whales in the North Pacific (Donovan 1991), but some evidence exists for multiple populations (Masaki 1977; Mizroch et al. 1984; Horwood 1987). Sei whales are distributed far out to sea in temperate regions of the world and do not appear to be associated with coastal features. Whaling effort for this species was distributed continuously across the North Pacific between 45-55°N (Masaki 1977). Two sei whales that were tagged off California were later killed in whaling operations off Washington and British Columbia (Rice 1974) and the movement of tagged animals has been noted in many other regions of the North Pacific. There is still insufficient information to accurately determine population structure, but from a conservation perspective it may be risky to assume panmixia in the entire North Pacific. Summer/fall shipboard surveys of the waters within the U.S. Exclusive Economic Zone (EEZ) of the Hawaiian Islands resulted in four sightings in 2002 and three in 2010 (Figure 1; Barlow 2003; Bradford et al. 2013). There have been no reported strandings of sei whales in the Hawaiian Islands.

For the Marine Mammal Protection Act (MMPA) stock assessment reports, sei whales within the Pacific U.S. EEZ are divided into three discrete areas: 1) waters around Hawaii (this report), 2) California, Oregon and Washington waters, and 3) Alaskan waters. The Hawaiian stock includes animals found both within the Hawaiian Islands EEZ and in adjacent high seas waters; however, because data on abundance, distribution, and human-caused impacts are largely lacking for high seas waters, the status of this stock is evaluated based on data from U.S. EEZ waters of the Hawaiian Islands (NMFS 2005).

**POPULATION SIZE**

Ohsumi and Wada (1974) estimate the pre-whaling abundance of sei whales to be 58,000-62,000 in the North Pacific. Later, Tillman (1977) used a variety of methods to estimate sei whale abundance in the North Pacific and revised the pre-whaling estimate to 42,000. His estimates for the year 1974, following 27 years of whaling, ranged from 7,260 to 12,620. All methods depend on using the history of catches and trends in CPUE or sighting rates; there have been no direct estimates of sei whale abundance in the entire North Pacific based on sighting surveys. A 2002 shipboard line-transect survey of the entire Hawaiian Islands EEZ resulted in a summer/fall abundance estimate of 77 (CV = 1.06) sei whales (Barlow 2003). More recently, the 2010 shipboard line-transect survey of the Hawaiian Islands EEZ resulted in a summer/fall abundance estimate of 178 (CV = 0.9) sei whales (Bradford et al. 2013). This is currently the best available abundance estimate for this stock, but the majority of sei whales would be expected to be in higher-latitude feeding grounds at this time of year.

**Minimum Population Estimate**

The minimum population size is calculated as the lower 20th percentile of the log-normal distribution (Barlow et al 1995) of the 2010 abundance estimate or 93 sei whales within the Hawaiian Islands EEZ.

**Current Population Trend**
No data are available on current population trend. Although the population in the North Pacific is expected to have grown since being given protected status in 1976, the possible effects of continued unauthorized takes (Yablokov 1994) make this uncertain. The broad and overlapping confidence intervals around the 2002 and 2010 estimates preclude assessment of trend with the available data.

**CURRENT AND MAXIMUM NET PRODUCTIVITY RATES**

No data are available on current or maximum net productivity rate for sei whales.

**POTENTIAL BIOLOGICAL REMOVAL**

The potential biological removal (PBR) level for this stock is calculated as the minimum population size within the U.S. EEZ of the Hawaiian Islands (93 times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.1 (the default value for an endangered species with $N_{\text{min}} < 1500$; Taylor et al. 2003), resulting in a PBR of 0.2 sei whales per year.

**HUMAN-CAUSED MORTALITY AND SERIOUS INJURY**

**New Serious Injury Guidelines**

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an “injury that is more likely than not to result in mortality”. Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

**Fishery Information**

Information on fishery-related mortality of cetaceans in Hawaiian waters is limited, but the gear types used in Hawaiian fisheries are responsible for marine mammal mortality and serious injury in other fisheries throughout U.S. waters. In March 2011 a subadult sei whale was found near Lahaina, Maui entangled with one or two wraps of heavy-gauge polypropylene line around the tailstock and trailing about 30 feet of line including a large bundle (Bradford & Lyman 2013). Closer examination also revealed line scars on the body near the dorsal fin. Although disentanglement was attempted, the gear could not be removed. Although the source of the line entangling the whale could not be determined, this injury is considered serious based on extent of trailing gear and condition of the whale (Bradford & Lyman 2013, NMFS 2012). This serious injury record results in an average annual serious injury and mortality rate of 0.2 sei whales for the period 2007 to 2011.

There are currently two distinct longline fisheries based in Hawaii: a deep-set longline (DSLL) fishery that targets primarily tunas, and a shallow-set longline fishery (SSLL) that targets swordfish. Both fisheries operate within U.S. waters and on the high seas. Between 2007 and 2011, no sei whales were observed hooked or entangled in the SSLL fishery (100% observer coverage) or the DSLL fishery (20-22% observer coverage) (McCracken 2013, Bradford & Forney 2013).

**Historical Whaling**

The reported take of North Pacific sei whales by commercial whalers totaled 61,500 between 1947 and 1987 (C. Allison, IWC, pers. comm.). There has been an IWC prohibition on taking sei whales since 1976, and commercial whaling in the U.S. has been prohibited since 1972.

**STATUS OF STOCK**

Previously, sei whales were estimated to have been reduced to 20% (8,600 out of 42,000) of their pre-whaling abundance in the North Pacific (Tillman 1977). Sei whales are formally listed as "endangered" under the Endangered Species Act (ESA), and consequently the Hawaiian stock is automatically considered as a "depleted" and "strategic" stock under the MMPA. The observed rate of fisheries-related mortality or serious injury within the Hawaiian Islands EEZ (0.2 animals per year) is equal to the PBR (0.2), though the responsible fishery is unknown. The increasing level of anthropogenic noise in the world’s oceans has been suggested to be a habitat concern for whales (Richardson et al. 1995). Behavioral changes associated with exposure to simulated mid-frequency sonar, including no change in behavior, cessation of feeding, increased swimming speeds, and movement away from simulated sound sources has been documented in tagged blue whales (Goldbogen et al. 2013), but it is unknown if sei whales respond in the same manner to such sounds.

MINKE WHALE (*Balaenoptera acutorostrata scammoni*): Hawaii Stock

**STOCK DEFINITION AND GEOGRAPHIC RANGE**

The International Whaling Commission (IWC) recognizes 3 stocks of minke whales in the North Pacific: one in the Sea of Japan/East China Sea, one in the rest of the western Pacific west of 180°N, and one in the "remainder" of the Pacific (Donovan 1991). The "remainder" stock only reflects the lack of exploitation in the eastern Pacific and does not imply that only one population exists in that area (Donovan 1991). In the "remainder" area, minke whales are relatively common in the Bering and Chukchi seas and in the Gulf of Alaska, but are not considered abundant in any other part of the eastern Pacific (Leatherwood et al. 1982; Brueggeman et al. 1990). In the Pacific, minke whales are usually seen over continental shelves (Brueggeman et al. 1990). In the extreme north, minke whales are believed to be migratory, but in inland waters of Washington and in central California they appear to establish home ranges (Dorsey et al. 1990).

Minke whales occur seasonally around the Hawaiian Islands (Barlow 2003, Rankin and Barlow, 2005), and their migration routes or destinations are unknown. Minke whale “boing” sounds have been detected near the Hawaiian Islands for decades, with detections by the U.S. Navy during February and March (Thompson and Friedl 1982) and at the ALOHA Cabled Observatory 100km north of Oahu from October to May (Oswald et al. 2011). Minke whales were observed within 22km of Kauai in February 2005 (Rankin et al. 2007) and by observers in the Hawaii-based longline fishery since 1994 (Figure 1; NMFS/PIR unpublished data). Two confirmed sightings of minke whale were made, one in November 2002 and the other during October 2010 during surveys of waters within the U.S. Exclusive Economic Zone (EEZ) of the Hawaiian Islands (Barlow 2003; Bradford et al. 2013). There are no known stranding records of this species from the main islands (Nitta 1991; Maldini et al. 2005).

For the Marine Mammal Protection Act (MMPA) stock assessment reports, there are three stocks of minke whale within the Pacific U.S. EEZ: 1) a Hawaiian stock (this report), 2) a California/Oregon/Washington stock, and 3) an Alaskan stock. The Hawaiian stock includes animals found both within the Hawaiian Islands EEZ and in adjacent high seas waters; however, because data on abundance, distribution, and human-caused impacts are largely lacking for high seas waters, the status of this stock is evaluated based on data from U.S. EEZ waters of the Hawaiian Islands (NMFS 2005).

**POPULATION SIZE**

Using passive acoustic detections from an array of seafloor hydrophones north of Kauai, Martin et al. (2012) estimate a preliminary average density of 2.15 "boing" calling minke whales per 1000 km² during the period February through April and within an area of 8,767 km² centered on the seafloor array positioned roughly 50km from shore. However, the relationship between the number of whales present and the number of calls detected is not known, and therefore this acoustic method does not provide an estimate of absolute abundance for minke whales.
Summer/fall 2002 and 2010 shipboard line-transect surveys of the entire Hawaiian Islands EEZ each resulted in one 'off effort' sighting of a minke whale (Barlow 2003, Bradford et al. 2013). These sightings were not part of regular survey operations and, therefore, could not be used to calculate estimates of abundance (Barlow 2003; Bradford et al. 2013). The majority of this survey took place during summer and early fall, when the Hawaiian stock of minke whale would be expected to be farther north. There currently is no abundance estimate for this stock of minke whales, which appears to occur seasonally (about October - April) around the Hawaiian Islands.

**Minimum Population Estimate**
There is no minimum population estimate for the Hawaiian stock of minke whales.

**Current Population Trend**
No data are available on population size or current population trend.

**CURRENT AND MAXIMUM NET PRODUCTIVITY RATES**
No data are available on current or maximum net productivity rate for Hawaiian minke whales.

**POTENTIAL BIOLOGICAL REMOVAL**
The potential biological removal (PBR) level for the Hawaii stock of minke whales is calculated as the minimum population estimate times one half the default maximum net growth rate for cetaceans (½ of 4%) times a recovery factor of 0.50 (for a species of unknown status with no estimated fishery mortality or serious injury within the U.S. EEZ of the Hawaiian Islands; Wade and Angliss 1997). Because there is no minimum population estimate for Hawaii minke whales, the PBR is undetermined.

**HUMAN CAUSED MORTALITY AND SERIOUS INJURY**

**New Serious Injury Guidelines**
NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998, Andersen et al. 2008, NOAA 2012). NMFS defines serious injury as an “injury that is more likely than not to result in mortality”. Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

**Fishery Information**
Information on fishery-related mortality and serious injury of cetaceans in Hawaiian waters is limited, but the gear types used in Hawaiian fisheries are responsible for marine mammal mortality and serious injury in other fisheries throughout U.S. waters. There are currently two distinct longline fisheries based in Hawaii: a deep-set longline (DSLL) fishery that targets primarily tunas, and a shallow-set longline fishery (SSLL) that targets swordfish. Both fisheries operate within U.S. waters and on the high seas. Between 2007 and 2011, no minke whales were observed hooked or entangled in the SSLL fishery (100% observer coverage) or the DSLL fishery (20-22% observer coverage) (McCracken 2013).

**STATUS OF STOCK**
The Hawaii stock of minke whales is not considered strategic under the 1994 amendments to the MMPA. The status of minke whales in Hawaiian waters relative to OSP is unknown, and there are insufficient data to evaluate trends in abundance. Minke whales are not listed as “threatened” or “endangered” under the Endangered Species Act (1973), nor designated as “depleted” under the MMPA. Because there has been no reported fisheries related mortality or serious injury within the Hawaiian Islands EEZ, the total fishery mortality and serious injury for minke whales can be considered insignificant and approaching zero mortality and serious injury rate. The increasing level of anthropogenic sound in the world’s oceans has been suggested to be a habitat concern for whales (Richardson et al. 1995).

HUMPBACK WHALE (*Megaptera novaeangliae*)
IUCN Oceania subpopulation – American Samoa Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

The humpback whale has a global distribution. Humpback whales migrate long distances between their feeding grounds at mid- to high latitudes and their calving and mating grounds in tropical waters. The Oceania subpopulation (as defined by the IUCN Red List process, see Childerhouse et al. 2008) ranges throughout the South Pacific, except the west coast of South America, and from the equator to the edges of the Antarctic ice. Humpback whales have been recorded across most of the lower latitudes of the South Pacific from approximately 30°S northwards to the equator during the austral autumn and winter. Although there have been no comprehensive surveys of this huge area, humpback whale densities are known to vary extensively from high densities in East Australia to low densities at many island groups. Many regional research projects have documented the presence of these whales around various island groups, but they are also found in open water away from islands (SPWRC 2008). Movements of individual whales between the tropical wintering grounds and the Antarctic summer feeding grounds have been documented by a variety of methods including Discovery tagging, photo-identification, matching genotypes from biopsies or carcasses, and satellite telemetry (Mackintosh 1942; Chittleborough 1965; Dawbin 1966; Mikhailov 2000; Rock et al. 2006, Franklin et al. 2007, Robbins et al. 2008). However, migratory routes and specific destinations remain poorly known. Unlike the other humpback stocks found in U. S. waters, the IUCN Oceania subpopulation is defined by structure on its calving grounds (Garrigue et al. 2006b, Olavarria et al. 2006, 2007) rather than on its feeding grounds. The Oceania subpopulation consists of breeding stocks E (including E1, E2 and E3) and F recognized by the International Whaling Commission (IWC). It is found in the area defined by the following approximate boundaries: 145°E (eastern Australia) in the west, 120°W (between French Polynesia and South America) in the east, the equator in the north, and 30°S in the south (Childerhouse et al. 2008).

For the Marine Mammal Protection Act (MMPA) stock assessment reports, there is need for only one South Pacific Island region management stock of humpback whales, the American Samoa stock. American Samoa lies at the boundary of breeding stocks E3 and F. Surveys have been undertaken annually at the primary island of Tutuila since 2003. A total of 150 unique individuals were identified by fluke photographs during 58 days at sea, 2003-2008 (D. Mattila and J. Robbins, unpublished data). Individuals have been resighted on multiple days in a single breeding season, but only three inter-annual re-sightings have been made to date (two based on dorsal fin photographs) (D. Mattila and J. Robbins, unpublished data). Breeding behavior and the presence of very young calves has been documented in American Samoa waters. One whale that was sighted initially without a calf was re-sighted later in the season with a calf. Individual exchange has been documented with Western Samoa (SPWRC 2008), as well as Tonga, French Polynesia and the Cook Islands (Garrigue et al. 2007). Although the feeding range of American Samoan whales has not yet been defined, there has been one photo-ID match to the Antarctic Peninsula (IWC Antarctic Area I, Robbins et al. 2008). Whales at Tonga have exhibited exchange with both Antarctic Area V (Dawbin 1959) and Area I (Brown 1957, Dawbin 1956) and so whales from American Samoa may have a similarly
wide feeding range.

On-going photographic studies indicate a higher frequency of certain types of skin lesions on humpback whales at American Samoa as compared to humpback whale populations at Hawaii or the Gulf of Maine (Mattila and Robbins, 2008). However, the cause and implications have yet to be determined. Some similar skin lesions on blue whales in Chilean waters have been observed (Brownell et al. 2008).

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Historic whaling

Southern Hemisphere humpback whales were hunted extensively during the last two centuries, and it is thought that populations have been reduced to a small percentage of their former levels (Chapman 1974). After correcting catch records for illegal Soviet whaling, (Clapham & Baker 2002) estimated that over 200,000 Southern Hemisphere humpback whales were killed from 1904 to 1980. Humpback whales were protected from commercial whaling in 1966 by the IWC but they continued to be killed illegally by the Soviet Union until 1972. Illegal Soviet catches of 25,000 humpback whales in two seasons (1959/60 and 1960/61) precipitated a population crash and the closure of land stations in Australia and New Zealand, including Norfolk Island (Mikhalev 2000; Clapham et al. 2005).

POPULATION SIZE

There is currently no estimate of abundance for humpback whales in American Samoan waters. The South Pacific Whale Research Consortium produced a number of preliminary mark-recapture estimates of abundance for Oceania and its subregions (SPWRC, 2006). A closed population estimate of 3,827 (CV 0.15) was calculated for eastern Oceania (breeding stocks E3 and F) for 1999-2004 and this may be the most relevant of those currently available, given observed exchange between American Samoa, Tonga, the Cook Islands, and French Polynesia (Garrigue et al. 2006a). However, the extent and biological significance of the documented interchange is still poorly understood.

Minimum Population Estimate

The minimum population estimate for this stock is 150 whales, which is the number of individual humpbacks identified in the waters around American Samoa between 2003-2008 by fluke photo identification (J. Robbins, personal communication). This is clearly an underestimation of the true minimum population size as photo ID studies have been conducted over a few weeks per year and there is also evidence of exchange with other areas in Oceania. There are also insufficient data to estimate the proportion of time Oceania humpback whales spend in waters of American Samoa.

Current Population Trend

No data are available on current population trend.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

No estimates of current or maximum net productivity rates are available for this species in Samoan waters. However, the maximum plausible growth rate for Southern Hemisphere humpback whale populations is estimated as 10.6% (Clapham et al. 2006).

POTENTIAL BIOLOGICAL REMOVAL

The potential biological removal (PBR) for this stock is calculated as the minimum population size (150) times one half the estimated maximum growth rate for humpback whales in the Southern Hemisphere (1/2 of 10.6%) times a recovery factor of 0.1 (for an endangered species with a total population size of less than 1,500), resulting in a PBR of 0.8. This stock of humpback whales is migratory and thus, it is reasonable to expect that animals spend at least half the year outside of the relatively small American Samoa EEZ. Therefore, the PBR allocation for U.S. waters is half of 0.8, or 0.4 whales.

HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

No human-related mortalities of humpback whales have been recorded in American Samoan waters. Human-related mortality of humpback whales due to entanglements in fishing gear and collisions with ship have been reported elsewhere in the Southern Hemisphere. Entanglement of humpback whales in pot lines has been reported in both New Zealand and Australia but there are no estimated rates available. There is little information
from the rest of the South Pacific but a humpback mother (with calf) was reported entangled in a longline in 2007 in the Cook Islands (N. Hauser, reported in SPWRC 2008).

A photographic-based scar study of the humpback whales of American Samoa has been initiated and there is some indication of healed entanglement and ship strike wounds, although perhaps not at the levels found in some Northern Hemisphere populations (D. Mattila and J. Robbins, unpublished data). However, the sample size to date is insufficient for robust comparison and the study is ongoing.

STATUS OF STOCK

The status of humpback whales in American Samoan EEZ waters relative to OSP is unknown and there are insufficient data to estimate trends in abundance. However, humpback whale populations throughout the South Pacific were drastically reduced by historical whaling and IUCN classifies the Oceania subpopulation as “Endangered” (Childerhouse et al. 2008). Worldwide humpback whales are listed as “endangered” under the Endangered Species Act (1973) so the Samoan stock is automatically considered a "depleted" and “strategic” stock under the MMPA. There are no habitat concerns for the stock.

Japan has proposed killing 50 humpback whales as part of its program of scientific research under special permit (scientific whaling) called JARPA II in the IWC management areas IV and V in the Antarctic (Gales et al. 2005). Areas IV and V have demonstrated links with breeding stock E. Japan postponed their proposed catch in the 2007/08 and 2008/09 seasons but have not removed them from their future whaling program. The JARPA II program has the potential to negatively impact the recovery of humpbacks in Oceania.

REFERENCES

Garrigue, C., T. Franklin, K. Russell, D. Burns, M. Poole, D. Paton, N. Hauser, M. Oremus, R. Constantine, S.

The Marine Mammal Protection Act (MMPA) requires NMFS to publish a list of commercial fisheries (List Of Fisheries or “LOF”) and classify each fishery based on whether incidental mortality and serious injury of marine mammals is frequent (Category I), occasional (Category II), or unlikely or unknown (Category III). The LOF is published annually in the Federal Register. The categorization of a fishery in the LOF determines whether participants in that fishery are subject to certain provisions of the MMPA, such as registration, observer coverage, and take reduction plan requirements. The categorization criteria as they appear in the LOF is reprinted below:

The fishery classification criteria consist of a two-tiered, stock-specific approach that first addresses the total impact of all fisheries on each marine mammal stock, and then addresses the impact of individual fisheries on each stock. This approach is based on consideration of the rate, in numbers of animals per year, of incidental mortality and serious injury of marine mammals due to commercial fishing operations relative to the Potential Biological Removal (PBR) level for each marine mammal stock. The MMPA (16 U.S.C. 1362 (20)) defines the PBR level as the maximum number of animals, not including natural mortality, that may be removed from a marine mammal stock while allowing that stock to reach or maintain its optimum sustainable population. This definition can also be found in the implementing regulations for section 118 at 50 CFR 229.2.

Tier 1: If the total annual mortality and serious injury across all fisheries that interact with a stock is less than or equal to 10 percent of the PBR level of the stock, all fisheries interacting with the stock would be placed in Category III. Otherwise, these fisheries are subject to the next tier (Tier 2) of analysis to determine their classification.

Tier 2, Category I: Annual mortality and serious injury of a stock in a given fishery is greater than or equal to 50 percent of the PBR level.

Tier 2, Category II: Annual mortality and serious injury of a stock in a given fishery is greater than 1 percent and less than 50 percent of the PBR level.

Tier 2, Category III: Annual mortality and serious injury of a stock in a given fishery is less than or equal to 1 percent of the PBR level.

While Tier 1 considers the cumulative fishery mortality and serious injury for a particular stock, Tier 2 considers fishery-specific mortality and serious injury for a particular stock. Additional details regarding how the categories were determined are provided in the preamble to the final rule implementing section 118 of the MMPA (60 FR 45086, August 30, 1995). Since fisheries are categorized on a per-stock basis, a fishery may qualify as one Category for one marine mammal stock and another Category for a different marine mammal stock. A fishery is typically categorized on the LOF at its highest level of classification (e.g., a fishery that qualifies for Category III for one marine mammal stock and for Category II for another marine mammal stock will be listed under Category II).

Other Criteria That May Be Considered

In the absence of reliable information indicating the frequency of incidental mortality and serious injury of marine mammals by a commercial fishery, NMFS will determine whether the incidental serious injury or mortality qualifies for Category II by evaluating other factors such as fishing techniques, gear used, methods used to deter marine mammals, target species, seasons and areas fished, qualitative data from logbooks or fisher reports, stranding data, and the species and distribution of marine mammals in the area, or at the discretion of the Assistant Administrator for Fisheries (50 CFR 229.2).

This appendix describes commercial fisheries that occur in California, Oregon, Washington, and Hawaiian waters and that interact or may interact with marine mammals. The first three sections describe sources of marine mammal mortality data for these fisheries. The fourth section describes the commercial fisheries for these states. A list of all known fisheries for these states was published as a proposed rule in the Federal Register, 71 FR 20941, 24 April 2006.

1. Sources of Mortality/Injury Data

There are three major sources of marine mammal mortality/injury data for the active commercial fisheries in California, Oregon, Washington, and Hawaii. These sources are the NMFS Observer Programs, the Marine Mammal
Appendix 1. Description of U.S. Commercial Fisheries

Authorization Program (MMAP) data, and the NMFS Marine Mammal Stranding Network (MMSN) data. Each of these data sources has a unique objective. Data on mammal mortality and injury are reported to the MMAP by fishers in any commercial fisheries. Marine mammal mortality and injury is also monitored by the NMFS Marine Mammal Stranding Network (MMSN). Data provided by the MMSN is not duplicated by either the NMFS Observer Program or MMAP reporting. Human-related data from the MMSN include occurrences of mortality due to entrapment in power station intakes, ship strikes, shooting, evidence of net and line fishery entanglement (net remaining on animal, net marks, severed flukes), and ingestion of hooks.

2. Marine Mammal Reporting from Fisheries

In 1994, the MMPA was amended to implement a long-term regime for managing mammal interactions with commercial fisheries (the Marine Mammal Authorization Program, or MMAP). Logbooks are no longer required - instead vessel owners/operators in any commercial fishery (Category I, II, or III) are required to submit one-page pre-printed reports for all interactions (including those that occur while an observer is onboard) resulting in an injury to or death of a marine mammal. The report must include owner/operator’s name and address, vessel name and ID, where and when the interaction occurred, the fishery, species involved, and type of injury (if the animal was released alive). These postage-paid report forms are mailed to all Category I and II fishery participants that have registered with NMFS, and must be completed and returned to NMFS within 48 hours of returning to port for trips in which a marine mammal injury or mortality occurred. The number of self-reported marine mammal interactions is considerably lower than the number reported by fishery observers, even though observer reports are typically based on 20% observer effort. For example, from 2000-2004, there were 112 fisher self-reports of marine mammal interactions in the California swordfish/thresher shark drift gillnet fishery. This compares with 141 observed interactions over the same period, based on only 20% observer coverage. This suggests that fisher self-reports are negatively-biased. From 2007-2011 there were 12 fisher self-reports of marine mammal interactions in the Hawaii-based deep-set longline fishery, 11 of which corresponded to observer records. This compares with 50 observed interactions over the same period, based on 20-22% observer coverage. This suggests fisher self-reports are significantly negatively biased.

3. NMFS Marine Mammal Stranding Network data

From 2000-2004, there were 1,022 cetacean and 13,215 pinniped strandings recorded in California, Oregon, and Washington states. Approximately 10% of all cetacean and 6% of all pinniped strandings showed evidence of human-caused mortality during this period. From 2007-2011, there were 144 cetacean strandings recorded in Hawaii, with 42% of all cetacean strandings showing evidence of human-caused mortality during this period. Human-related causes of mortality include: entrapment in power station intakes, shooting, net fishery entanglement, and hook/line, set-net and trap fishery interaction.

4. Fishery Descriptions

Category I, CA/OR thresher shark/swordfish drift gillnet fishery (≥14 inch mesh)

Number of permit holders: The numbers of eligible permit holders in California for, 2008 to 2012 ranged between 78 and 84 (data source: California Department of Fish and Wildlife website: www.dfg.ca.gov/licensing). Permits are non-transferable and are linked to individual fishermen, not vessels.

Number of active permit holders: The numbers of vessels active in this fishery declined from 40 in 2008 to 16 vessels in 2012.

Total effort: Both estimated and observed effort for the drift-net fishery during the calendar years 1990 through 2012 are shown in Figure 2.

Geographic range: Effort in this fishery ranges from the U.S./Mexico border north to waters off the state of Oregon. For this fishery there are area-season closures (see below). Figures 1 shows locations of observed sets for the period 1990 to 2012.

Seasons: This fishery is subject to season-area restrictions. From February 1 to May 15 effort must be further than 200 nautical miles (nmi) from shore; from May 16 to August 14, effort must be further than 75 nmi from shore, and from
August 15 to January 31 there is only the 3 nmi off-shore restriction for all gillnets in southern California (see halibut and white seabass fishery below). The majority of the effort occurs from October through December. A season-area closure to protect leatherback sea turtles was implemented in this fishery in August 2001. The closure area prohibits drift gillnet fishing from August 15 through November 15, in the area bounded by straight lines from Point Sur, California (N 36° 17’ W 123° 35’), west to W 129°, north to N 45°, then east to the Oregon coast. An additional season-area closure south of Point Conception and east of W120 degrees longitude is effective during the months of June, July, and August during El Niño years to protect loggerhead turtles (Federal Register, 68 FR 69962, 16 December 2003).

Gear type and fishing method: Typical gear used for this fishery is a 1000-fathom gillnet with a stretched mesh size typically ranging from 18-22 inches (14 inch minimum). The net is set at dusk and allowed to drift during the night after which, it is retrieved. The fishing vessel is typically attached to one end of the net. Soak duration is typically 12-14 hours depending on the length of the night. Net extender lengths of a minimum 36 ft. became mandatory for the 1997-1998 fishing season. The use of acoustic warning devices (pingers) became mandatory 28 October 1997.

Regulations: The fishery is managed under a Fishery Management Plan (FMP) developed by the Pacific Fishery Management Council and NMFS.

Management type: The drift-net fishery is a limited-entry fishery with seasonal closures and gear restrictions (see above). The state of Oregon restricts landing to swordfish only.

Comments: This fishery has had a NMFS observer program in place since 1990. Due to bycatch of strategic stocks including short-finned pilot whales, beaked whales, sperm whales and humpback whales, a Take Reduction Team was formed in 1996. Since then, the implementation of increased extender lengths and the deployment of pingers have substantially decreased cetacean entanglement. The fraction of active vessels in this fishery that are not observed owing to a lack of berthing space for observers has been increasing. The fishery currently operates under an emergency rule designed to reduce to the bycatch of sperm whales (Federal Register 4 September 2013, Volume 78: pages 54548-54552.

Category I, Hawaii deep-set (tuna target) longline/set line fishery

Note: The Hawaii-based longline fisheries of the Pelagic Fishery Ecosystem Plan (FEP) consist of two separately managed longline fisheries. One is the deep-set (tuna targeted) fishery which is classified as a Category I fishery under the MMPA. This fishery is discussed here. The classification of this fishery was elevated to Category I in 2004 based on revised PBR levels of false killer whales and observed false killer whale mortality in this fishery (Federal Register 69 FR 48407 1, 10 August 2004). The other Hawaii-based longline fishery is the Hawaii shallow-set longline (swordfish targeted) fishery which is classified as a Category II fishery under the MMPA and is discussed in the Category II section of this Appendix.

Number of permit holders: The number of Hawaii longline limited access permit holders is 164. Not all such permits are renewed and used every year. Permit holders may use the permits for either deep-set or shallow-set fishing, but must notify NMFS how they will fish before each trip. Most holders of Hawaii longline limited access permits are based in, or operate out of, Hawaii.

Number of active deep-set longline vessels targeting tuna: From 2007 to 2011, the number of active longline vessels based and landing in Hawaii was 129, 127, 127, 122, and 129, respectively (http://www.pifsc.noaa.gov/fmsd/reports.php).

Total effort: The number of trips ranged from a low of approximately 500 (in 1992) to 1,427 in 2007. Figure 4 shows the number of fishing trips by longline vessels based and landing in Hawaii, by year and trip type, 1991-2009. The number of sets for the deep-set tuna fishery in 2007-2011 was 17,885, 16,810, 16,070, and 17,155. The number of hooks set in 2007-2011 was 38.8 million, 40.1 million, 37.7 million, 37.1 million, and 40.7 million.

Geographic range: The Hawaii-based pelagic, deep-set longline fishery operates inside and outside the EEZ, primarily around the main Hawaiian Islands and Northwestern Hawaiian Islands, with some trips to the EEZs around the remote U.S. Pacific islands (however there are restricted areas, please refer to “Regulations”). Vessels vary their fishing grounds depending on their target species. Most of the deep-set fishing occurs south of 25° N.
Appendix 1. Description of U.S. Commercial Fisheries

Seasons: This fishery operates year-round, although vessel activity increases during the fall and is greatest during the winter and spring months.

Gear type: Deep-set longline gear typically consists of a continuous main line set on the surface and supported in the water column horizontally by floats with branch lines connected at intervals to the main line. In addition radio buoys are also used to keep track of the main line as it drifts at sea. A line shooter is used on deep-sets to deploy the mainline faster than the speed of the vessel, thus allowing the longline gear to sink to its target depth (average target depth is 167 m, target depth for bigeye tuna is approximately 400 m). The main line is typically 30 to 100 km (18 to 60 nm) long. A minimum of 15, but typically 20 to 30, weighted branch lines (gangions) are clipped to the mainline at regular intervals between the floats. Each gangion terminates with a single baited hook. The branch lines are typically 11 to 15 meters (35 to 50 feet) long. Sanma (saury) or sardines are used for bait. Lightsticks are not typically attached to the gangions on this type of longline set. Deep-set longline gear is set in the morning and hauled in the evening and at night.

Regulations: This fishery is managed under the Pelagics FEP and subject to Federal regulation. Measures that are currently applicable to the fishery include, but are not limited to, limited access (requirement for a permit), vessel and gear marking requirements, vessel length restrictions, Federal catch and effort logbooks, large longline restricted areas around the Hawaiian Archipelago, vessel monitoring system (VMS), annual protected species workshops, use of circle hooks with wire diameter not greater than 4.5mm and branch line not less than 2.0mm, and the use of sea turtle, seabird, and marine mammal handling and mitigation gear and techniques. The vessel operator must notify NMFS prior to departure whether the vessel is undertaking a deep-set or shallow-set trip. Once the trip type is set, it cannot be changed during the trip. Vessel operators must take a NMFS contracted observer if requested by NMFS – target observer coverage is 20 percent of trips. If any marine mammal interaction (hooking or entanglement) resulting in injury or mortality occurs, the vessel operator must complete and mail a pre-addressed, postage paid form to NOAA Fisheries within 48 hours of the end of the trip. Additional information on all applicable regulations for the deep-set longline fishery is available at http://www.fpir.noaa.gov/SFD/SFD_regs_2.html. This fishery is subject to the False Killer Whale Take-Reduction Team. NMFS is currently implementing the Take-Reduction Plan and associated regulations.

Management type: Federal limited access program. This fishery is managed under a Fishery Ecosystem Plan (FEP) developed by the Western Pacific Fishery Management Council and NMFS.

Comments: Non-target species are caught incidentally. Interactions with common bottlenose dolphins, false killer whales, humpback whales, short-finned pilot whales, pantropical spotted dolphins, Blainville's beaked whale, sperm whales, striped dolphins and Risso’s dolphins have been documented. Due to interactions with protected species, especially turtles, this fishery has been observed since February 24, 1994. Initially, observer coverage was less than 5%, increased to 10% in 2000, and equaled or exceeded 20% since 2001. Observed marine mammal injuries and deaths form 2007-2011 included 24 false killer whales, 4 short-finned pilot whales, 3 Risso’s dolphins, 2 common bottlenose dolphins, 1 sperm whale, 1 pantropical spotted dolphin, one striped dolphin, and 14 unidentified cetaceans. Four of the interactions were deaths, 32 were serious injuries, nine were non-serious injuries, one involved prorating a whale interaction as 0.75 serious (NMFS, 2012), and four were classified as cannot-be-determined.

Category II, CA halibut/white seabass and other species set gillnet fishery (>3.5 inch mesh).

Halibut are typically targeted using 8.5 inch mesh while the remainder of the fishery targets white seabass and yellowtail using 6.5 inch mesh. In recent years, there has been an increasing number of 6.0-6.5 inch mesh sets fished using drifting methods; this component is now identified as a separate fishery (see “CA yellowtail, barracuda, white seabass, and tuna drift gillnet fishery (>3.5 and <14 in mesh)” fishery described below).

Number of permit holders: There is no specific permit category for this fishery. Overall, the current number of legal permit holders for gill and trammel nets, excluding swordfish drift gillnets and herring gillnets were between 141 and 154 annually. Information on permit numbers is available from the California Department of Fish and Game website (http://www.dfg.ca.gov/licensing).

Number of active permit holders: Approximately 50 vessels participate in this fishery (NMFS List of Fisheries, Federal Register 29 August 2013).
Total effort:  Total fishing effort for the period 2008 to 2012 has been approximately 2,000 sets annually.

Geographic range:  Effort in this fishery previously ranged from the U.S./Mexico border north to Monterey Bay and was localized in more productive areas: San Ysidro, San Diego, Oceanside, Newport, San Pedro, Ventura, Santa Barbara, Morro Bay, and Monterey Bay.  Fishery effort is now predominantly in the Ventura Flats area off of Ventura, the San Pedro area between Pt. Vicente and Santa Catalina Island and in the Monterey Bay area.  The central California portion of the fishery from Point Arguello to Point Reyes has been closed since September 2002 when a ban on gillnets inshore of 60 fathoms took effect.

Seasons:  This fishery operates year round.  Effort generally increases during the summer months and declines during the last three months of a year.

Gear type and fishing method:  Typical gear used for this fishery is a 200 fathom gillnet with a stretched mesh size of 8.5 inches.  The component of this fishery that targets white seabass and yellowtail utilizes 6.5 inch mesh.  The net is generally set during the day and allowed to soak for up to 2 days.  Soak duration is typically 8-10, 19-24, or 44-49 hours.  The depth of water ranges from 15-50 fathoms with most sets in water depths of 15-35 fathoms.

Regulations:  This fishery is managed by the California Dept. of Fish and Game in accordance with state and federal laws.

Management type:  The halibut and white seabass set-net fishery is a limited-entry fishery with gear restrictions and area closures.

Comments:  An observer program for the halibut and white seabass portion of this fishery operated from 1990-94 and was discontinued after area closures were implemented in 1994, which prohibited gillnets within 3 nmi of the mainland and within 1 nmi of the Channel Islands in southern California.  NMFS re-established an observer program for this fishery in Monterey Bay in 1999-2000 due to a suspected increase in harbor porpoise mortality in Monterey Bay.  In 1999 and 2000, fishery mortality exceeded PBR for the Monterey Bay harbor porpoise stock, which at that time, was designated as strategic [the stock is currently non-strategic].  In the autumn of 2000, the California Department of Fish and Game implemented the first in a series of emergency area closures to set gillnets within 60 fathoms along the central California coast in response to mortality of common murres and threats to sea otters.  This effectively reduced fishing effort to negligible levels in 2001 and 2002 in Monterey Bay.  A ban on gill and trammel nets inside of 60 fathoms from Point Reyes to Point Arguello became effective in September 2002.  Bycatch of marine mammals, including California sea lions and harbor seals, continues in this fishery, based on limited observer data.

Category II, Hawaii shallow-set (swordfish target) longline/set line fishery

Note:  The Hawaii-based longline fisheries of the Pelagic Fishery Ecosystem Plan (FEP) consist of two separately managed longline fisheries.  One is the deep-set (tuna targeted) fishery which is classified as a Category I fishery under the MMPA.  The other is the Hawaii shallow-set longline (swordfish targeted) fishery which is classified as a Category II fishery under the MMPA and is discussed here.

Number of permit holders:  The number of Hawaii longline limited access permit holders is 164.  Not all such permits are renewed and used every year.  Permit holders may use the permits for either deep-set or shallow-set fishing, but must notify NMFS how they will fish before each trip.  Most holders of Hawaii longline limited access permits are based in, or operate out of, Hawaii.  Longline general permits are not limited by number.  These general permits are open access and usable in Guam, CNMI, and the Pacific Remote Island Areas; they are usually not more than a half dozen a year.

Number of active shallow-set longline vessels targeting swordfish:  From 2007 to 2011, the number of active shallow-set longline vessels based in and landing in Hawaii was 28, 27, 28, 28, and 20.

Total effort:  The number of trips since 1991 has ranged from zero (2002-2003) to approximately 300 in 1993.  Figure 4 shows the number of fishing trips by longline vessels based and landing in Hawaii, by year and trip type, 1991-2011.
number of sets for the shallow-set swordfish fishery in 2007-2011 was 1,570, 1,597, 1,762, 1,833, and 1,468. The number of hooks set in 2007-2011 was 1.4 million, 1.5 million, 1.7 million, 1.8 million, 1.5 million.

**Geographic range:**
The most productive swordfishing areas for Hawaii-based longline vessels are north of Hawaii outside the U.S. Exclusive Economic Zone (EEZ) on the high seas, and this fishery operates almost entirely north of Hawaii (north of approximately 20° N). In some years, when influenced by seawater temperature, this fishery may operate mostly north of 30° N.

**Seasons:** Shallow-set effort is highest in either the first or second quarter of the calendar year and drops off substantially in the latter half of the year.

**Gear type:** Shallow-set longline gear typically consists of a continuous main line set on the surface and supported in the water column horizontally by floats with branch lines connected at intervals to the main line. In addition radio buoys are also used to keep track of the mainline as it drifts at sea. Longline fishing for swordfish is known as shallow-set longline fishing as the bait is set at depths of 30–90 m. The portion of the mainline with branchlines attached is suspended between floats at about 20–75 m of depth, and the branchlines hang off the mainline another 10–15 m. Only 4-6 branchlines are clipped to the mainline between floats, and a typical set for swordfish uses about 1,000-1,200 hooks. Shallow-set longline gear is set at night, with luminescent light sticks attached to the branchlines. Formerly, J-hooks and squid bait were used, but since 2004, circle hooks and mackerel-type bait have been required. These gear restrictions were implemented to reduce sea turtle bycatch.

**Regulations:** This fishery is managed under the Pelagics FEP and subject to Federal regulation. Measures that are currently applicable to the fishery include, but are not limited to, limited access (requirement for a permit), vessel and gear marking requirements, vessel length restrictions, Federal catch and effort logbooks, 100-percent observer coverage, large longline restricted areas around the Hawaiian Archipelago, vessel monitoring system (VMS), annual protected species workshops, and the use of sea turtle, seabird, and marine mammal handling and mitigation gear and techniques. The vessel operator must notify NMFS prior to departure whether the vessel is undertaking a shallow-set or a deep-set trip. Once the trip type is set, the type cannot be changed during the trip. All shallow-set trips must have a NMFS contracted observer. If any marine mammal interaction (hooking or entanglement) resulting in injury or mortality occurs, the vessel operator must complete and mail a pre-addressed, postage paid form to NOAA Fisheries within 48 hours of the end of the trip. More information on all applicable regulations is available at [http://www.fpir.noaa.gov/SFD/SFD_regs_2.html](http://www.fpir.noaa.gov/SFD/SFD_regs_2.html). This fishery is subject to the False Killer Whale Take-Reduction Team. NMFS is currently implementing the Take-Reduction Plan and associated regulations.

**Management type:** Federal limited access program. This fishery is managed under a Fishery Ecosystem Plan (FEP) by the Western Pacific Fishery Management Council and NMFS.

**Comments:** Non-target species are caught incidentally. Interactions with common bottlenose dolphins, false killer whales, humpback whales, short-finned pilot whales, striped dolphins, Bryde’s whales, Risso’s dolphins, sperm whales, spinner dolphins, pygmy sperm or dwarf sperm whales, Blainville’s beaked whales, and common dolphins have been documented. The shallow-set fishery was completely closed in 2001 and reopened in 2004. One hundred percent observer coverage is required in this fishery. *Observed* injuries of marine mammals in this fishery in 2007-2011 included 3 false killer whales, 21 Risso’s dolphins, 2 humpback whale, 1 pygmy or dwarf sperm whale, 3 striped dolphins, 8 common bottlenose dolphins, 1 short-beaked common dolphin, 1 Blainville’s beaked whale, 2 unidentified beaked whales, and 2 unidentified dolphins. Three of the interactions were deaths, 31 were serious injuries, 10 were non-serious injuries, and 2 involved prorating a large whale interaction as 0.75 serious.

**Category II, Hawaii Shortline Fishery**

**Note:** The Hawaii shortline fishery was added to the 2010 List of Fisheries as a Category II fishery under the MMPA based on analogy with the Category I “HI deep-set (tuna-target) longline/set line” and Category II “HI shallow-set (swordfish-target) longline/set line” fisheries (Federal Register 74 FR 58859, 16 November 2009).
Appendix 1. Description of U.S. Commercial Fisheries

Number of permit holders: There are no specific fishing permits issued for this fishery. However, all persons with a State of Hawaii Commercial Marine License (CML) may participate in any fishery, including the “HI shortline” fishery.

Number of active shortline vessels: Of those persons possessing CMLs, shortline participation has varied between 5 and 14 vessels from 2003 - 2011.

Total effort: From 2003-2008, there was an average of 135,757 pounds (lbs) of fish landed each year. In 2008 alone, 104,152 lbs of fish were landed.

Geographic range: The Category II “HI shortline” fishery is a small-scale system operating off the State of HI, and targeting bigeye tuna (*Thunnus obesus*) or the lustrous pomfret (*Eumigistes illustris*). This fishery was developed to target these fish species when they concentrate over the summit of Cross Seamount, -290 km (180 mi) south of the State of HI.

Seasons: This fishery has no seasonal component and may operate year-round.

Gear type: The gear style is designed specifically to target the aggregating fish species over seamount structures. The primary gear type used is a horizontal main line (monofilament) less than 1 nautical mile long, and includes two baskets of approximately 50 hooks each. The gear is set before dawn and has a short soak time, with the gear retrieved about two hours after it is set.

Regulations: All persons with a State of Hawaii Commercial Marine License (CML) may participate in the “HI shortline” fishery. The mainline length must be less than 1 nautical mile.

Management type: Hawaii State managed fishery.

Comments: Currently, there is no Federal reporting system in place to document potential marine mammal interactions in this fishery. However, there are anecdotal reports of interactions off the north side of Maui, but the species and extent of interactions are unknown.

Category II, American Samoa Longline Fishery

Note: The American Samoa longline fishery was added to the 2006 List of Fisheries as a Category II fishery under the MMPA based on analogy with Category I “HI deep-set (tuna-target) longline/set line” and Category II “HI shallow-set (swordfish-target) longline/set line” fisheries.

Number of permit holders: 46

Number of active longline vessels: From 2007 to 2011, the number of active vessels was 29, 28, 26, 26, and 24.

Total effort: The number of trips for 2007-2011 was 377, 287, 175, 264, and 274. The number of sets for the American Samoa longline fishery in 2007-2011 was 5,910, 4,730, 4,601, 4,496, and 3,776. The number of hooks set in 2007-2011 was 17,524, 14,372, 14,207, 13,067, and 10,767.

Geographic range: Waters surrounding American Samoa year-round.

Seasons: Shallow-set effort is highest in either the first or second quarter of the calendar year and drops off substantially in the latter half of the year.

Gear type: This fishery uses longline gear. Vessels over 50 ft (15.2 m) may set 1,500-2,500 hooks and have a greater fishing range and capacity for storing fish (8-40 metric tons). The fleet reached a peak of 66 vessels in 2001, and set a peak of almost 7,000 sets in 2002. It is more common for fishermen to set their gear in the day and haul in the afternoon, mainly to improve their catch rates.
Appendix 1. Description of U.S. Commercial Fisheries

Regulations: This fishery is a limited entry fishery for pelagic longline vessels in the U.S. EEZ around American Samoa. In 2000, the fishery began to expand rapidly with the influx of large (more than 50 ft (15.2 m) overall length) conventional mono hull vessels, similar to the type used in the Hawaii-based longline fisheries. Regulations implemented in 2002 prohibit any large U.S. vessels (50 ft (15.2 m) and longer) from fishing within 50 nmi around the islands of American Samoa. In 2005, the rapid expansion of longline fishing effort within the U.S. EEZ waters around American Samoa prompted the implementation of a limited entry system. Under the limited access program, NMFS issued a total of 60 initial longline limited entry permits in 2005 to qualified candidates, spread among 4 vessel size classes: 22 permits issued in Class A (less than or equal to 40 ft (12.2 m) length); 5 in Class B (40-50 ft (12.2-15.2m)); 12 in Class C (50.1–70 ft (15.2–21.3 m)); and 21 in Class D (more than 70 ft (21.3 m)). The number of active vessels has shifted to large vessels (Class C and D), with only a couple of small vessels active in the past two years. Permits may be transferred and renewed. Under the limited entry program, vessel operators must submit federal catch and effort logbooks, vessels over 40 ft (12.2 m) must carry observers if requested by NMFS, and vessels over 50 ft (15.2 m) must have an operational vessel monitoring system (VMS). In addition, vessel owners and operators must attend a protected species workshop annually, carry and use dip nets, clippers, and bolt cutters, and follow handling, resuscitation, and release requirements for incidentally hooked or entangled sea turtles.

Management type: Federal limited access program. This fishery is managed under a Fishery Ecosystem Plan (FEP) by the Western Pacific Fishery Management Council and NMFS.

Comments: Non-target species are caught incidentally. Interactions with false killer whales, Risso’s dolphins, and Cuvier’s beaked whale have been documented. One hundred percent observer coverage is required in this fishery. Observed injuries of marine mammals in this fishery in 2007-2011 included 3 false killer whales, 21 Risso’s dolphins, 2 humpback whale, 1 pygmy or dwarf sperm whale, 3 striped dolphins, 8 common bottlenose dolphins, 1 short-beaked common dolphin, 1 Blainville’s beaked whale, 2 unidentified beaked whales, and 2 unidentified dolphins. Three of the interactions were deaths, 31 were serious injuries, 10 were non-serious injuries, and 2 involved prorating a large whale interaction as 0.75 serious.

Category II, CA yellowtail, barracuda, white seabass, and tuna drift gillnet fishery (>3.5 and <14 in mesh)

Number of permit holders: There are approximately 24 active permit holders in this fishery.

Total effort: From 2008 to 2012, there were between 207 and 271 small-mesh drift gillnet sets fished annually, as determined from California Department of Fish and Game logbook data.

Geographic range: This drift gillnet component of this fishery operates primarily south of Point Conception. Observed sets have been clustered around Santa Cruz Island, the east Santa Barbara Channel, and Cortez and Tanner Banks. Some effort has also been observed around San Clemente Island and San Nicolas Island.

Seasons: This fishery operates year round. Targeted species is typically determined by market demand on a short-term basis.

Gear type and fishing method: Typical gear used for this fishery is a 150 to 200-fathom gillnet, which is allowed to drift. The mesh size depends on the target species but typical values observed are 6.0 and 6.5 inches.

Regulations: This fishery is managed by the California Dept. of Fish and Game in accordance with State and Federal laws.

Management type: This fishery is a limited-entry fishery with gear restrictions and area closures.

Comments: This fishery primarily targets white seabass and yellowtail but also targets barracuda and albacore tuna. From 2002-2004, there have been 63 sets observed from 17 vessel trips. Marine mammal mortality includes two long-beaked common dolphin and 3 California sea lions. Also, 4 California sea lions were entangled and released alive during this period. In 2003, there was one coastal bottlenose dolphin stranded with 3.5-inch gillnet wrapped around its tailstock, the responsible fishery is unknown. Observer coverage in this fishery was 12% in 2002, 10% in 2003, and 17% in 2004.
Category II, California Anchovy, Mackerel, and Sardine Purse Seine Fishery.  

Number of active permit holders: There are 61 vessels actively fishing.

Total effort: The fishery is managed under a capacity goal, with gross tonnage of vessels used as a proxy for fishing capacity. Capacity for the fleet is approximately 5,400 gross tons. Harvest guidelines for sardine and mackerel are also set annually.

Geographic range: These fisheries occur along the coast of California predominantly from San Pedro, including the Channel Islands, north to San Francisco.

Seasons: This fishery operates year round. Targeted species vary seasonally with availability and market demand.

Gear type and fishing method: Purse seine, drum seine and lampara nets utilizing standard seining techniques.

Regulations: This is a limited-entry fishery.

Management type: The fishery is managed under a Coastal Pelagic Species Fisheries Management Plan developed by the Pacific Fishery Management Council and NMFS.

A NMFS pilot observer program began in July 2004 and continued through January 2006. A total of 93 sets have been observed. Observed marine mammal interactions with the fishery have included one California sea lion killed, 54 sea lions released alive, and one sea otter released alive. Under the MMAP self-reporting program, the following mortality was reported: In 2003, four California sea lions drowned after chewing through a bait barge net used by the anchovy lampara net fishery.

Category II, California tuna purse seine fishery.

Note: This fishery was previously included in the CA anchovy, mackerel, and sardine purse seine fishery (see above). Vessels in the anchovy, mackerel, and sardine fishery target tuna when oceanographic conditions result in an influx of tuna into southern California waters. Data for this fishery were obtained from the ‘Status of the U.S. West Coast Fisheries for Highly Migratory Species through 2004’, available at the Pacific Fishery Management Council website (http://www.pcouncil.org).

Number of active permit holders: Between one and 23 vessels actively purse seined for tunas during the period 2000-2004.

Total effort: The number of vessels landing bluefin, yellowfin, skipjack, and albacore in 2000-2004 varied between one and 23. Logbooks are not required for this fishery, and the overall number of sets fished is unknown.

---

1 Information for this fishery came from the following sources: Pacific Fishery Management Council. 2005. Status of the Pacific Coast coastal pelagic species fishery and recommended acceptable biological catches. Stock assessment and fishery evaluation – 2005; California Coastal Pelagic Species Pilot Observer Program Informational Report 12 October 2005 (NMFS SW Region, unpublished); Lyle Enriquez NMFS Southwest Regional Office (personal communication) and the Marine Mammal Authorization Program, Registration and Reporting System. This fishery was formerly known as the “CA anchovy, mackerel, and tuna purse seine fishery” and was renamed in the NMFS MMPA List of Fisheries for 2007 (Federal Register Volume 72, No. 59, 14466). The “tuna” component of this fishery was designated as a separate fishery in the 2007 List of Fisheries and is named the “CA tuna purse seine fishery” (see fishery description below).
Revised 7/15/2014

Appendix 1. Description of U.S. Commercial Fisheries

**Geographic range:** Observed sets in this fishery have occurred in the southern California Bight.

**Seasons:** Observed sets occurred in August and September. The timing of fishing effort varies with the availability of tuna species in this region.

**Gear type and fishing method:** Small coastal purse seine vessels with a <640 mt carrying capacity target bluefin, yellowfin, albacore and skipjack tuna during warm-water periods in southern California.

**Regulations:** This is a limited-entry fishery.

**Management type:** This fishery is managed under a Highly Migratory Species Management Plan developed by the Pacific Fishery Management Council and NMFS.

**Comments:** A pilot observer program for this fishery began in July 2004 and ended in January 2006. A total of 9 trips and 15 sets were observed with no marine mammal interactions.

**Category II, WA Puget Sound Region salmon drift gillnet fishery.**

**Number of permit holders:** This commercial fishery includes all inland waters south of the US-Canada border and east of the Bonilla/Tatoosh line, at the entrance to the Strait of Juan de Fuca. Treaty Indian salmon gillnet fishing is not included in this commercial fishery. The number of permit holders is reported to be 210 in the NMFS 2013 List of Fisheries (Federal Register 29 August 2013).

**Number of active permit holders:** The number of "active" permits is assumed to be equal to or less than the number of permits that are eligible to fish.

**Total effort:** Effort in the Puget Sound salmon drift gillnet fishery is regulated by systematic openings and closures that are specific to area and target salmon species.

**Geographic Range:** The fishery occurs in the inland marine waters south of the U.S./Canada border and east of the Bonilla/Tatoosh line at the entrance to the Strait of Juan de Fuca. The inland waters are divided into smaller statistical catch areas which are regulated independently.

**Seasons:** This fishery has multiple seasons throughout the year that vary among local areas dependent on local salmon runs. The seasons are managed to access harvestable surplus of robust stocks of salmon while minimizing impacts on weak stocks.

**Gear type and fishing methods:** Vessels operating in this fishery use a drift gillnet of single web construction, not exceeding 300 fathoms in length. Minimum mesh size for gillnet gear varies by target species. Fishing directed at sockeye and pink salmon are limited to gillnet gear with a 5-inch minimum mesh and a 6 inch maximum, with an additional "bird mesh" requirement that the first 20 meshes below the corkline be constructed of 5-inch opaque white mesh for visibility; the chinook season has a 7-inch minimum mesh; the coho season has a 5-inch minimum mesh; and the chum season has a 6- to 6.25-inch minimum mesh. The depth of gillnets can vary depending upon the fishery and the area fished. Normally they range from 180 to 220 meshes in depth, with 180 meshes as a common depth. It is the intention of the fisher to keep the net off the bottom. The vessel is attached to one end of the net and drifts with the net. The entire net is periodically retrieved onto the vessel and catch is removed. Drift times vary depending on fishing area, tidal condition and catch.

**Regulations:** The fishery is a limited-entry fishery with seasonal openings, area closures, and gear restrictions.

**Management type:** The fishery occurs in State waters and is managed by the Washington Department of Fish and Wildlife consistent with the U.S.-Canada Pacific Salmon Commission management regimes and the ocean salmon management objectives of the Pacific Fishery Management Council. U.S. and Canadian Fraser River sockeye and pink salmon fisheries are managed by the bilateral Fraser Panel in Panel Area waters. This includes the entire U.S. drift gillnet fishery for Fraser sockeye and pink salmon. For U.S. fisheries, Fraser Panel Orders are given effect by federal regulations that consist of In-
season Orders issued by the NMFS Regional Administrator of the NMFS Northwest Region. These regulations are filed in the Federal Register post-season.

Comments: Salmon drift gillnet fisheries in Washington inland waters were last observed in 1993 and 1994, with observer coverage levels typically less than 10% (Erstad et al. 1996, Pierce et al. 1994, Pierce et al. 1996, NWIFC 1995). Fishing effort in the inland waters drift gillnet fishery has declined considerably since 1994 because far fewer vessels participate today (NMFS NW Region, unpublished data). Past marine mammal entanglements in this fishery included harbor porpoise, Dall’s porpoise, and harbor seals.

Category II, CA squid purse seine fishery.

Number of Permit Holders: A permit has been required to participate in the squid fishery since April 1998. Originally, only two types of permits were issued, either a vessel or light boat permit during the moratorium period from 1998 to 2004. Since the adoption of the Market Squid Fishery Management Plan (MSFMP) in 2005, a total of seven different permit types are now allowed under the restricted access program. Permit types include both transferable and non-transferable vessel, brail and light boat permits whose qualifying criteria are based on historical participation in the fishery during the moratorium period. Market squid vessel and brail permits allow a vessel to use lights to attract and capture squid using either purse seines or brail gear. Light boat owner permits only allow the use of attracting lights to attract and aggregate squid. In addition, three experimental non-transferable permits are allowed for vessel fishing outside of historical fishing areas north of San Francisco. In the 2006/2007 season there were 91 vessel permits, 14 brail permits, 64 light boat permits and 3 experimental permits issued. A permit is not required when fishing for live bait or when landing two short tons or less, which is considered incidental.

Number of Active Permit Holders: The number of active permits varies by year depending on market conditions and availability of squid. During the 2006/2007 season (1 April 2006 – 31 March 2007) there were approximately 84 vessels active during some portion of the year. Twenty-nine vessels harvested 86% of the total landings greater than two tons. The 1999/2000 season had the highest squid landings to date (115,437mt), with 132 vessels making squid landings.

Total Effort: Logbooks have been mandatory for the squid fishery since May 2000. Results for the 2006 calendar year indicate that each hour of fishing required 1.4 hours of search time by light boats. Combined searching and fishing effort resulted in 6.9 metric tons (mt) of catch per hour. In the 2006/2007 season, the fishery made 1,611 landings. This is a 47% decrease from the previous season. In addition, the average landing decreased from 23.9 mt to 21.7 mt.

Geographic Range: Since the 1960’s there have been two distinct fisheries in operation north and south of Point Conception. Since the mid-1980’s the majority of the squid fishing harvest has occurred in the southern fishery, with efforts focused around the Channel Islands and along the mainland from Port Hueneme to La Jolla. In the 2006/2007 season, the southern fishery landed 98% of the catch with the majority of landings occurring around the northern Channel Islands. In contrast, during the 2005/2006 season, landings in the southern fishery were primarily around Catalina Island. The northern fishery, centered primarily in Monterey Bay, has been in operation since the mid-1860’s and has historical significance to California. During the 2002/2003 season, a moderate El Niño condition resulted in nearly 60% of the catch being landed in northern California.

Seasons: The fishery can occur year-round; however, fishing efforts differ north and south of Point Conception. Typically, the northern fishery operates from April through September while the southern fishery is most active from October through March. El Niño conditions generally hamper the fishery in the southern fishery and squid landings are minimal during these events. In contrast, landings in the northern fishery often increase during El Niño events and then are depressed for several years after.

Gear Type: There are several gears employed in this fishery. From 1996 to 2006, the vast majority (95%) of vessels use either purse (69%) or drum (26%) seine nets. Other types of nets used include brail (5%) and lampara nets (<1%). Another

---

2 This fishery description was provided by Dianna Porzio and Dale Sweetnam, California Department of Fish and Game. Details of marine mammal interactions with this fishery were obtained from NOAA Fisheries, Southwest Regional Office.
Appendix 1. Description of U.S. Commercial Fisheries

gear type associated with the fishery is attracting lights (30,000 watts maximum) that are used to attract and aggregate spawning squid in shallow waters.

**Regulations:** Since March 2005, the fishery operates under a restricted access program that requires all vessels to be permitted. A mandatory logbook program for fishing and lighting vessels has been in place since May 2000. A monitoring program has been in place since 2000 that samples the landings is designed to evaluate the impact of the fishery on the resource. Attracting lights were regulated with each vessel restricted to no more than 30,000 watts of light during fishing activities. These lights must also be shielded and oriented directly downward to reduce light scatter. The lighting restrictions were enacted to avoid risks to nesting brown pelicans and interactions with other seabird species of concern. A seabird closure area restricting the use of attracting lights for commercial purposes in any waters of the Gulf of the Farallones National Marine Sanctuary was enacted. A seasonal catch limitation of 107,047 mt (118,000 short tons) was established to limit further expansion of the fishery. Commercial squid fishing is prohibited between noon on Friday and noon on Sunday of each week to allow an uninterrupted consecutive two-day period of spawning. Additional closure areas to the fishery to protect squid spawning habitat include the Channel Islands Marine Protected Areas (MPAs) and the newly established MPAs along the central California coast as well as areas closed to the use of purse seine gear including the leeward side of Catalina Island, Carmel and Santa Monica Bays.

**Management Type:** The market squid fishery is under California State management. The fishery was largely unregulated until 1998 when it came under regulatory control of the California Fish and Game Commission and the Department of Fish and Game. The MSFMP was enacted on March 28, 2005. The MSFMP was developed to ensure sustainable long-term conservation and to be responsive to environmental and socioeconomic changes. Market squid is also considered a monitored species under the Pacific Fishery Management Council’s (PFMC) Coastal Pelagic Species Fishery Management Plan.

**Comments:** During the 1980’s, California’s squid fishery grew rapidly in fleet size and landings when international demand for squid increased due to declining fisheries in other parts of the world. In 1997 industry-sponsored legislation halted the growth of fleet size with a moratorium on new permits. Landing records were set several times during the 1990’s, but landings seem to fluctuate with changing environmental and atmospheric conditions of the California Current. Encounters with marine mammals and sea birds are documented in logbooks. Seal bombs are used regularly, but fishermen report that they no longer have an effect. A pilot observer program began in July 2004 and has documented one unidentified common dolphin death in 135 sets through January 2006. In addition, there have been 96 California sea lions and three harbor seals released alive (NMFS, Southwest Region, unpublished data). In addition to the observed death, there were three strandings of Risso’s dolphins from 2002-2003 where evidence of gunshot wounds was confirmed, suggesting interaction with this fishery (NMFS Southwest Regional Office, unpublished data). The squid fishery operates primarily at night and targets spawning aggregations of adult squid. In recent years the amount of daylight fishing has increased, especially in Monterey, in part due to better sonar gear, but also to reduce interactions with California sea lions. The PFMC adopted the egg escapement method to monitor the impact of market squid fishery since no reliable biomass estimate has been developed. It is a proxy for Maximum Sustainable Yield (MSY), setting an egg escapement threshold level at which to evaluate the magnitude of fishing mortality on the spawning potential of the squid stock. The egg escapement method was developed on conventional spawning biomass “per-recruit” theory. In general, the MSY Control Rule for market squid is based on evaluating levels of egg escapement associated with the exploited population. The egg escapement threshold, initially set at 30%, represents a biological reference point from which to evaluate fishery related impacts.

**Category III, CA Dungeness crab pot**

**Notes:** NMFS is reviewing several pot and trap fisheries along the U.S. west coast, in response to entanglements of humpback whales in pot and trap gear. An update on these fisheries will appear in the MMPA Proposed List of Fisheries for 2009. For all commercial pot and trap fisheries in California, a general trap permit is required, in addition to any specific permits required for an individual fishery. All traps are required to be tended and serviced at least every 96 hours, weather permitting. Descriptions of those pot and/or trap fisheries for which interactions with marine mammals have been documented or suspected are included in this Appendix.
Number of permit holders: The Dungeness crab fishery is a limited access fishery requiring a vessel-based permit that is transferable. This program was initiated in 1994 based on landing histories. The number of vessels participating on an annual basis does vary, but approximately 400 vessels have been landing crab in recent years.

Number of active permit holders: Approximately 400 vessels have been landing crabs in recent years.

Total effort: There is no restriction on the number of traps that may be fished at one time by a single vessel. Some vessels use as many as 1000 or more traps at the peak of the season (December/January).

Geographic range: This fishery operates in central and northern California.

Seasons: The fishery is divided into two management areas. The central region (south of the Mendocino-Sonoma county line) fishery opens November 15 and continues through June 30. The northern region (north of the Mendocino-Sonoma county line) is annually scheduled to open on December 1, but may be delayed by CDF&G based on the condition of market size crabs, and continues until July 15.

Gear type: For each trap fished there is one vertical line in the water, though only in the northern region, is fishing strings illegal. All traps are required to be marked with buoys bearing the commercial fishing license number. The normal operating depth for Dungeness crab is between 35 and 70 m. Traps are typically tended on a daily basis.

Regulations: There is no daily logbook requirement for the commercial Dungeness crab fishery. There is a recreation fishery for Dungeness crab, which allows for 10 crab per day to be harvested except when fishing on a commercial passenger fishing vessel (CPFV) in central California, the limit is 6 crab per person. There is no reliable estimate for the effort or landings in the sport fishery except that CPFVs are required to track catch and effort by species.

Management type: The Dungeness crab pot fishery is managed by the California legislature, CDF&G and also by the tri-state committee for Dungeness, which includes the states of Oregon and Washington.

Comments: Humpback whale entanglements with Dungeness crab gear have not been confirmed, but are suspected as the responsible fishery based on the location and timing of fishing effort and observed humpback entanglements.

Category III, OR Dungeness crab pot

Notes: Dungeness crab is the most significant pot/trap fishery in the state of Oregon. Over the long term, the fishery has averaged around 10 million lb of landings per year; although since 2003, annual landings have been approximately 25 to 30 million lb. This fishery requires an Oregon issued limited-entry permit, which is transferable.

Number of permit holders: There were 433 permit holders in 2006.

Number of active permit holders: A total of 364 vessels landed crabs in 2006.

Total effort: In 2006, the fishery made a transition to a three-tiered pot limitation program which allows a maximum of 200, 300, or 500 pots to be fished at any one time depending on previous landing history. The pot limitation is implemented through a buoy tag requirement. All Dungeness crab pots require buoy tags with the identifying associated permit attached. The expected result of the buoy tags and tier limits is to reduce the number of pots in Oregon waters down from 200,000 to approximately 150,000.

Geographic range: Oregon waters.

Seasons: The Dungeness crab season runs from December 1 to August 14. The highest landings are always recorded in December through February, at the beginning of the season.

Gear type: Pots.
Regulations:  All Oregon pot/trap gear must be marked on its terminal ends with pole and flag, light, radar reflector, and buoy with the owner/operator number clearly marked. By law, gear may not be left unattended for more than seven days. All vessel operators and deck hands must have a commercial fishing license or crewmembers license.

Management type: State management, Oregon Department of Fish and Wildlife.

Comments: Humpback whale entanglements with Dungeness crab gear have not been confirmed, but are suspected as the responsible fishery based on the location and timing of fishing effort and observed humpback entanglements.

Category III, CA spot prawn fishery

Number of permit holders: A three-tiered limited access permit system is used in this fishery to accommodate changes in the fishery that occurred when trawling methods were banned and replaced with trap fishing in 2003. Permits are linked to the vessel owner and only Tier 1 permits are transferable. Tier 1 permits allow a maximum of 500 traps in use at a time. Eighteen vessels had Tier 1 permits in 2007. Tier 2 permits allow 150 traps in use at a time. There were three vessels utilizing Tier 2 permits in 2007. Tier 3 permits were issued to allow vessels that previously used trawl gear to switch to trap gear to target spot prawn. There were nine Tier 3 permits issued in 2007. Information on 2007 license statistics was obtained from the CA Department of Fish and Game website, http://www.dfg.ca.gov/licensing/statistics/statistics.html.

Number of active permit holders: A total of 30 vessels participated in this fishery in 2007.

Total effort: Landings have increased every year since 2003. The total number of traps set is unknown, although the theoretical maximum number of traps that may be fished annually is approximately 13,000.

Geographic range: The fishery operates from Monterey south. Over half of the landings are made in Los Angeles and San Diego. Traps are typically set in waters of 182 m (100 fathoms) or more. South of Point Arguello, traps must be fished in waters 91 m (50 fathoms) or deeper.

Seasons: North of Point Arguello, the fishery is open from February 1 to October 30. North of Point Arguello, the open season is August 1 to April 30.

Gear type: Strings of 25 to 50 traps are fished in deep waters (>182 m).

Regulations: For all commercial pot and trap fisheries in California, a general trap permit is required, in addition to any specific permits required for an individual fishery. All traps are required to be tended and serviced at least every 96 hours, weather permitting. There is a daily logbook requirement in this fishery. There is no buoy marking requirement and no recreational fishery for this species.

Management type: This fishery is managed under state authority by the California Department of Fish and Game.

Comments: One humpback whale was seriously injured in 2006 as a result of entanglement in spot prawn trap gear.

Category III, WA/OR/CA sablefish pot

Notes: Sablefish is likely the most commonly targeted groundfish caught in pot gear in off the U.S. west coast.

Number of permit holders: There are 32 limited-entry permits (LEPs) to catch sablefish with pot gear. Open access privileges are also available to fishermen.

Number of active permit holders: Including all vessels which made landings with an LEP or under open access rules, a total of about 150 vessels participated in this fishery in 2007. This total fluctuates on an annual basis.

Total effort: Estimated annual landings indicate usually over 1 million lbs of sablefish are landed per year in this fishery.
Appendix 1. Description of U.S. Commercial Fisheries

Geographic range: The fishery is well distributed from central California north to the U.S./Canadian border. Most of the effort occurs out in deeper waters (200-400 m).

Seasons: Most fishing effort occurs January through September.

Gear type: Traps <6 ft. in any dimension.

Regulations: A general trap permit is all that is required for open access to this fishery by the states along the U.S. west coast. LEPs are divided into a three-tiered system which allocates annual landing limits to individual permits based on the status of the stock. Daily logbook reporting is required.

Management type: Sablefish is managed under the federal Groundfish Fishery Management Plan. This is the only trap fishery regulated by the federal government; all others are managed by the states.

Comments: One humpback whale was seriously injured in 2006 as a result of entanglement in sablefish trap gear.

Category III, CA rock crab

Number of permit holders: There were 134 permits issued in 2007.

Number of active permit holders: Unknown, but it is likely that most issued permits are active.

Total effort: Annual landings averaged approximately 1 million pounds from 2000 to 2005.

Geographic range: The fishery operates throughout California waters. Most landings are made south of Morro Bay, California, with approximately 65% of all landings coming from the Santa Barbara area.

Seasons: There are no seasonal restrictions, though some area closures exist.

Gear type: There is no restriction on the number of traps that may be fished at one time by the vessel but the typical number of traps operated at any given time is less than 200. Traps are usually buoyed singularly or in pairs, but fishing strings (multiple traps attached together between two buoys) is allowed. Buoys are required to be marked with the license number of the operator. The normal working depth of traps in this fishery is 10 to 35 fathoms.

Regulations: There is no daily logbook requirement for the commercial rock crab fishery.

Management type: The fishery is managed by the California Department of Fish and Game.

Comments: The recreational bag limit is 35 crabs per day, but there is no reliable estimate of the effort or landings in the sport fishery.

Category III, CA halibut bottom trawl.

Notes: This is a newly-listed fishery in the 2007 MMPA NMFS List of Fisheries (Federal Register Volume 72, No. 59, 14466). Information on fishing effort was provided by Stephen Wertz, California Department of Fish and Game.

Number of permit holders: There were 60 permits issued in 2006.

Number of active permit holders: There were 31 active permit holders in 2006.

Total effort: Thirty one vessels made 3,711 tows statewide in 2006, totaling 3,897 tow hours, in 332 days of fishing effort.

Geographic range: The fishery operates from Bodega Bay in northern California to San Diego in southern California, from 3 to 200 nautical miles offshore. Trawling is prohibited in state waters (0 to 3 nmi offshore) and within the entire Monterey
Appendix 1. Description of U.S. Commercial Fisheries

Bay, except in the designated “California halibut trawl grounds”, between Point Arguello and Point Mugu beyond 1 nautical mile from shore. Trawls used in this region must have a minimum mesh size of 7.5 in and trawling is prohibited here between 15 March and 15 June to protect spawning adults.

Seasons: Fishing is permitted year-round, except in state waters. State waters are closed between 15 March and 15 June.

Gear type: Otter trawls, with a minimum mesh size of 4.5 inches are required in federal waters, while fishing in state waters has a 7.5 inch mesh size requirement.

Regulations: Fishing in state waters is limited to the period 14 March – 16 June in the ‘California halibut trawl grounds’ in southern California between Point Arguello and Point Mugu. All other fishing must occur in federal waters beyond 3 nautical miles from shore.

Management type: The fishery is managed by the California Department of Fish and Game.

Comments: No marine mammal interactions have been documented for this fishery, but the gear type and fishing methods are similar to the WA/OR/CA groundfish trawl fishery (also category III), which is known to interact with marine mammals.

Category III, CA herring gillnet fishery.

The herring fishery is concentrated in four spawning areas which are managed separately by the California Department of Fish and Game (CDFG); catch quotas are based on population estimates derived from acoustic and spawning-ground surveys. The largest spawning aggregations occur in San Francisco Bay and produces more than 90% of the herring catch. Smaller spawning aggregations are fished in Tomales Bay, Humboldt Bay, and Crescent City Harbor. During the early 1990’s, there were 26 round haul permits (either purse seine or lampara nets). Between 1993 and 1998, all purse seine fishers converted their gear to gillnets with stretched mesh size less than 2.5 inches (which are not known to take mammals) as part of CDFG efforts to protect herring resources. The fishery is managed through a limited-entry program. The California Department of Fish and Game website lists a total of 447 herring gillnet permits for 2005 (http://www.dfg.ca.gov/mrd/herring/index.html). Of these, 406 permits exist for San Francisco Bay, 34 in Tomales Bay, 4 in Humboldt Bay, and 3 in Crescent City Harbor. This fishery begins in December (San Francisco Bay) or January (northern California) and ends when the quotas have been reached, but no later than mid-March.

Category III, WA Willapa Bay salmon drift gillnet fishery.

Number of permit holders: The total number of permit holders for this fishery in 1995 and 1996 was 300, but this number has declined in subsequent years. In 1997 there were 264 total permits and 243 in 1998. The NMFS 2001 List of Fisheries lists an estimate of 82 vessels/persons in this fishery.

Number of active permit holders: The number of active permit holders is assumed to be equal to or less than the number of permits eligible to fish in a given year. The number of permits renewed and eligible to fish in 1996 was 300 but declined to 224 in 1997 and 196 permits were renewed for 1998. The 1996-98 counts do not include permits held on waivers for those years, but do include permits that were eligible to fish at some point during the year and subsequently entered into a buyback program. The number of permits issued for this fishery has been reduced through a combination of State and federal permit buyback programs. Vessels permitted to fish in the Willapa Bay are also permitted to fish in the lower Columbia River drift gillnet fishery.

Total effort: Effort in this fishery is regulated through area and species openings. The fishery was observed in 1992 and 1993 when fishery opening were greater than in recent years. In 1992 and 1993 there were 42 and 19 days of open fishing time during the summer "dip-in" fishery. The "dip-in" fishery was closed in 1994 through 1999. Available openings have also declined in the fall chinook/coho fisheries. In 1992/93 respectively there were 44 and 78 days of available fishing time. There were 43, 45, 22 and 16.5 available open fishing days during 1995 through 1998.

Appendix 1. Description of U.S. Commercial Fisheries

Geographic range: This fishery includes all inland marine waters of Willapa Bay. The waters of the Bay are further divided into smaller statistical catch areas.

Seasons: Seasonal openings coincide with local salmon run timing and fish abundance.

Gear type: Fishing gear used in this fishery is a drift gillnet of single web construction, not exceeding 250 fathoms in length, with a minimum stretched mesh size ranging upward from 5 inches depending on target salmon species. The gear is commonly set during periods of low and high slack tides. It is the intention of the fisher to keep the net off the bottom. The vessel is attached to one end of the net and drifts with the net. The entire net is periodically retrieved onto the vessel and catch is removed. Drift times vary depending on fishing area, tidal condition, and catch.

Regulations: This fishery is a limited-entry fishery with seasonal openings and gear restrictions.

Management type: The salmon drift gillnet fishery is managed by the Washington Department of Fish and Wildlife.

Comments: Observers were placed onboard vessels in this fishery to monitor marine mammal interactions in the early 1980s and in 1990-93. Five incidentally taken harbor seals were recovered by observers in the fishery from 1991 through 1993 (3 in ’92 and 2 in ’93). Two incidentally taken northern elephant seals were recovered by observers from the fishery in 1991 but no takes of this species were observed. The summer fishery (July- August) in Willapa Bay has been closed since it was last observed in 1993 and available fishing time declined from 1996 through 1998.

Category III, WA Grays Harbor salmon drift gillnet fishery.

Number of permit holders: This commercial drift gillnet fishery does not include Treaty Indian salmon gillnet fishing. The total number of permit holders for this commercial fishery in 1995 and 1996 was 117 but this number has declined in subsequent years. In 1997 there were 101 total permits and 87 in 1998.

Number of active permit holders: The NMFS 2001 List of Fisheries lists a total of 24 vessels/persons operating in this fishery. The number of active permit holders is assumed to be equal to or less than the number of permits eligible to fish in a given year. The number of permits renewed and eligible to fish in 1996 was 117 but declined to 79 in 1997 and 59 permits were renewed for 1998. The 1996-98 counts do not include permits held on waivers for those years but do include permits that were eligible to fish at some point during the year and subsequently entered a buyback program. The number of permits issued for this fishery has been reduced through a combination of State and federal permit buyback programs. Vessels permitted to fish in Grays Harbor are also permitted to fish in the lower Columbia River salmon drift gillnet fishery.

Total effort: Effort in this fishery is regulated through area and species openings. The fishery was observed in 1992 and 1993 when fishery openings were greater than in recent years. In 1992 and 1993 there were 42 and 19 days of open fishing time during the summer "dip-in" fishery. The "dip-in" fishery was closed in 1994 through 1999. Available openings have also declined in the fall chinook/coho fisheries. There were 11, 17.5, 9 and 5 available open fishing days during the 1995 through 1998 fall season.

Geographic range: Effort in this fishery includes all marine waters of Grays Harbor. The waters are further divided into smaller statistical catch areas.

Seasons: This fishery is subject to seasonal openings which coincide with local salmon run timing and fish abundance.

Gear type: Fishing gear used in this fishery is a drift gillnet of single web construction, not exceeding 250 fathoms in length, with a minimum stretched mesh size ranging of 5 inches depending on target salmon species. The gear is commonly set during periods of low and high slack tides and retrieved periodically by the tending vessel. It is the intention of the fisher to keep the net off the bottom. The vessel is attached to one end of the net and drifts with the net. The entire net is periodically retrieved onto the vessel and catch is removed. Drift times vary depending on fishing area, tidal condition, and catch.
Regulations: The fishery is a limited-entry fishery with seasonal openings and gear restrictions.

Management type: The salmon drift gillnet fishery is managed by the Washington Department of Fish and Wildlife.

Comments: Observers were placed onboard vessels in this fishery to monitor marine mammal interactions in the early 1980s and in 1990-93. Incidental take of harbor seals was observed during the fishery in 1992 and 1993. In 1992, one harbor seal was observed entangled dead during the summer fishery and one additional seal was observed entangled during the fall fishery but it escaped uninjured. In 1993, one harbor seal was observed entangled dead and one additional seal was recovered by observers during the summer fishery. The summer fishery (July-August) in Grays Harbor has been closed since it was last observed in 1993. Available fishing time in the fall chinook fisheries declined from 1996 through 1998.

Category III, WA, OR lower Columbia River salmon drift gillnet fishery.

Number of permit holders: The total number of permit holders was 856 (344 from Oregon and 512 from Washington) when the fishery was last observed in 1993. In 1995 through 1998 the number of permits was 747, 693, 675 and 620 respectively. The number of permits issued for this fishery by Washington has been reduced through a combination of State and federal buy-back programs. This reduction is reflected in the overall decline in the total number of permits.

Number of active permit holders: The number of active permits is a subset of the total permits issued for the fishery. For example, in 1995, 110 vessels (of the 747 vessels holding permits) landed fish in the mainstem fishery.

Total effort: Effort in this fishery is regulated through species related seasonal openings and gear restrictions. The fishery was observed in 1991, 1992 and 1993 during several seasons of the year. The winter seasons (openings) for 1991 through 1993 totaled 13, 9.5, and 6 days respectively. The winter season has subsequently been reduced to remnant levels to protect upriver ESA listed salmon stocks. In 1995 there was no winter salmon season, in 1996 the fishery was open for 1 day. In 1997 and 1998 the season was shifted to earlier in the year and gear restrictions were imposed to target primarily sturgeon. The fall fishery in the mainstem was also observed 1992 and 1993 as was the Young's Bay terminal fishery in 1993, however, no marine mammal mortality was observed in these fisheries. The fall mainstem fishery openings varied from 1 day in 1995 to just under 19.5 days in 1997 and 6 days in 1998. The fall Youngs Bay terminal fishery fluctuated between 60 and 70 days for the 1995 through 1998 period which was similar to the fishery during the period observed.

Geographic range: This fishery occurs in the main stem of the Columbia river from the mouth at the Pacific Ocean upstream to river mile 140 near the Bonneville Dam. The lower Columbia is further subdivided into smaller statistical catch areas which can be regulated independently.

Seasons: This fishery is subject to season and statistical area openings which are designed to coincide with run timing of harvestable salmon runs while protecting weak salmon stocks and those listed under the Endangered Species Act. In recent years, early spring (winter) fisheries have been sharply curtailed for the protection of listed salmon species. In 1994, for example, the spring fishery was open for only three days with approximately 1900 fish landed. In 1995 the spring fishery was closed and in 1996 the fishery was open for one day but fishing effort was minimal owing to severe flooding. Only 100 fish were landed during the one day in 1996.

Gear type: Typical gear used in this fishery is a gillnet of single web construction, not exceeding 250 fathoms in length, with a minimum stretched mesh size ranging upwards from 5 inches depending on target salmon species. The gear is commonly set during periods of low and high slack tides. It is the intention of the fisher to keep the net off the bottom. The vessel is attached to one end of the net and drifts with the net. The entire net is periodically retrieved onto the vessel and catch is removed. Drift times vary depending on fishing area, tidal condition, and catch.

Regulations: The fishery is a limited-entry fishery with seasonal openings, area closures, and gear restrictions.

Management type: The lower Columbia River salmon drift gillnet fishery is managed jointly by the Washington Department of Fish and Wildlife and the Oregon Department of Fish and Wildlife.
Appendix 1. Description of U.S. Commercial Fisheries

Comments: Observers were placed onboard vessels in this fishery to monitor marine mammal interactions in the early 1980s and in 1990-93. Incidental takes of harbor seals and California sea lions were documented, but only during the winter seasons (which have been reduced dramatically in recent years to protect ESA-listed salmon). No mortality was observed during the fall fisheries.

Category III, WA, OR salmon net pens.

Number of permit holders: There were 12 commercial salmon net pen (“grow out”) facilities licensed in Washington in 1998. There are no commercial salmon net pen or aquaculture facilities currently licensed in Oregon. Non-commercial salmon enhancement pens are not included in the list of commercial fisheries.

Number of active permit holders: Twelve salmon net pen facilities in Washington.

Total effort: The 12 licensed facilities on Washington operate year-round.

Geographic range: In Washington, net pens are found in protected waters in the Straits (Port Angeles), northern Puget Sound (in the San Juan Island area) as well as in Puget Sound south of Admiralty Inlet. There are currently no commercial salmon pens in Oregon.

Seasons: Salmon net pens operate year-round.

Gear type: Net pens are large net impoundments suspended below a floating dock-like structure. The floating docks are anchored to the bottom and may also support guard (predator) net systems. Multiple pens are commonly rafted together and the entire facility is positioned in an area with adequate tidal flow to maintain water quality.

Regulations: Specific regulations unknown.

Management type: In Washington, the salmon net pen fishery is managed by the Washington Department of Natural Resources through Aquatic Lands Permits as well as the Washington Department of Fish and Wildlife.

Comments: Salmon net pen operations have not been monitored by NMFS for marine mammal interactions, however, incidental takes of California sea lions and harbor seals have been reported.

Category III, WA, OR, CA groundfish trawl.

Approximate number of vessels/persons: In 1998, approximately 332 vessels used bottom and mid-water trawl gear to harvest Pacific coast groundfish. This is down from 383 vessels in 1995. The NMFS List of Fisheries for 2001 lists 585 vessels as participating in this fishery. Groundfish trawl vessels harvest a variety of species including Pacific hake, flatfish, sablefish, lingcod, and rockfish. This commercial fishery does not include Treaty Indian fishing for groundfish.

All observed incidental marine mammal takes have occurred in the mid-water trawl fishery for Pacific hake. The annual hake allocation is divided between vessels that harvest and process catch at sea and those that harvest and deliver catch to shore-based processing facilities. At least one NMFS-trained observer is placed on board each at-sea processing vessel to provide comprehensive data on total catch, including marine mammal takes. In the California, Oregon, and Washington range of the fishery, the number of vessels fishing ranged between 12 and 16 (all with observers) during 1997-2001. Hake vessels that deliver to shore-based processors are issued Exempted Fishing Permits that requires the entire catch to be delivered unsorted to processing facilities where State technicians have the opportunity to sample. In 1998, 13% of the hake deliveries landed at shore-based processors were monitored. The following is a description of the commercial hake fishery.

Number of permit holders/active permit holders: A license limitation ("limited-entry") program has been in effect in the Pacific coast groundfish fishery since 1994. The number of limited-entry permits is limited to 404. Non-tribal trawl vessels that harvest groundfish are required to possess a limited-entry permit to operate in the fishery. Any vessel with a federal limited-entry trawl permit may fish for hake, but the number of vessels that do is smaller than the number of
Appendix 1. Description of U.S. Commercial Fisheries

permits. In 1998, approximately 61 limited-entry vessels, 7 catcher/processors and 50 catcher vessels delivering to shoreside and mothership processors, made commercial landings of hake during the regular season. In addition, 6 unpermitted mothership processors received unsorted hake catch.

Total effort: The hake allocation continues to be fully utilized. From 1997 to 1999 the annual allocation was 232,000 mt/year, this is an increase over the 1996 allocation of 212,000 mt and the 1995 allocation of 178,400 mt. In 1998, motherships vessels received 50,087 mt of hake in 17 days, catcher/processors took 70,365 mt of hake in 54 days and shore-based processors received 87,862 mt of hake over a 196 day period.

Geographic range: The fishery extends from northern California (about 40° 30' N. latitude) to the U.S.-Canada border. Pacific hake migrate from south to north during the fishing season, so effort in the south usually occurs earlier than in the north.

Seasons: From 1997 to 1999, season start dates have remained unchanged. The shore-based season in most of the Eureka area (between 42°. 40°30' N latitude) began on April 1, the fishery south of 40°30' N latitude opened April 15, and the fishery north of 42° N latitude started on June 15. In 1998, the primary season for the shore-based fleet closed on October 13, 1998. The primary seasons for the mothership and catcher/processor sectors began May 15, north of 42° N. lat. In 1998, the mothership fishery closed on May 31, the catcher/processor fishery closed on August 7.

Gear type: The Pacific hake trawl fishery is conducted with mid-water trawl gear with a minimum mesh size of 3 inches throughout the net.

Regulations/Management type: This fishery is managed through Federal regulations by the Pacific Fishery Management Council under the Groundfish Fishery Management Plan.

Comments: Since 1991, incidental takes of Steller sea lions, Pacific white-sided dolphins, Dall's porpoise, California sea lions, harbor seals, northern fur seals, and northern elephant seals have been documented in the hake fishery. From 1997-2001, 4 California sea lions, 2 harbor seals, 2 northern elephant seals, 1 Pacific white-sided dolphin, and 6 Dall’s’porpoise were reported taken in California/Oregon/Washington regions by this fishery.

Category III fisheries in Hawaii are managed primarily by the State of Hawaii. Some fisheries have undergone many changes in geographic and temporal extent in recent years and complete analyses of fishing effort for recent years are not yet available. For many, fishing season and specific gear types are not well defined. These fishery descriptions will be updated as new information and analyses become available.

Category III, Hawaii gillnet fishery.

Number of active permit holders: In 2011 there were 36 active commercial fishers. In 1995 there were approximately 115.

Total effort: In 2011 there were 495 trips. This fishery operates in nearshore and coastal pelagic regions.

Seasons: This fishery operates year-round with the exception of juvenile big-eyed scad less than 8.5 inches which cannot be taken from July through October.

Gear type: Gillnets are of stretched mesh greater than 2 inches and stretched mesh size greater than 2.75 inches for stationary gillnets. The net dimensions may not exceed 7 feet high and 125 feet long.

4Descriptions of Hawaii State managed fisheries provided by Reggie Kokubun and Sarah Courbis, State of Hawaii, Department of Land and Natural Resources, Division of Aquatic Resources and Hawaii Humpback Whale National Marine Sanctuary, Honolulu Hawaii.
Appendix 1. Description of U.S. Commercial Fisheries

Regulations: Stationary nets must be inspected every 2 hours and total soak time cannot exceed four hours in the same location. New restrictions implemented in 2007 include that nets may not: 1) be used more than once in a 24-hour period; 2) exceed a 7 ft stretched height limit; 3) exceed a single-panel; 4) be used at night; 5) be set within 250 ft. of another lay net; 6) be set in more than 80 ft depths; 7) be left unattended for more than ½ hour; 8) break coral during retrieval; 9) be set in freshwater streams or stream mouths, and nets must be 1) registered with the Division of Aquatic Resources; 2) inspected within two hours after being set; 2) tagged with two marker buoys while fished. Gillnets are prohibited around all of Maui and portions of Oahu and Hawaii Island.

Management type: A commercial marine license issued by the Hawaii Department of Land and Natural Resources, Division of Aquatic Resources (DAR) is required for all commercial fishing activities in Hawaii State waters. The Federal Fishery Ecosystem Plan for the Hawaii Archipelago contains no management measures applicable to this gear.

Comments: The principle catches include reef fishes and big-eyed scad (akule) and mackerel scad (opelu). Interactions have been documented with bottlenose dolphins and spinner dolphins.

Category III, Hawaii lift (opelu) net fishery

Number of active permit holders: In 2011 there were 22 active commercial fishers.

Total effort: In 2011 there were 843 trips.

Seasons: unknown.

Gear type: Fishing with a net that captures fish by raising the net from beneath a school of fish. Normally fish are encouraged over and into the new with chum.

Regulations: unknown.

Management type: A commercial marine license issued by the Hawaii Department of Land and Natural Resources, Division of Aquatic Resources (DAR) is required for all commercial fishing activities in Hawaii State waters. The Federal Fishery Ecosystem Plan for the Hawaii Archipelago contains no management measures applicable to this gear.

Category III, Hawaii inshore purse seine fishery

Number of active permit holders: In 2011 there were less than 3 active commercial fishers.

Total effort: Cannot be reported to protect confidentiality.

Seasons: Year round.

Gear type: Fishing with a net that is used to surround a school of fish and is closed by drawing the bottom of the net together to form a bag.

Regulations: It is unlawful for any person without a valid commercial marine license to take akule with any net that has less than 2-3/4" stretched mesh. It is unlawful to take akule less than 8.5 inches with net from July – October or possess or sell more than 200 lbs of akule less than 8.5 inches per day during July – October. Federal regulations governing this gear can be found in the Code of Federal Regulations, Title 50, Part 665, Subpart C.

Management type: A commercial marine license issued by the Hawaii Department of Land and Natural Resources, Division of Aquatic Resources (DAR) is required for all commercial fishing activities in Hawaii State waters. This fishery is also managed under the Federal Hawaiian Archipelago Fishery Ecosystem Plan in waters outside of 3 nmi from shore.
Category III, Hawaii throw net/cast net fishery

Number of active permit holders: In 2011 there were 29 active commercial fishers.

Total effort: In 2011 there were 445 fishing trips.

Seasons: unknown.

Gear type: Fishing with a round or conical shaped net with a weighted outer perimeter that is thrown over fish.

Regulations: Minimum size 2 inch stretched mesh. Possession of thrownets with mesh size less than 2 inches in or near the water where fish may be taken is unlawful. Nets with smaller mesh may be used to take shrimp (‘opae), ‘opelu, and makiawa.

Management type: A commercial marine license issued by the Hawaii Department of Land and Natural Resources, Division of Aquatic Resources (DAR) is required for all commercial fishing activities in Hawaii State waters. The Federal Fishery Ecosystem Plan for the Hawaii Archipelago contains no management measures applicable to this gear.

Comments: Targets inshore and reef fish.

Category III, Hawaii seine net fishery

Number of active permit holders: In 2011 there were 26 active commercial fishers.

Total effort: In 2011 there were 227 fishing trips.

Seasons: unknown.

Gear type: Includes hukilau, beach seine, dragnet, pen, surround, etc. Fishing with a net by moving it through the water to surround fish by corralling and trapping them within the walls of the net.

Regulations: Outside of 3 nmi from shore, the Federal Fishery Ecosystem Plan for the Hawaii Archipelago requires seine nets be attended to at all times. Federal regulations governing this gear can be found in the Code of Federal Regulations, Title 50, Part 665, Subpart C.

Management type: A commercial marine license issued by the Hawaii Department of Land and Natural Resources, Division of Aquatic Resources (DAR) is required for all commercial fishing activities in Hawaii State waters. This fishery is also managed under the Federal Hawaiian Archipelago Fishery Ecosystem Plan outside of 3 nmi from shore.

Comments: Typical species: usually inshore and reef fish.

Category III, Hawaii trolling, rod, and reel fishery.

Number of active permit holders: In 2011 there were 2,126 active commercial fishers.

Total effort: In 2011 there were 30,020 fishing trips.

Seasons: Year round.

Gear type: Fishing by towing or dragging line(s) with artificial lure(s), dead or live bait, or green stick and dnaplers using a sail, surf or motor-powered vessel underway. Up to six lines rigged with artificial lures may be trolled when outrigger
poles are used to keep gear from tangling. When using live bait, trollers move at slower speeds to permit the bait to swim naturally. Pelagic trollers generally fish at an average distance of 5 to 8 miles from shore, with a maximum distance of about 30 miles from shore. Trollers fish where water masses converge and where submarine cliffs, seamounts, and other underwater features dramatically change the bathymetry. Trolls often fish drifting logs, other flotsam, underneath bird aggregations, and near FADs. Typical target species include mahimahi, ono, billfishes (marlin, sailfishes, etc.), kaku, uluas, kamanu, tunas, etc.

Regulations: The Fishery Ecosystem Plan for Pelagic Fisheries of the Western Pacific contains no management regulation applicable to pelagic trolling in Federal waters around Hawaii.

Management type: A commercial marine license issued by the Hawaii Department of Land and Natural Resources, Division of Aquatic Resources (DAR) is required for all commercial fishing activities in Hawaii State waters. This fishery is also managed under the Federal Pacific Pelagics Fishery Ecosystem Plan outside of 3 nmi from shore.

Category III, Hawaii kaka line fishery.

Number of active permit holders: In 2011 there were 17 active commercial fishers.

Total effort: In 2011 there were 46 fishing trips.

Seasons: unknown.

Gear type: Fishing with a gear consisting of a mainline less than one nautical mile in length to which are attached multiple branchlines with baited hooks. Mainline is set horizontally, and fixed on or near the bottom, or in shallow midwater. Typical target species varies spending on set location, e.g., nearshore or pelagics.

Regulations: Managed under State of Hawaii regulations.

Management type: A commercial marine license issued by the Hawaii Department of Land and Natural Resources, Division of Aquatic Resources (DAR) is required for all commercial fishing activities in Hawaii State waters. The Fishery Ecosystem Plan for the Hawaii Archipelago contains no management measures applicable to this gear.

Category III, Hawaii vertical longline fishery.

Number of active permit holders: In 2011 there were 9 active commercial fishers.

Total effort: In 2011 there were 92 fishing trips.

Seasons: unknown.

Gear type: Fishing using a vertical mainline, less than one nautical mile in length and suspended from the surface with float, from which leaders with baited hooks are attached and ending with a terminal weight.

Regulations: unknown.

Management type: A commercial marine license issued by the Hawaii Department of Land and Natural Resources, Division of Aquatic Resources (DAR) is required for all commercial fishing activities in Hawaii State waters. The Fishery Ecosystem Plan for the Hawaii Archipelago contains no management measures applicable to this gear.

Category III, Hawaii crab trap fishery.
Appendix 1. Description of U.S. Commercial Fisheries

Category III, Hawaii fish trap fishery.

Number of active permit holders: In 2011 there were 9 active commercial fishers.

Total effort: In 2011, there were 125 fish trap trips.

Seasons: unknown.

Gear type: Fishing with any of various fishing devices made into the shape of a box, container, or enclosure, with one or more openings that allow marine life to get inside but keep them from leaving.

Regulations: Minimum mesh size: Netting - stretched mesh 2 inches; Rigid material - 2 inches by 1 inch. Entrance cones for traps have no minimum mesh size. Traps must be portable and not exceed 10 feet in length or 6 feet in height or width.

Management type: A commercial marine license issued by the Hawaii Department of Land and Natural Resources, Division of Aquatic Resources (DAR) is required for all commercial fishing activities in Hawaii State waters. The Fishery Ecosystem Plan for the Hawaii Archipelago contains no management measures applicable to this gear.

Category III, Main Hawaiian Islands lobster trap fishery.

Number of active permit holders: In 2011 there were less than 3 active commercial fishers.

Geographic range: Lobster fishing is prohibited within the NWHI.

Seasons: In the MHI, open season is from September through April.

Gear type: One string consists of approximately 100-fathom-plus plastic lobster traps. About 10 such strings are pulled and set each day. Since 1987 escape vents that allow small lobsters to escape from the trap have been mandatory. In 1996, the
Category III, Hawaii shrimp trap fishery.

Number of active permit holders: In 2011 there were 4 active commercial fishers

Total effort: In 2011 there were 69 shrimp trap trips.

Seasons: unknown.

Gear type: Fishing with any of various fishing devices made into the shape of a box, container, or enclosure, with one or more openings that allow marine life to enter but not exit.

Regulations: State regulations specify a minimum mesh size for traps: netting must be a minimum of 2 inches stretched mesh, and rigid material must be a minimum of 2 inches by 1 inch. Entrance cones for traps have no minimum mesh size. Traps must be portable and not exceed 10 feet in length or 6 feet in height or width.

Management type: A commercial marine license issued by the Hawaii Department of Land and Natural Resources, Division of Aquatic Resources (DAR) is required for all commercial fishing activities in Hawaii State waters. The Fishery Ecosystem Plan for the Hawaii Archipelago contains no management measures applicable to this gear.

Category III, Hawaii crab net fishery.

Number of active permit holders: In 2011 there were 6 active commercial fishers

Total effort: In 2011 there were 61 crab net trips.

Seasons: unknown.

Gear type: Fishing normally with a small circular lift net that is used to catch crabs. Ring nets set manually from the shoreline, mainly in estuarine areas. The nets are used singly, and are not connected with a ground line. Gear is typically tended.

Regulations: Managed under State of Hawaii regulations.

Management type: A commercial marine license issued by the Hawaii Department of Land and Natural Resources, Division of Aquatic Resources (DAR) is required for all commercial fishing activities in Hawaii State waters. The Fishery Ecosystem Plan for the Hawaii Archipelago contains no management measures applicable to this gear.

Category III, Hawaii Kona crab net fishery.

Number of active permit holders: In 2011 there were 48 active commercial fishers
Revised 7/15/2014

Appendix 1. Description of U.S. Commercial Fisheries

Total effort: In 2011 there were 179 Kona crab trips.

Seasons: Closed during breeding season May-August

Regulations: Only male crabs of at least 4 inches carapace length may be retained.

Management type: A commercial marine license issued by the Hawaii Department of Land and Natural Resources, Division of Aquatic Resources (DAR) is required for all commercial fishing activities in Hawaii State waters. The Fishery Ecosystem Plan for the Hawaii Archipelago contains no management measures applicable to this gear.

Category III, aku boat- pole and line fishery.

Number of active permit holders: In 2011 there were 3 active commercial fishers

Total effort: In 2011 there were 86 aku boat trips.

Seasons: unknown.

Gear type: Fishing for aku (skipjack tuna) using live bait (such as nehu or iao) and or artificial lures. Generally live bait and/or water is flung or sprayed out from the stern of the (often drifting) vessel to “chum up the school” and get them feeding. Fishers on the stern of the boat often jig and slap the water with their poles to increase surface feeding behavior. Fish are hooked with pole and line, using a barbless hook (feathered, baited or not).

Regulations: Managed under State of Hawaii regulations. Specific licenses administered by DAR for the taking of baitfish and nehu (Hawaiian anchovy) for baiting purposes may be required. No baitfish may be sold or transferred except for bait purposes and licensees must furnish monthly baitfish catch reports to the DAR.

Management type: A commercial marine license issued by the Hawaii Department of Land and Natural Resources, Division of Aquatic Resources (DAR) is required for all commercial fishing activities in Hawaii State waters. This fishery is also managed under the Federal Pacific Pelagics Fishery Ecosystem Plan outside of 3 nmi from shore.

Category III, Hawaii Main Hawaiian Islands deep sea bottomfish handline fishery.

Note: The Hawaii bottomfish complex is a U.S. fishery management unit comprised primarily of several species of snappers and jacks and a grouper inhabiting waters of the Hawaiian Archipelago. The federal fisheries management regime includes three fishing zones: the main Hawaiian Islands (MHI) Zone, and two zones in the Northwestern Hawaiian Islands, the Mau Zone and the Hoomalu Zone. All bottomfish fishing currently takes place in the MHI zone due to the closure of the Northwestern Hawaiian Islands under Presidential Proclamation 8031. The main Hawaiian Islands bottomfish fishery is managed jointly by NMFS and the State of Hawaii.

Number of permit holders: In 2010 there were 569 active commercial fishers.

Total effort: From 2008 to 2010 in the MHI the reported average annual catch was 221,500 lbs., with an additional 44,300 to 553,700 lbs. estimated to have been caught but not reported.

Seasons: Fishing occurs year-round, but effort is concentrated in the late fall and winter and peaks during periods of low wind and sea conditions.

Appendix 1. Description of U.S. Commercial Fisheries

Gear type: This fishery is a hook-and-line fishery that takes place in deep water. In the MHI the vessels are smaller than 30 ft and trips last from 1 to 3 days.

Regulations: In the MHI, the sale of snappers (opakapaka, onaga and uku) and jacks less than one pound is prohibited. In June of 1998, Hawaii Division of Aquatic Resources (HDAR) closed 19 areas to bottomfishing, and regulations pertaining to seven species (onaga, opakapaka, ehu, kalekale, gindai, hapuupuu and lehi) were enacted. Total Allowable Catch (TAC) limits have been established for the "Deep-7" bottomfish species; these are the 7 primary species targeted by the commercial fleet. The TAC applies to both commercial and non-commercial sectors of the fishery. To ensure the TAC is not exceeded, NMFS and the State of Hawaii monitor the catch of Deep-7 bottomfish during the annual fishing season. Annual TAC quota for Hawaii Restricted Bottomfish Species specified in Federal Register by August 31st each year.

Management type: The portion of the fishery in Federal waters is managed under the Fishery Ecosystem Plan for the Hawaiian Archipelago, and operates under an annual catch limit. The fishery is co-managed with the State of Hawaii, which has adopted complementary measures in State waters.

Comments: The deep-slope bottomfish fishery in Hawaii concentrates on species of eteline snappers, carangids, and a single species of grouper concentrated at depths of 30-150 fathoms. These fish have been fished on a subsistence basis since ancient times and commercially for at least 90 years. Effort in this fishery increases significantly around the Christmas season because a target species, a true snapper, is typically sought for cultural festivities.11

Category III, Hawaii inshore handline fishery.

Number of active permit holders: In 2011 there were 378 active commercial fishers

Total effort: In 2011 there were 4,577 inshore handline trips.

Seasons: unknown.

Gear type: Fishing from a vessel using a vertical mainline with single/multiple lures or baited hooks and weight, lowered near the bottom to include drifting for octopus (tako) while using a handline. Fishing tackle usually consists of lighter gear than deep-sea handline. Line can be retrieved manually or by any other powered method. This fishery occurs in nearshore and coastal pelagic regions.

Regulations: Managed under State of Hawaii regulations.

Management type: A commercial marine license issued by the Hawaii Department of Land and Natural Resources, Division of Aquatic Resources (DAR) is required for all commercial fishing activities in Hawaii State waters. The Pacific Pelagics Fishery Ecosystem Plan contains no management measures applicable to this gear.

Comments: The principal catches include reef fishes and big-eyed scad (akule) and mackerel scad (opelu). Bottlenose dolphins and rough-toothed dolphins have been reported as depredating bait or catch from handlines (Shallenberger 1981, Nitta and Henderson 1993). Depredation behavior may increase the risk of marine mammals becoming hooked or entangled.

Category III, Hawaii tuna handline and jig-fishery.

Number of active permit holders: In 2011 there were 498 active commercial fishers.

Total effort: In 2011 there were 4,619 trips classified as one of the three tuna handline methods, 74 hybrid, 1,626 ika-shibi, and 2,919 palu-ahi.

Seasons: unknown.
Appendix 1. Description of U.S. Commercial Fisheries

Gear type: Palu-ahi tuna handline fishing usually takes place during the daytime. Sometimes instead of using lead weights, the baited hook and cut pieces of bait (“chum”) are laid on a stone and the leader is wrapped around the stone and secured with a slipknot. The line wrapped stone is then lowered to the desired depth, where a tug on the line releases the slipknot, dispersing the chum and releasing the baited hook. The stone falls to the bottom, leaving the line free to be worked by the fisherman. This method also includes the use of “danglers” for reporting purposes. Iki-shibi tuna handline fishing occurs mainly at night also using a vertical mainline with high-test monofilament leader, from which is suspended a single baited hook. A weight may be used between the mainline and leader, with four or more lines usually attached to the vessel by breakaway links. A sea anchor is used to control and slow (at times stop) the drift of the vessel. A small light is usually suspended from the boat to attract muhe’e (“true squid”) or opelu, typically used as bait. Line may be hauled manually, mechanically or by any powered method. Hybrid tuna handline fishing is a unique mixture of fishing methods used to catch pelagic species primarily on offshore seamounts and near NOAA weather buoys. It is generally a combination of methods which could include handlining, trolling, baiting techniques and other methods which are used simultaneously.

Regulations: Managed under State of Hawaii regulations.

Management type: A commercial marine license issued by the Hawaii Department of Land and Natural Resources, Division of Aquatic Resources (DAR) is required for all commercial fishing activities in Hawaii State waters. The Fishery Ecosystem Plan for the Hawaii Archipelago contains no management measures applicable to this gear.

Comments: This fishery occurs around offshore fish aggregating devices and mid-ocean seamounts and pinnacles. The principal catches are small to medium sized bigeye, yellowfin and albacore tuna. There are several types of handline methods in the Hawaiian fisheries. Baited lines with chum are used in day fishing operations (palu-ahi), another version uses squid as bait during night operations (ika-shibi), and an operation called “danglers” uses multiple lines with artificial lures suspended or dangled over the water. Bottlenose dolphins and rough-toothed dolphins have been reported as depredating bait or catch from handlines (Shallenberger 1981, Nitta and Henderson 1993). Depredation behavior may increase the risk of marine mammals becoming hooked or entangled.

Category III, Hawaii spearfishing fishery.

Number of active permit holders: In 2011 there were 143 active commercial fishers

Total effort: In 2011 there were 2,142 spearfishing trips.

Seasons: unknown.

Gear type: Fishing with a shaft with one or more sharpened points at one end usually associated with diving. Includes bow and torch fishing.

Regulations: Managed under State of Hawaii regulations.

Management type: A commercial marine license issued by the Hawaii Department of Land and Natural Resources, Division of Aquatic Resources (DAR) is required for all commercial fishing activities in Hawaii State waters. The Fishery Ecosystem Plan for the Hawaii Archipelago contains no management measures applicable to this gear.

Comments: Interactions have been documented with Hawaiian monk seals.

Figure 1. Locations of 8,365 sets observed in the California/Oregon large-mesh drift gillnet fishery for thresher shark and swordfish, 1990-2012. The area in blue has been closed to gillnetting from 15 August to 15 November each year since 2001 to protect leatherback turtles. The outer dashed line represents the U.S. Exclusive Economic Zone. Observed sets represent approximately 15% of all fishing effort during the period 1990 to 2012, where the total estimate of fishing effort is approximately 53,000 sets.
Figure 2. Estimated (gray) and observed (black) days of fishing effort for 1990-2012 in the California/Oregon thresher shark/swordfish drift gillnet fishery (≥ 14 inch mesh). One fishing day is equal to one set in this fishery. The approximate observer coverage during this period has been 15% (Carretta and Barlow 2011).
Figure 3. Estimated (gray) and observed (black) days of fishing effort for 1990-2012 in the California halibut/white seabass set gillnet fishery (>3.5 inch mesh). The fishery has been observed only sporadically since 1994.
Figure 2. Number of fishing trips by longline vessels based and landing in Hawaii, by year and trip type, 1991-2012. [PIFSC IMS, Longline Logbook Data, 2/14/2013 6:41:55AM]

Figure 4. Number of fishing trips by longline vessels based and landing in Hawaii, by year and trip type, 1991-2012. Source: http://www.pifsc.noaa.gov/fmb/reports.php.
Appendix 2. Cetacean Survey Effort

Documentation of cetacean abundance estimates used in the 2008 draft Pacific Marine Mammal Stock Assessments.

Cetacean abundance estimates reported in the Pacific Marine Mammal Stock Assessments originate from several sources: vessel line-transect surveys of U.S. west coast and Pacific Island Exclusive Economic Zone (EEZ) waters (Barlow 2006, Barlow and Rankin 2007, Barlow and Forney 2007, Forney 2007); aerial line-transect surveys of harbor porpoises (Carretta and Forney 2004, Laake et al. 1998); photographic mark-recapture analyses of large whales (Calambokidis et al. 2007); Hawaiian small cetaceans (Baird et al. 2005); and southern resident killer whales (Center For Whale Research, unpublished data). Often, multiple abundance estimates are available for a given cetacean stock and decisions about which estimates to utilize in the stock assessment report must be made, based on what is known about the stock. Considerable interannual variability in abundance estimates can occur because the range of many cetacean stocks extends beyond the U.S. EEZ boundaries where surveys are conducted. For this reason, multi-year averages are utilized in the stock assessments when possible.

Abundance estimates for U.S. west coast cetacean stocks are available in two separate publications (Barlow and Forney 2007, Forney 2007). The Barlow and Forney (2007) paper presents a 1991-2005 time series of abundance estimates, based on large-scale vessel line-transect surveys of California, Oregon, and Washington waters out to 300 nm. The Forney (2007) report presents estimates from a 2005 vessel line transect survey that is included in the Barlow and Forney (2007) paper, however, the Forney (2007) report includes additional analyses from fine-scale strata from coastal waters of the Olympic, Farallones, and Monterey Bay National Marine Sanctuaries. These coastal strata appear to represent seasonally important habitat for some species as Dall’s porpoise, northern right whale dolphin, humpback whales, Pacific white-sided dolphin, and blue whales. Inclusion of these coastal strata resulted in improved estimates of abundance for several species and thus, the Forney (2007) report is used for reporting 2005 abundance estimates, while the Barlow and Forney (2007) paper is used for 2001 estimates. For most U.S. west coast cetaceans, average abundances reported in the draft 2008 Pacific Marine Mammal Stock Assessments represent the geometric mean* of 2001 estimates reported by Barlow and Forney (2007) and 2005 estimates reported by Forney (2005). In the case of humpback and blue whales, mark-recapture estimates may sometimes be substituted for line-transect estimates if the precision of the mark-recapture estimate is superior.

* Current stock assessment preparation guidelines currently recommend reporting a weighted arithmetic mean, weighted by the inverse of the variances of the individual abundance estimates. However, the authors of the Pacific stock assessment reports have found that the unweighted geometric mean is a more appropriate measure of mean abundance for cases where estimates are log-normally distributed. The problem with the weighted arithmetic mean is easily understood by example. Consider a case where two equally precise abundance estimates are available; one relatively large, the other small (e.g., \( N_1 = 20,000, \text{CV}_1 = 0.3; N_2 = 5,000, \text{CV}_2 = 0.3 \)). Calculating a mean abundance using the inverse variance method arbitrarily underweights the larger estimate (due to its larger variance), resulting in a negatively biased mean estimate (\( N_{\text{mean}} = 5,882 \)). By comparison, the geometric mean of the two estimates is \( N_{\text{geomean}} = 10,000 \), which is equivalent to calculating the mean of the logarithms of \( N_1 \) and \( N_2 \).

SOUTHERN SEA OTTER (*Enhydra lutris nereis*)  
U.S. Fish and Wildlife Service, Ventura, California

**STOCK DEFINITION AND GEOGRAPHIC RANGE**

Southern sea otters are listed as threatened under the Endangered Species Act. They occupy nearshore waters along the mainland coastline of California from San Mateo County to Santa Barbara County (Figure 1). A small colony of southern sea otters also exists at San Nicolas Island, Ventura County, as a result of translocation efforts initiated in 1987. Under Public Law 99-625, the San Nicolas Island colony was formerly considered to be an experimental population (52 FR 29754; August 11, 1987), but the experimental population designation was removed upon termination of the translocation program and its respective translocation and management zones (77 FR 75266; December 19, 2012). With the termination of the translocation program, the special status afforded to southern sea otters within the management and translocation zones pursuant to Public Law 99-625 also ended.

Historically, southern sea otters ranged from Punta Abreojos, Baja California, Mexico to Oregon (Valentine *et al.* 2008), or possibly as far north as Prince William Sound, Alaska (reviewed in Riedman and Estes 1990). During the 1700s and 1800s, the killing of sea otters for their pelts extirpated the subspecies throughout most of its range. A small population of southern sea otters survived near Bixby Creek in Monterey County, California, numbering an estimated 50 animals in 1914 (Bryant 1915). Since receiving protection under the International Fur Seal Treaty in 1911, southern sea otters have gradually expanded northward and southward along the central California coast. The estimated carrying capacity of California is approximately 16,000 animals (Laidre *et al.* 2001).

Sea otter abundance varies considerably across the range, with the highest densities occurring in the center part of the range (Monterey peninsula to Estero Bay), where sea otters have been present for the longest. Sea otter densities tend to be most stable from year-to-year in rocky, kelp-dominated areas that are primarily occupied by females, dependent pups, and territorial males. In contrast, sandy and soft-bottom habitats (in particular those in Monterey Bay, Estero Bay, and Pismo Beach to Pt. Sal) tend to be occupied by non-territorial males and sub-adult animals of both sexes (but rarely by adult females and pups) and are more variable in

abundance from year to year.\(^1\) This variation is apparently driven in part by the long-distance movements and seasonal redistribution of males (Tinker et al. 2006a). The variability of counts at the south end of the range is also related to seasonal movements: many males migrate to the range peripheries during the winter and early spring, apparently to take advantage of more abundant prey resources, but then return to the range center during the period when most breeding occurs (June to November) in search of estrous females (Jameson 1989, Ralls et al. 1996, Tinker et al. 2006a). Pupping of southern sea otters takes place year round, but a birth peak extending over several months occurs in the spring, and a secondary birth peak occurs in the fall (Siniff and Ralls 1991, Riedman et al. 1994).

All sea otters of the subspecies *Enhydra lutris nereis* are considered to belong to a single stock because of their recent descent from a single remnant population. Southern sea otters are geographically isolated from the other two recognized subspecies of sea otters, *E. l. lutris* and *E. l. kenyoni*, and have been shown to be distinct from these subspecies in studies of cranial morphology (Wilson et al. 1991) and variation at the molecular level (Sanchez 1992; Cronin et al. 1996; Larson et al. 2002).

**POPULATION SIZE**

Data on population size have been gathered for more than 50 years. In 1982, a standardized survey technique was adopted to ensure that subsequent counts were comparable (Estes and Jameson 1988). This survey method involves shore-based censuses of approximately 60% of the range, with the remainder surveyed from the air. These surveys are conducted once each year (in spring). At San Nicolas Island, counts are conducted from shore (formerly quarterly, but semi-annually as of 2013). The highest of the counts is used as the official count for the year. In 2013, the official population index reported by the U.S. Geological Survey (2,941) included the 3-year running average for the mainland population (2,882) and the previous year’s high count at San Nicolas Island (59). The 2011 mainland spring census was not completed due to weather conditions; therefore, the mainland 3-year running average is calculated from only the 2012 and 2013 raw counts (2,719 and 2,865, respectively) (U.S. Geological Survey, [http://www.werc.usgs.gov/seaottercount](http://www.werc.usgs.gov/seaottercount)).

**Minimum Population Estimate**

The minimum population estimate for the southern sea otter stock is taken as the lesser of the latest raw count or the latest 3-year running average for the mainland population, plus the count for San Nicolas Island. In 2013, the mainland count was 2,865. The 3-year running average was slightly higher, 2,882. Therefore, the minimum population estimate is 2,865 plus 59, or 2,924 animals.

**Current Population Trend**

As recommended in the Final Revised Recovery Plan for the Southern Sea Otter (U.S. Fish and Wildlife Service 2003), 3-year running averages are used to characterize trends in the mainland population to dampen the effects of anomalous counts in any given year. Based on 3-year running averages of the annual spring counts, population performance along the mainland coastline has been mixed over the past several years, increasing between 2006 and 2008,

---

\(^1\) Personal communication, M. Tim Tinker, 2008. Research Wildlife Biologist, USGS-Western Ecological Research Center, Santa Cruz Field Station, and Department of Ecology & Evolutionary Biology, University of California at Santa Cruz, 100 Shaffer Road, Santa Cruz, CA 95060.
decreasing between 2008 and 2010, and increasing again between 2010 and 2013 (Figure 2). The overall trend for the past 5 years has been essentially flat (0.16 percent), although this average growth rate masks considerable regional variation within the range. Growth of the colony at San Nicolas Island has averaged approximately 7.6 percent per year over the past 5 years (U.S. Geological Survey, [webpage](http://www.werc.usgs.gov/seaottercount)).

**CURRENT AND MAXIMUM NET PRODUCTIVITY RATES**

We use the 5-year population trend to characterize current net productivity rates. As stated above, the average growth rate for this period is approximately 0.16 percent annually for the mainland population and approximately 7.6 percent annually for the San Nicolas Island population.

The maximum growth rate ($R_{\text{max}}$) for southern sea otters along the mainland coastline since the early 1980s (when reliable trend data first become available) appears to be 6 percent per year, although localized sub-populations have been observed to grow at much higher rates immediately after re-colonization.\(^2\) In contrast, recovering or translocated populations at Attu Island, southeast Alaska, British Columbia, and Washington state all exhibited growth rates of up to 17 or 20 percent annually during the early stages of recovery (Estes 1990, Jameson and Jeffries 1999, Jameson and Jeffries 2005).

Although there has been speculation that the slower rate of population growth observed for the southern sea otter reflects some fundamental difference in survival or reproduction relative to northern sea otter populations, recent data and analyses call this assumption into question. First, a variety of evidence in recent years supports the conclusion that sea otters throughout much of central California are at or very near carrying capacity of the local environment, which explains the lack of growth in these areas (*i.e.*, further growth is limited by available food resources) (Tinker *et al.* 2006b, Tinker *et al.* 2008). Second, radio-tagging studies report age- and sex-specific rates of survival and reproduction that are comparable for southern sea otters and northern sea otters, at least when status with respect to carrying capacity is controlled for (Monson *et al.* 2000, Tinker *et al.* 2006b). Finally, recent modeling analyses

---

\(^2\) Personal communication, M. Tim Tinker, 2013. Research Wildlife Biologist, USGS-Western Ecological Research Center, Santa Cruz Field Station, and Department of Ecology & Evolutionary Biology, University of California at Santa Cruz, 100 Shaffer Road, Santa Cruz, CA 95060.
indicate that the spatial configuration of available habitat (the long narrow strip of coastal shelf characteristic of California versus the bays, islands, and complex matrices of inland channels characteristic of the habitat in Washington, British Columbia, and Alaska), combined with the high degree of spatial structure in sea otter populations (due to limited mobility of reproductive females), will result in greatly different expected population growth rates over the long term, and may account in large part for the differences in trends between the southern sea otter and northern sea otter populations.\(^3\)

From the early 1900s to the mid-1970s, the southern sea otter population is thought to have increased at about 5 percent annually (Estes 1990), although consistent surveys and trend data from early years are lacking. From 1983 to 1995, annual growth averaged about 6 percent. The population declined during the late 1990s, resumed growth in the early 2000s, and ceased growth again beginning in 2008. Growth rates at San Nicolas Island averaged approximately 9 percent annually from the early 1990s to the mid-2000s and approximately 7.6 percent over the past 5 years.

**POTENTIAL BIOLOGICAL REMOVAL**

Potential Biological Removal (PBR) is the product of three elements: the minimum population estimate \(N_{\text{min}}\); half the maximum net productivity rate \(0.5 R_{\text{max}}\); and a recovery factor \(F_r\). This can be written as: \(\text{PBR} = (N_{\text{min}}) \left(\frac{1}{2} \times R_{\text{max}}\right)(F_r)\).

For the southern sea otter stock, \(N_{\text{min}} = 2,924\), \(R_{\text{max}} = 6\) percent, and \(F_r = 0.1\). A recovery factor of 0.1 is used for the southern sea otter stock because, although the population appears to be stable, \(N_{\text{min}}\) is below 5,000, and the species is vulnerable to a natural or human-caused catastrophe, such as an oil spill, due to its restricted geographic distribution in nearshore waters (Taylor et al. 2002). Therefore, the PBR for the southern sea otter stock is 8.77, which when rounded down to the nearest whole animal is 8. It is important to note that take of southern sea otters incidental to commercial fishing operations cannot be authorized under the MMPA. Thus, the provisions governing the authorization of incidental take in commercial fisheries at MMPA Sections 101(a)(5)(E) and 118, which include requirements to develop take reduction plans with the goal of reducing incidental mortality or serious injury of marine mammals to levels less than the PBR, do not apply with respect to southern sea otters.

**HUMAN-CAUSED MORTALITY AND SERIOUS INJURY**

**Fishery Information**

Sea otters are susceptible to entanglement and drowning in gill nets. The set gill net fishery in California is estimated to have killed from 48 to 166 (average of 103) southern sea otters per year from 1973 to 1983 (Herrick and Hanan 1988) and 80 sea otters annually from June 1982 to June 1984 (Wendell et al. 1986). A 1991 closure restricted gill and trammel nets to waters deeper than 30 fathoms (55 meters) throughout most of the southern sea otter’s range (California Senate Bill No. 2563). In 1990, NMFS started an observer program using at-sea observers, which provided data on incidental mortality rates relative to the distribution of fishing effort. The observer program was active through 1994, discontinued from 1995 to 1998, and reinstated in the Monterey Bay area in 1999 and 2000 because of concern over increased harbor

---

\(^3\) Personal communication, M. Tim Tinker, 2013. Research Wildlife Biologist, USGS-Western Ecological Research Center, Santa Cruz Field Station, and Department of Ecology & Evolutionary Biology, University of California at Santa Cruz, 100 Shaffer Road, Santa Cruz, CA 95060.
porpoise mortality. Based on a detailed analysis of fishing effort, sea otter distributions by depth, and regional entanglement patterns during observed years, NMFS estimated southern sea otter mortality in the halibut set gill net fishery to have been 64 in 1990, zero from 1991 to 1994, 3 to 13 in 1995, 2 to 29 in 1996, 6 to 47 in 1997, 6 to 36 in 1998, 5 in 1999, and zero in 2000 (Cameron and Forney 2000; Carretta 2001; Forney et al. 2001). The increase in estimated mortality from 1995 to 1998 was attributed to a shift in set gill net fishing effort into areas where sea otters are found in waters deeper than 30 fathoms (55 meters).

Fishing with gill nets has since been further restricted throughout the range of the southern sea otter. An order prohibiting the use of gill and trammel nets year-round in ocean waters of 60 fathoms or less from Point Reyes, Marin County, to Point Arguello, Santa Barbara County was made permanent in September 2002. In the waters south of Point Arguello, the Marine Resources Protection Act of 1990 (California Constitution Article 10B) defined a Marine Resources Protection zone in which the use of gill and trammel nets is banned. This zone includes waters less than 70 fathoms (128 meters) or within one nautical mile (1.9 kilometers), whichever is less, around the Channel Islands, and waters generally within three nautical miles (5.6 kilometers) offshore of the mainland coast from Point Arguello to the Mexican border. Although sea otters occasionally dive to depths of 328 feet (100 meters), the vast majority (>99 percent) of dives are to depths of 131 feet (40 meters) or less. Because of these restrictions and the current extent of the southern sea otter’s range, southern sea otter mortalities resulting from entanglement in gill nets are likely to be at or near zero. Nevertheless, sea otters may occasionally transit areas that are not subject to closures, and levels of observer coverage of gill and trammel net fisheries are insufficient to confirm an annual incidental mortality and serious injury rate of zero in these fisheries (see Table 1) (Barlow 1989, Babcock et al. 2003). An estimated 50 vessels participate in the CA halibut/white seabass and other species set gillnet (>3.5” mesh) fishery (78 FR 53336, August 29, 2013). Approximately 30 vessels participate in the CA yellowtail, barracuda, and white seabass drift gillnet fishery (mesh size ≥3.5” and <14”) (78 FR 53336, August 29, 2013). Approximately 25 vessels participate in the CA thresher shark/swordfish drift gillnet fishery (≥14” mesh) (78 FR 53336, August 29, 2013).

Three southern sea otter interactions with the California purse seine fishery for Northern anchovy and Pacific sardine have been documented. In 2005, a contract observer in the NOAA Fisheries California Coastal Pelagic Species observer program documented the incidental, non-lethal capture of two sea otters that were temporarily encircled in a purse seine net targeting Northern anchovy but escaped unharmed by jumping over the corkline. In 2006, a contract observer in the same program documented the incidental, non-lethal capture of a sea otter in a purse seine net targeting Pacific sardine. Again, the sea otter escaped the net at end of the haul without assistance. Based on these observations and the levels of observer coverage in each year, 58 and 20 such interactions are estimated to have occurred in the CA sardine purse seine fishery in 2005 and 2006, respectively, but these estimates are accompanied by considerable uncertainty because of the low levels of observer coverage. There are no data available to assess whether sea otter interactions with purse-seine gear are currently resulting in mortality or

4 Personal communication, M. Tim Tinker, 2008. Research Wildlife Biologist, USGS-Western Ecological Research Center, Santa Cruz Field Station, and Department of Ecology & Evolutionary Biology, University of California at Santa Cruz, 100 Shaffer Road, Santa Cruz, CA 95060.
6 Personal communication, Jim Carretta, 2008. Southwest Fisheries Science Center, NOAA, U.S. National Marine Fisheries Service, 8604 La Jolla Shores Drive, La Jolla, CA 92037.
serious injury. The 2007 list of fisheries reorganized purse seine fisheries targeting anchovy and sardines into the “CA anchovy, mackerel, sardine purse seine” fishery. An estimated 65 vessels participate in the CA anchovy, mackerel, and sardine purse seine fishery (78 FR 53336, August 29, 2013).

The potential exists for sea otters to drown in traps set for crabs, lobsters, and finfish, but only limited documentation of mortalities is available. Hatfield and Estes (2000) summarize records of 18 sea otter mortalities in trap gear, 14 of which occurred in Alaska. With the exception of one sea otter, which was found in a crab trap, all of the reported Alaska mortalities involved Pacific cod traps and were either recorded by NMFS observers or reported to NMFS observers by fishers. Four sea otters are known to have died in trap gear in California: one in a lobster trap near Santa Cruz Island in 1987; a mother and pup in a trap with a 10-inch diameter opening (presumed to be an experimental trap) in Monterey Bay in 1987; and one in a rock crab trap 0.5 miles off Pt. Santa Cruz, California (Hatfield and Estes 2000). In 1995, the U.S. Geological Survey began opportunistic efforts to observe the finfish trap fishery in California. These efforts were supplemented with observations by the California Department of Fish and Game (CDFG) in 1997 and two hired observers in 1999. No sea otters were found in the 1,624 traps observed (Hatfield and Estes 2000). However, a very high level of observer coverage would be required to see any indication of trap mortality, even if mortality levels were high enough to substantially reduce the rate of population growth (Hatfield et al. 2011).

Controlled experiments conducted by the U.S. Geological Survey and the Monterey Bay Aquarium demonstrated that sea otters would enter a baited commercial finfish trap with inner trap funnel openings of 5.5 inches in diameter (Hatfield and Estes 2000). Hatfield et al. (2011) confirmed that some sea otters exposed to finfish, lobster, and mock Dungeness crab traps in a captive setting would succeed in entering them. Based on experiments with carcasses and live sea otters, they concluded that finfish traps with 5-inch-diameter circular openings would largely exclude diving sea otters; that circular openings of 5.5 to 6 inches in diameter and rectangular openings 4 inches high (typical of Dungeness crab pots) would allow the passage of sea otters up to about 2 years of age; and that the larger fyke openings of spiny lobster pots and finfish traps with openings larger than 5 inches would admit larger sea otters. Reducing the fyke-opening height of Dungeness crab traps by one inch (to 3 inches) would exclude nearly all diving sea otters while not significantly affecting the number or size of harvested crabs (Hatfield et al. 2011). Since January 2002, CDFG has required 5-inch sea-otter-exclusion rings to be placed in live-fish traps used along the central coast from Pt. Montara in San Mateo County to Pt. Arguello in Santa Barbara County. No rings are required for live-fish traps used in the waters south of Point Conception, and no rings are currently required for lobster or crab traps regardless of their location in California waters. Estimates of the number of vessels participating in pot and trap fisheries off California are given in parentheses: CA Dungeness crab pot (534); CA coonstripe shrimp, rock crab, tanner crab pot or trap (305); CA spiny lobster (225); and CA nearshore finfish live trap/hook-and-line (93) (78 FR 53336, August 29, 2013).

Available information on incidental mortality and serious injury of southern sea otters in commercial fisheries is very limited. Due to the lack of observer coverage, a reliable, science-based estimate of the annual rate of mortality and serious injury cannot be determined. Commercial fisheries believed to have the potential to kill or injure southern sea otters are listed in Table 1. Due to the nature of potential interactions (entrapment or entanglement followed by drowning), serious injury is unlikely to be detected prior to the death of the animal.
Table 1. Summary of available information on incidental mortality and serious injury of southern sea otters in commercial fisheries that have the potential to interact with southern sea otters.

Note: n/a indicates that data are not available or are insufficient to estimate mortality/serious injury.
1 Vessel numbers are from the final List of Fisheries for 2013 (78 FR 53336, August 29, 2013).
3 This fishery is classified as a Category III fishery (78 FR 53336, August 29, 2013). Category III fisheries are not required to accommodate observers aboard vessels due to the remote likelihood of mortality and serious injury of marine mammals.
4 This sea otter was also shot, apparently after becoming entangled in the net.
Other Mortality

Variation in reproductive success and survival rates of sea otters in central California appears to be influenced primarily by density-dependent resource limitation (Tinker 2013). Physiological condition and nutritional status in turn influence the susceptibility of sea otters to environmental stressors (including pathogens, pollutants, and intoxicants produced during harmful algal blooms), which may result in death by a variety of proximate causes, including infectious disease, intra-specific aggression, intoxication, and other pathological conditions (Tinker 2013).

Common causes of death identified for fresh beach-cast carcasses necropsied from 1998 to 2001 included protozoal encephalitis, acanthocephalan-related disease, shark attack, and cardiac disease (Kreuder et al. 2003, Kreuder et al. 2005). Encephalitis caused by *Toxoplasma gondii* was associated with shark attack and heart disease (Kreuder et al. 2003). Diseases (due to parasites, bacteria, fungi, or unspecified causes) were identified as the primary cause of death in 63.8 percent of the sea otter carcasses examined (Kreuder et al. 2003). Unusually high numbers of stranded southern sea otters were recovered in 2003, prompting declaration of an Unusual Mortality Event for the period from 23 May to 1 October 2003. The increase in strandings was not attributable to any one cause, although intoxication by domoic acid produced by blooms of the alga *Pseudonitzchia australis* is believed to have been an important contributor (Jessup et al. 2004).

From 2008 through 2012, the number of strandings relative to the spring count averaged 10.4 percent (Figure 3; the entry for 2011 is missing because the spring survey was not completed that year). However, relative strandings have increased sharply over this period, with record highs in 2010 and 2012, 11.2 and 12.8 percent of the spring count, respectively (U.S Geological Survey unpublished data). These spikes in relative strandings appear to be due largely to an upswing in shark bite mortality in the northern and southern portions of the range (north of Seaside and, most markedly, south of Cayucos) (Tinker et al. 2013). Increasing shark-bite mortality is also a longer-term trend. The proportion of sea otter deaths caused by shark bites has increased 4-fold over the last 20 years and accounts for 45 percent of the variation in population trends during this period (Tinker et al. 2013). The reasons for the increase in shark bite mortality are unknown.

Non-fishery-related anthropogenic mortality of sea otters is a result of indirect and direct causes. The ocean

![Figure 3. Strandings of southern sea otters relative to the spring count, 1983-2012. The entry for 2011 is missing because the spring survey was not completed that year. Source: U.S. Geological Survey unpublished data.](image-url)
discharge of freshwater microcystins (persistent biotoxins produced by cyanobacteria of the genus *Microcystis*, which can form toxic blooms under conditions of elevated nutrient concentration, salinity, and temperature), has been linked to the deaths of more than 30 sea otters (through 2012), with the earliest known case occurring in 1999 and the greatest number of cases occurring in 2007 (Miller *et al.* 2010; CDFG unpublished data). Boat strikes typically cause several deaths each year. Shootings are a relatively low but persistent source of anthropogenic mortality. Other rare sources of anthropogenic mortality include debris entanglement and complications associated with research activities. Stranding data indicate that during the period from 2008 through 2012, at least 10 sea otters died of microcystin intoxication, 2 were shot, 12 were suspected to have been struck by boats, 1 was entangled in debris, and 3 died as a result of complications related to research activities (U.S. Geological Survey and CDFG unpublished data). Total observed anthropogenic mortality from 2008-2012, excluding any fisheries-related mortality, is 28, yielding an estimated mortality of ≥28 and a mean annual mortality of ≥5.6. Disease is an important proximate cause of death in sea otters, but due to several complicating factors (including the complexity of the pathways by which sea otters are being exposed to land-borne pathogens, the synergistic relationship between sea otter susceptibility to disease and density-dependent resource limitation, and other factors), the anthropogenic contribution to disease-related mortality in sea otters is not well understood. Therefore, animals that died of disease (other than acute liver failure resulting from microcystin poisoning) are not included in the anthropogenic mortalities reported here.

It should be noted that the mean annual mortality/serious injury reported here and in Table 1 are minimum estimates. Documentation of these sources of mortality comes primarily from necropsies of beach-cast carcasses, which constitute a subset (roughly half) of all dead southern sea otters and likely do not represent an unbiased sample with respect to cause of death because carcass deposition and retrieval are dependent on carcass size, location, wind, currents and other factors, including the cause of death itself (Gerber *et al.* 2004, Tinker *et al.* 2006a). Within this subset, the cause of death of many recovered carcasses is unknown, either because the carcass is too decomposed for examination or because cause of death cannot be determined (Gerber *et al.* 2004). Because it is unknown to what extent the levels of human-caused mortality documented in beach-cast carcasses are representative of the relative contributions of known causes or of human-caused mortality as a whole, we are unable to give upper bounds for these estimates.

**STATUS OF STOCK**

The southern sea otter is designated a fully protected mammal under California State law (California Fish and Game Code §4700) and was listed as a threatened species in 1977 (42 FR 2965) pursuant to the federal Endangered Species Act, as amended (16 U.S.C. 1531 et seq.). As a consequence of its threatened status, the southern sea otter is considered to be a “strategic stock” and “depleted” under the MMPA.

---

7 An additional animal, not included in this total, was also shot, apparently after becoming entangled in a net (fishery unknown).
8 This statement applies to all causes of death mentioned here except research-related mortalities. Research-related mortalities are unlikely to be undetected because of the intensive monitoring that tagged sea otters receive.
9 In 2012, the cause of death of approximately 35 percent of recovered carcasses was unknown. Personal communication, Brian Hatfield, 2013. Wildlife Biologist, USGS-Western Ecological Research Center, Hwy. 1, P.O. Box 70. San Simeon, CA 93452.
The status of the southern sea otter in relation to its optimum sustainable population (OSP) level has not been formally determined, but population counts are well below the estimated lower bound of the OSP level for southern sea otters, about 8,400 animals (U.S. Fish and Wildlife Service 2003), which is roughly 50 percent of the estimated carrying capacity of California (Laidre et al. 2001). Because of the lack of observer data for several commercial fisheries that may interact with sea otters, it is not possible to make a science-based determination of whether the total mortality and serious injury of sea otters due to interactions with commercial fisheries is insignificant and approaching a zero mortality and serious injury rate.

**Habitat Issues**

Sea otters are particularly vulnerable to oil contamination (Kooyman and Costa 1979; Siniff et al. 1982), and oil spill risk from large vessels that transit the California coast remains a primary threat to the southern sea otter. Studies of contaminants have documented accumulations of dichlorodiphenyltrichloro-ethane (DDT), dichlorodiphenyl-dichloroethylene (DDE) (Bacon 1994; Bacon et al. 1999), and polychlorinated biphenyls (PCBs) in stranded sea otters (Nakata et al. 1998), as well as the presence of butyltin residues, which are known to be immunosuppressant (Kannan et al. 1998). Kannan et al. (2006, 2007) found a significant association between infectious diseases and elevated concentrations of perfluorinated contaminants and polychlorinated biphenyls (PCBs) in the livers of sea otters, suggesting that chemical contaminants may influence patterns of sea otter mortality. Harmful algal blooms are increasingly recognized as a source of mortality (e.g., Miller et al. 2010). Food limitation and nutritional deficiencies appear to be the primary driver of sea otter mortality (particularly in the central portion of the range from Seaside to Cayucos), either directly or as a consequence of dietary specialization (by increasing the exposure to protozoal pathogens of sea otters that specialize on non-preferred prey types) (Bentall 2005, Tinker et al. 2006b, Tinker et al. 2008, Johnson et al. 2009, Tinker 2013). Changes in the carbonate chemistry of the oceans due to increasing atmospheric CO₂ levels (ocean acidification) may pose a serious threat to marine organisms, particularly calcifying organisms (Kroeker et al. 2010, Kurihara et al. 2008, Stumpp et al. 2011), many of which are important prey for sea otters. However, effects on sea otters will depend on numerous factors (such as potential ecological shifts arising from variable responses among marine organisms) that cannot currently be predicted.
REFERENCES

SEA OTTER (Enhydra lutris kenyoni)
WASHINGTON STOCK
U.S. Fish and Wildlife Service
Lacey, Washington

STOCK DEFINITION AND GEOGRAPHIC RANGE

The northern sea otter, *Enhydra lutris kenyoni*, historically ranged throughout the North Pacific, from Asia along the Aleutian Islands, originally as far north as the Pribilof Islands and in the eastern Pacific Ocean from the Alaska Peninsula south along the coast to Oregon (Wilson et al. 1991). In Washington, areas of sea otter concentration were reported from the Columbia River to along the Olympic Peninsula coast (Scheffer 1940). Sea otters were extirpated from most of their range during the 1700s and 1800s as the species was exploited for its fur. Washington’s sea otter population was extirpated by the early 1900s. In 1969 and 1970, a total of 59 sea otters were captured at Amchitka Island, Alaska, and released near Point Grenville and LaPush off Washington’s Olympic Peninsula coast (Jameson et al. 1982; Jameson et al. 1986). Washington’s current sea otter population originated from the Amchitka Island genotype (*Enhydra lutris kenyoni*).

For management purposes pursuant to the Marine Mammal Protection Act (MMPA), the range of the Washington sea otter stock is within the marine waters of Washington State. However, if the stock expands southward into Oregon or northward into British Columbia, a revised stock assessment would consider this expanded range.

In 2006, the distribution of the majority of the Washington sea otter stock ranged from Pillar Point in the Strait of Juan de Fuca, west to Cape Flattery and as far south as Cape Elizabeth on the outer Olympic Peninsula coast (Figure 1). However, scattered individuals (usually one or two individuals at a time) have been seen outside of this range. For example, sick or injured sea otters have come ashore as far south as Ocean Shores and repeated sightings have been reported in Grays Harbor and as far east as Port Townsend. Sightings around the San Juan Islands, near Deception Pass, off Dumas Bay, off the Nisqually River, and in southern Puget Sound near Squaxin and Hartstene Islands have also been reported. Several of the sea otters in Puget Sound became relatively “tame,” and in some cases local residents were feeding these individuals and promoting their “friendly” behavior. The U. S. Fish and Wildlife Service (USFWS) and Washington Department of Fish and Wildlife (WDFW) intervened, to the extent necessary, when these individual sea otters exhibited behaviors that presented a danger to themselves or to human health and safety.
In waters to the north of the Washington stock is the British Columbia sea otter population, which originated from animals also translocated from Amchitka Island and additional individuals from Prince William Sound, Alaska (Watson 2000). British Columbia’s sea otter population, which is also increasing, includes at least 3,180 animals distributed mainly along the west coast of Vancouver Island from Barkley Sound to Cape Scott with a separate population along the mainland coast near Goose Island in Queen Charlotte Sound (COSEWIC 2007). Although most of the British Columbia sea otter population remains north of Estevan Point along the west coast of Vancouver Island, groups of 100 to 150 animals have recently been observed south of Estevan Point near Hesquiat Harbor and Flores Island just north of Tofino. Small numbers of animals have also been reported in Barkley Sound and scattered along the coast of the Strait of Juan de Fuca to Victoria. Currently there is no evidence of interchange between the Washington and British Columbia sea otter populations. However, as the Washington and British Columbia populations grow and expand their respective ranges, movement between these populations can be expected.

Sea otters breed and give birth year-round (Riedman and Estes 1990). Pupping period for Washington’s sea otter stock is not well defined, with dependent pups observed in all months. However, births in Washington sea otters are believed to occur primarily from March to April, with peak numbers of dependent pups expected to be present from May to September (Ron Jameson, pers. comm.).

POPULATION SIZE

Original Washington Translocation

Fifty-nine sea otters were released off the Washington coast in 1969 and 1970, although almost half of the otters released in 1969 died. Sightings of sea otters were sporadic for several years after the translocations and during surveys through 1976, no more than 10 otters were observed at a time (Jameson et al. 1982). The current Washington sea otter population descended from no more than 43 otters and possibly as few as 10 (Jameson et al. 1982). Reproduction was first documented in 1974 (Jameson et al. 1982) and pups have been observed in all subsequent surveys.

Minimum Population Estimate

The first comprehensive post-release surveys of Washington’s sea otter population were conducted by boat in 1977 and again in 1981 (Jameson et al. 1986). Boat, ground, and aerial surveys for sea otters were conducted biennially from 1981 to 1989. Starting in 1989 and continuing to present, Washington’s sea otter population estimate has been developed from a combined aerial and ground survey conducted in early July by United States Geological Survey and/or WDFW. Based on the 2007 survey (actual count), the minimum population estimate of the Washington sea otter population is 1,125 individuals (Jameson and Jeffries 2008). No correction factor for missed animals has been applied to count data to determine a total population estimate from survey counts for Washington.
Current Population Trend

Based on count totals from 1977 to 1989, the Washington sea otter population increased at an annual rate of 20 percent (Jameson and Jeffries 1999). As has been done for the southern sea otter (Enhydra lutris nereis), three-year running averages are used to characterize population trends to dampen the effects of anomalous counts in any given year (U.S. Fish and Wildlife Service 2003). Jameson and Jeffries (2006) indicate “the finite rate of increase for this population since 1989 is 8 percent.” Survey data indicate the Washington stock is nearing equilibrium density north of La Push, where the rate of increase has shown no growth since 2000 (Jameson and Jeffries 2008). South of La Push, the stock has been growing at about 20 percent per year since 1989 (Jameson and Jeffries 2006).

Laidre et al. (2002) provides a carrying capacity (K) estimate of 1,019 sea otters (95 percent CI 754-1,284) for Washington’s sea otter stock to reoccupy rocky habitat from Destruction Island to Neah Bay (e.g., Seal and Sail Rocks). Laidre et al. (2002) also provide a total carrying capacity estimate for Washington of 1,836 sea otters (95 percent CI 1,386-2,286) based on an assumption that sea otters will reoccupy most of their historic habitat along the outer Washington coast (excluding reoccupation of the Columbia River, Willapa Bay, and Grays Harbor estuaries due to significant human alterations and use) and eastward into the Strait of Juan de Fuca as far as Protection Island. The Washington sea otter stock appears to be approaching equilibrium in the rocky habitat along the Olympic Peninsula coast; the reasons why the population has not dispersed into the unoccupied portions of its historic range are unclear.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

The maximum annual growth rate ($R_{max}$) for sea otter populations for which data are available has been reported as 17 to 20 percent (Estes 1990). From 1977 to 1989, the Washington stock grew at 20 percent (Jameson and Jeffries 1999) and appears to still be growing at this rate south of La Push (Jameson and Jeffries 2008). However, between 1989 and 2007, the growth rate of the entire Washington sea otter stock has slowed to an annual rate of 8 percent (Jameson and Jeffries 2008).

POTENTIAL BIOLOGICAL REMOVAL

The Potential Biological Removal (PBR) is the product of three elements: the minimum population estimate ($N_{min}$); half the maximum net productivity rate ($0.5 R_{max}$); and a recovery factor ($F_{r}$). For the Washington sea otter stock, $N_{min}$=1,125; $R_{max}$ uses a maximum sea otter growth rate of 20 percent; and $F_{r}$=0.1. A $F_{r}$ of 0.1 was used for the Washington sea otter stock because even though the population is increasing, the minimum population size is less than 1,500 and the population is restricted in its geographical range making it vulnerable to natural or human-caused catastrophe (Taylor et al. 2002). Therefore, the calculated PBR for the Washington sea otter stock is 11 animals.
ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Fisheries Information

Sea otters are susceptible to drowning in gillnets and have been taken in the Makah Northern Washington Marine Set-gillnet Fishery (Gearin et al. 1996). Based on observer data collected from 1988 through 2001, a total of 11 sea otters were taken when fishing effort occurred (Makah Tribe/Makah Tribal Resources and National Marine Fisheries Service (NMFS)/National Marine Mammal Lab (NMML) observer data). Although the fishing effort in this fishery began declining in the mid 1990s, sea otters continue to be taken in this fishery (Table 1). Pre-2000 data indicates sea otter mortalities are likely to occur when there is fishing effort in Areas 4 and 4A (Makah Bay). Only mortalities, not serious injuries, are reflected in Table 1 because the nets set by the Makah fishery do not rise to the surface of the water and any otters that get caught in the nets will likely drown. Due to inconsistent reporting between fishing areas, years, and the associated fishing effort, observer coverage, and otter mortalities (see Table 1), a reliable estimation of the annual sea otter mortality and serious injury in the Makah Northern Washington Marine Set Gillnet Fishery is assumed to be a minimum of 2 when there is fishing effort. In order to provide a more accurate estimate of the annual mortality and serious injury associated with this fishery, the USFWS requested information from the NMFS and the Makah Tribe. The information provided by the NMFS and the Makah Tribe was not sufficient to provide a more accurate estimate.

 a Overall fishing effort is not available
 b Observer coverage is presented in format supplied to USFWS

Other fisheries that occur within the range of the sea otter in Washington include treaty and non-treaty gillnet fisheries in the Strait of Juan de Fuca, Puget Sound, and Grays Harbor. Neither the USFWS or the NMFS have received any voluntary or observer reports of sea otters killed or seriously injured in these fisheries. However, the lack of information cannot be interpreted to mean that no sea otters have been killed or seriously injured because there has not been marine mammal observer coverage of these fisheries since 1994, rather, incidental takings of marine mammals in these fisheries are reported to NMFS through self-reporting (Sources: Treaty/Non-treaty sum of landings submitted to the USFWS as part of Biological Opinion reporting requirements, USDC NMFS 2003). The fisheries subject to self-reporting do not
include tribal fisheries. An accurate estimate of sea otter mortality and serious injury associated with these fisheries requires instituting an observer program and obtaining fishing effort data. Because this information is not currently available, we cannot provide an accurate estimate of the annual mortality and serious injury associated with these fisheries. Sea otter densities along the Strait of Juan de Fuca in the summer and fall are low, when the fisheries generally operate, so few entanglements would be expected. However, as the Washington sea otter population continues to grow, the possibility of fisheries-related incidental take in these gillnet fisheries will grow.

Other fisheries that also occur within the range of the Washington sea otter stock include: 1) treaty set-gillnet fisheries that occur in the coastal rivers (Quinault, Queets, Hoh, Quillayute, Hoko, and Waatch); 2) treaty and non-treaty groundfish trawl fisheries that occur offshore of the Olympic Peninsula coast; and 3) treaty and non-treaty drift gillnet fisheries that occur in Willapa Bay. These fisheries are unlikely to result in mortality or serious injury because sea otters are unlikely to occur in these areas.

As sea otters expand their range eastward into the Strait of Juan de Fuca or south along the outer Washington coast, they will also encounter important sport and commercial shellfish fisheries (urchins, razor clams, Dungeness crabs, steamer clams, geoducks). “Evidence from California and Alaska suggests that the potential for incidental take of sea otters in crab traps will increase as the population expands its range south of Destruction Island into prime Dungeness crab habitat” (Lance et al. 2004). In addition, the potential exists for increased interactions with invertebrate fisheries, particularly sea urchins and geoducks, as the sea otter population expands eastward into the Strait of Juan de Fuca (Gerber and VanBlaricom 1999).

**Other Human-Caused Mortality and Serious Injury**

Other sources of human-caused mortality and serious injury affecting the Washington sea otter population are not well documented. Documented sources of human-caused mortality for the southern sea otter include shooting, boat strikes, capture and relocation efforts, oil spills, and possibly elevated levels of polychlorinated biphenyls and other toxic contaminants. In 2003, one Washington sea otter death was presumed to have been caused by a boat strike because of the type of injuries observed during necropsy. However, these injuries could also have been sustained in a variety of other ways.

In the past decade, a number of oil spills have occurred within the range of Washington’s sea otter population, with one documented oil related death recorded during one of these spills (Jameson 1996). Additionally, with the increasing volume of shipping traffic into and out of the Strait of Juan de Fuca, the potential for a catastrophic spill exists and most, if not all, of the Washington sea otter population and range is vulnerable to the effects of such a spill. Significant oil-related mortalities and habitat damage would be expected to occur if an oil spill of this nature were to happen and impinge directly on sea otter habitat along Washington’s Olympic Peninsula and Strait of Juan de Fuca coastlines.

However, due to the lack of documented mortalities or serious injuries resulting from other human-caused sources and the unpredictability of oil spills, we are unable to provide an estimate of the annual mortality and serious injuries associated with other human-caused mortality and serious injury.

**Harvest by Northwest treaty Indian tribes**
A number of Native American tribes of the Pacific Northwest have treaty rights to harvest various fish and wildlife resources in Washington State. Currently there is no authorization for harvest of sea otters by Native Americans; however, there is a developing interest in such a program. As affirmed by the Court of Appeals for the Ninth Circuit in Anderson v. Evans (9th Cir. June 7, 2004), any take of sea otters by Native Americans other than Alaskan natives residing in Alaska has to be authorized under the MMPA.

STATUS OF STOCK

The Washington sea otter stock is not listed as “depleted” under the MMPA nor listed as “threatened” or “endangered” under the Endangered Species Act. Sea otters are listed by the State of Washington as “State endangered” under Revised Code of Washington 77.12.020 and Washington Administrative Code (WAC) 232.12.014 due to small population size, restricted distribution, and vulnerability (Lance et al. 2004). The WDFW finalized their sea otter recovery plan in 2004 (Lance et al. 2004).

This stock is not classified as strategic because the population is growing and is not listed as “depleted” under the MMPA or “threatened” or “endangered” under the Endangered Species Act of 1973.

The lower end of the Optimum Sustainable Population (OSP) range is assumed to occur at approximately 60 percent of the maximum population size the environment will support (i.e. carrying capacity) (DeMaster et al. 1996). The total carrying capacity estimate for Washington is 1,836 sea otters (95 CI 1,386 – 2,286) (Laidre et al. 2002). The current population estimate of 1,125 (Jameson and Jeffries 2008) is above the lower end of the OSP (60 percent of 1,836).

The mortality and serious injury for the Makah Northern Washington Marine Set Gillnet Fishery is estimated to be a minimum of two mortalities annually when there is fishing effort. We are unable to provide an estimate of the annual mortality and serious injury associated with other fisheries and other sources of human-caused mortality and serious injury, due to the lack of information. Therefore, we are unable to determine whether the level of human-caused mortalities and serious injuries are insignificant and approaching a zero mortality and serious injury rate.

ABSTRACT

Habitat utilization and prey species of Vancouver Island gray whales were investigated by (1) summarizing 26 yr of distribution and feeding data and (2) conducting intensive observations in Clayoquot Sound, Vancouver Island, from 1989 to 1996. Whale distribution and movements were monitored from March to November through systematic boat surveys and whale-watch sighting programs. Prey species were collected by suction hose and plankton net or determined through analysis of fecal samples. Gray whales utilized virtually all of the southern west coast of Vancouver Island over the 26-yr observation period. Distribution, prey species, and feeding behavior showed marked variability during any one season and between years. Some feeding areas were used on an annual basis, others with >10-yr intervals between use. Feeding occurred in shallow sand or mud bays, eel grass beds, kelp beds, in the open water column, and at the surface. Young whales appeared to utilize habitat and prey species differently than adults. Main prey species included herring eggs/larvae (Clupea harengus pallasi), crab larvae (Cancer magister megalops, Pachycheles spp. zoea), mysids (Holmesimysis sculpta, Neomysis rayii, Acanthomysis spp.), amphipods (Ampelisca spp., Atylus borealis), and ghost shrimp (Callianassa californiensis). The definition and relative importance of specific feeding grounds and the study of human impacts on this population are complicated by its broad and variable use of habitat and prey species.

Key words: gray whale, Eschrichtius robustus, prey, feeding patterns, habitat, Vancouver Island, oil.

The majority of eastern Pacific gray whales (Eschrichtius robustus) migrate annually between winter breeding grounds along the Mexican coast and summer feeding grounds in the Bering and Chuckchi Seas (Scammon 1869, Pike
1962, Rice and Wolman 1971, Rugh 1984). Small populations of gray whales inhabit portions of the North American coast from California to Alaska during the summer (Gilmore 1960a, b, Pike 1962, Pike and MacAskie 1969, Rice and Wolman 1971, Darling 1984, Nerini 1984, Calambokidis et al. 1991). A gray whale population occupying a summer range along the west coast of Vancouver Island, British Columbia, has been studied since the early 1970s (e.g., Hatler and Darling 1974; Darling 1978, 1984; Oliver et al. 1984; Guerrero 1989; Duffus 1996).

The Vancouver Island gray whale population consists of 35–50 whales which occupy the region for 8–9 mo between northern and southern migrations, the period from approximately March to December. During the summer they range and feed over a distance at least the length of the central Vancouver Island coastline. Between the 1970s and the present, a number of individually identified whales returned to this location each year, suggesting that the area may be a “home summer range” of a specific group of animals. Adults were typically identified over multiple years, and small, very young whales were usually present for 1–2 seasons only (Darling 1984).

Several authors have described gray whale feeding behavior off Vancouver Island. They documented benthic feeding on amphipods, ghost shrimp, and possibly polychaete worms (Hatler and Darling 1974, Darling 1978, Oliver et al. 1984, Plewes et al. 1984, Kvittek and Oliver 1986) and planktonic feeding on mysids (Murison et al. 1984, Guerrero 1989). Collectively, these observations indicate gray whales exploit several types of prey off Vancouver Island.

In December 1988 the Nestucca oil spill resulted in substantial amounts of oil being deposited in gray whale feeding grounds off Vancouver Island (Canadian Coast Guard 1989). In the follow-up assessment, JDD was asked by the Department of Fisheries and Oceans to investigate the impact of the spill on the gray whales feeding in the area. Limited knowledge about the patterns of utilization of feeding grounds and specific prey species obscured our understanding of the impacts of the spill. Such information is key to our ability to determine the impacts of human activity or natural phenomena on the whales. The purpose of this study was to document patterns of habitat and prey utilization by gray whales in the Clayoquot Sound region of Vancouver Island.

**Methods**

**Study Area**

Vancouver Island (Fig. 1) is a 480-km long island approximately half-way between gray whale breeding areas in Mexico and northern feeding grounds.

---

1 The spill of 875,000 liters of Number 6 Fuel Oil occurred off Oregon on 28 December 1988, and currents brought oil to Vancouver Island within a few days. Substantial amounts of oil washed onto beaches in gray whale feeding grounds. The majority of gray whales were on their winter migration south of Vancouver Island at the time of the spill.
Figure 1. Vancouver Island, study area, and locations of feeding whales, 1971–1996. Primary study area indicated by circle. Dotted lines joining locations indicate actual movements of individuals within one summer and show study area smaller than summer range (Darling 1984).
Between 1971 and 1996, gray whale observations were conducted on the coasts of Vancouver Island between Victoria and Cape Scott and in waters northward on the British Columbia mainland coast. Most of the observations occurred along the 225-km central–southwest coast of Vancouver Island, with the primary study area in the Clayoquot Sound region, extending approximately 80 km from Wickaninnish Bay in the southeast to Estevan Point in the northwest (Fig. 1). Our primary study area is only a portion of the overall summer range of the Vancouver Island population (Darling 1984). This coastline is characterized by open, shallow, sandy bays with surf-swept beaches separated by rocky headlands, coastal islands creating protected inside waterways, and extensive fjords reaching up to 30 km inland.

**Vancouver Island and Adjacent B.C Coast Sightings**

Sightings were collected along the Vancouver Island and mainland British Columbia coast by JDD and other knowledgeable observers over the 26-yr period, 1971–1996 (Fig. 1). These were recorded in a series of field notebooks, and some have been previously published (Hatler and Darling 1974, Darling 1984).

**Clayoquot Sound Observations**

The majority of observations that focused on habitat use and prey species were made during an eight-year period from 1989 to 1996. Some of the observations presented originated from earlier work in the region by JDD. Habitat use information was gathered using both research surveys and whale-watch sighting programs. The research effort included systematic small-craft surveys of the study area at least weekly from May through October each year, 1992–1996. Additional surveys were conducted in March–April and November each year as weather allowed. Presence and absence of whales on known feeding grounds were documented. All whales were individually identified by photographs of natural markings on their sides (Darling 1984) and locations, behavior, and associates noted. Photoidentified whales were compared to those in an identification catalog developed over the last 20 yr for sighting histories. Changes in location and habitat use by whales were monitored through these surveys and from the daily whale-watch effort in the region.

Whale watching is a significant industry in the study area and provided an opportunity for an intensive documentation of whale distribution between early March and late October each year. Whale-watch boats searched for whales on a minimum of 175 d between these dates each year, leading to a total of over 1,400 d of observation, 1989–1996. Six–12 boats and one to three planes were involved on any one day, operating from dawn to dusk. A specific marine radio channel allowed all interested to be party to all sightings. Beginning in 1989, whale-watch boats were asked by JDD to record whale sightings. Forms with maps of the region were provided, and boat operators were asked to record trip time, locations, and whale activity (feeding, resting, traveling,
rubbing). The majority of the boat operators had at least five years' experience with the whales and were proficient at determining behavior mode. Daily contact between whale-watch operators and researchers conveyed current whale activity, and boat operators contacted a researcher if unusual events occurred. The whale-watch activity amounted to an enormous sighting effort that was difficult to quantify due to variable participation and experience of specific operators. However, we cannot overemphasize the ongoing intensity of this effort, and we are convinced most whale activity in daylight hours in the region was recorded through this program.

The study effort for the years 1992–1996 was nested, with prey collections occurring within regular distribution and abundance surveys occurring within the ongoing whale-watching effort. Combined, these provided an accurate overview of activity in the area.

**Prey Collection and Identification**

In each feeding location the prey species was determined by collections, or, if needed, fecal analysis. Benthic samples were collected with a suction hose and fine-mesh net. A diver held the collection hose (PVC pipe) on the bottom in the close vicinity of feeding whales and, through use of a scuba tank to create a vacuum, suctioned the sediment/organism mixture into a fine-mesh net. Later, the predominant organisms were sorted and identified. When whales were feeding on deeper plankton or hyperbenthic organisms, collections were made using a plankton net with a cannonball weight attached to drop it to the bottom. It was towed within meters of feeding whales. Patches of prey were usually dense, and the net would often be filled beyond the collection cylinder within a few minutes of tow. When whales were feeding on the surface, the plankton net was used without the weight. If these techniques failed to catch organisms in quantities clearly indicating the prey species, the feces of the whales were collected and examined for body parts identifiable to species.

Once prey organisms were collected from a particular feeding event, the whales were monitored by researchers and whale-watch operators. Any change in behavior or feeding location warranted another collection of prey. Periodic collections were made whether whales had changed behavior or locations or not. This routine was followed throughout the May-November period, 1992–1996. In known benthic-feeding areas in which samples had been repeatedly taken over years (this study and others: e.g., Kvitek and Oliver 1986), collections were made only to confirm prey species. It was presumed that when bottom feeding in these locations the whales were consuming benthic species known to inhabit the region.

Prey organisms were preserved in 5% formalin in seawater and identified by local identification keys such as Kozloff (1983) or by amphipod specialist E. Bousfield at the Royal British Columbia Provincial Museum.
RESULTS

HABITAT UTILIZATION

Vancouver Island and Adjacent B.C. Coast

Observations included both planktonic and benthic feeding activity (Fig. 1). Sightings ranged from Georgia Strait and Victoria on the southern tip of the island to Cape Scott in the north. Whales were also sighted feeding in the Inside Passage, between Vancouver Island and the mainland and along the B.C. mainland coast northwest of Vancouver Island. Research effort was considerably less over the northern half of the Vancouver Island west coast and the mainland coast; the fewer sightings in these regions compared to the southern Vancouver Island west coast, therefore, may reflect effort rather than habitat use. Gray whales occupied a variety of habitats when sighted, ranging from protected, shallow, mud-bottomed bays to exposed surf-swept bays and beaches, to stretches of sandstone shelf, or rugged rocky shoreline with extensive fringing kelp beds. Gray whales were not present in all locations each year, and some locations were more regularly occupied than others. However, the long-term records clearly indicate that virtually all of the central-southern outer Vancouver Island coastline was utilized by gray whales over the 26 yr.

Clayoquot Sound Region

Habitat types included feeding sites, divided into herring, benthic, and plankton feeding locations, and “rubbing” sites (Fig. 2). The whales made use of all of these locations and habitats over time, although not all locations were used each year. Some feeding areas were used regularly, and these are indicated as primary grounds; others were utilized irregularly, and these are shown as secondary feeding grounds (Fig. 2). Primary grounds were those where we observed feeding for at least some portion of the season in most years; secondary grounds included those in which several years separated periods of utilization. The status of sites could change from primary to secondary use over the long term.

Feeding Habitat

Herring sites—These sites could occur wherever herring spawned. Characteristics of herring spawning sites included eel grass or algae beds in semi-protected or protected waters. There was substantial annual variability in the timing, location, and size of the “spawn” and in gray whale use of herring spawn habitat. The most consistent location in the study area was Hesquiat Harbour, at the west end of Clayoquot Sound, a 6 × 10-km shallow bay fringed with eel grass and algae beds and protected from northwesterly seas and weather. Spawning sites within the bay varied somewhat year to year. Other herring spawning habitat utilized by gray whales included sites on the west and east shores of Flores Island and north and east shores of Vargas Island.
*Figure 2.* Gray whale habitat use and prey types in Clayoquot Sound, 1971–1996. Primary sites were those used regularly; secondary sites were those used irregularly. Wickaninnish Bay was primary site until early 1980s and now considered secondary site. "U" behind prey type indicates suspected but unconfirmed. Note rubbing areas off Tofino, Catface, and Grice Bay.
and adjacent shorelines (Fig. 2). Gray whale utilization of herring spawn areas occurred also at other locations along the Vancouver Island and Queen Charlotte Island coastlines (JDD, unpublished data).

_Benthic feeding sites_—Benthic feeding sites were the most definable and predictable of all feeding habitats. The primary sites included Cow Bay on the outside coast of Flores Island and Ahous Bay on the outside of Vargas Island (Fig. 2). Until the late 1970s, Wickanninish Bay and Chesterman Beach, approximately 20 km and 9 km, respectively, to the south of Ahous Bay (Fig. 2) would also have been considered primary benthic feeding sites. However, this has changed in recent years (discussed below). These are all relatively large, shallow, sand-bottom bays with feeding activity ranging from the intertidal zone to approximately 30 m of depth. Many smaller sandy bays in the region were used on occasion. An example of a secondary site was Cypre Bay, a protected passage between Meares Island and the Catface Range (Fig. 2). Several years passed without any extended gray whale use, but in some years this region was occupied by 6–8 whales for weeks at a time. Another important secondary site was Grice Bay, a protected mud-bottom bay so shallow that the majority of it is dry at low tide. It is reached through a 10-km long, narrow, inland passage from the entrance to the open sea at Tofino.

_Plankton feeding sites_—The plankton feeding sites most consistent over the period of this study were the section of coastline from Wickanninish Bay to Chestermans Beach near Tofino, the entire outer Flores Island coast from its southern point around to the Sydney Inlet entrance, and the outer coast of Estevan Point (Fig. 2). Different sites within these larger regions were occupied for utilization of different prey species. The boundaries of these sites were quite flexible, with the prey and whales shifting with tide and current. Depending on prey species, the whales were found within and along kelp beds and in the surf zones of rocks (mysids) or slightly farther offshore in open water (crab larvae). Plankton feeding often occurred at locations distinct from benthic feeding sites, but overlap did occur.

**Young Whale Habitat**

Young whales generally tended to be separated from adult animals and were sometimes found together in small groups. This separation was subtle at times, with the younger animal(s) just several hundred meters away from adult assemblages, often inshore or in a kelp bed; or it was quite marked, when young animals occupied physically separate habitat with nearest adults 10+ km distant. The latter case is exemplified with the utilization of Grice Bay habitat. All sightings in this location over a period of 26 yr were of young whales. Between one and five whales spent months and in some cases a year or more in the bay, feeding benthically.

**Sand Bar (Rubbing) Activity**

Gray whales used specific habitat in Clayoquot Sound presumably for rubbing purposes. The whales regularly moved to sand bars and gravel spits in
the region where they rubbed their bodies and “stood” on their tails with heads lunging above the water. This behavior occurred regularly at a sand bar in Templar Channel off Tonquin Beach at the south entrance to Tofino harbor and on a sand bar off Catface Mountain in Calmus Passage (Fig. 2). Whales moved into the area from feeding grounds, or from the migratory route, rubbed for a few minutes to several hours, then moved away again (Darling 1978). Some local observers have suggested that feeding occurs at these sites; however, we have no evidence either way. Whales periodically inhabiting Grice Bay were observed similarly rubbing on the gravel spit off Indian Island. It is possible this activity also occurred regularly on the bottom.

**Prey Species**

Benthic species (Table 1) included amphipods (Amphelisca spp.) and ghost shrimp (*Callianassa californiensis*); planktonic or mobile species included mysids (*Holmesimysis sculpa*, *Neomysis rayii*, *Acanthomyysis* spp.), crab larvae (*Cancer magister* megalops, *Pachycheles* spp. zoea), and mobile amphipods (*Atylus borealis*). Herring eggs and larvae (*Clupea harengus pallasi*) were also prey for gray whales off Vancouver island.

Appendix 1 gives the prey collection record from 1984 to 1996, including date, locations (Fig. 2), method of collection, and prey species. A total of 43 collections were made. The numbers of collections by species generally reflect only our need to confirm prey during ongoing monitoring and not the relative utilization of the different species.

The leveling off of the graph of “new” species (Fig. 3) indicates that the later collections produced species already documented as prey items. The last 16 collections in 1995 and 1996 and 27 of the last 28 collections since 1994 produced no previously unknown prey species. This suggests that the nine species identified to date make up the predominant prey species of gray whales in the study area during the period of observation. However, we do not wish to imply that this is a complete list. For example, highly suggestive but unconfirmed observations of gray whales feeding on juvenile rockfish and needlefish or sandlance have been made in the region.

We observed several different feeding techniques and behavior patterns depending on type of prey, including feeding on the bottom, in the water column, and at the surface. Bottom-feeding activity, characterized by whales diving for several minutes and surfacing in approximately the same location streaming sediments from the baleen, and mysid feeding characterized by short dives and more random movements in kelp beds and within the surf zone of rock and islets, have been described by several authors (e.g., Rice and Wolman 1971, Nerini 1984, Murison et al. 1984, Guerrero 1989). Feeding on crab larvae included skim feeding, with the whales moving along the surface, the upper jaw above the water, repeatedly “biting” down on the plankton streams along tide lines. When the crab larvae were deeper, the surface activity was similar to benthic feeding, except that the whales generally moved over a greater distance during dives. Feeding on herring eggs often occurred in water several meters deep, the whales on their sides with a flipper and half fluke above the surface. We presume that the whales used suction to engulf the egg masses but this has not been confirmed. A whale that died in the area in April 1997 was found to have its stomach filled with herring eggs (JDD, field notes).

**Feeding Patterns in Clayoquot Sound**

*Early Season Herring Spawn Events*

Each spring gray whales left the northward migration to feed on herring eggs recently deposited on eel grass and algae beds (Fig. 2). The location, time, and intensity of this activity varied substantially from year to year depending on the timing and abundance of herring. Hesquiat Harbour was the only site in Clayoquot Sound where this feeding occurred on an annual basis throughout the period of study. At Hesquiat the spawn and feeding activity occurred between mid-February and early April and usually lasted two to three weeks, with several separate spawns in some years extending this time consid-
erably. During this period dozens to hundreds of whales utilized the site. It appeared the whales fed until the eggs hatched, which occurs approximately 10 d after spawning (Hart 1973), although we suspect they may also feed on the larvae in some circumstances. There can be an enormous volume of eggs, with egg drifts on beaches a meter or more high. Several other locations in the study area had smaller herring-related feeding events during one or two of the years between 1989 and 1996 (Fig. 2). When this occurred, whales moved into the area for a week or two, then departed. It is likely that herring provided the first food of the season to a portion of the migrating herd. Herring spawn times occurred progressively later along the coastal migratory route of the whales, just ahead of the migration itself. Herring-egg-feeding locations were not included in the annual feeding maps discussed below, as there is no confirmation at this stage that summer resident whales were involved in these events—although there is also no reason to believe they are not.

Summer Feeding Patterns

From observations conducted between 1989 and 1996, we have chosen four years to illustrate feeding patterns in detail: 1992, 1993, 1994, and 1995 (Fig. 4A–D). Observations from other years are referred to in relation to these examples. The terms early-season, mid-season, and late-season are used to generally designate the periods May–June, July–August, and September–November, respectively; and the terms “short-lived” and “extended”, “minor,” and “major” are arbitrary and used to describe the relative duration and number of whales participating in feeding events. A short-lived event was less than seven days; a major event involved more than ten whales.

1992 (Fig. 4A)—During the early- and mid-season there were several short-lived plankton-feeding events, including: (1) off Cox Point for one week in May (A. borealis), (2) north of Rafael Point in late June (Pachycheles spp.), and (3) off Estevan Point in mid-July (Pachycheles spp.). Beyond these events and through much of the summer, there were few whale sightings in Clayoquot Sound. There were occasional sightings of whales passing through or staying just a few days. On 18 August whales moved into Cow Bay and Ahous Bay and began feeding on benthic amphipods (Ampelisca spp.). This activity continued through the rest of the season. Numbers ranged from two to seven whales in Cow Bay through October and one to four in Ahous Bay through November. Noteworthy for this year is that sightings occurred over the period, 8–11 September, in the Cypre Bay region, a secondary ground with the last extended period of use in July–September 1982.

1993 (Fig. 4B)—An extended plankton-feeding event (A. borealis) occurred during the period from early May to early June along the coastline from Wickaninnish Bay to Chesterman Beach near Tofino, with up to seven to eight whales involved. During this time, and throughout most of the summer, whales were present in Ahous Bay and Cow Bay feeding on benthic prey (Ampelisca spp.). From June to October, one to six whales were periodically
present in Ahous Bay. From May to November, one to eleven whales were present in Cow Bay. In the latter an obvious increase in numbers occurred in mid-August, leading to a constant seven to eight whales present through September. Whales also fed on mysids: \textit{(N. rayii)} off Estevan Point in July and \textit{(H. sculpta)} off Rafael Point for a period in July and August.

1994 (Fig. 4C)—This was primarily a plankton-feeding year. Whales were present for a week in early May in Wickanninish Bay (food unknown). From mid-May through late June up to 14 whales were involved in a major mysid-feeding event \textit{(H. sculpta)} in the south Cow Bay area. By July most had moved to Rafael Point, where as many as eight whales fed on crab larva \textit{(Pachycheles spp.)} through the end of August, although the number of whales present declined after 20 August. Whales were present off the Rafael Point–Siwash Point region feeding on plankton through September and October, but the prey species was not confirmed until 2 November: mysids \textit{(N. rayii} and \textit{Acanthomysis} spp.). The whales apparently shifted from crab larvae to mysid prey sometime during this period. Benthic feeding was not observed in the region until 2 November in Ahous Bay.

1995 (Fig. 4D)—Sporadic bottom feeding occurred in Ahous Bay from May to July, with one or two whales present for one or two days at a time. Similarly, sporadic bottom feeding occurred in Cow Bay in June, July, and early August, with one to four whales moving in and out of the area. In Ahous Bay, one to two whales were present continually by mid-September, five to six by early October, and seven to eight by late October. In Cow Bay from mid-August through September whale numbers were steady at three to four, and none were present in October. Through periods of July and August, two to five whales were present in the Rafael Point–Sydney Inlet area feeding on crab larva \textit{(Pachycheles spp.)}, and in September a major feeding event occurred off Estevan Point with 10–15 whales also feeding on crab larvae. The Grice Bay secondary ground was utilized throughout the season, as described below.

Grice Bay utilization—During 1995, one to five young whales occupied the Grice Bay secondary ground from March through August feeding on ghost shrimp \textit{(C. californiensis)}. One of the same individuals was also present in the same area in June, July, and September 1996, also feeding on ghost shrimp. This feeding ground had been last utilized extensively in 1984–1985 by one or two young whales, and prior to that, in 1971, by one whale (Fig. 5; Hatler and Darling 1974). During the three documented periods of extended sightings since 1971, at least eight individual whales utilized this habitat for periods up to one year or more. The individual whale present in 1985 was one of the two animals present in 1984 and stayed the winter (JDD, unpublished data). No adults were sighted in the vicinity.

Between-Year Comparisons

It is clear that the differences between years are more striking than any repetitive patterns of occupancy or prey type (Fig. 6). For example, benthic feeding occurred throughout the season in 1993, was virtually non-existent in
Figure 4. Patterns of habitat and prey utilization: (A) 1992, (B) 1993, (C) 1994, (D) 1995. P = plankton; B = benthic; Uk = unknown; Uk P = unknown plankton; Uk B = unknown benthic; A spp = Amplelisa spp; Ab = Atylus boraliis; Hs = Holmesimysis sculpta; Nr = Neomysis rayii; P spp = Pachycheles spp; Cc = Callianassa californiensis. Numerals indicate approximate number of whales involved in feeding event (determined by individual identification). Patterned circles inside "unknown" designation indicates likely prey (e.g., 1993, 1994). Prey collections made within shaded areas.
Figure 4. Continued.
Figure 5. Utilization of Grice Bay, 1971–1996. Only young whales were found in this site in each occupation over 26-yr period, feeding on ghost shrimp (*Callianassa californiensis*). Whale present in 1985 was one of individuals present in 1984 and apparently stayed through winter. Whale present in 1996 was one of five present in 1995.

1994, and occurred for part of the summer in the other two years. Whales were present throughout the entire summer in 1994 due to successive plankton events, whereas in 1992 whales were rare for the first half of the season except for isolated, short-lived plankton events. Mysids were an important part of the prey for two years (1993 and 1994) but were not recorded as prey in the other two years. Early season mobile-amphipod-feeding occurred in essentially the same location for two years (1992, 1993) but over different lengths of time, then was absent in the following two years. Year-to-year variability in timing, prey type, and feeding location is the key feature of observations to date.

Several very generalized patterns may be emerging; these may or may not prove to be significant over the longer term. They are (1) a greater likelihood of feeding on benthic amphipods in the latter half of the season, (2) if there is steady whale-feeding activity in early and mid-season, it is more likely to be on plankton than benthic species, and (3) the Grice Bay ground may be

Figure 6. Comparison of gray whale presence and prey types between years, 1992–1995. All locations, except Grice Bay, combined; prey divided only into plankton and benthic types.
utilized by young whales steadily for one- to two-year periods separated by extended periods of non-use.

Our observations (Fig. 4) suggest that the predominant prey species for adult whales were crab larvae and benthic amphipods in 1992, swarming amphipods and benthic amphipods in 1993, mysids and crab larvae in 1994, and crab larva and benthic amphipods in 1995. It should be noted that our study area is only a portion of the animals' overall summer range.

Different Prey Species Utilized Simultaneously

On several occasions adult whales a few km from each other were observed feeding on different prey species. Examples are (1) on 11 August 1993 two whales were feeding on mysids (*H. sculpa*) in kelp off Rafael Point, and two whales were feeding on benthic amphipods (*Ampelisca spp.*) in Cow Bay, 4–5 km distant; (2) on 5 September 1996 two whales were feeding on mysids (*H. sculpa*) off Siwash Point and four to five whales were feeding on crab larvae (*Pachycheles spp.*) of Dagger Point 4 km distant; (3) on 19 October 1996 two to four whales were feeding on mysids between Siwash and Rafael Points, and two to eight whales were feeding on benthic amphipods (*Ampelisca spp.*) in Cow Bay, 3–4 km distant.

Changes in Density of Feeding Whales

The numbers of whales involved in each feeding event could vary substantially in a 24-h period (Fig. 4 A–D). Over the study period (1989–1996), at any one time and location, 1–14 whales were observed preying on mysids, 1–15+ on crab larvae, and 1–12 on benthic amphipods. Changing prey density could have been a factor but was not measured in this study.

A pattern repeated in several of the years was an increase in numbers of benthic feeding whales in late season (mid-August and later; Fig. 7). The numbers clearly increased after mid-August and remained high through the
fall. An example of this increase in numbers occurred in 1995 in Ahous Bay. No whales were present through most of the year; then numbers increased from one or two in mid-September to seven to eight by the end of October. In 1994, the "odd" year in terms of benthic feeding, the only record of such feeding occurred in early November.

Longterm Change in Use of a Feeding Ground

Wickaninnish Bay is a 12-km-long open bay, with shallow sandy bottom at the eastern end of the Clayoquot Sound study area (Fig. 2). Sighting effort varied over the 30-yr period, ranging from intensive to sporadic in any one year (Table 2).

A change in use of Wickaninnish Bay as a feeding ground has clearly occurred over the last 30 yr. During the first decade of reports, from 1966–1977, whales were present throughout most summers. The period of most consistent observation was from 1972 to 1976, due to a whale-watch operation operating in the bay and Darling's (1978) observation that whales consistently used the area from May to September. From 1977 to 1979, whale presence became less consistent. From 1980 to 1996, gray whale utilization in summer was sporadic to absent. In some of these later years, whales utilized the area in May and early June. Since 1989 the whales in this region were observed feeding on plankton (crab larvae) or swarming amphipods more often than on benthic amphipods. Occasional bouts of benthic feeding occurred throughout this time, such as in April 1996, when several well-known resident whales (one of which was present in the 1970s when the site was used regularly) were observed in Wickaninnish Bay clearly bottom feeding. Nonetheless, consistent, season-long use has not occurred in the last 20 yr.

DISCUSSION

Broad Utilization of Coastal Habitat

Hatler and Darling (1974) speculated that "pockets" of gray whale habitat occur along the North American coast, and Votrogov and Bogoslovskaya (1980) and Bogoslovskaya et al. (1981) discussed "divisions" of gray whale habitat on the Asian coast, separated by empty areas through which whales passed rapidly. These terms were not defined or given scale and so may inadvertently leave the impression of discrete gray whale habitat within a section of coastline, say the length of Vancouver Island. Kvitek and Oliver (1986) described benthic feeding grounds of Vancouver Island as "discrete isolated habitats . . . separated by many kilometers of coast," leaving a specific impression of uneven coastal use. Our review of feeding locations over a 26-yr period questions the perception of an uneven use of coastal habitat by gray whales. At any one time, whales utilized discrete pockets of habitat depending on prey availability, but over the extended period virtually all of the southern half of the Vancouver Island west coast was used by feeding gray whales. We

suggest that the idea of a "foraging route or range" that covers extended sections of coastline provides a more accurate view of gray whale habitat utilization than the concept of discrete pockets of habitat.

Clayoquot Sound may provide a representative sample of the Vancouver Island gray whale foraging range. Virtually all of the outer Sound was used by gray whales over the study period. Different areas and habitat were used for different purposes, such as herring-egg feeding, benthic feeding, plankton feeding, and "rubbing." In one case, the use was by young whales only. Some habitats were used on a regular basis, often annually, others on some irregular basis that may have included ten or more years between use. Whales likely traveled between different habitats as prey availability and abundance, social behavior, or rubbing activity dictated. The specific function and importance of presumed rubbing behavior and hence habitat has not been investigated. The activity is common in specific areas and may serve a "grooming" or "recreation" function (Hatler and Darling 1974; Darling 1978, 1984).

**Variety of Prey Resources: Benthic and Planktonic**

Nerini (1984), in a definitive review of gray whale prey and feeding behavior, concluded that "the most extraordinary aspect of the gray whale's feeding ecology is its apparent dietary flexibility" and noted that with three modes of feeding (benthic suction, engulfing, and skimming) the gray whale has perhaps a greater range of foraging techniques than any other great whale. Benthic amphipods are generally considered the predominant prey species in northern seas, but numerous observations of gray whales feeding on fish and planktonic crustaceans exist throughout their range (Pike 1962, Rice and Wolman 1971, Nerini 1984, Kim and Oliver 1989). A review of examinations of gray whale stomach contents since 1874 indicated a broad array of some 70 genera of both benthic and pelagic organisms (Nerini 1984).

The most striking feature of our observations, consistent with Nerini's (1984) review, was the variety of prey and foraging techniques utilized by the whales. Since collections began, at least nine prey species supported the gray whale population in this region. Previous reports of gray whales feeding on benthic amphipods (Oliver et al. 1984, Kivetek and Oliver 1986), mysids (Murrison et al. 1984, Guerrero 1989), and ghost shrimp (Plewes et al. 1984) are confirmed in this study. In addition, one species of mobile amphipod (A. borealis), at least two species of crab larvae (C. magister megalops and Pachycheles spp. zoea), and herring eggs and larva (Clupea harengus pallasi) were added to the list of Vancouver Island prey species. All three feeding techniques described by Nerini (1984) were utilized by the Vancouver Island whales to exploit these prey.

The polychaete worm, Onuphis elegans, has been discussed as a prey species off Vancouver Island in several reports (Darling 1977, 1978; Oliver et al. 1984; Kivitek and Oliver 1986; Kim and Oliver 1989; Weitkamp et al. 1992), but we do not believe this has been confirmed and therefore leave it in the unconfirmed category with juvenile rockfish and sand lance at this time. All of
the prey species reported for Vancouver Island have been reported previously as prey of gray whales somewhere in their range, albeit in some cases from a single observation (Nerini 1984).

The current importance of planktonic prey off Vancouver Island vs. earlier observations of extensive bottom feeding (e.g., Hatler and Darling 1974, Darling 1978) raises the question whether a change in prey species has occurred over the last 20 yr, or whether observations have simply become more complete. We lean towards the latter explanation for several reasons: most observations in 1960s and 1970s were in Wickaninnish or Ahous Bay, now well known as bottom-feeding grounds, and whales were documented in locations along the West Coast Trail (now known as a plankton-feeding area) as early as 1972 (Darling 1973). However, two points make us hesitant to entirely discount the idea that predominant prey species may have changed. These are (1) the virtual abandonment of Wickaninnish Bay and adjacent waters as a primary benthic feeding area by the early 1980s, and (2) Highsmith and Coyles’ (1992) suggestion of the potential for long-term loss of amphipod habitat, and alterations of ecosystem structure, caused by feeding gray whales.

Overall, the literature has emphasized the benthic feeding behavior and prey of gray whales (Scammon 1869, Nemoto 1959, Pike 1962, Walker 1971, Rice and Wolman 1971). Nerini (1984) revisited this view and noted that observations of feeding in the water column were concentrated in southern regions, whereas whales feeding while migrating or summering along the northern half of the migration route were nearly always consuming benthic resources—that is to say, prey types could be region-specific. Kim and Oliver (1988) furthered this idea and proposed primary, secondary, and tertiary feeding grounds defined by location and predominant prey, with more planktonic prey species farther south in the range. Our Vancouver Island work suggests another view of gray whale feeding behavior. Rather than a region-specific prey regime (Nerini 1984, Kim and Oliver 1988), the whales utilize a variety of prey resources, both benthic and pelagic, within a feeding range. We propose they exploit the most suitable prey species at any one time, on a cyclic or otherwise recurring basis. In this view, pelagic feeding and prey may have equal importance to benthic feeding and prey overall. This clearly was the case on Vancouver Island during this study. Further, it may account for the numerous observations of plankton feeding and the variety of prey species found in gray whale stomachs in other parts of their range (Nerini 1984).

In related discussions, several authors have indicated that one or another prey species was the “most important” for gray whales. Benthic or near-benthic amphipods were often listed as the primary prey (Pike 1962, Rice and Wolman 1971, Nerini 1984) at least in northern seas, and Kivitek and Oliver (1986) and Kim and Oliver (1988) stated that mysids are the major prey along the coast of British Columbia. The species noted may well have been the predominant or most important prey at the time of collection or observation, but our study strongly suggests that such results should not be generalized over time and place. We propose that rather than a single species, it is an assemblage of species that is important to the whale. We speculate that the whales are
attuned to natural patterns of abundance and absence occurring within this prey assemblage, and that different species play equal roles over a season or several years.

**Variable Patterns of Utilization of Resources and Habitat**

Gray whale feeding has been proposed as a major source of physical disturbance to the benthic community, with the activity being part of a cycle of exploitation, recolonization, succession, and maturing of the prey community (Nerini 1984, Oliver et al. 1984, Oliver and Slattery 1985). Periods of non-use by whales are presumed to correspond to recovery and maturing of the prey species. Highsmith and Coyle (1992) and Weitkamp et al. (1992) raised the possibility that gray whale exploitation may, in some circumstances, be a one-way street and lead to permanent loss of the amphipod or other prey communities and, hence, changing feeding patterns. The virtual abandonment of Wickaninnish Bay as a primary benthic feeding area since the 1980s may be such an example, although it should be noted that the current status of prey species there has not been investigated.

An additional explanation for variable use of benthic grounds arises from the idea that an assemblage of prey species is potentially available and utilized over a season. A whale may change location and habitat to exploit the “optimum” prey species at any one time. The optimum prey is probably determined by factors such as abundance, density, size, caloric content, and predation pressure, all which may vary throughout the season and year to year, depending on environmental factors and life cycles. This study suggests that a progression from one prey species to the next may occur through the season. A generalized progression of gray whale prey in Clayoquot Sound from spring to fall was seen (herring eggs, mobile amphipods, mysids, porcilid crab larvae, and benthic amphipods), as each presumably became the optimum species to “harvest.” A shift from one habitat and prey species to another may not necessarily reflect the loss of the initial prey, only that a better option has developed.

Several authors have noted differences in caloric content among gray whale prey species and within species at different times of their life cycles, especially in relation to reproductive condition. This information combined with bioenergetic considerations in foraging effort may well explain variable use of resources (Guerrero 1989, Highsmith and Coyle 1992, Weitkamp et al. 1992). For example, in the Bering Sea, the dry weight, energy content per unit weight, and caloric content of the benthic amphipod, *Amphiliscs macrocephala*, increased significantly throughout the summer, with highest values in September–November (Highsmith and Coyle 1992). If the *Amphiliscs* spp. in the study area grow similarly, this may explain the later-season progression to this prey species in Clayoquot Sound.

Our observation that patterns of utilization of resources and habitat were highly variable refers to utilization of a specific prey species and its habitat. However, if the assemblage of prey species is considered as a whole, the ob-
servation changes substantially. Utilization of the prey assemblage and its overall habitat was remarkably consistent and resulted in the highly predictable presence of gray whales in the region each summer. We speculate that it is the assemblage of prey species that allows the ongoing use of a specific feeding range over time.

**Whale Age a Factor in Habitat or Prey Use**

Very young whales, apparently ranging from several months in age and recently weaned to a 1-yr-old, made up a portion of the Vancouver Island population each year (Hatler and Darling 1974; Darling 1978, 1984; Oliver 1984; Rice and Wolman 1971; JDD, unpublished data.) The relationship of these whales with other adults in the area is yet to be determined. Darling (1978) noted “small whale characteristics” off Vancouver Island, including occupation of areas not frequented by larger feeding whales and an apparent affinity for kelp beds. Since then, some degree of separation of young whales from adults has been a recurring observation each year (JDD, unpublished data). The periodic use of Grice Bay by young whales best illustrates the apparent age-specific utilization of habitat (Hatler and Darling 1974, Plewes et al. 1984, this study).

Zenkovich (1937) suggested that specific areas along the Russian coast may be permanent feeding grounds for younger, apparently recently weaned, animals. Almost all whales captured in these areas were less than two years old, an observation from which he concluded that young gray whales form separate schools at weaning. Bogoslovskaya et al. (1981), from investigations in the same region, suggested that such separation does exist but may not be so well defined. Our observations of separation of adults and young, at times very distinct and at other times subtle, are consistent with these reports.

The reason for different habitat utilization patterns by young animals is not known. The Grice Bay young whales were feeding primarily on ghost shrimp at the same time that adults were feeding on other prey species in other parts of the study area. Weitkamp et al. (1992) suggested from a study of gray whale predation on ghost shrimp in Puget Sound that, due to density of this species, less foraging time was necessary than with benthic amphipods to obtain comparable bioenergetic gain. If true, this may be of significant benefit to young whales that are possibly learning how to feed and which may have high energy requirements. However, to complicate this view, young whales were commonly sighted in kelp beds in the general vicinity of adult whales feeding on mysids and in benthic grounds near whales feeding on benthic amphipods, and were observed to skim feed crab larvae (JDD, unpublished data). Oliver et al. (1984) reported that the small whale he observed was feeding on the benthic *Ampelisca* community. Apparent attributes of Grice Bay are shallow water, protection from storms, and possibly increased protection from predators, as well as abundant food supply. This is also true of kelp beds. Perhaps young whales seek out these relatively protective and productive habitats after weaning.
Management Considerations

1. The determination of the relative importance of specific locations and habitat to gray whales is complex. It is confounded by the whales utilizing different locations and habitat at different times within one season and from year to year. A coastal foraging route extending over hundreds of kilometers may be the appropriate view of gray whale habitat use. Certainly some locations are utilized more regularly than others, but at any one time or season the lesser-used locations may be critical to the survival of the whales, when food in the prime area is less abundant or if used for other purposes such as young whale care. Therefore, efforts to designate priority gray whale habitat within the overall coastline for management purposes may not be meaningful.

2. Determination of impacts of pollution or other human activity on gray whales is complicated by the highly variable patterns of specific habitat and prey utilization. The apparent potentially high natural variability in prey status due to normal environmental and biological fluctuations will likely lead to a corresponding variability in the distribution and behavior of the whales. The separation of natural and human impacts on the whales' distribution and behavior with current knowledge will be difficult below the lethal stage.

3. The ability of gray whales to exploit a variety of prey species, combined with a feeding range that may extend over hundreds of kilometers, may enhance the population's chances of surviving temporary catastrophic impacts on specific prey species or highly localized and contained pollution events or other disturbances. However this "enhancement" relies on the chance that the species or habitat affected is not critical at the time of impact.

4. The variable utilization of habitat and prey resources by gray whales over a large section of coastline strongly indicates that information from partial-season and single-site research projects must be taken in context. Such studies may well determine what is occurring at the particular time or place, or in a specific age class, but they may not be adequate to draw general conclusions about the entire population over time. These limitations should be noted when considering some of the inferences and conclusions in Oliver et al. 1984, Kivete and Oliver (1986), and Duffus (1996).

5. The information presented provides a broad-stroke, preliminary outline of feeding patterns in Clayoquot Sound. Several avenues of research would significantly further our insight into gray whale behavior in the region. These include (1) studies of factors influencing prey life cycles, distribution, and abundance; (2) quantitative studies of prey density and quality (in terms of caloric content) in relation to whale utilization patterns; (3) studies of the means by which whales locate prey, including potential communication between animals; and (4) investigation as to how social factors such as age, status and genetic relatedness may govern feeding distribution and behavior.

Duffus (1996) studied gray whales in Clayoquot Sound and reported on "shifts" in whale distribution and prey from 1992–1994. He then proposed a pattern of whales moving away from Tofino and the center of "commercial" activity. His observations were limited in time and area and led to different interpretations than would occur with a broader database.
ACKNOWLEDGMENTS

We gratefully acknowledge the numerous people and organizations who assisted with this study over the years. We thank all whale-watch operators in Tofino, including Don Travers and Kati Martini at Remote Passages; Richard Beaupied at the Whale Centre; Joe and Carl Martin and Mike Woods of Clayoquot Whaler; Jamie Bray and Nora Christianson at Jamie's Whaling Station; Rod and Sharon Palm, Leigh Hilbert and John Forde at R & S Tours; Mike Hanson and Earl Thomas at Chinook Charters; Wilfred Atleo of Clayoquot Sound Adventures; Didier Midavaine at Sea Trek Tours; and Gary Richards, Doug Banks, and other pilots at Tofino Air. Many individuals contributed substantially to different aspects of the study. We thank Rod Palm, who assisted in collecting benthic samples; Phil Lambert and Ed Bousfield at Royal B.C. Provincial Museum for assistance with identification of prey species; Peter Buckland, Dave and Diane Ignace, and Steve Charleson who relayed observations from Hesquiat; Josie Cleland, Tom Stere, Kara Shaw, Scott Rogers, Steve Diggon, Marnie Egan, and Chiemi Ogawa at the Clayoquot Biosphere Project who assisted in the field and office; and many residents of Tofino and Clayoquot Sound who provided sightings. Special thanks to Leah Gerber for offering suggestions on the draft of the manuscript. The work was funded by a variety of sources: organizations supporting the Clayoquot Biosphere Project programs including Kendall Foundation, Alton Jones Foundation,布尔itt Foundation, Rockefeller Brothers Foundation, and B.C. Ministry of Environment (E-team); Jamie's Whaling Station; Whale Centre; West Coast Whale Research Foundation; and Department of Fisheries and Oceans.

ABSTRACT

Counts of southbound migrating whales off California form the basis of abundance estimation for the eastern North Pacific stock of gray whales (Eschrichtius robustus). Previous assessments (1967–2007) have estimated detection probability (p) from the detection-non detection of pods by two independent observers. However, tracking distinct pods in the field can be difficult for single observers; resulting in biased estimates of pod sizes that needed correcting, and matching observations of the same pod by both observers involved key assumptions. Due to these limitations, a new observation approach has been adopted wherein a paired team of observers work together and use a computerised mapping application to better track and enumerate distinct pods and tally the number of whales passing during watch periods. This approach has produced consistent counts over four recently monitored migrations (2006/7, 2007/8, 2009/10 and 2010/11), with an apparent increase in p compared to the previous method. To evaluate p and estimate abundance in these four years, counts from two independent stations of paired observers operating simultaneously were compared using a hierarchical Bayesian ‘N-mixture’ model to jointly estimate p and abundance without the challenge of matching pods between stations. The baseline detectability p was estimated as 0.80 (95% Highest Posterior Density Interval [HPDI] = 0.75–0.85), which varied with observation conditions, observer effects and changes in whale abundance during the migration. Abundance changes were described using Bayesian model selection between a parametric model for a normally distributed common migration trend and a semi-parametric model that estimated the time trends independently for each year; the resultant migration curve was a weighted compromise between models, allowing for key departures from the common trend. The summed estimates of migration abundance ranged from 17,820 (95% HPDI = 16,150–19,920) in 2007/08 to 21,210 (95% HPDI = 19,420–23,230) in 2009/10, consistent with previous estimates and indicative of a stable population.

KEYWORDS: ABUNDANCE ESTIMATE; MIGRATION; MODELLING; GRAY WHALE; SURVEY – SHORE BASED; PACIFIC OCEAN; NORTHERN HEMISPHERE

INTRODUCTION

The eastern North Pacific stock of gray whales migrates annually along the west coast of North America from high latitude feeding grounds to winter breeding grounds in the lagoons and adjacent ocean areas off Baja California, Mexico (Rugh et al., 2001). This nearshore migration pattern has enabled repeated abundance estimates from shore-based counts off Granite Canyon, central California. In 23 years, between 1967 and 2007, counts of the number of observed pods travelling southbound have been rescaled using estimates of pods undetected during watch periods, pods passing outside watch periods, and night travel rate (Buckland and Breivik, 2002; Buckland et al., 1993; Hobbs et al., 2004; Laake et al., 2012; Laake et al., 1994; Rugh et al., 2005). Population models based on these estimates indicate that gray whales have increased substantially in population size, recovering from whaling operations in the 19th and 20th centuries, and are now close to carrying capacity and likely pre-exploitation levels (Punt and Wade, 2012). The most recent population estimate from abundance counts in 2006/07 was approximately 19,000 whales (Laake et al., 2012).

To facilitate continued population monitoring, the abundance estimation approach has seen continual evolution throughout this time series to more realistically estimate detection probability (p) to link observed counts to true abundance; this paper describes the latest modification. Notably, previous assessments have estimated p from the detection and non-detection of pods by independent observers using an analytical mark-recapture approach. However, tracking distinct pods in the field is difficult (Rugh et al., 2008), particularly for a single observer using just hand-recorded entries onto a paper data form. As a result, matching observations of the same pod by both observers involved key (and untestable) assumptions and limited observations of a given pod required corrections for bias in pod size estimation (Rugh et al., 2008; Laake et al., 2012). Due to these limitations, a new observation approach has been developed wherein a paired team of observers work together and use a computerised mapping application to help better track distinct pods and tally the number of whales passing during watch periods (Durban et al., 2010). This approach has a number of advantages, including open communication between observers, enabling observers to search for whales continually without the distraction of looking down to record data, and easier separation and tracking of distinct pods due to the precise computerised data recording and visualisation. As a result, this approach enables more repeated observations of each pod, leading to larger (and presumably less biased) estimates of pod size (Durban et al., 2010) and has produced consistent counts over four recently monitored migrations (2006/07, 2007/08, 2009/10 and 2010/11), with an apparent increase in p compared to the previous method (Durban et al., 2011).

To evaluate p for this new approach, watch period counts from two independent stations of paired observers operating simultaneously were compared during two of the four years (2009/10 and 2010/11), using a hierarchical Bayesian ‘N-mixture’ model (Royle, 2004) to jointly estimate the probability of detection and abundance in all four years, without the challenge of matching pods between stations.
This ‘N-mixture’ approach has been successfully used to estimate abundance and detectability from replicate count data for a range of wildlife species where it has not been possible to match repeat sightings of individuals (e.g. Chelgren et al., 2011; Joseph et al., 2009; Kery et al., 2005). The utility of this approach to extend the time series of abundance estimates for eastern North Pacific gray whales is demonstrated in this paper.

METHODS

Data samples

Counts of gray whales were conducted from shore-based watch stations at Granite Canyon, California, during the 2006/07, 2007/08, 2009/10 and 2010/11 southbound migrations (see Table 1). Counts were made by rotating teams of observer pairs using naked eye aided by 7×50 binoculars; the primary observer in the pair kept continual visual watch while the secondary observer served as a data recorder but also kept watch and assisted with tracking already identified pods whenever possible. Each observer had one 90 minute shift as primary observer, followed by a second 90 minute shift as secondary observer and then a 90 minute break. Sightings were entered into a real-time data logging PC program, which had a mapping screen to help track repeated sightings of the same pod. The map projected the likely movement tracks (and error ellipses) of the pods using predicted swimming speeds (1.44–1.95 ms⁻¹), allowing the likely movement tracks (and error ellipses) of the pods to be queried. Up to six lots of 1.5 hour watch periods were used to cover daylight hours from 07:30 to 16:30 local time, during which the observers recorded passing whales and environmental conditions, specifically visibility (subjectively categorized from 1–6 for excellent to unusable) and sea state (Beaufort scale). To control for weather conditions and for consistency with previous abundance estimations, only counts during watch periods with acceptable weather conditions throughout their entire duration were used, specifically visibility code <5 (excellent to fair) and Beaufort Scale <5.

Estimating detection probability

The ‘N-mixture’ approach was used (Royle, 2004) to simultaneously estimate detection probability \( p_{ijt} \) and abundance \( N_{jt} \) for each watch period \( j \) in each year \( t \), based on the total aggregated counts \( n_{jt} \) of passing whales recorded by each of \( j = 1:2 \) watch stations in each period. The observed counts \( n_{jt} \) were modelled as a binomial outcome conditional on the unknown true number of whales passing \( N_{jt} \) and the detection probability \( p_{ijt} \), with hierarchical models assumed to describe variability in both \( N \) and \( p \) (e.g. Chelgren et al., 2011). The power to estimate detectability was achieved by comparing gray whale counts from two independent stations of paired observers operating simultaneously during two years (2009/10 and 2010/11) from watch stations that were positioned 35m apart at the same elevation (22.5m) above sea level. In 2009/10 counts were compared from the two watch stations operating simultaneously during 70 lots of 1.5 hour watch periods with acceptable weather conditions, covering 20 different days of the migration; in 2010/11 simultaneous counts were available from 94 watch periods over 24 different days (see Table 1). However, detectability was extrapolated for all monitored watch periods in each of the four years based on the fitted model for detectability. In order to accomplish this, the counts for the south watch station were treated as zero-inflated binomial outcomes, with the binomial probability specified as a function \( u_{ijt} p_{ijt} \) where \( u = 1 \) or 0 to indicate whether or not count data were actually collected from that station, thus ensuring that structural zero counts from periods without a second watch did not contribute to the likelihood estimation of \( p \) or \( N \).

Consistent with Laake et al. (2012), the model for detectability incorporated fixed effects \( \beta \) for visibility (VS) and Beaufort Scale (BF), as well as random effects associated with each observer \( o \) in 1:OB observers. These were modelled as additive effects on a general intercept so that the direction and magnitude of the estimated effects away from zero (no effect) could be assessed. The selection for the inclusion of these effects using Bayesian model selection with stochastic binary indicator variables \( g \) to switch each of the three possible effects either in or out of the model depending on their relevance to the observed data (Kuo and Mallick, 1998):

\[
\logit(p_{ijt}) = \logit(p_o) + g^{\beta_{BF}} BF_j + g^{\beta_{VS}} VS_j + g^{\beta_{OB}} Ob_o,
\]

where the intercept \( p_o \) was the base detection probability in the absence of covariate effects, assigned a Uniform(0,1) prior distribution, and \( \logit(p_o) = \ln(p_o/1-p_o) \). Centred around this base detectability, each of the fixed effects \( \beta_{BF} \) and \( \beta_{VS} \) was assigned a Normal prior distribution with mean zero and large standard deviation of 10; this prior value was smaller than the corresponding posterior estimates of standard deviation, and as such this was vague prior distribution that allowed any non-zero effects to emerge if supported. The random effect for each observer was drawn from a Normal distribution with mean zero and standard deviation \( \sigma_{Ob} \cdot \text{Uniform}(0,10) \). Each of the binary indicator variables, \( g \), was assigned a Bernoulli(0.5) distribution to specify equal probability of inclusion or not of the effect in the model.

Fitting migration curves

The $N$-mixture approach also accounted for variation in $p$ relative to changes in $N$ (latent watch period abundances) during the migration. So, some power to estimate detectability was achieved by assuming a model for changes in watch period abundance over the course of the migration. A Poisson distribution $N_j \sim \text{Poisson}(\lambda_j)$ was adopted as a hierarchical prior for the distribution of abundances, and a model was specified for the Poisson mean $\lambda$ in terms of the number of whales passing each day ($d$), with an offset for the effort duration of each watch period, $E_j$ in decimal days (e.g. Laake et al., 2012):

$$\log(\lambda_j) = \log(E_j) + \text{model}_{a,j}$$

$$\text{model}_{a,j} = z_{a,j} \text{Common}_{a,j} + (1-z_{a,j}) \text{Specific}_{a,j}$$

Days were specified as $d = 0$ to $D_t$. In all four years $t$ we used $D_t = 90$, where days were counted from 12:00am on 1 December, and we added an abundance of 0 whales passing for day 0 and $D_t$ to anchor the fitted model when we assumed whales did not pass (following Buckland et al., 1993). Estimates from the remaining days were derived from a mixture (or compromise) of two competing models (‘Common’ and ‘Specific’, e.g. Li et al., 2012) describing changes in abundance across each annual migration. The model contributing each daily estimate was indicated using stochastic binary indicator variables $z_{a,j}$, each assigned a non-informative Bernoulli(0.5) prior distribution. As such, each $z_{a,j}$ indicated the probability of a daily estimate conforming to the common trend, allowing flexibility for departures from this trend that may only exist on certain days in certain years to be identified and modelled (rather than assuming all counts from an entire year conform to or depart from a common trend, which would be represented by $z$). The total number of whales passing during each migration was then estimated by summing the expected value from the model-averaged number of whales passing each day from time 0 to $D_t$ (e.g. Laake et al., 2012). These estimates were then rescaled to account for the differential passage rate at night (Perryman et al., 1999), based on the nine hour day multiplicative correction factor of Rugh et al. (2005). Specifically, we applied a constant night time correction factor that was assumed to be a Normally distributed fixed multiplicative correction factor of Rugh et al. (2005).

Estimates of this trend that may only exist on certain days in certain years were regression coefficients to be estimated separately for each year and $k_1, \ldots, k_n$ were fixed knots. We used $m = 15$ knots, a relatively large number to ensure the desired flexibility, and let $k_n$ be the sample quantile of $\tau$ corresponding to probability $k(m + 1)$. To avoid overfitting, the $\lambda$’s were penalised by assuming that these coefficients were Normally distributed random variables with mean 0 and standard deviation ~Uniform(0,10). The parameters $S_{a,1}, S_{a,2}$ were modeled as fixed effects with Normal(0, 10) prior distributions.

Bayesian inference using MCMC

The multi-level model was fit using Markov Chain Monte Carlo (MCMC) sampling using the WinBUGS software (Lunn et al., 2000). Inference was based on 15,000 repeated draws from the posterior distribution of each model parameter conditional on the observed data, following 5,000 iterations that were discarded as burn-in. Convergence of parameters within these initial 5,000 iterations was determined based on Gelman-Rubin statistics below 1.05 (Brooks and Gelman, 1998) calculated from three independent chains begun from over-dispersed starting values. To gauge the adequacy of the model for each annual set of count data, Bayesian P-values were computed (Gelman et al., 1996) by using the same MCMC sampler to predict a distribution for each watch-period count from the posterior estimates of model parameters and comparing the total predicted and observed counts. For each year, there was good agreement between the model predictions and observed counts, with Bayesian P-values ranging from 0.45 to 0.53; values close to 0.5 would indicate that the data was consistent with replications under the model, with the distribution of the observed count symmetrically overlapping the observed count (Gelman et al., 1996).

The MCMC sampling approach allowed uncertainty to be propagated across levels of the model. Notably, estimates of parameter values across MCMC iterations were used to estimate the probability of inclusion of covariate effects in the model for detectability, given by the posterior probability $p(g = 1)$ of each indicator variable $g$. Fitting and selection of the two competing migration models was achieved within the same MCMC run using the ‘cut’ function in WinBUGS.
to ensure that estimation of the two models was not affected by the selection of the model indicator (e.g. Li et al., 2012). The posterior probability of conforming to the common trend model was then calculated by the relative frequency that each model was selected by the indicator \( z_u \) in the overarching mixture model, and inference about abundance on each day was based on a weighted compromise between the competing models by sampling across the posterior distribution of \( z_u \).

RESULTS

The base detectability was estimated as \( p = 0.80 \) (95% Highest Posterior Density Interval [HPDI] = 0.75–0.85), which was modified by observation conditions and observer effects (see Table 2). The posterior distribution for the effect of sea state \( \beta_{bf} \), measured using the Beaufort scale, largely overlapped with zero and there was therefore low support for including this effect in the model with \( \rho(g_{bf} = 1) = 0.004 \). In contrast, there was a relatively strong negative effect of visibility on detectability (higher visibility code = lower detectability), with the entire distribution for \( \beta_{bf} \) falling below zero \( [\rho(g_{bf} = 1) = 1] \). There was also support for inclusion of observer effects \( [\rho(g_{obf} = 1) = 1] \), with both positive and negative effects reflecting relatively high and low counts by different observers. A total of 35 different observers were used over 4 years between North and South stations; 15/35 counted in multiple years (2 years = 7, 3 years = 4, 4 years = 4). The Posterior medians for observers’ effects ranged from –0.59 to 0.80, but only five observer effects (all positive) had posterior distributions that did not include zero.

Detectability also varied with changes in whale abundance during the migration, as shown by the extent of extrapolation from the daily summed counts (effort adjusted) to the estimated daily abundances (Fig. 1). Detectability declined with increasing abundance, with a greater proportion of whales estimated to be missed as more whales passed during busy watch periods. In general, changes in abundance during the migrations were adequately described by a Normal curve over time, but there was greater uncertainty in the tails of the distribution resulting from generally sparse coverage. The Normal trend was useful for comparing migration timing: the median of the curve midpoints was 53.5 days since December 01 (23–24 January), ranging between 49–57 days. However, there were some notable deviations from the Normal trend, with estimates from the year-specific non-parametric trend model being favoured for some days in each of the four years. In particular, there was a high probability in favour of the Specific model \( [\rho(z = 0) > 0.75] \) on 9 days in 2006/07, 9 days in 2007/08, 16 days in 2009/10 and 11 days in 2010/11, representing key departures from the Normal migration trend. The summed (model-averaged) estimates of migration abundance ranged from a posterior median of 17,820 (95% HPD = 16,150–19,920) in 2007/08 to 21,210 (95% HPD = 19,420–23,230) in 2009/10, consistent with previous estimates (Fig. 2). These new estimates were also relatively precise with coefficients of variation (CV = Posterior Standard Deviation/Posterior Median) ranging from 0.04 to 0.06 (median = 0.05), but nonetheless the 95% HDI’s of all four estimates overlapped.

DISCUSSION

The new counting method adopted here was intended to reduce reliance on the ability of single observers acting independently to record and track distinct whale groups. By adopting teams of paired observers working together, with the benefit of a real-time computerised tracking and

Observers are arbitrarily numbered, differently for each year.

Table 2
Parameters of models for detectability, p. All estimates are presented as the 2.5%, 50%, 97.5% highest density posterior probability intervals, plus the probability of inclusion in a model (if tested), given by the posterior probability \( p(g = 1) \) of each indicator variable g. Observers are arbitrarily numbered, differently for each year.
Fig. 1. Observed whale passage rates expressed as total counts per day/proportion of day observed (circles) and fitted migrations models (lines) for the four southbound gray whale migration counts from 2006/07 to 2010/11. Solid circles represent counts from a second watch station, when operating. The broken line represents the median estimates from a hierarchical Normal model for migration and the solid line represents a semi-parametric model of penalised splines; the abundance estimate for each day (95% highest posterior density interval shown by vertical lines) is a model averaged compromise between the migration models, and these were summed to estimate the overall abundance for the migrations.

Fig. 2. Gray whale abundance estimates for each of 23 southbound migrations with an end year between 1967 and 2007 (open circles, with 95% confidence intervals; from Laake et al., 2012) together with the four recent migrations reported here (closed circles show posterior medians, lines are 95% highest posterior density intervals).
visualisation tool, this approach has proved successful in increasing detection probability (Durban et al., 2011) and also reducing variability in detections due to observer effects. Although still present, the magnitude of observer effects estimated from the new counts (see Table 2) was generally not as great as those apparent with the traditional counting approach (see Laake et al., 2012, table 7).

Furthermore, our method for estimating detectability departed from the mark-recapture approach of matching detections and non-detections of specific pods by independent observers. Instead, inference was based on total watch period counts that were not sensitive to differential lumping and splitting of pods by observers, and avoided the assumptions required to match observed pods between pairs of observers. As an alternative to the mark-recapture analytic approach, we have shown how tallied watch period counts from two observer pairs counting simultaneously can lead to similar inference when analysed using with the N-mixture approach (Royle, 2004).

The N-mixture approach is conceptually simple: multiple observations of watch period counts, \( n \), from the different observer teams represented different samples from an unknown binomial distribution with total population size \( N \) and detection probability \( p \). A binomial likelihood function could then be easily used to estimate \( N \) and \( p \) from the sample of \( n \)'s. Although there were only a maximum of two samples of \( N \) during any specific watch period, a large sample of \( n \)'s was built up across many watch periods, allowing the estimation of the parameters. Layered on top of this core estimation process were both a trend model for true daily abundance through time based on the migration pattern and a model for how detection varied according to environmental conditions and different observers. Specifically, a hierarchical model fit to the replicate count samples allowed us to link detectability to key covariates, as in previous gray whale assessments (e.g. Laake et al., 2012), and also extrapolate detectability based on these covariate relationships for watch periods without replicate counts. Similarly, by assuming a common underlying model for the migration pattern, this approach notably accounted for variation in \( p \) relative to changes in abundance \( N \) during the migration. Furthermore, this joint modelling of data from multiple years allowed the borrowing of strength across years to better parameterise the migration during years with sparse data.

Previously, two contrasting approaches have been used to model changes in abundance over the course of the annual gray whale migration: either by assuming a parametric model to determine the shape of the migration curve (Buckland et al., 1993) or by fitting a non-parametric smoother to allow the data to determine the trend in abundance over time (Laake et al., 2012). Here we drew on elements of both these approaches in a flexible framework using Bayesian model selection between a parametric model for a common migration trend and a semi-parametric model that estimated the time trends independently for each year; the resultant migration curve was a weighted compromise between models, allowing for key departures from the common trend.

The abundance estimates produced for 2006/07, 2007/08, 2009/10 and 2010/11 were internally consistent, consistent with previous estimates and indicative of a stable population (Fig. 2). The 95% HDPI’s of all four estimates overlapped, and there was substantial overlap between the 95% HDPI from the 2006/7 estimate with the 95% confidence intervals of the estimate for the same migration produced using the previous counting and estimation approach (Laake et al. 2012). Further, our estimates are very similar to the predictions of Punt and Wade (2012) based on assessment models for the full time series; their baseline model prediction for 2009/10 had 90% posterior density intervals ranging from 17,726 to 23,247; the posterior distribution for our 2009/10 estimate was centered within these intervals at 21,210 (95% HPDI = 19,420–23,250). It is noteworthy that the estimates produced using our approach were relatively precise with CVs ranging from 0.04 to 0.06 (median = 0.05) in contrast to CVs ranging from 0.06 to 0.09 (median = 0.08) for the 23 previous estimates.

This consistency provides a level of confidence in our approach and resultant estimates, but nonetheless there are limitations to address. Our approach makes a number of important modelling assumptions, both in terms of distributional forms and model structure. It was assumed that the detectability relationships described by modelling repeated counts during two years were also applicable in the remaining two years with no replicate counts. We also assumed observer effects remained constant, although in reality this may change with experience. Additionally, the definition of what constituted the common migration trend was dependent on the joint modelling of just four years of data, and precise inference about the shape of the migration curve relies on count data being collected from throughout the migration time span. During at least 3/4 of the years reported here, count data were sparse (or non-existent) during the tails of the migration, resulting in uncertainty over the shape of the abundance curve. While this uncertainty was propagated into inference about overall abundance in our Bayesian inference using MCMC sampling, the resulting imprecision will ultimately constrain power to detect between-year changes in migration patterns and abundance. Data collected during further migrations will be incorporated into this hierarchical model and therefore used to refine parameter estimates; this will benefit from replicate counting experiments, repeated when possible. As the time series grows, specific goodness-of-fit tests should be adopted to investigate aspects of model structure and suggested changes as necessary.

There are also practical considerations as well as modelling assumptions. Previous work has shown that the new counting approach produces estimates of pod size that are typically larger (and presumably less biased) than the traditional counting approach (Durban et al., 2010), likely because the computerised tracking software facilitates more repeated observations of the same groups. In fact, it has been assumed that estimates of pod size using this observation approach are effectively unbiased and have not been rescaled to tally watch period counts. This is an assumption that remains to be tested, but suitable calibration experiments are difficult to design and implement, particularly due to the inherently subjective differences between observers in lumping and splitting whales to define groups. Similarly, although observer effects have been accommodated in the model for detectability, it is clear that too many observers
(35 in total) counted too infrequently to allow precise parameterisation of their relative effects on detectability in many cases. This will have resulted in further imprecision.

Although there may be field protocols that could be adapted to address these limitations within the current approach, further modernisation of the observation process is recommended. Specifically, more accurate information could be gleaned from observations recorded with high-definition video files to allow subsequent review and re-review, rather than relying on instantaneous assessment by visual observers. The use of infra-red sensors would further allow for 24 hour monitoring (e.g. Perryman et al., 1999) and provide greater coverage of the entire migration during acceptable weather conditions; automated blow detectors (e.g. Santhaseelan et al., 2012) can be developed to eliminate observer effects and standardise detectability to provide counts with minimal (and quantifiable) bias. These extensions would further serve to build a more robust and automated observation model to combine with the flexible abundance model for the migration process described in this paper.

ACKNOWLEDGEMENTS

The observers are thanked for their participation in the field work. Also appreciation is given for the advice from Steve Reilly, Bill Perrin, Jeff Breiwick, Dave Rugh, Rod Hobbs and Jeff Laake, Thanks also to Paul Wade, Andre Punt and Jeff Laake for providing valuable comments on an earlier version of this manuscript.

METHODS AND COUNT DATA

This paper presents updated counts and abundance estimates for gray whales (Eschrichtius robustus) migrating southbound off the central California coast between December and February 2014/15 and 2015/16. Counting and analytical methods followed those described by Durban et al. (2015) for four previous abundance estimates between 2006/7 and 2011/12. Counts were made from a shore-based watch station at Granite Canyon, California, by teams of observer pairs rotating from a larger pool. A total of 16 observers were used over the two years, 10 in 2014/15 and 12 in 2015/16; six observers counted in both years. Only five of these 16 observers were not involved in the previous independent counting experiments when the detection models were parameterized; in these cases, observer effects were predicted (with uncertainty) from the hierarchical model for observer effects (Durban et al. 2015).

Data were the total counts of whales from each 1.5-hour watch period that had acceptable weather conditions (see Durban et al. 2015). These comprised 179 watch periods in 2014/15 and 151 in 2015/16, totaling 269 and 226 hours of watch effort over 39 and 37 days, respectively (Table 1). The result was 2978 and 2666 whales counted in each of these years, the former representing the highest count since our new watch protocol was started in 2006/2007 (Durban et al. 2015).

Table 1: The number of whales recorded during the southbound gray whale surveys in 2014/15 and 2015/16. Data are the total counts of whales, hours and distinct days for watches during acceptable observation conditions.

ABUNDANCE ESTIMATES AND DISCUSSION
Bayesian Markov Chain Monte Carlo (MCMC) sampling was used to simultaneously rescale counts for detectability and also smooth to abundance changes over the course of each migration (Durban et al. 2015). These abundance changes were described using Bayesian model selection between a parametric model for a Normally distributed migration trend that borrowed strength across years and a semi-parametric model that estimated the time trends independently for each year; the resultant migration curve was a weighted compromise between models, allowing for key departures from the common trend. The total number of whales passing during each migration was then estimated by summing the expected value (along with associated uncertainty, see error bars in Fig 1) from the model-averaged number of whales passing each day from time 0 (01 December) to 90 days, and these estimates were then rescaled to account for the differential passage rate at night (see Durban et al. 2015).

Figure 1. Observed whale passage rates expressed as total counts per day / proportion of day observed (circles) and fitted migrations models (lines) for two gray whale migration counts in 2014/15 and 2015/16. The broken line represents the median estimates from a hierarchical Normal model for migration and the solid line represents a semi-parametric model of penalized splines (see Durban et al. 2015). The abundance estimate for each day (95% highest posterior density interval shown by vertical lines) is a model averaged compromise between the migration models, and these were summed to estimate the overall abundance for the migrations.

To sample the full extent of the uncertainty associated with model parameters, inference was based on each 10th iteration of the MCMC sampler to generate a sample of 30,000 iterations following a burn-in of 10,000. There was consistency between the model predictions and observed counts for both years, with Bayesian P-values of 0.49 and 0.54, respectively; values close to 0.5 would indicate that the data were consistent with replications under the model such that the distribution of the predicted count would symmetrically overlap the observed count (Gelman et al. 1996). However, daily and total abundance in 2014/15 were subject to considerable uncertainty, as shown by the large error bars associated with each of the daily estimates (Figure 1) and the large coefficient of variation (CV = posterior standard deviation / posterior median; CV2015 = 0.13). This is likely explained in part by the results of model fitting, as significant departures from the Normal migration model (probability of Normal model <0.25) were estimated in 18/90 days in 2014/2015 compared to only 9/90 days in 2015/16. These
departures, and the uncertainty associated with estimating an independent migration curve, constrained estimation of a precise migration curve. In contrast the CV$^{2016} = 0.05$ was consistent with previous estimates using this counting approach and model (CV = 0.04-0.06 for four previous estimates since 2006/2007), and this estimate was therefore more useful for interpreting in the context of the abundance time series. Differences in the CVs from the two years demonstrated the value of completing two counts and abundance estimates in back-to-back years, which provided a measure of redundancy.

The 2015/16 estimate of 26,960 (95% highest posterior density interval = 24,420-29,830) represented a 22% (5970 whales) increase in the five years since the 2010/11 estimate of 20,990. This is consistent with high estimates of calf production (Perryman et al. SC/67a), with a total of >6000 calves estimated during this period, including four of the highest years of calf production (>1000 calves per year) since our calf counts began in 1994. This increase in gray whale abundance also supports inference that gray whales have been experiencing a period of favorable feeding conditions in the Arctic due to a combination of expanding ice-free habitat (Moore 2016), increased primary production (Arrigo and Dijken 2015) and increased flow of nutrient-rich waters through the Bering Strait (Woodgate et al. 2012).

Figure 2: Gray whale abundance estimates for southbound migrations with an end year between 1967 and 2011 (open circles, with 95% confidence intervals; from Laake et al., 2012 and Durban et al. 2015) together with the two recent migrations reported here for 2015 and 2016.

Population structure in the eastern North Pacific gray whale: 
Implications for management of aboriginal whaling

ABSTRACT

The eastern North Pacific gray whale (Eschrichtius robustus) was removed from the Endangered Species List in 1994, and as a result several aboriginal groups in Washington and British Columbia have proposed to resume whaling. In particular, the Makah are currently in litigation with the National Marine Fisheries Service regarding this issue. Although the majority of whales in this population migrate to summer feeding grounds in the Bering, Chukchi, and Beaufort Seas, a small number of individuals (~200) spend the summers feeding in the waters of Oregon, Washington, and British Columbia. The relationship of these “southern feeding group” whales to the rest of the population is unknown. This information is key to making appropriate management decisions, because these whales would represent the primary target of the aboriginal hunt. We compared mitochondrial sequence data from 53 southern feeding group individuals to sequences from 87 individuals representing the larger population. We found small but significant differences in haplotype frequencies between the two groups (Fst = 0.0189, P = 0.00090; φST = 0.0169, P = 0.0030), with estimated migration rates << 1%. Moreover, estimates of Θ (Neµ for mtDNA data) were significantly different between the two groups (P = 0.0249), indicating that the maternal lineages of the southern feeding group are demographically independent of those from the rest of the population. Combined, these data show that the southern feeding group of gray whales qualifies as a separate management unit (MU), which should be considered when making conservation decisions.
INTRODUCTION

The eastern North Pacific gray whale (*Eschrichtius robustus*) represents one of the few populations that have been removed from the Endangered Species List, with the classification changing from “Endangered” to “Recovered” in 1994. Commercial whaling targeting gray whales in the eastern Pacific began in ~1845 (Henderson 1984), and reduced the population from an estimate of 12,000-15,000 individuals to as low as 1,500-1,900 individuals by 1900 (Henderson 1984; Reilly 1992; Butterworth et al. 2002). International protection began in 1937, when the United States and Norway ended their gray whale hunts, but it was not until 1951 that all modern whaling countries agreed to stop hunting gray whales (Reeves 1984). Systematic surveys from 1967-1998 showed that the population increased at an annual rate of ~2.6%, reaching as many as 30,000 individuals (Shelden & Laake 2002; Rugh et al. 2005). Current estimates hover around 20,000 individuals, and there are even some suggestions that the population has reached carrying capacity (Moore et al. 2001; Wade 2002; Rugh et al. 2005).

During the late fall and early winter, whales migrate to the lagoons of Baja California and the Gulf of California, which represent the winter breeding and calving grounds for this population (Swartz 1986; Findley & Vidal 2002; Swartz et al. 2006). During the spring, the majority of whales migrate to their northern feeding grounds in the Bering, Chukchi, and Beaufort Seas (Moore & Ljungblad 1984). However, a small subset of the population (~200 individuals) remains in more southerly feeding grounds along the coasts of Oregon, Washington, and British Columbia (Pike 1962; Hatler & Darling 1974; Darling 1984; Calambokidis et al. 2002; Swartz et al. 2006). These two subsets of the population will be referred to as the northern and southern feeding groups, respectively.

Subdivision with respect to summer feeding ground use is common in baleen whales, and results from maternally-directed site fidelity to different feeding grounds. For example, in humpback whales (*Megaptera novaeangliae*) and North Atlantic right whales (*Eubalaena glacialis*) calves nurse for ~11 months (and occasionally longer), and learn migration routes and the location of summer feeding grounds through cultural transmission from their mother (e.g. Baker et al. 1990; Malik et al. 1999). Thus, if there is differential use of feeding grounds by mothers, these preferences will be passed on to their offspring and result in substructuring with respect to summer feeding ground use. Gray whale calves nurse for a much shorter period of time (~6 months) (Swartz 1986). Although this is still long enough to learn migratory routes and the location of summer feeding grounds, it is not yet clear whether or not gray whales show this maternally-directed site fidelity. Because of its maternal inheritance, patterns of mitochondrial DNA (mtDNA) diversity should reflect any maternally-based patterns of movement and distribution. Therefore, analysis of mtDNA is ideal for testing hypotheses of maternally-based site fidelity and subsequent population structure in baleen whales.

The relationship between the northern and southern feeding groups is unknown. It is currently assumed that both of these groups use the same breeding ground, and therefore represent the same breeding population (e.g. Swartz et al. 2006). Given the known patterns in other baleen whale species, it seems likely that the northern and southern feeding groups result from maternally-directed site fidelity to different feeding grounds by gray whale mothers. Photo-identification data are consistent with this hypothesis, showing that the majority of whales sighted in the southern feeding areas are resighted there in subsequent years, and therefore show the expected site fidelity (Darling 1984; Calambokidis et al. 2002). However, preliminary genetic analyses based on mtDNA were inconclusive (Steeves et al. 2001).

Understanding the relationship between the northern and southern feeding groups is becoming of increasing importance due to the desire of some aboriginal communities in Washington and British Columbia to resume hunting the gray whale. Several aboriginal groups historically hunted gray whales in this area, but voluntarily stopped hunting as whale numbers decreased and/or were required to stop.
when the population received international protection (O’Leary 1984; Russell 2004). The one
exception was aboriginal whaling in Chukotka, Russia, which was allowed to continue. In 1999 the
Makah (in Washington State) resumed whaling, but have since been prevented from doing so by
litigation. Specifically, the Makah were given the right to hunt gray whales at traditional sites under
the Treaty of Neah Bay in 1855. However, they have been prevented from doing so under the court
ruling (in 2004) that in order to continue their hunt they must follow the necessary procedures for
obtaining authorization to “take” whales under the Marine Mammal Protection Act (MMPA). The
Makah have applied for a waiver from the MMPA regulations, and this request is still in litigation. The
outcome of the Makah lawsuit will have large implications for the resumption of whaling by other
aboriginal communities in the area as well (Russell 2004).

The majority of the proposed aboriginal whaling will take place in the waters of Washington
and British Columbia – the feeding ground of the much smaller southern feeding group. The negative
consequences of ignoring potential population structure when making management decisions are well
known (e.g. Daugherty et al. 1990; Taylor 1997; Frankham et al. 2002). Therefore, if informed
management decisions are to be made regarding resuming this hunt, it is first necessary to understand
the relationship of this southern feeding group to the rest of the larger population. Here, we conducted
analyses of the mitochondrial DNA of gray whales from the both the southern and northern feeding
groups in order to better understand their relationship, and therefore guide management decisions.

MATERIALS AND METHODS

Skin samples were collected from whales representing the southern feeding group in Clayoquot
Sound, British Columbia from 1995-2008, using a crossbow and modified bolt (e.g. Lambertsen 1987;
Palsbøll et al. 1991) or a pneumatic rifle biopsy system (Barrett-Lennard et al. 1996). Tissue samples
were stored in a 20% dimethyl sulfoxide (DMSO) solution (Seutin et al. 1991). Approximately 40 mg
from each sample was used for subsequent DNA extraction procedures. The skin was frozen in liquid
nitrogen, ground to a fine powder, and transferred to a tube with 500 µl of lysis buffer (4 M urea, 0.2 M
NaCl, 0.5% n-lauroyl sarcosine, 10 mM 1,2-cyclohexanediaminetetraacetic acid, 100 mM Tris-HCL,
pH 8.0). Samples were rotated in the lysis buffer at room temperature for ≥ 5 days, after which time
they were subjected to three aliquots of proteinase K, each at a concentration of 0.5 U of proteinase K
per milligram of tissue. The addition of proteinase K was as follows: after adding the first aliquot,
samples were rotated at room temperature overnight; after adding the second aliquot the samples were
placed in a 65°C waterbath for 1 hour, then transferred to a 37°C incubator for 1 hour; after adding the
third aliquot, the samples were rotated at room temperature overnight. Approximately 250 µl of the
tissue/lysis buffer solution was subsequently extracted using Qiagen DNeasy Tissue Extraction Kits
(Qiagen Inc., Mississauga, Ontario, Canada). DNA quantity was estimated using PicoGreen (Singer et
al. 1997). Extracted samples included those previously analyzed by Steeves et al. (2001), which were
re-extracted and analyzed here along with the newly collected samples.

A 345 bp portion of the mitochondrial DNA control region was amplified using the primers t-
PRO and Primer-2 from Yoshida et al. (2001). PCR cycling conditions consisted of: (i) an initial
denaturation step of 5 minutes at 94°C; (ii) 30 cycles of 94°C for 30 seconds, 57°C for 1 minute, and
72°C for 1 minute; and (iii) a final extension step of 60°C for 45 minutes. Reactions were carried out
in 20 µl volumes containing 1X PCR Buffer (20 mM Tris-HCl pH 8.0, 50 mM KCl), 0.05 U µl⁻¹ Taq
polymerase (Invitrogen), 1.5 mM MgCl₂, 0.2 mM each dNTP (Invitrogen), and 10 ng of DNA. After
amplification, primers and unincorporated dNTPs were degraded using EXOSAP-IT (Dugan et al.
2002), and products were sequenced using the DYEnamic dye terminator kit (GE Healthcare,
To compare the data from southern feeding group whales to those of the northern feeding group, we compared our mitochondrial sequence data to those reported in Goerlitz et al. (2003). These samples were collected from 83 individuals in the winter calving and breeding lagoons around Baja California. The rationale is that although whales with different summer feeding distributions may congregate on the same area in the winter, the probability of one of these samples representing a southern feeding group individual is low; given that the total population size estimate is ~ 20,000 individuals (Swartz et al. 2006), and the estimate for the southern feeding group is ~ 200 (Calambokidis et al. 2002). This approach would also make our results conservative – where true differentiation will likely be greater than that observed due to this potential for some southern feeding group whales to be represented in the winter sample set.

Sequences were aligned with CLUSTALX (Thompson et al. 1994). Alignments were conducted under a range of gap opening and extension penalties and compared by eye to establish the optimal alignment. The sequences were very similar, and all alignments were the same under the tested conditions. Haplotype and nucleotide diversity (\( \pi \)) (Nei 1987) were estimated using Arlequin ver. 3.1 (Excoffier et al. 2005). Variations between mtDNA sequences were recorded and identical sequences were grouped into haplotypes. Final haplotype assignments were confirmed with FaBox ver. 1.35 (Villesen 2007). Population differentiation of the mtDNA sequences between the southern feeding group and the winter samples was estimated using the analysis of molecular variance approach described in Excoffier et al. (1992) as implemented in the program Arlequin. The significance of the resulting estimates of \( F_{ST} \) and \( \phi_{ST} \) was tested using 1000 permutations. Relationships between haplotypes were visualized via a median-joining network using the program Network 4.5.1.6 (Fluxus Technology Ltd.).

To gain insight into the nature of the observed population structure, we estimated effective population sizes, migration rates, time since divergence, and growth rates for the two feeding groups using the Isolation with Migration program (IM, Nielsen & Wakeley 2001; Hey & Nielsen 2004; Hey et al. 2004). However, repeated trials with various parameter options suggested that there was not enough information in our data set to obtain accurate estimates for all of these values (data not shown). Instead, we focused on estimating just the effective population sizes and migration rates using the program MIGRATE (Beerli & Felsenstein 2001; Beerli 2006). The Bayesian inference approach was implemented, using a transition/transversion ratio of 11.22 and an \( \alpha \) estimate of 0.09 for the gamma distribution of mutation rate heterogeneity among sites (both estimated using TREE-PUZZLE, Schmidt et al. 2002). We used the Metropolis method of generating posterior distributions. The program was run with uniform prior distributions and one long chain. To ensure consistency between runs, MIGRATE was run four times with a burn-in of 100,000 steps, and a run length of 10,000,000 steps with data recorded every 500 steps. The likelihood ratio test option of MIGRATE was also used to test the hypothesis that the northern and southern feeding groups have different effective population sizes. Specifically, the hypothesis tested was \( \Theta_{\text{southern}} = \Theta_{\text{northern}} \), where \( \Theta = N_e \mu \) for mitochondrial data, where \( \mu \) is the mutation rate per site per generation.

RESULTS

DNA was extracted and mtDNA control regions sequenced from 57 summer resident gray whales. The sequencing protocol resulted in 336 bp of comparable sequence between individuals. Twenty-seven polymorphic sites were identified, which resulted in 18 haplotypes in the summer
resident whales (Tables 1 and 2). None of the variable sites identified in the southern feeding group were new - all were also represented by the sequences described by Goerlitz et al. (2003) (Table 2).

The sequenced region from the summer resident whales was slightly different than those in Goerlitz et al. (2003), and therefore to align all sequences for analyses 15 bp were excluded from one end of the sequences from the Goerlitz et al. (2003) sequences, and 45 bp were excluded from the opposite end of the southern feeding group sequences. This resulted in a total of 291 bp that could be compared between the two sample sets. Trimming the sequences in this manner did not remove any variable sites within the southern feeding group samples, but did remove the variation differentiating sequences 1, 2 and 28 from Goerlitz et al. (2003), which were subsequently collapsed into one haplotype for these analyses. For the purposes of this study, these ‘collapsed’ sequences are referred to as haplotype 1.

Fifteen of the 29 haplotypes (52%) were shared between both groups, 11 (38%) were only found in the northern feeding group, and three (10%) were found only in the southern feeding group (Table 2). Estimates of differentiation for haplotype frequencies between groups were small but significant, with values of 0.01890 for $F_{ST}$ ($P = 0.00090$) and 0.01688 for $\phi_{ST}$ ($P = 0.0030$). The median-joining network shows that although there is some evolutionary differentiation between the haplotypes from the two feeding groups, for the most part the haplotypes from each are scattered throughout the network (Fig. 1). Haplotype and nucleotide diversity ($\pi$) were estimated at 0.9279 and 0.019910, respectively for the southern feeding group. These values are very similar to estimates obtained based on samples from the winter breeding/calving ground, which were 0.95 and 0.02, respectively (Goerlitz et al. 2003).

The results from the MIGRATE analyses are shown in Table 3. Estimates for each value are very similar across iterations, suggesting that the program was run long enough to reach convergence on the estimates. The estimates of $\Theta$ for the northern and southern feeding groups are clearly different. This observation was confirmed by the likelihood ratio test, which rejected the hypothesis of $\Theta_{southern} = \Theta_{northern}$ ($P = 0.024878$). The 95% confidence intervals for the migration rate estimates are extremely large, making them uninformative. This result is not surprising, however, because the approach implemented by MIGRATE is known to recover precise and accurate estimates of $\Theta$ even in situations where there is not enough information in the data to recover meaningful migration rate estimates (Beerli 2006).

DISCUSSION

The conservation and/or management of wildlife populations requires knowledge of how individuals are subdivided into separate entities that have relatively independent demographic processes, which are often referred to as “management units”. Such information is required to identify how each unit, and the population as a whole, will respond to exploitation and/or unintentional impacts. Moritz (1994) was the first to provide a working definition of a management unit (MU) in a population genetics context, and defined them as “…populations with significant divergence of allele frequencies at nuclear or mitochondrial loci, regardless of the phylogenetic distinctiveness of the alleles.” While this definition has been widely applied in population genetics studies, it has recently been argued that management units should be defined based on criteria demonstrating demographic isolation rather than simply rejecting the hypothesis of panmixia (Palsbøll et al. 2007). This idea makes intuitive sense, because the true question for management is whether or not the units will respond differently to the pressures of concern (e.g. exploitation and/or unintentional mortality).
The data presented here show that the southern feeding group of gray whales represents a distinct management unit under both of these criteria. The analysis showing statistically significant differentiation of mitochondrial haplotypes demonstrates qualification as an MU under the criteria of Mortiz (1994). Moreover, the analysis showing that the effective sizes of both groups are different ($\Theta_{\text{southern}} \neq \Theta_{\text{nortern}}$) shows that the maternal lineages of the southern feeding group are demographically independent of those of the northern feeding group. Indeed, if they were not an independent unit, then estimates of $\Theta$ from the two data sets should converge on the same value. Thus, the southern feeding group qualifies as a separate management unit under the criterion of Palsbøll et al. (2007). Combined, these data show that the southern feeding group requires separate management consideration with regards to resuming aboriginal (or any) whaling.

Hastings (1993) showed that populations behave in a demographically independent manner when migration rates are less than $\sim 10\%$. We have intentionally not converted $\Theta$ estimates to $N_e$ estimates (where $\Theta = N_e\mu$ for mtDNA data) because this requires knowledge of the substitution rate ($\mu$). Estimates of $\mu$ for the control region of baleen whale mtDNA vary by over an order of magnitude (e.g. Rooney et al. 2001). Moreover, $\mu$, whatever its true value is, is undoubtedly the same for the northern and southern feeding groups, and therefore comparing estimates of $\Theta$ is an appropriate and less controversial method for comparing $N_e$. Regardless, if we apply the $\mu$ estimate of $1.8 \times 10^{-8}$ from Rooney et al. (2001) to our data, the resulting estimates of migration rates are $\ll 1\%$. Again, this result shows that the southern feeding group is demographically independent.

Previous studies have suggested that the haplotype diversity in the southern feeding group is too high to have resulted from strict maternally-directed site fidelity beginning with a few founders after the cessation of commercial whaling within the past century (Ramakrishnan et al. 2001). Our results are consistent with this interpretation. Under that hypothesis only a few closely related haplotypes should be represented within the southern feeding group, as opposed to the pattern seen in Figure 1. However, the hypothesis of a founding event within the past century is not consistent with the known sighting information. Indeed, gray whales have been seen in the southern feeding grounds throughout their history, including in times of lowest abundance (Swartz et al. 2006, and references therein). Moreover, if a few individuals recently founded the southern feeding group then the estimate of $\Theta_{\text{southern}}$ should be substantially smaller, as effective population size estimates are heavily influenced by bottlenecks.

Instead, what the sighting and genetic data suggest is that the southern feeding group of gray whales pre-dates whaling. Under this hypothesis, the haplotype diversity is expected to be high, because those lineages that survived whaling would be a random sample from a much larger population. Substantial gaps would also be expected between existing haplotypes resulting from the removal of haplotypes by whaling. This pattern is exactly what is seen in Figure 1. The similarity of haplotypes, and the degree of haplotype sharing between the northern and southern feeding groups, suggest that there is some degree of migration between the two. However, although reliable estimates of migration rates could not be obtained here, the data clearly show that the rate of migration is low enough that the two groups represent independent demographic entities. The southern feeding group therefore qualifies as a separate management unit, and requires separate management consideration.

Table 3. Results from the MIGRATE analysis. Included is the estimated mode for each parameter, as well as the 95% confidence intervals in parentheses. $M$ is the immigration rate $m$ divided by the mutation rate $\mu$. For mitochondrial DNA data, the number of immigrants per generation can be calculated by multiplying $M$ by $\Theta$. Included are the estimates for each of the four runs, as well as the average across all four runs.

Figure 1. Median-joining network for the gray whale sequences. Transitional mutations are indicated with a line, and transversions are indicated with a box. Sizes of the circles are proportional to the haplotype frequencies in the entire data set. Pie charts indicate the proportion of that haplotype found in the northern (black) and southern (gray) feeding groups.

Editorial Notes

Information Quality Act Compliance: In accordance with section 515 of Public Law 106-554, the Northeast Fisheries Science Center completed both technical and policy reviews for this report. These predissemination reviews are on file at the NEFSC Editorial Office.

Species Names: The NEFSC Editorial Office’s policy on the use of species names in all technical communications is generally to follow the American Fisheries Society’s lists of scientific and common names for fishes, mollusks, and decapod crustaceans and to follow the Society for Marine Mammalogy's guidance on scientific and common names for marine mammals. Exceptions to this policy occur when there are subsequent compelling revisions in the classifications of species, resulting in changes in the names of species.

Statistical Terms: The NEFSC Editorial Office’s policy on the use of statistical terms in all technical communications is generally to follow the International Standards Organization’s handbook of statistical methods.

Internet Availability: This issue of the NOAA Technical Memorandum NMFS-NE series is being as a paper and Web document in HTML (and thus searchable) and PDF formats and can be accessed at: http://www.nefsc.noaa.gov/publications/.

Editorial Treatment: To distribute this report quickly, it has not undergone the normal technical and copy editing by the Northeast Fisheries Science Center’s (NEFSC's) Editorial Office as have most other issues in the NOAA Technical Memorandum NMFS-NE series. Other than the covers and first two preliminary pages, all writing and editing have been performed by – and all credit for such writing and editing rightfully belongs to – those so listed on the title page.
ACKNOWLEDGMENTS

The authors wish to acknowledge advice, comments and valuable contributions provided by the Northeast Fisheries Science Center Fisheries Sampling Branch; members of the Northeast and Southeast Marine Mammal Stranding Networks; Mendy Garron, Amanda Johnson, David Gouveia, and Allison Rosner of the Northeast Regional Office; John Carlson, Ruth Ewing, LaGena Fantroy, Wayne Hoggard, Aleta Hohn, Alyssa Mathers, Blair Mase, Wayne McFee, Gina Rappucci, Elizabeth Scott-Denton, and Elizabeth Stratton of the Southeast Fisheries Science Center; Jarita Davis, Sheena Steiner, Michael Simpkins, and Jon Hare of the Northeast Fisheries Science Center; Jessica Powell of the Southeast Regional Office; Brian Balmer, Todd Speakman, and Lori Schwacke of the National Ocean Service; William McLellan of University of North Carolina Wilington; Reny Tyson and Randall Wells of Chicago Zoological Society's Sarasota Dolphin Research Program; and James Gilbert, Robert Kenney, Jack Lawson, Michael Moore, Douglas Nowacek, James ‘Buddy’ Powell, Andy Read, Richard Seagraves, Randall Wells, Trent McDonald, Chris Clark, and Sharon Young of the Atlantic Scientific Review Group. We also thank the Marine Mammal Commission, the Maine Lobstermen’s Association and the Humane Society of the United States for their constructive comments and advice.
EXECUTIVE SUMMARY

Under the 1994 amendments of the Marine Mammal Protection Act (MMPA), the National Marine Fisheries Service (NMFS) and the United States Fish and Wildlife Service (USFWS) were required to generate stock assessment reports (SARs) for all marine mammal stocks in waters within the U.S. Exclusive Economic Zone (EEZ). The first reports for the Atlantic (includes the Gulf of Mexico) were published in July 1995 (Blaylock et al. 1995). The MMPA requires NMFS and USFWS to review these reports annually for strategic stocks of marine mammals and at least every 3 years for stocks determined to be non-strategic. Included in this report as appendices are: 1) a summary of serious injury/mortality estimates of marine mammals in observed U.S. fisheries (Appendix I), 2) a summary of NMFS records of large whale human-caused serious injury and mortality (Appendix II), 3) detailed fisheries information (Appendix III), 4) summary tables of abundance estimates generated over recent years and the surveys from which they are derived (Appendix IV), a summary of observed fisheries bycatch (Appendix V), and a list of reports not updated in the current year (Appendix VI).

Table I contains a summary, by species, of the information included in the stock assessments, and also indicates those that have been revised since the 2015 publication. Most of the changes incorporate new information into sections on population size and/or mortality estimates. A total of 18 of the Atlantic and Gulf of Mexico stock assessment reports were revised for 2016. The revised SARs include 6 strategic and 12 non-strategic stocks.

This report was prepared by staff of the Northeast Fisheries Science Center (NEFSC) and Southeast Fisheries Science Center (SEFSC). NMFS staff presented the reports at the February 2016 meeting of the Atlantic Scientific Review Group (ASRG), and subsequent revisions were based on their contributions and constructive criticism. This is a working document and individual stock assessment reports will be updated as new information becomes available and as changes to marine mammal stocks and fisheries occur. The authors solicit any new information or comments which would improve future stock assessment reports.
INTRODUCTION

Section 117 of the 1994 amendments to the Marine Mammal Protection Act (MMPA) requires that an annual stock assessment report (SAR) for each stock of marine mammals that occurs in waters under USA jurisdiction, be prepared by the National Marine Fisheries Service (NMFS) and the U.S. Fish and Wildlife Service (USFWS), in consultation with regional Scientific Review Groups (SRGs). The SRGs are a broad representation of marine mammal and fishery scientists and members of the commercial fishing industry mandated to review the marine mammal stock assessments and provide advice to the NOAA Assistant Administrator for Fisheries. The reports are then made available on the Federal Register for public review and comment before final publication.

The MMPA requires that each SAR contain several items, including: (1) a description of the stock, including its geographic range; (2) a minimum population estimate, a maximum net productivity rate, and a description of current population trend, including a description of the information upon which these are based; (3) an estimate of the annual human-caused mortality and serious injury of the stock, and, for a strategic stock, other factors that may be causing a decline or impeding recovery of the stock, including effects on marine mammal habitat and prey; (4) a description of the commercial fisheries that interact with the stock, including the estimated number of vessels actively participating in the fishery and the level of incidental mortality and serious injury of the stock by each fishery on an annual basis; (5) a statement categorizing the stock as strategic or not, and why; and (6) an estimate of the potential biological removal (PBR) level for the stock, describing the information used to calculate it. The MMPA also requires that SARs be updated annually for stocks which are specified as strategic stocks, or for which significant new information is available, and once every three years for non-strategic stocks.

Following enactment of the 1994 amendments, the NMFS and USFWS held a series of workshops to develop guidelines for preparing the SARs. The first set of stock assessments for the Atlantic Coast (including the Gulf of Mexico) were published in July 1995 in the NOAA Technical Memorandum series (Blaylock et al. 1995). In April 1996, the NMFS held a workshop to review proposed additions and revisions to the guidelines for preparing SARs (Wade and Angliss 1997). Guidelines developed at the workshop were followed in preparing the 1996 through 2015 SARs. In 1997 and 2004 SARs were not produced.

In this document, major revisions and updating of the SARs were completed for stocks for which significant new information was available. These are identified by the February 2017 date-stamp at the top right corner at the beginning of each report. Stocks not updated in 2016 are listed in Appendix VI.

TABLE 1. A SUMMARY (including footnotes) OF ATLANTIC MARINE MAMMAL STOCK ASSESSMENT REPORTS FOR STOCKS OF MARINE MAMMALS UNDER NMFS AUTHORITY THAT OCCUPY WATERS UNDER USA JURISDICTION.

Total Annual S.I. (serious injury) and Mortality and Annual Fisheries S.I. and Mortality are mean annual figures for the period 2010-2014. The “SAR revised” column indicates 2016 stock assessment reports that have been revised relative to the 2015 reports (Y=yes, N=no). If abundance, mortality, PBR or status have been revised, they are indicated with the letters “a”, “m”, “p” and “status” respectively. For those species not updated in this edition, the year of last revision is indicated. Unk = unknown and undet=undetermined (PBR for species with outdated abundance estimates is considered "undetermined").

</table>

a. The R given for right whales is the default Rmax of 0.04. The total estimated human-caused mortality and serious injury to right whales is estimated at 5.66 per year. This is derived from two components: 1) non-observed fishery entanglement records at 4.65 per year, and 2) ship strike records at 1.01 per year.

b. The total estimated human-caused mortality and serious injury to the Gulf of Maine humpback whale stock is estimated as 9.05 per year. This average is derived from two components: 1) incidental fishery interaction records 7.25; 2) records of vessel collisions, 1.8.

c. The total estimated human-caused mortality and serious injury to the Western North Atlantic fin whale stock is estimated as 3.8 per year. This average is derived from two components: 1) incidental fishery interaction records 1.8; 2) records of vessel collisions, 2.0.

d. The total estimated human-caused mortality and serious injury to the Nova Scotia sei whale stock is estimated as 0.8 per year. This average is derived from two components: 1) incidental fishery interaction records 0; 2) records of vessel collisions, 0.8.

e. The total estimated human-caused mortality and serious injury to the Canadian East Coast minke whale stock is estimated as 8.25 per year. This average is derived from three components: 1) 0.2 minke whales per year from observed U.S. fisheries; 2) 6.45 minke whales per year (unknown CV) from U.S. and Canadian fisheries using strandings and entanglement data; and 3) 1.6 per year from ship strikes.

f. Estimates may include sightings of the coastal form.

g. The total estimated human caused annual mortality and serious injury to harp seals is 306,082. Estimated annual human caused mortality in US waters is 271 harp seals (CV=0.19) from the observed US fisheries. The remaining mortality is derived from five components: 1) 2007-2011 average catches of Northwest Atlantic harp seals by Canada, 125,751; 2) 2007-2011 average Greenland Catch, 79,181; 3) 1,000 average catches in the Canadian Arctic; 4) 12,330 average bycatches in the Newfoundland lumpfish fishery; and 5) 87,546 average struck and lost animals.

h. This is derived from three components: 1) 5,173 from 2001-2005 (2001 = 3,960; 2002 = 7,341; 2003 = 5,446; 2004=5,270; and 2005=3,846) average catches of Northwest Atlantic population of hooded seals by Canada and Greenland; 2) 25 hooded seals (CV=0.82) from the observed U.S. fisheries; and 3) one hooded seal from average 2001-2005 stranding mortalities resulting from non-fishery human interactions.

i. This estimate includes Gervais’ beaked whales and Blainville’s beaked whales for the Gulf of Mexico stocks, and all species of *Mesoplodon* in the Atlantic.

j. This estimate includes both the dwarf and pygmy sperm whales.

k. This estimate includes all *Globicephala* sp., though it is presumed that only short-finned pilot whales are present in the Gulf of Mexico.

l. The individual SAR for this stock was not updated; however, Table 1 within the "Northern Gulf of Mexico Bay, Sound and Estuary Stocks" SAR, that includes basic information for all individual bay, sound and estuary stocks, was updated to reflect the changes in Nmin and PBR.
NORTH ATLANTIC RIGHT WHALE (Eubalaena glacialis):
Western Atlantic Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

The western North Atlantic right whale population ranges primarily from calving grounds in coastal waters of the southeastern United States to feeding grounds in New England waters and the Canadian Bay of Fundy, Scotian Shelf, and Gulf of St. Lawrence. Mellinger et al. (2011) reported acoustic detections of right whales near the nineteenth-century whaling grounds east of southern Greenland, but the number of whales and their origin is unknown. However, Knowlton et al. (1992) reported several long-distance movements as far north as Newfoundland, the Labrador Basin, and southeast of Greenland. In addition, resightings of photographically identified individuals have been made off Iceland, in the old Cape Farewell whaling ground east of Greenland (Hamilton et al. 2007), northern Norway (Jacobsen et al. 2004), and the Azores (Silva et al. 2012). The September 1999 Norwegian sighting represents one of only two published sightings in the 20th century of a right whale in Norwegian waters, and the first since 1926. Together, these long-range matches indicate an extended range for at least some individuals and perhaps the existence of important habitat areas not presently well described. A few published records from the Gulf of Mexico (Moore and Clark 1963; Schmidly et al. 1972; Ward-Geiger et al. 2011) likely represent occasional wanderings of individual female and calf pairs beyond the sole known calving and wintering ground in the waters of the southeastern United States. Whatever the case, the location of much of the population is unknown during the winter. Surveys flown in an area from 17 to 86 miles from the shoreline off northeastern Florida and southeastern Georgia from 1996 to 2001 had 3 sightings in 1996, 1 in 1997, 13 in 1998, 6 in 1999, 11 in 2000, and 6 in 2001 (within each year, some were repeat sightings of previously recorded individuals). All but 1 of the sightings occurred within 49 miles of the shoreline—the remaining sighting occurred ~75 miles offshore (search effort was unevenly distributed). An offshore survey in March 2010 observed the birth of a right whale in waters 40 miles off Jacksonville, Florida (Foley et al. 2011). Several years of aerial survey counts for calves and adults were the lowest recorded since comprehensive surveys began in the Southeast calving grounds. Although habitat models predict right whales are not likely to occur further than 49 miles from the shoreline (Gowan and Ortega-Ortiz, 2015), the frequency with which right whales occur in offshore waters in the southeastern United States remains unclear.

Visual and acoustic surveys have demonstrated the existence of seven areas where western North Atlantic right whales aggregate seasonally: the coastal waters of the southeastern United States; the Great South Channel; Jordan Basin; Georges Basin along the northeastern edge of Georges Bank; Cape Cod and Massachusetts Bays; the Bay of Fundy; and the Roseway Basin on the Scotian Shelf (Brown et al. 2001; Cole et al. 2013). Passive acoustic studies of right whales have demonstrated their year-round presence in the Gulf of Maine (Morano et al. 2012; Bort et al. 2015), New Jersey (Whitt et al. 2013), and Virginia (Salisbury et al. 2015). Additionally, right whales were acoustically detected off Georgia and North Carolina in 7 of 11 months monitored (Hodge et al. 2015). All of this work further demonstrates the highly mobile nature of right whales. Movements within and between habitats are extensive and the area off the mid-Atlantic states is an important migratory corridor. In 2000, one whale was photographed in Florida waters on 12 January, then again 11 days later (23 January) in Cape Cod Bay, less than a

Figure 1. Distribution of sightings of known North Atlantic right whales, 2007-2011. Isobaths are the 100-m, 1000-m and 4000-m depth contours.
month later off Georgia (16 February), and back in Cape Cod Bay on 23 March, effectively making the round-trip migration to the Southeast and back at least twice during the winter season (Brown and Marx 2000). Results from satellite tagging studies clearly indicate that sightings separated by perhaps two weeks should not necessarily be assumed to indicate a stationary or resident animal. Instead, telemetry data have shown rather lengthy and somewhat distant excursions, including into deep water off the continental shelf (Mate et al. 1997; Baumgartner and Mate 2005). Systematic visual surveys conducted off the coast of North Carolina during the winters of 2001 and 2002 sighted 8 calves, suggesting the calving grounds may extend as far north as Cape Fear (McLelland, et al., 2008, Contract report available from SE regional Office, NMFS). Four of those calves were not sighted by surveys conducted further south. One of the females photographed was new to researchers, having effectively eluded identification over the period of its maturation. In 2016 the Southeastern U.S. Calving Area Critical Habitat was expanded north to Cape Fear, North Carolina. There is also at least one recent case of a calf apparently being born in the Gulf of Maine (Patrician et al. 2009) and another newborn was detected in Cape Cod Bay in 2013.

New England waters are important feeding habitats for right whales, where they feed primarily on copepods (largely of the genera Calanus and Pseudocalanus). Right whales must locate and exploit extremely dense patches of zooplankton to feed efficiently (Mayo and Marx 1990). These dense zooplankton patches are likely a primary characteristic of the spring, summer, and fall right whale habitats (Kenney et al. 1986, 1995). While feeding in the coastal waters off Massachusetts has been better studied than in other areas, right whale feeding has also been observed on the margins of Georges Bank, in the Great South Channel, in the Gulf of Maine, in the Bay of Fundy, and over the Scotian Shelf (Baumgartner et al. 2007). The characteristics of acceptable prey distribution in these areas are beginning to emerge (Baumgartner et al. 2003; Baumgartner and Mate 2003). NMFS (National Marine Fisheries Service) and Center for Coastal Studies aerial surveys during springs of 1999–2006 found right whales along the Northern Edge of Georges Bank, in the Great South Channel, in Georges Basin, and in various locations in the Gulf of Maine including Cashes Ledge, Platts Bank, and Wilkinson Basin. Analysis of the sightings data has shown that utilization of these areas has a strong seasonal component (Pace and Merrick 2008). Although right whales are consistently found in these locations, studies also highlight the high interannual variability in right whale use of some habitats (Pendleton et al. 2009). In 2016, the Northeastern U.S. Foraging Area Critical Habitat was expanded to include all U.S. waters of the Gulf of Maine. In the most recent years (2012–2015), surveys have detected fewer individuals in the Great South Channel and the Bay of Fundy, indicating an important shift in habitat use patterns.

Right whale calls have been detected by autonomous passive acoustic sensors deployed between 2005 and 2010 at three sites (Massachusetts Bay, Stellwagen Bank, and Jeffreys Ledge) in the southern Gulf of Maine (Morano et al. 2012, Mussoline et al. 2012). Comparisons between detections from passive acoustic recorders and observations from aerial surveys in Cape Cod Bay between 2001 and 2005 demonstrated that aerial surveys found whales on approximately two-thirds of the days during which acoustic monitoring detected whales (Clark et al. 2010). These data suggest that the current understanding of the distribution and movements of right whales in the Gulf of Maine and surrounding waters is incomplete.

Genetic analyses based upon direct sequencing of mitochondrial DNA (mtDNA) have identified 7 mtDNA haplotypes in the western North Atlantic right whale, including heteroplasm that led to the declaration of the 7th haplotype (Malik et al. 1999, McLeod and White 2010). Schaeff et al. (1997) compared the genetic variability of North Atlantic and southern right whales (E. australis), and found the former to be significantly less diverse, a finding broadly replicated by Malik et al. (2000). The low diversity in North Atlantic right whales might be indicative of inbreeding, but no definitive conclusion can be reached using current data. Modern and historic genetic population structures were compared using DNA extracted from museum and archaeological specimens of baleen and bone. This work suggested that the eastern and western North Atlantic populations were not genetically distinct (Rosenbaum et al. 1997, 2000). However, the virtual extirpation of the eastern stock and its lack of recovery in the last hundred years strongly suggest population subdivision over a protracted (but not evolutionary) timescale. Genetic studies concluded that the principal loss of genetic diversity occurred prior to the 18th century (Waldick et al. 2002). However, revised conclusions that nearly all the remains in the North American Basque whaling archaeological sites were bowhead whales (Balaena mysticetus) and not right whales (Rastogi et al. 2004; McLeod et al. 2008) contradict the previously held belief that Basque whaling during the 16th and 17th centuries was principally responsible for the loss of genetic diversity.

High-resolution (i.e., using 35 microsatellite loci) genetic profiling has been completed for 66% of all North Atlantic right whales identified through 2001. This work has improved our understanding of genetic variability, number of reproductively active individuals, reproductive fitness, parentage, and relatedness of individuals (Frasier et al. 2007).

One emerging result of the genetic studies is the importance of obtaining biopsy samples from calves on the
calving grounds. Only 60% of all known calves are seen with their mothers in summering areas, when their callosity patterns are stable enough to reliably make a photo-ID match later in life. The remaining 40% are not seen on a known summering ground. Because the calf’s genetic profile is the only reliable way to establish parentage, if the calf is not sampled when associated with its mother early on, then it is not possible to link it with a calving event or to its mother, and information such as age and familial relationships is lost. From 1980 to 2001, there were 64 calves born that were not sighted later with their mothers and thus unavailable to provide age-specific mortality information (Frasier et al. 2007). An additional interpretation of paternity analyses is that the population size may be larger than was previously thought. Fathers for only 45% of known calves have been genetically determined. However, genetic profiles were available for 69% of all photo-identified males (Frasier 2005). The conclusion was that the majority of these calves must have different fathers that cannot be accounted for by the unsampled males, therefore the population of males must be larger (Frasier 2005). This inference of additional animals that have never been captured photographically and/or genetically suggests the existence of potentially important habitats that remain to be described.

**POPULATION SIZE**

The western North Atlantic minimum stock size is based on a census of individual whales identified using photo-identification techniques. A review of the photo-ID recapture database as it existed on 17 November 2015 indicated that 440 individually recognized whales in the catalog were known to be alive during 2012. This number represents a minimum population size. This is a direct count and has no associated coefficient of variation.

**Historical Abundance**

An estimate of pre-exploitation population size is not available. Basque whalers were thought to have taken right whales during the 1500s in the Strait of Belle Isle region (Aguilar 1986), however, genetic analysis has shown that nearly all of the remains found in that area are, in fact, those of bowhead whales (Rastogi et al. 2004; Frasier et al. 2007). The stock of right whales may have already been substantially reduced by the time whaling was begun by colonists in the Plymouth area in the 1600s (Reeves et al. 2001, 2007). A modest but persistent whaling effort along the coast of the eastern U.S. lasted three centuries, and the records include one report of 29 whales killed in Cape Cod Bay in a single day during January 1700. Reeves et al. (2007) calculated that a minimum of 5500 right whales were taken in the western North Atlantic between 1634 and 1950, with nearly 80% taken in a 50-year period between 1680 and 1730. They concluded “there were at least a few thousand whales present in the mid-1600s.” The authors cautioned, however, that the record of removals is incomplete, the results were preliminary, and refinements are required. Based on back calculations using the present population size and growth rate, the population may have numbered fewer than 100 individuals by 1935 when international protection for right whales came into effect (Hain 1975; Reeves et al. 1992; Kenney et al. 1995). However, little is known about the population dynamics of right whales in the intervening years.

**Minimum Population Estimate**

The western North Atlantic population size was estimated to be at least 440 individuals in 2012.

**Current Population Trend**

The population growth rate reported for the period 1986–1992 by Knowlton et al. (1994) was 2.5% (CV=0.12), suggesting that the stock was recovering slowly, but that number may have been influenced by discovery phenomenon as existing whales were recruited to the catalog. Work by Caswell et al. (1999) suggested that crude survival probability declined from about 0.99 in the early 1980s to about 0.94 in the late 1990s. The decline was statistically significant. Additional work conducted in 1999 was reviewed by the IWC workshop on status and trends in this population (Best et al. 2001); the workshop concluded based on several analytical approaches that survival had indeed declined in the 1990s. Although capture heterogeneity could negatively bias survival estimates, the workshop concluded that this factor could not account for the entire observed decline, which appeared to be particularly marked in adult females. Another workshop was convened by NMFS in September 2002, and it reached similar conclusions regarding the decline in the population (Clapham 2002). At the time, the early part of the recapture series had not been examined for excessive retrospective recaptures which had the potential to positively bias survival as the catalog was being developed.

An increase in carcass detections in 2004 and 2005 was cause for serious concern (Kraus et al. 2005). Of those mortalities, six were adult females, three of which were carrying near-term fetuses. Furthermore, four of these females were just starting to bear calves, losing their complete lifetime reproduction potential. Calculations based on
demographic data through 1999 (Fujiwara and Caswell 2001) indicated that this mortality rate increase would reduce population growth by approximately 10% per year (Kraus et al. 2005). Strong evidence for flat or negative growth exists in the time series of minimum number alive during 1998-2000, which coincided with very low calf production in 2004. However, the population continued to grow since that apparent interval of decline until the most recent year included in this analysis (Figure 2).

Examination of the minimum number alive calculated from the individual sightings database, as it existed on 27 October 2015, for the years 1990–2012 (Figure 2) suggests that abundance has declined. As noted above, there seems to have been a considerable change in right whale habitat use patterns in areas where most of the population has been observed in previous years. This apparent change in habitat use has the effect that, despite relatively constant effort to find whales, the chance of seeing an individual that is alive has decreased. Some caution is advised in interpreting the apparent downward trend in abundance in 2012, but without evidence to the contrary, it is possible that this deflection represents a true population decline.

![Figure 2. Minimum number alive (a) for North Atlantic right whales. Minimum number alive (diamonds) of cataloged individuals known to be alive in any given year includes all whales known to be alive prior to that year and not seen in that year or subsequently plus all whales newly cataloged that year. Cataloged whales may include some but not all calves produced each year. Bracketing the minimum number of cataloged whales is the number without calves (below) and that plus calves above, the former which yields Nmin for purposes of stock assessment. (b) Crude annual growth rates from the minimum number alive values. Mean crude growth rate (dashed line) is the exponentiated mean of loge [(Nt+1-Nt)/Nt] for each year (t), where Nt is the max of the accounting procedure and the estimated abundance for year t.]

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

During 1980–1992, at least 145 calves were born to 65 identified females. The number of calves born annually ranged from 5 to 17, with a mean of 11.2 (SE=0.90). The reproductively active female pool was static at approximately 51 individuals during 1987–1992. Mean calving interval, based on 86 records, was 3.67 years. There was an indication that calving intervals may have been increasing over time, although the trend was not statistically significant (P=0.083) (Knowlton et al. 1994). Since 1993, calf production has been more variable than a simple stochastic model would predict.

During 1990–2014, at least 411 calves were born into the population. The number of calves born annually ranged from 1 to 39, and averaged 16.4 but was highly variable (SD=9.2). The fluctuating abundance observed from 1990 to 2014 makes interpreting a count of calves by year less clear than measuring population productivity, which we index by the number of calves detected/Nmin. Productivity for this stock has been highly variable over time and has been characterized by periodic swings in per capita birth rates (Figure 3). Notwithstanding the high variability observed, which might be expected from a small population, productivity in North Atlantic right whales lacks a definitive trend.
North Atlantic right whales have thinner blubber than southern right whales off South Africa (Miller et al. 2011). Blubber thickness of male North Atlantic right whales (males were selected to avoid the effects of pregnancy and lactation) varied with Calanus abundance in the Gulf of Maine (Miller et al. 2011). Sightings of North Atlantic right whales correlated with satellite-derived sea-surface chlorophyll concentration (as a proxy for productivity), and calving rates correlated with chlorophyll concentration prior to gestation (Hlista et al. 2009). On a regional scale, observations of North Atlantic right whales correlate well with copepod concentrations (Pendleton et al. 2009). The available evidence suggests that at least some of the observed variability in the calving rates of North Atlantic right whales is related to variability in nutrition.

An analysis of the age structure of this population suggests that it contains a smaller proportion of juvenile whales than expected (Hamilton et al. 1998; Best et al. 2001), which may reflect lowered recruitment and/or high juvenile mortality. Calf and perinatal mortality was estimated by Browning et al. (2010) to be between 17 and 45 animals during the period 1989 and 2003. In addition, it is possible that the apparently low reproductive rate is due in part to an unstable age structure or to reproductive dysfunction in some females. However, few data are available on either factor and senescence has not been documented for any baleen whale.

The maximum net productivity rate is unknown for this stock. For purposes of this assessment, the maximum net productivity rate was assumed to be the default value of 0.04. This value is based on theoretical modeling showing that cetacean populations may not grow at rates much greater than 4% given the constraints of their reproductive life history (Barlow et al. 1995).

POTENTIAL BIOLOGICAL REMOVAL

Potential biological removal (PBR) is the product of minimum population size, one-half the maximum net productivity rate and a recovery factor for endangered, depleted, threatened stocks, or stocks of unknown status relative to OSP (MMPA Sec. 3. 16 U.S.C. 1362; Wade and Angliss 1997). The recovery factor for right whales is 0.10 because this species is listed as endangered under the Endangered Species Act (ESA). The minimum population size is 440. The maximum productivity rate is 0.04, the default value for cetaceans. PBR for the Western Atlantic stock of the North Atlantic right whale is 1.

ANNUAL HUMAN-CAUSED SERIOUS INJURY AND MORTALITY

For the period 2010 through 2014, the minimum rate of annual human-caused mortality and serious injury to right whales averaged 5.66 per year. This is derived from two components: 1) incidental fishery entanglement records at 4.65 per year, and 2) vessel strike records at 1.01 per year. Early analyses of the effectiveness of the ship
strike rule were reported by Silber and Bettridge (2012). Recently, van der Hoop et al. (2015) concluded that large whale mortalities due to vessel strikes decreased inside active SMAs and increased outside inactive SMAs. Analysis by Laist et al. (2014) incorporated an adjustment for drift around areas regulated under the ship strike rule and produced weak evidence that the rule was effective inside the SMAs.

Beginning with the 2001 Stock Assessment Report, Canadian records have been incorporated into the mortality and serious injury rates to reflect the effective range of this stock. It is also important to stress that serious injury determinations are made based upon the best available information; these determinations may change with the availability of new information (Henry et al. 2016). For the purposes of this report, discussion is primarily limited to those records considered confirmed human-caused mortalities or serious injuries. Annual rates calculated from detected mortalities should not be considered an unbiased estimate of human-caused mortality, but they represent a definitive lower bound. Detections are haphazard, incomplete, and not the result of a designed sampling scheme. As such they represent a minimum estimate of human-caused mortality, which is biased low.

Background

The details of a particular mortality or serious injury record often require a degree of interpretation (Moore et al. 2005). The assigned cause is based on the best judgment of the available data; additional information may result in revisions. When reviewing Table 1 below, several factors should be considered: 1) a vessel strike or entanglement may have occurred at some distance from the location where the animal is detected/reported; 2) the mortality or injury may involve multiple factors; for example, whales that have been both vessel struck and entangled are not uncommon; 3) the actual vessel or gear type/source is often uncertain; and 4) in entanglements, several types of gear may be involved.

Further, the small population size and low annual reproductive rate of right whales suggest that human sources of mortality may have a greater effect relative to population growth rates than for other whales. The principal factors believed to be retarding growth and recovery of the population are vessel strikes and entanglement with fishing gear. Between 1970 and 1999, a total of 45 right whale mortalities was recorded (IWC 1999; Knowlton and Kraus 2001; Glass et al. 2009). Of these, 13 (28.9%) were neonates that were believed to have died from perinatal complications or other natural causes. Of the remainder, 16 (35.6%) resulted from vessel strikes, 3 (6.7%) were related to entanglement in fishing gear (in two cases lobster gear, and one gillnet gear), and 13 (28.9%) were of unknown cause. At a minimum, therefore, 42.2% of the observed total for the period and 50% of the 32 non-calf deaths was attributable to human impacts (calves accounted for three deaths from ship strikes). Young animals, ages 0-4 years, are apparently the most impacted portion of the population (Kraus 1990).

Finally, entanglement or minor vessel collisions may not kill an animal directly, but may weaken or otherwise affect it so that it is more likely to become vulnerable to further injury. Serious injury determinations for large whales commonly include animals carrying gear when these entanglements are constricting or appear to interfere with foraging (Henry et al. 2016).

Fishery-Related Mortality and Serious Injury

Reports of mortality and serious injury relative to PBR as well as total human impacts are contained in records maintained by the New England Aquarium and the NMFS Northeast and Southeast Regional Offices (Table 1). From 2010 through 2014, 24 records of mortality or serious injury (including records from both U.S. and Canadian waters, pro-rated to 23.25 using serious injury guidelines) involved entanglement or fishery interactions. For this time frame, the average reported mortality and serious injury to right whales due to fishery entanglement was 4.65 whales per year. Information from an entanglement event often does not include the detail necessary to assign the entanglements to a particular fishery or location.

Although disentanglement is often unsuccessful or not possible for many cases, there are several documented cases of entanglements for which the intervention of disentanglement teams averted a likely serious-injury determination. Four serious injuries were prevented by intervention during 2010–2014 (Henry et al. 2016). Sometimes, even with disentanglement, an animal may die of injuries sustained from fishing gear. A female yearling right whale, #3107, was first sighted with gear wrapping its caudal peduncle on 6 July 2002 near Briar Island, Nova Scotia. Although the gear was removed on 1 September by the New England Aquarium disentanglement team, and the animal seen alive during an aerial survey on 1 October, its carcass washed ashore at Nantucket on 12 October 2002 with deep entanglement injuries on the caudal peduncle. Additionally, but infrequently, a whale listed as seriously injured becomes gear-free without a disentanglement effort and is seen later in reasonable health. Such was the case for whale #1980, listed as a serious injury in 2008 but seen gear-free and apparently healthy in 2011.

The only bycatch of a right whale observed by the Northeast Fisheries Observer Program was in the pelagic drift gillnet fishery in 1993. No mortalities or serious injuries have been documented by fisheries observers in any of
the other fisheries monitored by NMFS.

Whales often free themselves of gear following an entanglement event, and as such scarring may be a better indicator of fisheries interaction than entanglement records. A review of scars detected on identified individual right whales over a period of 30 years (1980–2009) documented 1032 definite, unique entanglement events on the 626 individual whales identified (Knowlton et al. 2012). Most individual whales (83%) were entangled at least once, and almost half of them (306 of 626) were entangled more than once. About a quarter of the individuals identified in each year (26%) were entangled in that year. Juveniles and calves were entangled at higher rates than were adults. Scarring rates suggest that entanglements are occurring at about an order of magnitude greater than that detected from observations of whales with gear on them. More recently, analyses of whales carrying entangling gear also suggest that entanglement wounds have become more severe since 1990, possibly due to increased use of stronger lines in fixed fishing gear (Knowlton et al. 2015).

Knowlton et al. (2012) concluded from their analysis of entanglement scarring rates over time that efforts made since 1997 to reduce right whale entanglement had not worked. Working from a completely different data source (observed mortalities of eight large whale species, 1970–2009), van der Hoop et al. (2012) arrived at a similar conclusion. Vessel strikes and entanglements were the two leading causes of death for known mortalities of right whales for which a cause of death could be determined. Across all 8 species of large whales, there was no detectable change in causes of anthropogenic mortality over time (van der Hoop et al. 2012). Pace et al. (2015) analyzed entanglement rates and serious injuries due to entanglement during 1999-2009 and found no support that mitigation measures that were implemented prior to 2009 were effective at reducing takes due to commercial fishing.

Incidents of entanglements in waters of Atlantic Canada and the U.S. east coast were summarized by Read (1994) and Johnson et al. (2005). In six records of right whales that were entangled in groundfish gillnet gear in the Bay of Fundy and Gulf of Maine between 1975 and 1990, the whales were either released or escaped on their own, although several whales were observed carrying net or line fragments. A right whale mother and calf were released alive from a herring weir in the Bay of Fundy in 1976. Gillnet gear entanglements in the U.S. can also be fatal. A calf died in 2006, apparently victim of a gillnet entanglement, and other whales initially detected in gillnet gear have subsequently not been seen alive (NMFS unpub. data).

For all areas, specific details of right whale entanglement in fishing gear are often lacking. When direct or indirect mortality occurs, some carcasses come ashore and are subsequently examined, or are reported as "floaters" at sea. The number of unreported and unexamined carcasses is unknown, but may be significant in the case of floaters. More information is needed about fisheries interactions and where they occur.

**Other Mortality**

Vessel strikes are a major cause of mortality and injury to right whales (Kraus 1990; Knowlton and Kraus 2001, van der Hoop et al. 2012). Records from 2010 through 2014 have been summarized in Table 1. For this time frame, the average reported mortality and serious injury to right whales due to vessel strikes was 1.01 whales per year.
Table 1. Confirmed human-caused mortality and serious injury records of North Atlantic right whales (*Eubalaena glacialis*) where the cause was assigned as either an entanglement (EN) or a vessel strike (VS): 2010-2014

**STATUS OF STOCK**

The size of this stock is considered to be extremely low relative to OSP in the U.S. Atlantic EEZ, and this species is listed as endangered under the ESA. The North Atlantic right whale is considered one of the most critically endangered populations of large whales in the world (Clapham et al. 1999). Status review by the National Marine Fisheries Service affirms endangered status (NMFS Northeast Regional Office 2012). The total level of human-caused mortality and serious injury is unknown, but reported human-caused mortality and serious injury was a minimum of 5.65 right whales per year from 2010 through 2014. Given that PBR has been calculated as 1, any human-caused mortality or serious injury for this stock can be considered significant. This is a strategic stock because the average annual human-related mortality and serious injury exceeds PBR, and also because the North Atlantic right whale is an endangered species.

HUMPBACK WHALE (*Megaptera novaeangliae*): Gulf of Maine Stock

**STOCK DEFINITION AND GEOGRAPHIC RANGE**

In the western North Atlantic, humpback whales feed during spring, summer and fall over a geographic range encompassing the eastern coast of the United States (including the Gulf of Maine), the Gulf of St. Lawrence, Newfoundland/Labrador, and western Greenland (Katona and Beard 1990). Other North Atlantic feeding grounds occur off Iceland, the Norwegian Sea, and northern Norway, including off Bear Island, Jan Mayen, and Franz Josef Land (Christensen *et al.* 1992; Palsbøll *et al.* 1997). These six regions represent relatively discrete subpopulations, fidelity to which is determined matrilineally (Clapham and Mayo 1987), which is supported by studies of the mitochondrial genome (Palsbøll *et al.* 1995; Palsbøll *et al.* 2001) and individual animal movements (Stevick *et al.* 2006). In early stock assessment reports, the North Atlantic humpback whale population was treated as a single stock for management purposes (Waring *et al.* 1999). Subsequently, a decision was made to reclassify the Gulf of Maine as a separate feeding stock (Waring *et al.* 2000) based upon the strong fidelity by individual whales to this region, and the attendant assumption that, were this subpopulation wiped out, repopulation by immigration from adjacent areas would not occur on any reasonable management timescale. During the 2002 Comprehensive Assessment of North Atlantic humpback whales, the International Whaling Commission acknowledged the evidence for treating the Gulf of Maine as a separate management unit (IWC 2002). During the summers of 1998 and 1999, the Northeast Fisheries Science Center conducted surveys for humpback whales on the Scotian Shelf to establish the occurrence and population identity of the animals found in this region, which lies between the well-studied populations of the Gulf of Maine and Newfoundland. Photographs from both surveys were compared to both the overall North Atlantic Humpback Whale Catalogue and a large regional catalogue from the Gulf of Maine (maintained by the College of the Atlantic and the Center for Coastal Studies, respectively); this work is summarized in Clapham *et al.* (2003). The match rate between the Scotian Shelf and the Gulf of Maine was 27% (14 of 52 Scotian Shelf individuals from both years). Comparable rates of exchange were obtained from the southern (28%, n=10 of 36 whales) and northern (27%, n=4 of 15 whales) ends of the Scotian Shelf (one whale was observed in both areas). In contrast, all of the 36 humpback whales identified by the same NMFS surveys elsewhere in the Gulf of Maine (including Georges Bank, southwestern Nova Scotia and the Bay of Fundy) had been previously observed in the Gulf of Maine region. The sighting histories of the 14 Scotian Shelf whales matched to the Gulf of Maine suggested that many of them were transient through the latter area. There were no matches between the Scotian Shelf and any other North Atlantic feeding ground, except the Gulf of Maine; however, instructive comparisons are compromised by the often low sampling effort in other regions in recent years. Overall, it appears that the northern range of many members of the Gulf of Maine stock does not extend onto the Scotian Shelf.

During winter, whales from most North Atlantic feeding areas (including the Gulf of Maine) mate and calve in the West Indies, where spatial and genetic mixing among feeding groups occurs (Katona and Beard 1990; Clapham *et al.* 1993; Palsbøll *et al.* 1997; Stevick *et al.* 1998). Some whales using eastern North Atlantic feeding areas

**Figure 1.** Distribution of humpback whale sightings from NEFSC and SEFSC shipboard and aerial surveys during the summers of 1995, 1998, 1999, 2002, 2004, 2006, 2007, 2008, 2010 and 2011. Isobaths are the 100-m, 1000-m and 4000-m depth contours.
migrate to the Cape Verde Islands (Reiner et al. 1996; Wenzel et al. 2009, Stevick et al. 2016), and some individuals have been recorded in both the Cape Verde Islands and the Caribbean (Stevick et al. 2016). In the West Indies, the majority of whales are found in the waters of the Dominican Republic, notably on Silver Bank and Navidad Bank, and in Samana Bay (Balcomb and Nichols 1982; Whitehead and Moore 1982; Mattila et al. 1989, 1994). Humpback whales are also found at much lower densities throughout the remainder of the Antillean arc (Winn et al. 1975; Levenson and Leapley 1978; Price 1985; Mattila and Clapham 1989). Although recognition of 2 breeding areas for North Atlantic humpbacks is the prevailing model, our knowledge of breeding season distribution is far from complete (see Smith and Pike 2009, Stevick et al. 2016).

All whales from this stock do not migrate to the West Indies every winter, because significant numbers of animals are found in mid- and high-latitude regions at this time (Clapham et al. 1993; Swingle et al. 1993) and some individuals have been sighted repeatedly within the same winter season (Clapham et al. 1993; Robbins 2007). Acoustic recordings made within the Massachusetts Bay area detected some level of humpback song and non-song detections in almost all months, with two prominent periods, March through May and September through December (Clark and Clapham 2004, Vu et al. 2012, Murray et al. 2013). This pattern of acoustic occurrence, especially for song, confirms the presence of male humpback whales in the area (a mid-latitude feeding ground) during periods that bracket male occurrence in the Caribbean region, where singing is highest during winter months. A complementary pattern of humpback singer occurrence was observed during the January – May period in the deep-ocean region north of the Caribbean and to the east of Bermuda during April (Clark and Gagnon 2002). These acoustic observations from both coastal and deep-ocean regions support the conclusion that at least male humpbacks are seasonally distributed throughout broad regions of the western North Atlantic. In addition, photographic records from Newfoundland have shown a number of adult humpbacks remain there year-round, particularly on the island’s north coast. In collaboration with colleagues in the French islands of St. Pierre and Miquelon, a new photographic catalogue and concurrent matching effort is being undertaken for this region (J. Lawson, DFO, pers. comm.).

Within the U.S. Atlantic EEZ, humpback whales have been sighted well away from the Gulf of Maine. Sightings of humpback whales in the vicinity of the Chesapeake and Delaware Bays occurred in 1992 (Swingle et al. 1993). Wiley et al. (1995) reported that 38 humpback whale strandings occurred during 1985–1992 in the U.S. mid-Atlantic and southeastern states. Humpback whale strandings increased, particularly along the Virginia and North Carolina coasts, and most stranded animals were sexually immature; in addition, the small size of many of these whales strongly suggested that they had only recently separated from their mothers. Wiley et al. (1995) concluded that these areas were becoming an increasingly important habitat for juvenile humpback whales and that anthropogenic factors may negatively impact whales in this area. There have also been a number of wintertime humpback sightings in coastal waters of the southeastern U.S. Whether the increased numbers of sightings represent a distributional change, or are simply due to an increase in sighting effort and/or whale abundance, is unknown. Other sightings of note include multiple humpbacks feeding off Long Island during July of 2016 (https://www.greateratlantic.fisheries.noaa.gov/mediacenter/2016/july/26_humpback_whales_visit_new_york.html, accessed 28 April 2017) and sightings during November-December 2016 near New York City (https://www.greateratlantic.fisheries.noaa.gov/mediacenter/2016/december/09_humans_and_humpbacks_of_new_york_2.html, accessed 28 April 2017).

A key question with regard to humpback whales off the southeastern and mid-Atlantic states is their population identity. This topic was investigated using fluke photographs of living and dead whales observed in the region (Barco et al. 2002). In this study, photographs of 40 whales (alive or dead) were of sufficient quality to be compared to catalogs from the Gulf of Maine (i.e., the closest feeding ground) and other areas in the North Atlantic. Of 21 live whales, 9 (43%) matched to the Gulf of Maine, 4 (19%) to Newfoundland, and 1 (4.8%) to the Gulf of St Lawrence. Of 19 dead humpbacks, 6 (31.6%) were known Gulf of Maine whales. Although the population composition of the mid-Atlantic is apparently dominated by Gulf of Maine humpback whales, lack of photographic effort in Newfoundland makes it likely that the observed match rates under-represent the true presence of Canadian whales in the region. A new photographic catalog and concurrent matching effort is being undertaken for this region which may improve knowledge in this regard. Barco et al. (2002) suggested that the mid-Atlantic region primarily represents a supplemental winter feeding ground used by humpbacks.

In New England waters, feeding is the principal activity of humpback whales, and their distribution in this region has been largely correlated to abundance of prey species, although behavior and bathymetry are factors influencing foraging strategy (Payne et al. 1986, 1990). Humpback whales are frequently piscivorous when in New England waters, feeding on herring (Clupea harengus), sand lance (Ammodytes spp.), and other small fishes. In the northern Gulf of Maine, euphausiids are also frequently taken (Paquet et al. 1997). Commercial depletion of herring and mackerel led to an increase in sand lance in the southwestern Gulf of Maine in the mid-1970s, with a concurrent decrease in humpback whale abundance in the northern Gulf of Maine. Humpback whales were densest over the
sandy shoals in the southwestern Gulf of Maine favored by the sand lance during much of the late 1970s and early 1980s, and humpback distribution appeared to have shifted to this area (Payne et al. 1986). An apparent reversal began in the mid-1980s, and herring and mackerel increased as sand lance again decreased (Fogarty et al. 1991). Humpback whale abundance in the northern Gulf of Maine increased markedly during 1992–1993, along with a major influx of herring (P. Stevick, pers. comm.). Humpback whales were few in nearshore Massachusetts waters in the 1992–1993 summer seasons. They were more abundant in the offshore waters of Cultivator Shoal and on the Northeast Peak on Georges Bank and on Jeffreys Ledge; these latter areas are traditional locations of herring occurrence. In 1996 and 1997, sand lance and therefore humpback whales were once again abundant in the Stellwagen Bank area. However, unlike previous cycles, when an increase in sand lance corresponded to a decrease in herring, herring remained relatively abundant in the northern Gulf of Maine, and humpbacks correspondingly continued to occupy this portion of the habitat, where they also fed on euphausiids (Wienrich et al. 1997). Diel patterns in humpback foraging behavior have been shown to correlate with diel patterns in sand lance behavior (Friedlaender et al. 2009).

In early 1992, a major research program known as the Years of the North Atlantic Humpback (YONAH) (Smith et al. 1999) was initiated. This was a large-scale, intensive study of humpback whales throughout almost their entire North Atlantic range, from the West Indies to the Arctic. During two primary years of field work, photographs for individual identification and biopsy samples for genetic analysis were collected from summer feeding areas and from the breeding grounds in the West Indies. Additional samples were collected from certain areas in other years. Results pertaining to the estimation of abundance and to genetic population structure are summarized below.

### POPULATION SIZE

#### North Atlantic Population

The overall North Atlantic population (including the Gulf of Maine), derived from genetic tagging data collected by the YONAH project on the breeding grounds, was estimated to be 4,894 males (95% CI=3,374-7,123) and 2,804 females (95% CI=1,776-4,463) (Palsbøll et al. 1997). Because the sex ratio in this population is known to be even (Palsbøll et al. 1997), the excess of males is presumed a result of sampling bias, lower rates of migration among females, or sex-specific habitat partitioning in the West Indies; whatever the reason, the combined total is an underestimate of overall population size. Photographic mark-recapture analyses from the YONAH project provided an ocean-basin-wide estimate of 11,570 animals during 1992/1993 (CV=0.068, Stevick et al. 2003), and an additional genotype-based analysis yielded a similar but less precise estimate of 10,400 whales (CV=0.138, 95% CI=8,000 to 13,600) (Smith et al. 1999).

#### Gulf of Maine stock - earlier estimates

Please see Appendix IV for earlier estimates. As recommended in the GAMMS Workshop Report (Wade and Angliss 1997), estimates older than eight years are deemed unreliable and should not be used for PBR determinations.

#### Gulf of Maine Stock - Recent surveys and abundance estimates

An abundance of 335 (CV=0.42) humpback whales was estimated from a line-transect survey conducted during June-August 2011 by ship and plane (Palka 2012). The aerial portion that contributed to the abundance estimate covered 5,313 km of tracklines that were over waters north of New Jersey and shallower than the 100-m depth contour through the U.S. and Canadian Gulf of Maine and up to and including the lower Bay of Fundy. The shipboard portion covered 3,107 km of tracklines that were in waters that were deeper than the 100-m depth contour out to beyond the U.S. EEZ. Both sighting platforms used a two-simultaneous-team data collection procedure, which allows estimation of abundance corrected for perception bias (Laake and Borchers, 2004). Estimation of abundance was based on the independent observer approach assuming point independence (Laake and Borchers 2004) and calculated using the mark-recapture distance sampling option in the computer program Distance (version 6.0, release 2, Thomas et al. 2009). This estimate did not include the portion of the Scotian Shelf that is known to be part of the range used by Gulf of Maine humpback whales. These various line-transect surveys lack consistency in geographic coverage, and because of the mobility of humpback whales, pooling stratum estimates across years to produce a single estimate is not advisable. However, similar to an estimate that appeared in Clapham et al. (2003), J. Robbins (Center for Coastal Studies, pers. comm.) used photo-id evidence of presence (see Robbins 2009, 2010, 2011 for data description) to calculate the minimum number alive of catalogued individuals seen during the 2008 feeding season within the Gulf of Maine, or seen both before and after 2008, plus whales seen for the first time as non-calves in 2009. That procedure placed the minimum number alive in 2008 at 823 animals.
**Minimum Population Estimate**

For statistically-based estimates, the minimum population estimate is the lower limit of the two-tailed 60% confidence interval of the log-normally distributed best abundance estimate. This is equivalent to the 20th percentile of the log-normal distribution as specified by Wade and Angliss (1997). The most recent line-transect survey, which did not include the Scotian Shelf portion of the stock, produced an estimate of abundance for Gulf of Maine humpback whales of 331 animals (CV=0.48) with a resultant minimum population estimate for this stock of 228 animals. The line-transect based Nmin is unrealistic because at least 500 uniquely identifiable individual whales from the GOM stock were seen during the calendar year of that survey and the actual population would have been larger because re-sighting rates of GOM humpbacks have historically been <1 (Robbins 2007). Using the minimum count from at least 2 years prior to the year of a stock assessment report allows time to resight whales known to be alive prior to and after the focal year. Thus, the minimum population estimate is set to the 2008 mark-recapture based count of 823.

| Table 1. Summary of abundance estimates for Gulf of Maine humpback whales with month, year, and area covered during each abundance survey, and resulting abundance estimate (N_{best}) and coefficient of variation (CV). Note that the second row represents the results from an analysis of resights of individually identified animals. |
|---|---|---|---|
| Month/Year | Type | N_{best} | CV |
| Jun-Oct 2008 | Gulf of Maine and Bay of Fundy | 823 | 0.00 |
| Jun-Aug 2011 | Virginia to lower Bay of Fundy | 335 | 0.42 |

**Current Population Trend**

As detailed below, the most recent available data suggest that the Gulf of Maine humpback whale stock is characterized by a positive trend in size. This is consistent with an estimated average trend of 3.1% (SE=0.005) in the North Atlantic population overall for the period 1979–1993 (Stevick et al. 2003), although there are no feeding-area-specific estimates. The best available estimate of the average rate of increase for the West Indies breeding population [which includes the Gulf of Maine feeding stock] is 3.1% per year (SE=0.005) for the period 1979–1993 (Stevick et al. 2003), although this estimate is now over 20 years old. An analysis of demographic parameters for the Gulf of Maine (Clapham et al. 2003) suggested a lower rate of increase than the 6.5% reported by Barlow and Clapham (1997), but results may have been confounded by distribution shifts.

**CURRENT AND MAXIMUM NET PRODUCTIVITY RATES**

Zerbini et al. (2010) reviewed various estimates of maximum productivity rates for humpback whale populations, and, based on simulation studies, they proposed that 11.8% be considered as the maximum rate at which the species could grow. Barlow and Clapham (1997), applying an interbirth interval model to photographic mark-recapture data, estimated the population growth rate of the Gulf of Maine humpback whale stock at 6.5% (CV=0.012). Maximum net productivity is unknown for this population, although a theoretical maximum for any humpback population can be calculated using known values for biological parameters (Brandão et al. 2000; Clapham et al. 2001). For the Gulf of Maine stock, data supplied by Barlow and Clapham (1997) and Clapham et al. (1995) give values of 0.96 for survival rate, 6 years as mean age at first parturition, 0.5 as the proportion of females, and 0.42 for annual pregnancy rate. From this, a maximum population growth rate of 0.072 is obtained according to the method described by Brandão et al. (2000). This suggests that the observed rate of 6.5% (Barlow and Clapham 1997) is close to the maximum for this stock.

Clapham et al. (2003) updated the Barlow and Clapham (1997) analysis using data from the period 1992 to 2000. The population growth estimate was either 0% (for a calf survival rate of 0.51) or 4.0% (for a calf survival rate of 0.875). Although uncertainty was not strictly characterized by Clapham et al. (2003), their work might reflect a decline in population growth rates from the earlier study period. More recent work by Robbins (2007) places apparent survival of calves at 0.664 (95% CI: 0.517-0.784), a value between those used by Barlow and Clapham (1997) and in addition found productivity to be highly variable and well less than maximum.

Despite the uncertainty accompanying the more recent estimates of observed population growth rate for the Gulf of Maine stock, the maximum net productivity rate was assumed to be 6.5% calculated by Barlow and
Clapham (1997) because it represents an observation greater than the default of 0.04 for cetaceans (Barlow et al. 1995) but is conservative in that it is well below the results of Zerbini et al. (2010).

**POTENTIAL BIOLOGICAL REMOVAL**

Potential Biological Removal (PBR) is the product of minimum population size, one-half the maximum productivity rate, and a recovery factor (MMPA Sec. 3. 16 U.S.C. 1362; Wade and Angliss 1997). The minimum population size for the Gulf of Maine stock is 823 whales. The maximum productivity rate is 0.065. In the previous SAR, the recovery factor was 0.10 because this stock was listed as an endangered species under the Endangered Species Act. Due to the 2016 revision to the ESA listing of humpback whales, in which the West Indies Distinct Population Segment (of which the Gulf of Maine stock is a part) was identified as not warranting listing (81 FR 62259, September 8, 2016), the recovery factor is revised to 0.5, the default value for stocks of unknown status relative to OSP (Wade and Angliss 1997). Values other than the defaults for any stock should usually not be used without the approval of the regional Scientific Review Group, and scientific justification for the change should be provided in the Report (NMFS 2016). As the revision to the species’ ESA listing occurred after the February 2016 Scientific Review Group meeting, the default recovery factor is applied here. The Atlantic SRG will review the recovery factor for this stock at its February 2017 meeting. PBR for the Gulf of Maine humpback whale stock is 13 whales.

**ANNUAL HUMAN-CAUSED SERIOUS INJURY AND MORTALITY**

For the period 2010 through 2014, the minimum annual rate of human-caused mortality and serious injury to the Gulf of Maine humpback whale stock averaged 9.05 animals per year. This value includes incidental fishery interaction records, 7.25; and records of vessel collisions, 1.8 (Table 2; Henry et al. 2016).

In contrast to stock assessment reports before 2007, these averages include humpback mortalities and serious injuries that occurred in the southeastern and mid-Atlantic states that could not be confirmed as involving members of the Gulf of Maine stock. In past reports, only events involving whales confirmed to be members of the Gulf of Maine stock were counted against the PBR. Starting in the 2007 report, we assumed whales were from the Gulf of Maine unless they were identified as members of another stock. At the time of this writing, no whale was identified as a member of another stock. These determinations may change with the availability of new information. Canadian records from the southern side of Nova Scotia were incorporated into the mortality and serious injury rates, to reflect the effective range of this stock as described above. For the purposes of this report, discussion is primarily limited to those records considered to be confirmed human-caused mortalities or serious injuries.

To better assess human impacts (both vessel collision and commercial fishery mortality and serious injury) there needs to be greater emphasis on the timely recovery of carcasses and complete necropsies. The literature and review of records described here suggest that there are significant human impacts beyond those recorded in the data assessed for serious injury and mortality. For example, a study of entanglement-related scarring on the caudal peduncle of 134 individual humpback whales in the Gulf of Maine suggested that between 48% and 65% had experienced entanglements (Robbins and Mattila 2001). Decomposed and/or unexamined animals (e.g., carcasses reported but not retrieved or no necropsy performed) represent 'lost data', some of which may relate to human impacts.

**Background**

As with right whales, human impacts (vessel collisions and entanglements) may be slowing recovery of the humpback whale population. Van der Hoop et al. (2013) reviewed 1762 mortalities and serious injuries recorded for 8 species of large whales in the Northwest Atlantic for the 40 years 1970–2009. Of 473 records of humpback whales, cause of death could be attributed for 203. Of the 203, 116 (57%) mortalities were caused by entanglements in fishing gear, and 31 (15%) were attributable to vessel strikes.

Robbins and Mattila (2001) reported that males were more likely to be entangled than females. Annually updated inferences made from scar prevalence and multistate models of GOM humpback whales that (1) younger animals are more likely to become entangled than adults, (2) juvenile scarring rates may be trending up, (3) maybe less than 10% of humpback entanglements are ever reported, and (4) 3 % of the population maybe dying annually as the result of entanglements (Robbins 2009, 2010, 2011, 2012). Humpback whale entanglements also occur in relatively high numbers in Canadian waters. Reports of interactions with fixed fishing gear set for groundfish around Newfoundland averaged 365 annually from 1979 to 1987 (range 174-813). An average of 50 humpback whale entanglements (range 26-66) was reported annually between 1979 and 1988, and 12 of 66 humpback whales entangled in 1988 died (Lien et al. 1988). A total of 965 humpbacks was reported entangled in fishing gear in Newfoundland and Labrador from 1979 to 2008 (Benjamins et al. 2012). Volgenau et al. (1995) reported that in
Newfoundland and Labrador, cod traps caused the most entanglements and entanglement mortalities (21%) of humpbacks between 1979 and 1992. They also reported that gillnets were the primary cause of entanglements and entanglement mortalities (20%) of humpbacks in the Gulf of Maine between 1975 and 1990. In more recent times, following the collapse of the cod fishery, groundfish gillnets for other fish species and crab pot lines have been the most common sources of humpback entanglement in Newfoundland. Since the crab pot fishery is primarily an offshore activity on the Grand Banks, these entanglements are hard to respond to and are likely underreported. One humpback whale was reported released alive (status unknown) from a herring weir off Grand Manan in 2009 (H. Koopman, UNC Wilmington, pers. comm.). In U.S. waters, Johnson et al. (2005) found 40% of humpback entanglements were in trap/pot gear and 50% were in gillnet, but sample sizes were small and much uncertainty still exists about the frequency of certain gear types involved in entanglement.

Wiley et al. (1995) reported that serious injuries attributable to ship strikes are more common and probably more serious than those from entanglements, but this claim is not supported by more recent analysis. Non-lethal interactions with gear are extremely common (see Robbins 2010, 2011, 2012) and recent analysis suggests entanglement serious injuries and mortalities are more common than ship strikes (van der Hoop et al. 2013). Furthermore, in the NMFS records for 2010 through 2014, there are only 9 reports of serious injuries and mortalities as a result of collision with a vessel and 40 records of injuries (prorated or serious) and mortalities attributed to entanglement. Because it has never been shown that serious injuries and mortalities related to ships or to fisheries interactions are equally detectable, it is unclear as to which human source of mortality is more prevalent. A major aspect of vessel collision that will be cryptic as a serious injury is blunt trauma, where when lethal it is usually undetectable from an external exam (Moore et al. 2013). No whale involved in the recorded vessel collisions had been identified as a member of a stock other than the Gulf of Maine stock at the time of this writing (Henry et al. 2016).

Fishery-Related Serious Injuries and Mortalities

A description of fisheries is provided in Appendix III. Two mortalities were observed in the pelagic drift gillnet fishery, one in 1993 and the other in 1995. In winter 1993, a juvenile humpback was observed entangled and dead in a pelagic drift gillnet along the 200-m isobath northeast of Cape Hatteras. In early summer 1995, a humpback was entangled and found dead in a pelagic drift gillnet on southwestern Georges Bank. Additional reports of mortality and serious injury, as well as description of total human impacts, are contained in records maintained by NMFS. A number of these records (11 entanglements involving lobster pot/trap gear) from the 1990–1994 period were the basis used to reclassify the lobster fishery (62 FR 33, Jan. 2, 1997). Large whale entanglements are rarely observed during fisheries sampling operations. However, during 2008, 3 humpback whales were observed as incidental bycatch: 2 in gillnet gear (1 no serious injury; 1 undetermined) and 1 in a purse seine (released alive), in 2011 a humpback was caught on an observed gillnet trip (disentangled and released free of gear; Henry et al. 2016), and in 2012 there was an observed interaction with a humpback whale in mid-Atlantic gillnet gear (non-serious injury). A recent review (Cassoff et al. 2011) describes in detail the types of injuries that baleen whales, including humpbacks, suffer as a result of entanglement in fishing gear.

For this report, the records of dead, injured, and/or entangled humpbacks (found either stranded or at sea) for the period 2010 through 2014 were reviewed. When there was no evidence to the contrary, events were assumed to involve members of the Gulf of Maine stock. While these records are not statistically quantifiable in the same way as observer fishery records, they provide some indication of the minimum frequency of entanglements. Specifically to this stock, if the calculations of Robbins (2011, 2012) are reasonable then the 3% mortality due to entanglement that she calculates equates to a minimum average rate of 25, which is nearly 10 times PBR.

**Other Mortality**

Between November 1987 and January 1988, at least 14 humpback whales died after consuming Atlantic mackerel containing a dinoflagellate saxitoxin (Geraci et al. 1989). The whales subsequently stranded or were recovered in the vicinity of Cape Cod Bay and Nantucket Sound, and it is highly likely that other unrecorded mortalities occurred during this event. During the first six months of 1990, seven dead juvenile (7.6 to 9.1 m long)
humpback whales stranded between North Carolina and New Jersey. The significance of these strandings is unknown.

Between July and September 2003, an Unusual Mortality Event (UME) that included 16 humpback whales was invoked in offshore waters of coastal New England and the Gulf of Maine. Biotoxin analyses of samples taken from some of these whales found saxitoxin at very low/questionable levels and domoic acid at low levels, but neither were adequately documented and therefore no definitive conclusions could be drawn. Seven humpback whales were considered part of a large whale UME in New England in 2005. Twenty-one dead humpback whales found between 10 July and 31 December 2006 triggered a humpback whale UME declaration. Causes of these UME events have not been determined.

STATUS OF STOCK

NMFS conducted a global status review of humpback whales (Bettridge et al. 2015) and recently revised the ESA listing of the species (81 FR 62259, September 8, 2016). The distinct population segments (DPSs) established in the final rule that occur in waters under the jurisdiction of the United States do not necessarily equate to the existing MMPA stocks. NMFS is evaluating the stock structure of humpback whales under the MMPA, but no changes to current stock structure are presented at this time. As noted within the humpback whale ESA-listing final rule, in the case of a species or stock that achieved its depleted status solely on the basis of its ESA status, such as the humpback whale, the species or stock would cease to qualify as depleted under the terms of the definition set forth in MMPA Section 3(1) if the species or stock is no longer listed as threatened or endangered. The final rule indicated that until the stock delineations are reviewed in light of the DPS designations, NMFS would consider stocks that do not fully or partially coincide with a listed DPS as not depleted for management purposes. Therefore, the Gulf of Maine stock is considered not depleted because it does not coincide with any ESA-listed DPS. The detected level of U.S. fishery-caused mortality and serious injury derived from the available records, which is likely biased low, is more than 10% of the calculated PBR and, therefore, cannot be considered to be insignificant or approaching a zero mortality and serious injury rate. This is not a strategic stock because the average annual human-related mortality and serious injury does not exceed PBR.

FIN WHALE (Balaenoptera physalus):
Western North Atlantic Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

The Scientific Committee of the International Whaling Commission (IWC) has proposed stock boundaries for North Atlantic fin whales. Fin whales off the eastern United States, Nova Scotia, and the southeastern coast of Newfoundland are believed to constitute a single stock under the present IWC scheme (Donovan 1991). Although the stock identity of North Atlantic fin whales has received much recent attention from the IWC, current understanding of stock boundaries remains uncertain. The existence of a subpopulation structure was suggested by local depletions that resulted from commercial overharvesting (Mizroch et al. 1984).

A genetic study conducted by Bérubé et al. (1998) using both mitochondrial and nuclear DNA provided strong support for an earlier population model proposed by Kellogg (1929) and others. This postulates the existence of several subpopulations of fin whales in the North Atlantic and Mediterranean with limited gene flow among them. Bérubé et al. (1998) also proposed that the North Atlantic population showed recent divergence due to climatic changes (i.e., postglacial expansion), as well as substructuring over even relatively short distances. The genetic data are consistent with the idea that different subpopulations use the same feeding ground, a hypothesis that was also originally proposed by Kellogg (1929). More recent genetic studies have called into question conclusions drawn from early allosyme work (Olsen et al. 2014) and North Atlantic fin whales show a very low rate of genetic diversity throughout their range excluding the Mediterranean (Pampoulie et al. 2008).

Fin whales are common in waters of the U. S. Atlantic Exclusive Economic Zone (EEZ), principally from Cape Hatteras northward (Figure 1). In a recent globally-scaled review of sightings data, Edwards et al. (2015) found evidence to confirm the presence of fin whales in every season throughout much of the US EEZ north of 35°. Fin whales accounted for 46% of the large whales and 24% of all cetaceans sighted over the continental shelf during aerial surveys (CETAP 1982) between Cape Hatteras and Nova Scotia during 1978–1982. While much remains unknown, the magnitude of the ecological role of the fin whale is impressive. In this region fin whales are the dominant large cetacean species during all seasons, having the largest standing stock, the largest food requirements, and therefore the largest influence on ecosystem processes of any cetacean species (Hain et al. 1992; Kenney et al. 1997). Acoustic detections of fin whale singers augment and confirm these visual sighting conclusions for males. Recordings from Massachusetts Bay, New York bight, and deep-ocean areas detected some level of fin whale singing from September through June (Watkins et al. 1987, Clark and Gagnon 2002, Morano et al. 2012). These acoustic observations from both coastal and deep-ocean regions support the conclusion that male fin whales are broadly distributed throughout the western North Atlantic for most of the year.

New England waters represent a major feeding ground for fin whales. There is evidence of site fidelity by females, and perhaps some segregation by sexual, maturational, or reproductive class in the feeding area (Agler et
al. 1993). Seipt et al. (1990) reported that 49% of identified fin whales sighted on the Massachusetts Bay area feeding grounds were resighted within the same year, and 45% were resighted in multiple years. The authors suggested that fin whales on these grounds exhibited patterns of seasonal occurrence and annual return that in some respects were similar to those shown for humpback whales. This was reinforced by Clapham and Seipt (1991), who showed maternally-directed site fidelity for fin whales in the Gulf of Maine.

Hain et al. (1992), based on an analysis of neonate stranding data, suggested that calving takes place during October to January in latitudes of the U.S. mid-Atlantic region; however, it is unknown where calving, mating, and wintering occur for most of the population. Results from the Navy's SOSUS program (Clark 1995) indicated a substantial deep-ocean distribution of fin whales. It is likely that fin whales occurring in the U.S. Atlantic EEZ undergo migrations into Canadian waters, open-ocean areas, and perhaps even subtropical or tropical regions. However, the popular notion that entire fin whale populations make distinct annual migrations like some other mysticetes has questionable support in the data; in the North Pacific, year-round monitoring of fin whale calls found no evidence for large-scale migratory movements (Watkins et al. 2000).

**POPULATION SIZE**

The best abundance estimate available for the western North Atlantic fin whale stock is 1,618 (CV=0.33). This is the estimate derived from the 2011 NOAA shipboard surveys and is considered best because it represents the only current data. It is likely that the available estimate underestimates this stock’s abundance because much of the stock’s range was not included in the surveys upon which the estimate is based.

**Earlier abundance estimates**

Please see Appendix IV for earlier abundance estimates. As recommended in the GAMMS II Workshop Report (Wade and Angliss 1997), estimates older than eight years are deemed unreliable for the determination of a current PBR.

**Recent surveys and abundance estimates**

An abundance estimate of 1,595 (CV=0.33) fin whales was generated from a shipboard and aerial survey conducted during June–August 2011 (Palka 2012). The aerial portion that contributed to the abundance estimate covered 5,313 km of tracklines that were over waters north of New Jersey from the coastline to the 100-m depth contour, through the U.S. and Canadian Gulf of Maine and up to and including the lower Bay of Fundy. The shipboard portion covered 3,107 km of tracklines that were in waters offshore of North Carolina to Massachusetts (waters that were deeper than the 100-m depth contour out to beyond the U.S. EEZ). Both sighting platforms used a double-platform data collection procedure, which allows estimation of abundance corrected for perception bias of the detected species (Laake and Borchers 2004). Estimation of the abundance was based on the independent observer approach assuming point independence (Laake and Borchers 2004) and calculated using the multiple-covariate distance sampling (MCDS) option in the computer program Distance (version 6.0, release 2, Thomas et al. 2009). The abundance estimates of fin whales include a percentage of the estimate of animals identified as fin/sei whales (the two species being sometimes hard to distinguish). The percentage used is the ratio of positively identified fin whales to the total number of positively identified fin whales and positively identified sei whales; the CV of the abundance estimate includes the variance of the estimated fraction.

An abundance estimate of 23 (CV=0.87) fin whales was generated from a shipboard survey conducted concurrently (June–August 2011) in waters between central Virginia and central Florida. This shipboard survey included shelf-break and inner continental slope waters deeper than the 50-m depth contour within the U.S. EEZ. The survey employed two independent visual teams searching with 25× bigeye binoculars. A total of 4,445 km of tracklines was surveyed, yielding 290 cetacean sightings. The majority of sightings occurred along the continental shelf break with generally lower sighting rates over the continental slope. Estimation of the abundance was based on the independent observer approach assuming point independence (Laake and Borchers 2004) and calculated using the mark-recapture distance sampling option in the computer program Distance (version 6.0, release 2, Thomas et al. 2009).

Minimum Population Estimate

The minimum population estimate is the lower limit of the two-tailed 60% confidence interval of the log-normally distributed best abundance estimate. This is equivalent to the 20th percentile of the log-normal distribution as specified by Wade and Angliss (1997). The best estimate of abundance for fin whales is 1,618 (CV=0.33). The minimum population estimate for the western North Atlantic fin whale is 1,234.

Current Population Trend

A trend analysis has not been conducted for this stock. The statistical power to detect a trend in abundance for this stock is poor due to the relatively imprecise abundance estimates and long survey interval. For example, the power to detect a precipitous decline in abundance (i.e., 50% decrease in 15 years) with estimates of low precision (e.g., CV > 0.30) remains below 80% (alpha = 0.30) unless surveys are conducted on an annual basis (Taylor et al. 2007).

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Current and maximum net productivity rates are unknown for this stock. Based on photographically identified fin whales, Agler et al. (1993) estimated that the gross annual reproduction rate was 8%, with a mean calving interval of 2.7 years.

For purposes of this assessment, the maximum net productivity rate was assumed to be 0.04. This value is based on theoretical modeling showing that cetacean populations may not grow at rates much greater than 4% given the constraints of their reproductive life history (Barlow et al. 1995).

POTENTIAL BIOLOGICAL REMOVAL

Potential Biological Removal (PBR) is the product of minimum population size, one-half the maximum productivity rate, and a recovery factor (MMPA Sec. 3. 16 U.S.C. 1362; Wade and Angliss 1997). The minimum population size is 1,234. The maximum productivity rate is 0.04, the default value for cetaceans. The recovery factor is 0.10 because the fin whale is listed as endangered under the Endangered Species Act (ESA). PBR for the western North Atlantic fin whale is 2.5. Because there is a strong likelihood the abundance estimate used to calculate PBR was biased low due to incomplete coverage of the stock’s range, it is therefore likely that this PBR calculation is low.

ANNUAL HUMAN- CAUSED MORTALITY AND SERIOUS INJURY

For the period 2010 through 2014, the minimum annual rate of human-caused mortality and serious injury to fin whales was 3.8 per year. This value includes incidental fishery interaction records, 1.8 (0.2 U.S./0.8 Canadian/0.8 unknown but first reported in U.S. waters); and records of vessel collisions, 2.0 (all U.S.) (Table 2; Henry et al. 2016). Annual rates calculated from detected mortalities should not be considered an unbiased representation of human-caused mortality, but they represent a definitive lower bound. Detections are haphazard and not the result of a designed sampling scheme. As such they represent a minimum estimate of human-caused mortality which is almost certainly biased low.

Fishery-Related Serious Injury and Mortality

No confirmed fishery-related mortalities or serious injuries of fin whales have been reported in the NMFS Sea Sampling bycatch database. A review of the records of stranded, floating, or injured fin whales for the period 2010 through 2014 on file at NMFS found 4 records with substantial evidence of fishery interactions causing mortality (Henry et al. 2016). Serious injury determinations from non-fatal fishery interaction records yielded a value of 5.0 over five years, for an annual average of 1.0 (Henry et al. 2016). The resultant estimated minimum annual rate of serious injury and mortality from fishery interactions for this fin whale stock is 1.8. These records are not statistically quantifiable in the same way as the observer fishery records, and they almost surely undercount entanglements for the stock.

Other Mortality
After reviewing NMFS records for 2010 through 2014, 10 were found that had sufficient information to confirm the cause of death as collisions with vessels (Table 2; Henry et al. 2016). These records constitute an annual rate of serious injury or mortality of 2.0 fin whales from vessel collisions.

STATUS OF STOCK
This is a strategic stock because the fin whale is listed as an endangered species under the ESA. The total level of human-caused mortality and serious injury is unknown. NMFS records represent coverage of only a portion of the area surveyed for the population estimate for the stock. The total U.S. fishery-related mortality and serious injury for this stock derived from the available records is likely biased low and is not less than 10% of the calculated PBR. Therefore entanglement rates cannot be considered insignificant and approaching a zero mortality and serious injury rate. The status of this stock relative to OSP in the U.S. Atlantic EEZ is unknown. There are insufficient data to determine the population trend for fin whales.

REFERENCES CITED

SEI WHALE (Balaenoptera borealis borealis): Nova Scotia Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Mitchell and Chapman (1977) reviewed the sparse evidence on stock identity of northwestern Atlantic sei whales, and suggested two stocks—a Nova Scotia stock and a Labrador Sea stock. The range of the Nova Scotia stock includes the continental shelf waters of the northeastern U.S., and extends northeastward to south of Newfoundland. The Scientific Committee of the International Whaling Commission (IWC), while adopting these general boundaries, noted that the stock identity of sei whales (and indeed all North Atlantic whales) was a major research problem (Donovan 1991). In the absence of evidence to the contrary, the proposed IWC stock definition is provisionally adopted, and the “Nova Scotia stock” is used here as the management unit for this stock assessment. The IWC boundaries for this stock are from the U.S. east coast to Cape Breton, Nova Scotia, thence east to longitude 42°W. Recent telemetry evidence offers some support that sei whales foraging in the Labrador Sea winter in the Azores and constitute a separate stock (Prieto et al. 2014).

Indications are that, at least during the feeding season, a major portion of the Nova Scotia sei whale stock is centered in northerly waters, perhaps on the Scotian Shelf (Mitchell and Chapman 1977). The southern portion of the species’ range during spring and summer includes the northern portions of the U.S. Atlantic Exclusive Economic Zone (EEZ)—the Gulf of Maine and Georges Bank. Spring is the period of greatest abundance in U.S. waters, with sightings concentrated along the eastern margin of Georges Bank and into the Northeast Channel area, and along the southwestern edge of Georges Bank in the area of Hydrographer Canyon (CETAP 1982). NMFS aerial surveys since 1999 have found concentrations of sei and right whales along the northern edge of Georges Bank in the spring. The sei whale is often found in the deeper waters characteristic of the continental shelf edge region (Hain et al. 1985), and NMFS aerial surveys found substantial numbers of sei whales in this region, in particular south of Nantucket, in the spring of 2001. Similarly, Mitchell (1975) reported that sei whales off Nova Scotia were often distributed closer to the 2,000-m depth contour than were fin whales.

This general offshore pattern of sei whale distribution is disrupted during episodic incursions into shallower, more inshore waters. Although known to eat fish in other oceans, sei whales (like right whales) are largely planktivorous, feeding primarily on euphausiids and copepods (Flinn et al. 2002). A review of prey preferences by Horwood (1987) showed that, in the North Atlantic, sei whales seem to prefer copepods over all other prey species. In Nova Scotia sampled stomachs from captured sei whales showed a clear preference for copepods between June and October, and euphausiids were taken only in May and November (Mitchell 1975). Sei whales are reported in some years in more inshore locations, such as the Great South Channel (in 1987 and 1989) and Stellwagen Bank (in 1986) areas (R.D. Kenney, pers. comm.; Payne et al. 1990). An influx of sei whales into the southern Gulf of Maine occurred in the summer of 1986 (Schilling et al. 1993). Such episodes, often punctuated by years or even decades of absence from an area, have been reported for sei whales from various places worldwide (Jonsgård and Darling 1977).

Based on analysis of records from the Blandford, Nova Scotia, whaling station, where 825 sei whales were
taken between 1965 and 1972, Mitchell (1975) described two "runs" of sei whales, in June–July and in September–October. He speculated that the sei whale stock migrates from south of Cape Cod and along the coast of eastern Canada in June and July, and returns on a southward migration again in September and October; however, such a migration remains unverified.

**POPULATION SIZE**

The summer 2011 abundance estimate of 357 (CV=0.52) is considered the best available for the Nova Scotia stock of sei whales. However, this estimate must be considered conservative because all of the known range of this stock was not surveyed, because it did not include an availability-bias correction for animals missed while submerged, and because of uncertainties regarding population structure and whale movements between surveyed and unsurveyed areas.

**Earlier abundance estimates**

Please see appendix IV for earlier abundance estimates. As recommended in the GAMMS Workshop Report (Wade and Angliss 1997), estimates older than eight years are deemed unreliable for determination of the current PBR.

**Recent surveys and abundance estimates**

An abundance estimate of 357 (CV=0.52) sei whales was generated from a shipboard and aerial survey conducted during June–August 2011 (Palka 2012). The aerial portion that contributed to the abundance estimate covered 5,313 km of tracklines that were over waters from north of New Jersey from the coastline to the 100-m depth contour, through the U.S. and Canadian Gulf of Maine and up to and including the lower Bay of Fundy. The shipboard portion covered 3,107 km of tracklines that were in waters offshore of Virginia to Massachusetts (waters that were deeper than the 100-m depth contour out to beyond the U.S. EEZ). Both sighting platforms used a double-platform data collection procedure, which allows estimation of abundance corrected for perception bias of the detected species (Laake and Borchers 2004). Estimation of the abundance was based on the independent observer approach assuming point independence (Laake and Borchers 2004) and calculated using the multiple-covariate distance sampling (MCDS) option in the computer program Distance (version 6.0, release 2, Thomas et al. 2009).

The abundance estimates of sei whales include a percentage of the estimate of animals identified as fin/sei whales (the two species being sometimes hard to distinguish). The percentage used is the ratio of positively identified sei whales to the total of positively identified fin whales and positively identified sei whales; the CV of the abundance estimate includes the variance of the estimated fraction. Although this is the best estimate available for this stock, it should be noted that the abundance survey from which it was derived excluded waters off the Scotian Shelf, an area encompassing a large portion of the stated range of the stock.

| Table 1. Summary of recent abundance estimates for Nova Scotia sei whales with month, year, and area covered during each abundance survey, and resulting abundance estimate (N_{best}) and coefficient of variation (CV). |
|--------------------------------------------------|-------------------------------|-----------------|-------|
| Month/Year | Area                          | N_{best} | CV    |
| Jun-Aug 2011 | Central Virginia to lower Bay of Fundy | 357      | 0.52  |

**Minimum Population Estimate**

The minimum population estimate is the lower limit of the two-tailed 60% confidence interval of the log-normally distributed best abundance estimate. This is equivalent to the 20th percentile of the log-normal distribution as specified by (Wade and Angliss 1997). The best estimate of abundance for the Nova Scotia stock sei whales is 357 (CV=0.52). The minimum population estimate is 236.

**Current Population Trend**

A trend analysis has not been conducted for this stock. The statistical power to detect a trend in abundance for this stock is poor due to the relatively imprecise abundance estimates and long survey interval. For example, the power to detect a precipitous decline in abundance (i.e., 50% decrease in 15 years) with estimates of low precision (e.g., CV > 0.30) remains below 80% (alpha = 0.30) unless surveys are conducted on an annual basis (Taylor et al. 2007).
CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Current and maximum net productivity rates are unknown for this stock. For purposes of this assessment, the maximum net productivity rate was assumed to be 0.04. This value is based on theoretical modeling showing that cetacean populations may not grow at rates much greater than 4% given the constraints of their reproductive life history (Barlow et al. 1995).

POTENTIAL BIOLOGICAL REMOVAL

Potential Biological Removal (PBR) is the product of minimum population size, one-half the maximum productivity rate, and a recovery factor (MMPA Sec. 3, 16 U.S.C. 1362; Wade and Angliss 1997). The minimum population size is 236. The maximum productivity rate is 0.04, the default value for cetaceans. The recovery factor is 0.10 because the sei whale is listed as endangered under the Endangered Species Act (ESA). PBR for the Nova Scotia stock of the sei whale is 0.5.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

For the period 2010 through 2014, the minimum annual rate of human-caused mortality and serious injury to sei whales was 0.8. This value includes incidental fishery interaction records, 0, and records of vessel collisions, 0.8 (Table 2; Henry et al. 2016). Annual rates calculated from detected mortalities should not be considered an unbiased estimate of human-caused mortality, but they represent a definitive lower bound. Detections are haphazard, incomplete, and not the result of a designed sampling scheme. As such they represent a minimum estimate of human-caused mortality which is almost certainly biased low.

Fishery-Related Serious Injury and Mortality

No confirmed fishery-related mortalities or serious injuries of sei whales have been reported in the NMFS Sea Sampling bycatch database. A review of the records of stranded, floating, or injured sei whales for the period 2010 through 2014 on file at NMFS found no records with substantial evidence of fishery interactions causing serious injury or mortality (Table 2), which results in an annual serious injury and mortality rate of 0 sei whales from fishery interactions.

e. H=hook, GN=gillnet, GU=gear unidentifiable, MF=monofilament, NP=none present, NR=none recovered/received, PT=pot/trap, WE=weir

Other Mortality

For the period 2010 through 2014 files at NMFS included four records with substantial evidence of vessel collision causing serious injury or mortality (Table 2), which resulted in an annual rate of serious injury and mortality of 0.8 sei whales from vessel collisions.

STATUS OF STOCK

This is a strategic stock because the sei whale is listed as an endangered species under the ESA. The total U.S. fishery-related mortality and serious injury for this stock derived from the available records was less than 10% of the calculated PBR, and therefore could be considered insignificant and approaching a zero mortality and serious injury rate. However, evidence for fisheries interactions with large whales are subject to imperfect detection, and caution should be used in interpreting these results. The status of this stock relative to OSP in the U.S. Atlantic EEZ is unknown. There are insufficient data to determine population trends for sei whales.

REFERENCES CITED

CETAP 1982. A characterization of marine mammals and turtles in the mid- and north Atlantic areas of the U.S.

MINKE WHALE (Balaenoptera acutorostrata acutorostrata):
Canadian East Coast Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

Minke whales have a cosmopolitan distribution in temperate, tropical and high-latitude waters. In the North Atlantic, there are four recognized populations—Canadian East Coast, west Greenland, central North Atlantic, and northeastern North Atlantic (Donovan 1991). These divisions were defined by examining segregation by sex and length, catch distributions, sightings, marking data, and pre-existing ICES boundaries. However, there were very few data from the Canadian East Coast population. Anderwald et al. (2011) found no evidence for geographic structure comparing these putative populations but did, using individual genotypes and likelihood assignment methods, identify two cryptic stocks distributed across the North Atlantic. Until better information is available, minke whales off the eastern coast of the United States are considered to be part of the Canadian East Coast stock, which inhabits the area from the western half of the Davis Strait (45°W) to the Gulf of Mexico. It is also uncertain if there are separate sub-stocks within the Canadian East Coast stock.

The minke whale is common and widely distributed within the U.S. Atlantic Exclusive Economic Zone (EEZ) (CETAP 1982). There appears to be a strong seasonal component to minke whale distribution on both the continental shelf and in deeper, off-shelf waters. Spring to fall are times of relatively widespread and common occurrence on the shelf, and when the whales are most abundant in New England waters (e.g., Risch et al. 2013; 2014), while during the fall to spring period the species appears to be relatively widespread and common on deep-ocean waters (Clark and Gagnon 2002). Records based on visual sightings and summarized by Mitchell (1991) hinted at a possible winter distribution in the West Indies, and in the mid-ocean south and east of Bermuda. In contrast, acoustic monitoring for minke whales have revealed minke acoustic occurrence throughout broad, deep-ocean areas of the western North Atlantic from late October through early June (Clark and Gagnon 2002).

POPULATION SIZE

The best recent abundance estimate for this stock is 2,591 (CV=0.81) minke whales. This estimate, derived from 2011 shipboard and aerial surveys, is the only current estimate available. This estimate is substantially lower than the estimate from the previous (2015) SAR. This is because the previous estimate included data from the 2007 TNASS surveys of Canadian waters. For the purposes of this SAR, as recommended in the GAMMS II Workshop Report (Wade and Angliss 1997), estimates older than eight years are deemed unreliable, so this new estimate must not include data from the 2007 TNASS survey. This new estimate should not be interpreted as a decline in abundance of this stock, as previous estimates are not directly comparable.

Earlier estimates
Please see Appendix IV for a summary of abundance estimates, including earlier estimates and survey descriptions. As recommended in the GAMMS II Workshop Report (Wade and Angliss 1997), estimates older than eight years are deemed unreliable for the determination of the current PBR.

Recent surveys and abundance estimates
An abundance estimate of 2,591 (CV=0.81) minke whales was generated from a shipboard and aerial survey conducted during June-August 2011 (Palka 2012). The aerial portion that contributed to the abundance estimate covered 5,313 km of tracklines that were over waters north of New Jersey from the coastline to the 100-m depth contour through the U.S. and Canadian Gulf of Maine, and up to and including the lower Bay of Fundy. The shipboard portion covered 3,107 km of tracklines that were in waters offshore of central Virginia to Massachusetts (waters that were deeper than the 100-m depth contour out to beyond the U.S. EEZ). Both sighting platforms used a double-platform data collection procedure, which allows estimation of abundance corrected for perception bias of the visually detected species (Laake and Borchers, 2004). Estimation of the abundance was based on the independent-observer approach assuming point independence (Laake and Borchers 2004) and calculated using the multiple-covariate distance sampling (MCDS) option in the computer program Distance (version 6.0, release 2, Thomas et al. 2009).

Table 1. Summary of recent abundance estimates for the Canadian East Coast stock of minke whales (Balaenoptera acutorostrata acutorostrata) by month, year, and area covered during each abundance survey, and resulting abundance estimate (N_{best}) and coefficient of variation. (CV).

Minimum Population Estimate
The minimum population estimate is the lower limit of the two-tailed 60% confidence interval of the log-normally distributed best abundance estimate. This is equivalent to the 20th percentile of the log-normal distribution as specified by Wade and Angliss (1997). The best estimate of abundance for the Canadian East Coast stock of minke whales is 2,591 animals (CV=0.81). The minimum population estimate is 1,425 animals.

Current Population Trend
A trend analysis has not been conducted for this stock. The statistical power to detect a trend in abundance for this stock is poor due to the relatively imprecise abundance estimates and long survey interval. For example, the power to detect a precipitous decline in abundance (i.e., 50% decrease in 15 years) with estimates of low precision (e.g., CV > 0.30) remains below 80% (alpha = 0.30) unless surveys are conducted on an annual basis (Taylor et al. 2007).

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES
Current and maximum net productivity rates are unknown for this stock. Life history parameters that could be used to estimate net productivity are that females mature between 6 and 8 years of age, and pregnancy rates are approximately 0.86 to 0.93. Based on these parameters, the calving interval is between 1 and 2 years. Calves are probably born during October to March after 10 to 11 months gestation and nursing lasts for less than 6 months. Maximum ages are not known, but for Southern Hemisphere minke whales maximum age appears to be about 50 years (IWC 1991; Katona et al. 1993).

For purposes of this assessment, the maximum net productivity rate was assumed to be 0.04. This value is based on theoretical modeling showing that cetacean populations may not grow at rates much greater than 4% given the constraints of their reproductive life history (Barlow et al. 1995).

POSSIBLE BIOLOGICAL REMOVAL
Potential Biological Removal (PBR) is the product of minimum population size, one-half the maximum productivity rate, and a recovery factor (MMPA Sec. 3. 16 U.S.C. 1362; Wade and Angliss 1997). The minimum population size is 1,425. The maximum productivity rate is 0.04, the default value for cetaceans. The recovery factor is 0.5, the default value for stocks of unknown status relative to OSP, and the CV of the average mortality estimate
is less than 0.3 (Wade and Angliss 1997). PBR for the Canadian east coast minke whale is 14.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

During 2010 to 2014, the average annual minimum detected human-caused mortality and serious injury was 8.25 minke whales per year: 0.2 minke whales per year from observed U.S. fisheries, 6.45 (1.7 U.S./2.5 Canada/2.25 unassigned but first reported in the U.S.) minke whales per year from U.S. and Canadian fisheries using strandings and entanglement data, and 1.6 (1.2 U.S./0.4 Canada) per year from vessel strikes.

Data to estimate the mortality and serious injury of minke whales come from the Northeast Fisheries Science Center Observer Program, the At-Sea Monitor Program, and from records of strandings and entanglements in U.S. and Canadian waters. For the purposes of this report, mortalities and serious injuries from reports of strandings and entanglements considered confirmed human-caused mortalities or serious injuries are shown in Table 2 while those recorded by the Observer or At-Sea Monitor Programs are shown in Table 3.

Detected interactions in the strandings and entanglement data should not be considered an unbiased representation of human-caused mortality. Detections are haphazard and not the result of a designed sampling scheme. As such they represent a minimum estimate, which is almost certainly biased low.

Fishery Information

Detailed fishery information is reported in Appendix III.

Earlier Interactions

For more details on the historical fishery interactions prior to 1999, see Waring et al. (2007).

In 2002, one minke whale mortality and one live release were attributed to the lobster trap fishery. A June 2003 mortality, while wrapped in lobster gear, cannot be confirmed to have become entangled in the area, and so is not attributed to the fishery. Annual mortalities due to the northeast/mid-Atlantic Lobster Trap/Pot fishery, as determined from strandings and entanglement records that have been audited, were 1 in 1991, 2 in 1992, 1 in 1994, 1 in 1995, 0 in 1996, 1 in 1997, 0 in 1998 to 2001, 1 in 2002, and 0 in 2003 through 2011. See Appendix V for more information on historical takes.

U.S.

Northeast Mid-water Trawl Fishery (Including Pair Trawl)

During July 2013, one minke whale was observed dead in the mid-water otter trawl on Georges Bank. Due to the small sample size of observed takes, an expanded estimate was not calculated. Annual average estimated minke whale mortality and serious injury from the mid-Atlantic mid-water trawl (including pair trawl) during 2010 to 2014 was 0.2 (Table 3).

Atlantic Large Pelagics Longline Fishery

In 2010, a minke whale was caught but released alive (no serious injury) in the large pelagics longline fishery, South Atlantic Bight fishing area (Garrison and Stokes 2012).

Other Fisheries

The audited NE Regional Office/NMFS entanglement/stranding database contains records of minke whales, of which the confirmed mortalities and serious injuries from the last five years are reported in Table 2. During 2010 to 2014, as determined from strandings and entanglement records confirmed to be of U.S. origin or first sighted in U.S. waters, the minimum detected average annual mortality and serious injury was 3.95 minke whales per year in U.S. fisheries (Table 2a). Most cases where gear was recovered and identified involved gillnet or pot/trap gear.

CANADA

Read (1994) reported interactions between minke whales and gillnets in Newfoundland and Labrador, in cod traps in Newfoundland, and in herring weirs in the Bay of Fundy. Hooker et al. (1997) summarized bycatch data from a Canadian fisheries observer program that placed observers on all foreign fishing vessels operating in Canadian waters, on between 25% and 40% of large Canadian fishing vessels (greater than 100 feet long), and on approximately 5% of smaller Canadian fishing vessels. During 1991 through 1996, no minke whales were observed taken.

Herring Weirs
During 1980 to 1990, 15 of 17 minke whales were released alive from herring weirs in the Bay of Fundy. During January 1991 to September 2002, 26 minke whales were trapped in herring weirs in the Bay of Fundy. Of these 26, 1 died (H. Koopman, pers. comm.) and several (number unknown) were released alive and unharmed (A. Westgate, pers. comm.). Weir interactions that may have resulted in serious injury to minke whales are reported in Table 2b.

**Other Fisheries**

Mortalities and serious injuries that were likely a result of an interaction with an unknown Canadian fishery are detailed in Table 2b. During 2010 to 2014, as determined from stranding and entanglement records confirmed to be of Canadian origin or first sighted in Canadian waters, the minimum detected average annual mortality and serious injury was 2.5 minke whales per year in Canadian fisheries (Table 2b; prorated value).

a. Observer data (Obs. Data), used to measure bycatch rates, are collected within the Northeast Fisheries Observer Program and mandatory Vessel Trip Reports (VTR) (Trip Logbook) are used to determine the spatial distribution of landings and fishing effort.

b. Northeast mid-water trawl (including pair trawl) fisheries coverage is ratios based on trips.

**Other Mortality**

North Atlantic minke whales have been and continue to be hunted. From the Canadian East Coast population, documented whaling occurred from 1948 to 1972 with a total kill of 1,103 animals (IWC 1992). Animals from other North Atlantic minke populations (e.g. Iceland) are being harvested presently.

**U.S.**

Minke whales inhabit coastal waters during much of the year and are thus susceptible to collision with vessels. In 2010 a juvenile male minke was discovered killed by vessel strike off Fire Island, New York. In 2011, three juvenile minkes were confirmed dead due to vessel strikes; a female off Sandy Hook, New Jersey, a female off Moriches, New York, and a male off Carolina Beach, North Carolina. In 2012, a confirmed vessel strike resulted in a mortality off Newark, New Jersey. In 2014, a confirmed vessel strike resulted in a mortality off Dam Neck, Virginia. Thus, during 2010–2014, as determined from stranding and entanglement records, the minimum detected annual average was 1.2 minke whales per year struck by vessels in U.S. waters or first seen in U.S. waters (Table 2a;
CANADA

The Nova Scotia Stranding Network documented whales and dolphins stranded on the coast of Nova Scotia between 1991 and 1996 (Hooker et al. 1997). Researchers with the Department of Fisheries and Oceans, Canada documented strandings on the beaches of Sable Island (Lucas and Hooker 2000). Starting in 1997, minke whales stranded on the coast of Nova Scotia were recorded by the Marine Animal Response Society (MARS) and the Nova Scotia Stranding Network. The events that are determined to be human-caused serious injury or mortality are included in Table 2b.

The Whale Release and Strandings program has reported the following minke whale stranding mortalities in Newfoundland and Labrador for the time period of this report: 1 in 2010, 0 in 2011, 3 in 2012, and 0 in 2013 and 1 in 2014. Those that have been determined to be human-caused serious injury or mortality are included in Table 2b (Ledwell and Huntington 2011, 2012, 2012b, 2013, 2014).

During 2010–2014, as determined from stranding and entanglement records, the minimum detected annual average was 0.4 minke whales per year struck by vessels in Canadian waters or first seen in Canadian waters (Table 2b; Henry et al. 2016).

STATUS OF STOCK

Minke whales are not listed as threatened or endangered under the Endangered Species Act, and the Canadian East Coast stock is not considered strategic under the Marine Mammal Protection Act. The total U.S. fishery-related mortality and serious injury for this stock is not less than 10% of the calculated PBR and, therefore, cannot be considered to be insignificant and approaching zero mortality and serious injury rate. The status of minke whales relative to OSP in the U.S. Atlantic EEZ is unknown.

DWARF SPERM WHALE (Kogia sima):
Western North Atlantic Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

The dwarf sperm whale (Kogia sima) is distributed worldwide in temperate to tropical waters (Caldwell and Caldwell 1989; McAlpine 2009). Sightings of Kogia whales in the western North Atlantic occur in oceanic waters (Figure 1; Mullin and Fulling 2003; Roberts et al. 2015). Stranding records exist from Florida to Maine, but there are no stranding records for the eastern Canadian coast (Willis and Baird 1998).

Dwarf sperm whales and pygmy sperm whales (K. breviceps) are difficult to differentiate at sea due to similarities in appearance (Caldwell and Caldwell 1989; Bloodworth and Odell 2008; McAlpine 2009), and sightings of either species are often categorized as Kogia sp. When measurements can be obtained, diagnostic morphological characters have been useful in distinguishing the two Kogia species (Handley 1966; Barros and Duffield 2003), thus enabling researchers to use stranding data in distributional and ecological studies. Specifically, the distance from the snout to the center of the blowhole in proportion to the animal’s total length, as well as the height of the dorsal fin in proportion to the animal’s total length, can be used to differentiate between the two Kogia species (Handley 1966; Barros and Duffield 2003).

In addition to similarities in appearance, dwarf sperm whales and pygmy sperm whales demonstrate similarities in their foraging ecology. Staudinger et al. (2014) conducted diet and stable isotope analyses on stranded pygmy and dwarf sperm whales from the mid-Atlantic coast and found that the 2 species shared the same primary prey and fed in similar habitats.

Across its geographic range, including the western North Atlantic, the population biology of dwarf sperm whales is inadequately known (Staudinger et al. 2014). The western North Atlantic dwarf sperm whale population is being considered a separate stock for management purposes, although there is currently no information to differentiate this stock from the northern Gulf of Mexico stock(s). Additional morphological, genetic and/or behavioral data are needed to provide further information on stock delineation.

POPULATION SIZE

Total numbers of dwarf sperm whales off the U.S. Atlantic coast are unknown, although abundance estimates from selected regions of dwarf sperm whale habitat exist for select time periods. Because K. sima and K. breviceps are difficult to differentiate at sea, the reported abundance estimates are for both species of Kogia combined. The best estimate for Kogia spp. in the western North Atlantic is 3,785 (CV=0.47; Table 1; Palka 2012; Garrison 2016). This estimate is from summer 2011 surveys covering waters from central Florida to the lower Bay of Fundy.
estimate is almost certainly negatively biased. One component of line transect estimates is \( g(0) \), the probability of seeing an animal on the transect line. Estimating \( g(0) \) is difficult because it consists of accounting for both perception bias (i.e., at the surface but missed) and availability bias (i.e., below the surface while in range of the observers), and many uncertainties (e.g., group size and diving behavior) can confound both (Marsh and Sinclair 1989; Barlow 1999). The best estimate was corrected for perception bias (see below) but not availability bias and is therefore an underestimate.

**Earlier abundance estimates**

Please see Appendix IV for a summary of abundance estimates, including earlier estimates and survey descriptions.

**Recent surveys and abundance estimates**

An abundance estimate of 1,783 (CV=0.62) *Kogia* spp. was generated from aerial and shipboard surveys conducted during June–August 2011 between central Virginia and the lower Bay of Fundy (Palka 2012). The aerial portion covered 6,850 km of tracklines over waters north of New Jersey between the coastline and the 100-m depth contour through the U.S. and Canadian Gulf of Maine, and up to and including the lower Bay of Fundy. The shipboard portion covered 3,811 km of trackline between central Virginia and Massachusetts in waters deeper than the 100-m depth contour out to beyond the U.S. EEZ. Both sighting platforms used a double-platform data collection procedure, which allowed estimation of abundance corrected for perception bias of the detected species (Laake and Borchers 2004). Estimation of the abundance was based on the independent observer approach assuming point independence (Laake and Borchers 2004) and calculated using the mark-recapture distance sampling option in the computer program Distance (version 6.0, release 2, Thomas et al. 2009).

An abundance estimate of 2,002 (CV=0.69) *Kogia* spp. was generated from a shipboard survey conducted concurrently (June–August 2011) in waters between central Virginia and central Florida (Garrison 2016). This shipboard survey included shelf-break and inner continental slope waters deeper than the 50-m depth contour within the U.S. EEZ. The survey employed two independent visual teams searching with 25x bigeye binoculars. A total of 4,445 km of trackline were surveyed, yielding 290 cetacean sightings. The majority of sightings occurred along the continental shelf break with generally lower sighting rates over the continental slope. Estimation of the abundance was based on the independent observer approach assuming point independence (Laake and Borchers 2004) and calculated using the mark-recapture distance sampling option in the computer program Distance (version 6.0, release 2, Thomas et al. 2009).

**Minimum Population Estimate**

The minimum population estimate is the lower limit of the two-tailed 60% confidence interval of the log-normally distributed best abundance estimate. This is equivalent to the 20th percentile of the log-normal distribution as specified by Wade and Angliss (1997). The best estimate of abundance for *Kogia* spp. is 3,785 (CV=0.47). The minimum population estimate for *Kogia* spp. is 2,598 animals.

**Current Population Trend**

A trend analysis has not been conducted for this stock. There are 3 abundance estimates for *Kogia* spp. from: 1) summer 1998 surveys (536; CV=0.45); 2) summer 2004 surveys (395; CV=0.4); and 3) summer 2011 surveys (3,785; CV=0.47). Methodological differences between the estimates need to be evaluated to quantify trends.

**CURRENT AND MAXIMUM NET PRODUCTIVITY RATES**

Current and maximum net productivity rates are unknown for this stock. For purposes of this assessment, the maximum net productivity rate was assumed to be 0.04. This value is based on theoretical modeling showing that
cetacean populations may not grow at rates much greater than 4% given the constraints of their reproductive life history (Barlow et al. 1995).

**POTENTIAL BIOLOGICAL REMOVAL**

Potential Biological Removal (PBR) is the product of minimum population size, one-half the maximum productivity rate, and a recovery factor (MMPA Sec. 3. 16 U.S.C. 1362; Wade and Angliss 1997). The minimum population size for *Kogia* spp. is 2,598. The maximum productivity rate is 0.04, the default value for cetaceans. The recovery factor is 0.40 because the CV of the average mortality estimate is greater than 0.8 (Wade and Angliss 1997). PBR for western North Atlantic *Kogia* spp. is 21.

**ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY**

The estimated annual average fishery-related mortality or serious injury for *Kogia* sp. during 2010–2014 was 3.5 (CV=1.0; Table 2).

**Fishery Information**

The commercial fisheries that interact, or that could potentially interact, with this stock in the Atlantic Ocean are the Category I Atlantic Highly Migratory Species longline and Atlantic Ocean, Caribbean, Gulf of Mexico large pelagics longline fisheries (Appendix III).

The large pelagics longline fishery operates in the U.S. Atlantic (including Caribbean) and Gulf of Mexico EEZ. Pelagic swordfish, tunas and billfish are the targets of the large pelagics longline fishery. Total estimated annual average fishery-related mortality and serious injury during 2010–2014 was unknown for Atlantic dwarf sperm whales because species-specific mortality estimates could not be made. However, there was 1 report of a *Kogia* sp. seriously injured by the pelagic longline fishery during quarter 4 of 2011 in the mid-Atlantic Bight region. Estimated total serious injury of *Kogia* sp. attributable to the pelagic longline fishery during 2011 was 17.4 (CV=1.0; Garrison and Stokes 2012b). The annual average serious injury and mortality attributable to the Atlantic large pelagics longline fishery for the 5-year period from 2010 to 2014 was 3.5 animals (CV=1.0; Table 2) (Garrison and Stokes 2012a,b; 2013; 2014; 2016).

The Atlantic Highly Migratory Species longline fishery operates outside the U.S. EEZ. No takes of dwarf sperm whales or *Kogia* sp. within high seas waters of the Atlantic Ocean have been observed or reported thus far.

See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical estimates of annual mortality and serious injury.

### Table 2. Summary of the incidental mortality and serious injury of Atlantic Ocean *Kogia* sp. in the pelagic longline commercial fishery including the years sampled (Years), the number of vessels active within the fishery (Vessels), the type of data used (Data Type), the annual observer coverage (Observer Coverage), the annual observed serious injury and mortality recorded by on-board observers, the annual estimated serious injury and mortality, the combined annual estimates of serious injury and mortality (Estimated Combined Mortality), the estimated CV of the combined annual mortality estimates (Est. CVs) and the mean of the combined mortality estimates (CV in parentheses).

*a* Number of vessels in the fishery is based on vessels reporting effort to the pelagic longline logbook.

*b* Observer data (Obs. Data) are used to measure bycatch rates, and the data are collected within the Northeast Fisheries Observer Program. Mandatory logbook data were used to measure total effort for the longline fishery. These data are collected at the Southeast Fisheries Science Center (SEFSC).

*c* Proportion of sets observed.
Earlier Interactions

Between 1992 and 2009, 1 Kogia sp. was hooked, released alive and considered seriously injured in 2000 (in the Florida East coast fishing area) (Yeung 2001).

Other Mortality

During 2010–2014, 34 dwarf sperm whales were reported stranded along the U.S. Atlantic coast and Puerto Rico (Table 3; Northeast Regional Marine Mammal Stranding Network, Southeast Regional Marine Mammal Stranding Network; NOAA National Marine Mammal Health and Stranding Response Database unpublished data, accessed 15 June 2015 (SER) and 9 June 2015 (NER)). In addition, there were 11 records of unidentified stranded Kogia.

Table 3. Dwarf and pygmy sperm whale (Kogia sima (Ks), Kogia breviceps (Kb) and Kogia sp. (Sp)) strandings along the Atlantic coast, 2010–2014. Strandings that were not reported to species have been reported as Kogia sp. The level of technical expertise among stranding network personnel varies, and given the potential difficulty in correctly identifying stranded Kogia whales to species, reports to specific species should be viewed with caution.

There were two documented strandings of dwarf sperm whales along the U.S. Atlantic coast during 2010–2014 with evidence of human interactions. The first was a whale stranded in Florida during 2010 whose flukes were cut off by a public person on the beach. For the second, plastic was found in the stomach of an animal that stranded in New Jersey during 2011.

Stranding data probably underestimate the extent of human and fishery-related mortality and serious injury because not all of the dolphins that die or are seriously injured in human interactions wash ashore, or, if they do, they are not all recovered (Peltier et al. 2012; Wells et al. 2015). Additionally, not all carcasses will show evidence of human interaction, entanglement or other fishery-related interaction due to decomposition, scavenger damage, etc. (Byrd et al. 2014). Finally, the level of technical expertise among stranding network personnel varies widely as does the ability to recognize signs of human interaction.

STATUS OF STOCK

Dwarf sperm whales are not listed as threatened or endangered under the Endangered Species Act, and the western North Atlantic stock is not considered strategic under the Marine Mammal Protection Act. Total U.S. fishery-related mortality and serious injury for Kogia sp. is not less than 10% of the calculated PBR and, therefore, cannot be considered to be insignificant and approaching zero mortality and serious injury rate. The status of dwarf sperm whales in the U.S. Atlantic EEZ relative to OSP is unknown. There are insufficient data to determine population trends for this species.

Garrison, L.P. 2016. Abundance of marine mammals in waters of the U.S. East Coast during summer 2011. Southeast Fisheries Science Center, Protected Resources and Biodiversity Division, 75 Virginia Beach Dr., Miami, FL 33140. PRBD Contribution # PRBD-2016-08, 21 pp.

STOCK DEFINITION AND GEOGRAPHIC RANGE

The pygmy sperm whale (*Kogia breviceps*) is distributed worldwide in temperate to tropical waters (Caldwell and Caldwell 1989; McAlpine 2009). Sightings of *Kogia* whales in the western North Atlantic occur in oceanic waters (Figure 1; Mullin and Fulling 2003; Roberts *et al.* 2015). Stranding records exist from Florida to Maine, but there are no stranding records for the east Canadian coast (Willis and Baird 1998).

Pygmy sperm whales and dwarf sperm whales (*K. sima*) are difficult to differentiate at sea (Caldwell and Caldwell 1989; Bloodworth and Odell 2008; McAlpine 2009), and sightings of either species are often categorized as *Kogia* sp. When measurements can be obtained, diagnostic morphological characters have been useful in distinguishing the two *Kogia* species (Handley 1966; Barros and Duffield 2003), thus enabling researchers to use stranding data in distributional and ecological studies. Specifically, the distance from the snout to the center of the blowhole in proportion to the animal’s total length, as well as the height of the dorsal fin in proportion to the animal’s total length, can be used to differentiate between the two *Kogia* species (Handley 1966; Barros and Duffield 2003).

In addition to similarities in appearance, dwarf sperm whales and pygmy sperm whales demonstrate similarities in their foraging ecology. Staudinger *et al.* (2014) conducted diet and stable isotope analyses on stranded pygmy and dwarf sperm whales from the mid-Atlantic coast and found that the two species shared the same primary prey and fed in similar habitats.

Across its geographic range, including the western North Atlantic, the population biology of dwarf sperm whales is inadequately known (Staudinger *et al.* 2014). The western North Atlantic pygmy sperm whale population is being considered a separate stock for management purposes, although there is currently no information to differentiate this stock from the northern Gulf of Mexico stock(s). Additional morphological, genetic and/or behavioral data are needed to provide further information on stock delineation.

POPULATION SIZE

Total numbers of pygmy sperm whales off the U.S. Atlantic coast are unknown, although abundance estimates from selected regions of pygmy sperm whale habitat do exist for select time periods. Because *K. breviceps* and *K. sima* are difficult to differentiate at sea, the reported abundance estimates are for both species of *Kogia* combined. The best abundance estimate for *Kogia* spp. in the western North Atlantic is 3,785 (CV=0.47; Table 1; Palka 2012; Garrison 2016). This estimate is from summer 2011 surveys covering waters from central Florida to the lower Bay of Fundy. This estimate is almost certainly negatively biased. One component of line transect estimates is $g(0)$, the
probability of seeing an animal on the transect line. Estimating $g(0)$ is difficult because it consists of accounting for both perception bias (i.e., at the surface but missed) and availability bias (i.e., below the surface while in range of the observers), and many uncertainties (e.g., group size and diving behavior) can confound both (Marsh and Sinclair 1989; Barlow 1999). The best estimate was corrected for perception bias (see below) but not availability bias and is therefore an underestimate.

Earlier abundance estimates

Please see Appendix IV for a summary of abundance estimates, including earlier estimates and survey descriptions.

Recent surveys and abundance estimates

An abundance estimate of 1,783 (CV=0.62) *Kogia* spp. was generated from aerial and shipboard surveys conducted during June–August 2011 between central Virginia and the lower Bay of Fundy (Palka 2012). The aerial portion covered 6,850 km of trackline over waters north of New Jersey between the coastline and the 100-m depth contour through the U.S. and Canadian Gulf of Maine, and up to and including the lower Bay of Fundy. The shipboard portion covered 3,811 km of trackline between central Virginia and Massachusetts in waters deeper than the 100-m depth contour out to beyond the U.S. EEZ. Both sighting platforms used a double-platform data collection procedure, which allowed estimation of abundance corrected for perception bias of the detected species (Laake and Borchers 2004). Estimation of the abundance was based on the independent observer approach assuming point independence (Laake and Borchers 2004) and calculated using the mark-recapture distance sampling option in the computer program Distance (version 6.0, release 2, Thomas et al. 2009).

An abundance estimate of 2,002 (CV=0.69) *Kogia* spp. was generated from a shipboard survey conducted concurrently (June–August 2011) in waters between central Virginia and central Florida (Garrison 2016). This shipboard survey included shelf-break and inner continental slope waters deeper than the 50-m depth contour within the U.S. EEZ. The survey employed two independent visual teams searching with 25x bigeye binoculars. A total of 4,445 km of trackline were surveyed, yielding 290 cetacean sightings. The majority of sightings occurred along the continental shelf break with generally lower sighting rates over the continental slope. Estimation of the abundance was based on the independent observer approach assuming point independence (Laake and Borchers 2004) and calculated using the mark-recapture distance sampling option in the computer program Distance (version 6.0, release 2, Thomas et al. 2009).

Minimum Population Estimate

The minimum population estimate is the lower limit of the two-tailed 60% confidence interval of the log-normally distributed best abundance estimate. This is equivalent to the 20th percentile of the log-normal distribution as specified by Wade and Angliss (1997). The best estimate of abundance for *Kogia* spp. is 3,785 (CV=0.47). The minimum population estimate for *Kogia* spp. is 2,598 animals.

Current Population Trend

A trend analysis has not been conducted for this stock. There are 3 abundance estimates for *Kogia* spp. from: 1) summer 1998 surveys (536; CV=0.45); 2) summer 2004 surveys (395; CV=0.4); and 3) summer 2011 surveys (3,785; CV=0.47). Methodological differences between the estimates need to be evaluated to quantify trends.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Current and maximum net productivity rates are unknown for this stock. For purposes of this assessment, the maximum net productivity rate was assumed to be 0.04. This value is based on theoretical modeling showing that cetacean populations may not grow at rates much greater than 4% given the constraints of their reproductive life
history (Barlow et al. 1995).

**POTENTIAL BIOLOGICAL REMOVAL**

Potential Biological Removal (PBR) is the product of minimum population size, one-half the maximum productivity rate, and a recovery factor (MMPA Sec. 3. 16 U.S.C. 1362; Wade and Angliss 1997). The minimum population size for *Kogia* spp. is 2,598. The maximum productivity rate is 0.04, the default value for cetaceans. The recovery factor is 0.40 because the CV of the average mortality estimate is greater than 0.8 (Wade and Angliss 1997). PBR for western North Atlantic *Kogia* spp. is 21.

**ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY**

The estimated annual average fishery-related mortality or serious injury for *Kogia* sp. during 2010–2014 was 3.5 (CV=1.0; Table 2).

**Fishery Information**

The commercial fisheries that interact, or that could potentially interact, with this stock in the Atlantic Ocean are the Category I Atlantic Highly Migratory Species longline and Atlantic Ocean, Caribbean, Gulf of Mexico large pelagics longline fisheries (Appendix III).

The large pelagics longline fishery operates in the U.S. Atlantic (including Caribbean) and Gulf of Mexico EEZ. Pelagic swordfish, tunas and billfish are the targets of the large pelagics longline fishery. Total estimated annual average fishery-related mortality and serious injury during 2010–2014 was unknown for Atlantic pygmy sperm whales because species-specific mortality estimates could not be made. However, there was 1 report of a *Kogia* sp. seriously injured by the pelagic longline fishery during quarter 4 of 2011 in the mid-Atlantic Bight region. Estimated total serious injury of *Kogia* attributable to the pelagic longline fishery during 2011 was 17.4 (CV=1.0; Garrison and Stokes 2012b). The annual average serious injury and mortality for *Kogia* sp. attributable to the Atlantic large pelagics longline fishery for the 5-year period from 2010 to 2014 was 3.5 animals (CV=1.0; Table 2) (Garrison and Stokes 2012a,b; 2013; 2014; 2016).

The Atlantic Highly Migratory Species longline fishery operates outside the U.S. EEZ. No takes of pygmy sperm whales or *Kogia* sp. within high seas waters of the Atlantic Ocean have been observed or reported thus far.

See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical estimates of annual mortality and serious injury.

Other Mortality
During 2010–2014, 142 pygmy sperm whales were reported stranded along the U.S. Atlantic coast and Puerto Rico (Table 3; Northeast Regional Marine Mammal Stranding Network, Southeast Regional Marine Mammal Stranding Network; NOAA National Marine Mammal Health and Stranding Response Database unpublished data, accessed 15 June 2015 (SER) and 9 June 2015 (NER)). In addition, there were 11 records of unidentified Kogia. In 2014 in North Carolina there was also 1 stranding with evidence of human interaction (both animals ingested debris). In 2013 in Georgia there was 1 stranding with evidence of human interaction, entanglement or other fishery-related interaction due to decomposition, scavenger damage, etc. (Byrd et al. 2014). Finally, the level of technical expertise among stranding network personnel varies widely as does the ability to recognize signs of human interaction.

</table>

There were 14 documented strandings of pygmy sperm whales along the U.S. Atlantic coast during 2010–2014 with evidence of human interactions. There were 7 strandings with evidence of human interactions in 2010—3 in Florida, 2 in New Jersey and 2 in South Carolina (1 of them classified as a fishery interaction due to ingested fishing gear, 5 animals ingested plastic, and 1 carcass had some teeth removed by public). In 2011, there were 4 strandings with evidence of human interactions—1 in Virginia (public attempted to move the animal), 1 in Florida (pushed out to sea by public) and 2 in Georgia (plastic ingestion). In 2012 there was 1 stranding in Florida with evidence of human interaction (ingested debris). In 2013 in Georgia there was 1 stranding with evidence of human interaction, and in 2014 in North Carolina there was also 1 stranding with evidence of human interaction (both animals ingested plastic).

Stranding data probably underestimate the extent of human and fishery-related mortality and serious injury because not all of the dolphins that die or are seriously injured in human interactions wash ashore, or, if they do, they are not all recovered (Peltier et al. 2012; Wells et al. 2015). Additionally, not all carcasses will show evidence of human interaction, entanglement or other fishery-related interaction due to decomposition, scavenger damage, etc. (Byrd et al. 2014). Finally, the level of technical expertise among stranding network personnel varies widely as does the ability to recognize signs of human interaction.

STATUS OF STOCK
Pygmy sperm whales are not listed as threatened or endangered under the Endangered Species Act, and the western North Atlantic stock is not considered strategic under the Marine Mammal Protection Act. Total U.S. fishery-related mortality and serious injury for Kogia sp. is not less than 10% of the calculated PBR and, therefore, cannot be considered to be insignificant and approaching zero mortality and serious injury rate. The status of pygmy sperm whales in the U.S. Atlantic EEZ relative to OSP is unknown. There are insufficient data to determine population trends for this species.

Garrison, L.P. 2016. Abundance of marine mammals in waters of the U.S. East Coast during summer 2011. Southeast Fisheries Science Center, Protected Resources and Biodiversity Division, 75 Virginia Beach Dr., Miami, FL 33140. PRBD Contribution # PRBD-2016-08, 21 pp.

RISSO'S DOLPHIN (Grampus griseus):
Western North Atlantic Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE
Risso's dolphins are distributed worldwide in tropical and temperate seas (Jefferson et al. 2008, 2014), and in the Northwest Atlantic occur from Florida to eastern Newfoundland (Leatherwood et al. 1976; Baird and Stacey 1991). Off the northeastern U.S. coast, Risso's dolphins are distributed along the continental shelf edge from Cape Hatteras northward to Georges Bank during spring, summer, and autumn (CETAP 1982; Payne et al. 1984) (Figure 1). In winter, the range is in the mid-Atlantic Bight and extends outward into oceanic waters (Payne et al. 1984). In general, the population occupies the mid-Atlantic continental shelf edge year round, and is rarely seen in the Gulf of Maine (Payne et al. 1984). During 1990, 1991 and 1993, spring/summer surveys conducted along the continental shelf edge and in deeper oceanic waters sighted Risso's dolphins associated with strong bathymetric features, Gulf Stream warm-core rings, and the Gulf Stream north wall (Waring et al. 1992, 1993; Hamazaki 2002). There is no information on stock structure of Risso's dolphin in the western North Atlantic, or to determine if separate stocks exist in the Gulf of Mexico and Atlantic. Thus, it is plausible that the stock could actually contain multiple demographically independent populations that should themselves be stocks, because the current stock spans multiple eco-regions (Longhurst 1998; Spalding et al. 2007). In 2006, a rehabilitated adult male Risso's dolphin stranded and released in the Gulf of Mexico off Florida was tracked via satellite-linked tag to waters off Delaware (Wells et al. 2009). The Gulf of Mexico and Atlantic stocks are currently being treated as two separate stocks.

POPULATION SIZE
The best abundance estimate for Risso’s dolphins is the sum of the estimates from the 2011 surveys—18,250 (CV = 0.46).

Earlier abundance estimates
Please see Appendix IV for a summary of abundance estimates, including earlier estimates and survey descriptions. As recommended in the GAMMS II Workshop Report (Wade and Angliss 1997), estimates older than eight years are deemed unreliable for the determination of the current PBR.

Recent surveys and abundance estimates
An abundance estimate of 15,197 (CV = 0.55) Risso’s dolphins was generated from a shipboard and aerial survey conducted during June–August 2011 (Palka 2012). The aerial portion that contributed to the abundance estimate covered 5,313 km of tracklines that were over waters north of New Jersey from the coastline to the 100-m depth contour, through the U.S. and Canadian Gulf of Maine and up to and including the lower Bay of Fundy. The shipboard portion covered 3,107 km of tracklines that were in waters offshore of central Virginia to Massachusetts.
(waters that were deeper than the 100-m depth contour out to beyond the U.S. EEZ). Both sighting platforms used a double-platform data-collection procedure, which allows estimation of abundance corrected for perception bias of the detected species (Laake and Borchers, 2004). Shipboard data were inspected to determine if there was significant responsive movement to the ship (Palka and Hammond 2001). Because there was evidence of responsive (evasive) movement of this species to the ship, estimation of the abundance was based on Palka and Hammond (2001) and the independent-observer approach assuming full independence (Laake and Borchers 2004), and calculated using the mark-recapture distance sampling option in the computer program Distance (version 6.0, release 2, Thomas et al. 2009).

An abundance estimate of 3,053 (CV = 0.44) Risso’s dolphins was generated from a shipboard survey conducted concurrently (June–August 2011) in waters between central Virginia and central Florida. This shipboard survey included shelf-break and inner continental slope waters deeper than the 50-m depth contour within the U.S. EEZ. The survey employed the double-platform methodology searching with 25×150 “bigeye” binoculars. A total of 4,445 km of tracklines was surveyed, yielding 290 cetacean sightings. The majority of sightings occurred along the continental shelf break with generally lower sighting rates over the continental slope. Estimation of the abundance was based on the independent-observer approach assuming point independence (Laake and Borchers 2004) and calculated using the mark-recapture distance sampling option in the computer program Distance (version 6.0, release 2, Thomas et al. 2009).

Minimum Population Estimate
The minimum population estimate is the lower limit of the two-tailed 60% confidence interval of the log-normally distributed best abundance estimate. This is equivalent to the 20th percentile of the log-normal distribution as specified by Wade and Angliss (1997). The best estimate of abundance for Risso’s dolphins is 18,250 (CV = 0.46), obtained from the 2011 surveys. The minimum population estimate for the western North Atlantic Risso’s dolphin is 12,619.

Current Population Trend
A trend analysis has not been conducted for this stock. The statistical power to detect a trend in abundance for this stock is poor due to the relatively imprecise abundance estimates and long survey interval. For example, the power to detect a precipitous decline in abundance (i.e., 50% decrease in 15 years) with estimates of low precision (e.g., CV > 0.30) remains below 80% (alpha = 0.30) unless surveys are conducted on an annual basis (Taylor et al. 2007).

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES
Current and maximum net productivity rates are unknown for this stock. For purposes of this assessment, the maximum net productivity rate was assumed to be 0.04. This value is based on theoretical modeling showing that cetacean populations may not grow at rates much greater than 4% given the constraints of their reproductive life history (Barlow et al. 1995).

POTENTIAL BIOLOGICAL REMOVAL
Potential Biological Removal (PBR) is the product of minimum population size, one-half the maximum productivity rate, and a recovery factor (MMPA Sec. 3. 16 U.S.C. 1362; Wade and Angliss 1997). The minimum population size is 12,619. The maximum productivity rate is 0.04, the default value for cetaceans (Barlow et al. 1995). The recovery factor is 0.5, the default value for stocks of unknown status relative to OSP, and the CV of the average mortality estimate is less than 0.3 (Wade and Angliss 1997). PBR for the western North Atlantic stock of
Risso’s dolphin is 126.

**ANNUAL HUMAN-CAUSED MORTALITY**

Total annual estimated average fishery-related mortality or serious injury to this stock during 2010–2014 was 53.6 Risso’s dolphins, derived from 2 components: 1) 53 estimated mortalities in observed fisheries (CV = 0.28; Table 2) and 2) 0.6 from average 2010–2014 non-fishery related, human interaction stranding mortalities (NOAA National Marine Mammal Health and Stranding Response Database, accessed 08 October 2015).

**Fishery Information**

Detailed fishery information is reported in Appendix III.

**Earlier Interactions**

One Risso’s dolphin mortality was observed in the mid-Atlantic midwater trawl fishery in 2008. No bycatch estimate was developed, so the 2008 average annual serious injury and mortality attributed to the mid-Atlantic midwater trawl was calculated as a minimum value of 1 animal.

Historically, fishery interactions have been documented with Risso’s dolphins in squid and mackerel trawl activities (1977–1991), the pelagic drift gillnet fishery (1989–1998), the pelagic pair trawl fishery (1992), and the mid-Atlantic gillnet fishery (2007). See Appendix V for more information on historical takes.

**Pelagic Longline**

Pelagic longline bycatch estimates of Risso’s dolphins for 2010–2014 are documented in Garrison and Stokes (2012a, 2012b, 2013, 2014, 2016). Most of the estimated marine mammal bycatch was from U.S. Atlantic EEZ waters between South Carolina and Cape Cod. There is a high likelihood that dolphins released alive with ingested gear or gear wrapped around appendages will not survive (Wells et al. 2008). See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

**Northeast Bottom Trawl**

One Risso’s dolphin was observed taken in northeast bottom trawl fisheries in 2010 and one in 2014 (Table 2). Annual Risso’s dolphin mortalities were estimated using annual stratified ratio-estimator methods (Lyssikatos 2015). See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

**Mid-Atlantic Bottom Trawl**

Risso’s dolphins have been observed taken in mid-Atlantic bottom trawl fisheries (Table 2). No seriously injured Risso’s dolphins have been observed in this fishery. It was discovered in 2010 that a small segment of the mid-Atlantic bottom trawl fleet was equipping fishing nets with acoustic deterrent devices (i.e., pingers). To the extent possible, the use of pingers on bottom trawl gear has been taken into account when estimating bycatch mortality of Risso’s dolphins (methodology is detailed in Lyssikatos 2015). Annual Risso’s dolphin mortalities were estimated using annual stratified ratio-estimator methods (Lyssikatos 2015). See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

**Northeast Sink Gillnet**

In the northeast sink gillnet fishery, Risso’s dolphin interactions have historically been rare, but in 2012 and 2013 one animal was observed each year in the waters south of Massachusetts (Hatch and Orphanides 2014, 2015, 2016). See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.
Table 2. Summary of the incidental serious injury and mortality of Risso’s dolphin (*Grampus griseus*) by commercial fishery including the years sampled, the type of data used, the annual observer coverage, the observed mortalities and serious injuries recorded by on-board observers, the estimated annual mortality and serious injury, the combined annual estimates of mortality and serious injury, the estimated CV of the combined estimates and the mean of the combined estimates (CV in parentheses).

 Observer data (Obs. Data) are used to measure bycatch rates and the data are collected within the Northeast Fisheries Observer Program. NEFSC collects landings data (unallocated Dealer Data and Allocated Dealer Data) which are used as a measure of total landings and mandatory Vessel Trip Reports (VTR) (Trip Logbook) are used to determine the spatial distribution of landings and fishing effort. Total landings are used as a measure of total effort for the coastal gillnet fishery.

 The observer coverages for the northeast and mid-Atlantic sink gillnet fishery are ratios based on tons of fish landed. Northeast bottom trawl, mid-Atlantic bottom trawl, northeast mid-water and mid-Atlantic mid-water trawl fishery coverages are ratios based on trips. Total observer coverage reported for gillnet and bottom trawl gear in the years starting in 2010 include samples collected from traditional fisheries observers in addition to fishery at-sea monitors through the Northeast Fisheries Observer Program (NEFOP). For 2010 only the NEFOP observed data were reported in this table, since the at-sea monitoring program just started in May 2010. Both at-sea monitor and traditional fisheries observer data were used for 2011 and onwards.

 Estimates can include data pooled across years, so years without observed SI or Mortality may still have an estimated value.

 Fishery related bycatch rates were estimated using an annual stratified ratio-estimator.

Other Mortality

From 2010 to 2014, 30 Risso’s dolphin strandings were recorded along the U.S. Atlantic coast (NOAA National Marine Mammal Health and Stranding Response Database unpublished data, accessed 08 October 2015). Five animals had indications of human interaction, 2 of which were fishery interactions. Indications of human interaction are not necessarily the cause of death (Table 3).
Table 3. Risso’s dolphin (*Grampus griseus*) reported strandings along the U.S. Atlantic coast and Puerto Rico, 2010–2014.

<sup>a</sup> One animal in 2014 was classified as human interaction due to signs of ear trauma.

<sup>b</sup> One animal in 2014 classified as HI due to plastic ingestion.

<sup>c</sup> One animal in 2010 classified as human interaction due to beach mutilation. Two animals in 2012 showed signs of fishery interaction.

Stranding data probably underestimate the extent of fishery-related mortality and serious injury because all of the marine mammals that die or are seriously injured may not wash ashore, nor will all of those that do wash ashore necessarily show signs of entanglement or other fishery-interaction. Finally, the level of technical expertise among stranding network personnel varies widely as does the ability to recognize signs of fishery interaction.

**STATUS OF STOCK**

Risso’s dolphins are not listed as threatened or endangered under the Endangered Species Act and the Western North Atlantic stock is not considered strategic under the Marine Mammal Protection Act. The 2010–2014 average annual human-related mortality does not exceed PBR. The total U.S. fishery mortality and serious injury for this stock is not less than 10% of the calculated PBR and, therefore, cannot be considered to be insignificant and approaching a zero mortality and serious injury rate. The status of Risso's dolphins relative to OSP in the U.S. Atlantic EEZ is unknown. Population trends for this species have not been investigated.

**REFERENCES CITED**

LONG-FINNED PILOT WHALE (*Globicephala melas melas*): Western North Atlantic Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

There are two species of pilot whales in the western Atlantic—the long-finned pilot whale, *Globicephala melas melas*, and the short-finned pilot whale, *G. macrorhynchus*. These species are difficult to differentiate at sea and cannot be reliably visually identified during either abundance surveys or observations of fishery mortality without high-quality photographs (Rone and Pace 2012); therefore, the ability to separately assess the two species in U.S. Atlantic waters is complex and requires additional information on seasonal spatial distribution. The long-finned pilot whale is distributed from North Carolina to North Africa (and the Mediterranean) and north to Iceland, Greenland and the Barents Sea (Sergeant 1962; Leatherwood *et al.* 1976; Abend 1993; Bloch *et al.* 1993; Abend and Smith 1999). The stock structure of the North Atlantic population is uncertain (ICES 1993; Fullard *et al.* 2000). Morphometric (Bloch and Lastein 1993) and genetic (Siemann 1994; Fullard *et al.* 2000) studies have provided little support for stock separation across the Atlantic (Fullard *et al.* 2000). However, Fullard *et al.* (2000) have proposed a stock structure that is related to sea-surface temperature: 1) a cold-water population west of the Labrador/North Atlantic current, and 2) a warm-water population that extends across the Atlantic in the Gulf Stream.

In U.S. Atlantic waters, pilot whales (*Globicephala* sp.) are distributed principally along the continental shelf edge off the northeastern U.S. coast in winter and early spring (CETAP 1982; Payne and Heinemann 1993; Abend and Smith 1999; Hamazaki 2002). In late spring, pilot whales move onto Georges Bank and into the Gulf of Maine and more northern waters, and remain in these areas through late autumn (CETAP 1982; Payne and Heinemann 1993). Pilot whales tend to occupy areas of high relief or submerged banks. They are also associated with the Gulf Stream wall and thermal fronts along the continental shelf edge (Waring *et al.* 1992). Long-finned and short-finned pilot whales overlap spatially along the mid-Atlantic shelf break between New Jersey and the southern flank of Georges Bank (Payne and Heinemann 1993; Rone and Pace 2012). Long-finned pilot whales have occasionally been observed stranded as far south as South Carolina, and short-finned pilot whales have occasionally been observed stranded as far north as Massachusetts. The latitudinal ranges of the two species therefore remain uncertain, although south of Cape Hatteras, most pilot whale sightings are expected to be short-finned.

---

Figure 1. Distribution of long-finned (open symbols), short-finned (black symbols), and possible mixed (gray symbols; could be either species) pilot whale sightings from NEFSC and SEFSC shipboard and aerial surveys during the summers of 1998, 1999, 2002, 2004, 2006, 2007 and 2011. The inferred distribution of the two species is preliminary and is valid for June-August only. Isobaths are the 100-m, 1,000-m, and 4,000-m depth contours.
pilot whales, while north of ~42°N most pilot whale sightings are expected to be long-finned pilot whales (Figure 1).

POPULATION SIZE
The best available estimate for long-finned pilot whales in the western North Atlantic is 5,636 (CV=0.63; Table 1; Palka 2012). This estimate is from summer 2011 surveys covering waters from central Virginia to the lower Bay of Fundy. It should be noted, however, that these surveys did not include areas of the Scotian Shelf where the highest densities of pilot whales were observed in the summer of 2006, therefore they represent an underestimate of the overall abundance of this stock. Because long-finned and short-finned pilot whales are difficult to distinguish at sea, sightings data are reported as Globicephala sp. These survey data have been combined with an analysis of the spatial distribution of the 2 species based on genetic analyses of biopsy samples to derive separate abundance estimates (Garrison and Rosel 2017).

Earlier estimates
Please see appendix IV for a summary of abundance estimates including earlier estimates and survey descriptions. As recommended in the GAMMS II Workshop Report (Wade and Angliss 1997), estimates older than eight years are deemed unreliable for the determination of the current PBR. Due to changes in survey methodology, these historical data should not be used to make comparisons with more current estimates.

Recent surveys and abundance estimates for Globicephala sp.
An abundance estimate of 11,865 (CV=0.57) Globicephala sp. was generated from aerial and shipboard surveys conducted during June–August 2011 between central Virginia and the lower Bay of Fundy (Palka 2012). The aerial portion covered 6,850 km of tracklines over waters north of New Jersey between the coastline and the 100-m depth contour through the U.S. and Canadian Gulf of Maine, and up to and including the lower Bay of Fundy. Pilot whales were not observed during the aerial portion of the survey. The shipboard portion covered 3,811 km of tracklines between central Virginia and Massachusetts in waters deeper than the 100-m depth contour out to beyond the U.S. Exclusive Economic Zone (EEZ). Both sighting platforms used a double-platform data-collection procedure, which allows estimation of abundance corrected for perception bias of the detected species (Laake and Borchers 2004). Estimation of the abundance was based on the independent-observer approach assuming point independence (Laake and Borchers 2004) and calculated using the mark-recapture distance sampling option in the computer program Distance (version 6.0, release 2, Thomas et al. 2009). The vessel portion of this survey included habitats where both short-finned and long-finned pilot whales occur. A logistic regression (see next section) was used to estimate the abundance of long-finned pilot whales from this survey as 5,636 (CV=0.63).

An abundance estimate of 16,946 (CV=0.43) Globicephala sp. was generated from a shipboard survey conducted concurrently (June–August 2011) in waters between central Virginia and central Florida (Garrison 2016). This shipboard survey included shelf-break and inner continental slope waters deeper than the 50-m depth contour within the U.S. EEZ. The survey employed two independent visual teams searching with 25× bigeye binoculars. A total of 4,445 km of tracklines was surveyed, yielding 290 cetacean sightings. The majority of sightings occurred along the continental shelf break north of Cape Hatteras, North Carolina, with a lower number of sightings over the continental slope in the southern portion of the survey. Estimation of pilot whale abundance was based on the independent-observer approach assuming point independence (Laake and Borchers 2004) and calculated using the mark-recapture distance sampling option in the computer program Distance (version 6.0, release 2, Thomas et al. 2009). This survey included habitats where only short-finned pilot whales are expected to occur.

Spatial Distribution and Abundance Estimates for Globicephala melas
Biopsy samples from pilot whales were collected during summer months (June–August) from South Carolina to the southern flank of Georges Bank between 1998 and 2007. These samples were identified to species using genetic analysis of mitochondrial DNA sequences. A portion of the mtDNA genome was sequenced from each biopsy sample collected in the field, and genetic species identification was performed through phylogenetic reconstruction of the haplotypes. Stranded specimens that were morphologically identified to species were used to assign clades in the phylogeny to species and thereby identify all samples. The probability of a sample being from a long-finned (or short-finned) pilot whale was evaluated as a function of sea-surface temperature and water depth using logistic regression. This analysis indicated that the probability of a sample coming from a long-finned pilot whale was near 1 at water temperatures <22°C, and near 0 at temperatures >25°C. The probability of a long-finned pilot whale also decreased with increasing water depth. Spatially, during summer months, this regression model predicts that all pilot whales observed in offshore waters near the Gulf Stream are most likely short-finned pilot whales. The area of overlap between the 2 species occurs primarily along the shelf break off the coast of New Jersey between 38°N and
40°N latitude (Garrison and Rosel 2017). This model was used to partition the abundance estimates from surveys conducted during the summer of 2011. The sightings from the southeast shipboard survey covering waters from Florida to central Virginia were predicted to consist entirely of short-finned pilot whales. The aerial portion of the northeast surveys covered the Gulf of Maine and the Bay of Fundy and surveys where the model predicted that only long-finned pilot whales would occur, but no pilot whales were observed. The vessel portion of the northeast survey recorded a mix of both species along the shelf break, and the sightings in offshore waters near the Gulf Stream were predicted to consist predominantly of short-finned pilot whales (Garrison and Rosel 2017). The abundance estimate for long-finned pilot whales from the northeast summer 2011 vessel survey was 5,636 (CV=0.63; Palka 2012). The summer 2011 aerial survey of the Gulf of Maine to the Bay of Fundy did not include areas of the Scotian Shelf where the highest densities of pilot whales were observed in the summer of 2006, therefore the 2011 summer surveys are an underestimate of the overall abundance of this stock.

Table 1. Summary of recent abundance estimates for the western North Atlantic long-finned pilot whale (*Globicephala melas melas*) by month, year, and area covered during each abundance survey, and resulting abundance estimate ($N_{best}$) and coefficient of variation (CV).

Minimum Population Estimate

The minimum population estimate is the lower limit of the two-tailed 60% confidence interval of the log-normally distributed best abundance estimate. This is equivalent to the 20th percentile of the log-normal distribution as specified by Wade and Angliss (1997). The best estimate of abundance for western North Atlantic long-finned pilot whales is 5,636 animals (CV=0.63). The minimum population estimate for long-finned pilot whales is 3,464.

Current Population Trend

A trend analysis has not been conducted for this stock. There are 2 abundance estimates for *Globicephala* spp. from summer 1998 (14,909; CV=0.26) and summer 2004 surveys (31,139; CV=0.27), and 1 abundance estimate of *G. melas* from summer 2011 surveys (5,636; CV=0.63). Because the 1998 and 2004 surveys did not derive separate abundance estimates for each pilot whale species, comparisons to the 2011 estimate are inappropriate.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Current and maximum net productivity rates are unknown for this stock. For purposes of this assessment, the maximum net productivity rate was assumed to be 0.04. This value is based on theoretical modeling showing that cetacean populations may not grow at rates much greater than 4% given the constraints of their reproductive life history (Barlow et al. 1995).

POTENTIAL BIOLOGICAL REMOVAL

Potential Biological Removal (PBR) is the product of minimum population size, one-half the maximum productivity rate, and a “recovery” factor (MMPA Sec. 3. 16 U.S.C. 1362; Wade and Angliss 1997). The minimum population size for long-finned pilot whales is 3,464. The maximum productivity rate is 0.04, the default value for cetaceans. The “recovery” factor is 0.5 because this stock is of unknown status relative to optimum sustainable population (OSP) and the CV of the average mortality estimate is less than 0.3 (Wade and Angliss 1997). PBR for the western North Atlantic long-finned pilot whale is 35.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Total annual observed average fishery-related mortality or serious injury during 2010–2014 was 38 for long-finned pilot whales (CV=0.15; see Table 2). In bottom trawls and mid-water trawls and in the gillnet fisheries, mortalities were more generally observed north of 40°N latitude and in areas expected to have only long-finned pilot whales. Takes in these fisheries were therefore attributed to the long-finned pilot whales. Takes in the pelagic longline fishery were partitioned according to a logistic regression model (Garrison and Rosel 2017).

Fishery Information

The commercial fisheries that could potentially interact with this stock in the Atlantic Ocean are the Category I northeast sink gillnet and the Atlantic Ocean, Caribbean, Gulf of Mexico large pelagics longline fisheries; and the
Category II northeast bottom trawl and northeast mid-water trawl (including pair trawl) fisheries. Detailed fishery information is reported in Appendix III.

Earlier Interactions
Historically, fishery interactions have been documented with pilot whales in the Atlantic pelagic drift gillnet fishery, Atlantic tuna pair trawl and tuna purse seine fisheries, northeast and mid-Atlantic gillnet fisheries, northeast and mid-Atlantic bottom trawl fisheries, northeast midwater trawl fishery, and the pelagic longline fishery. See Appendix V for more information on historical takes.

Northeast Sink Gillnet
One pilot whale was caught in this fishery in 2010. According to modeled species distribution, this whale was a long-finned pilot whale. See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

Longline
Most of the estimated marine mammal bycatch in the U.S. pelagic longline fishery was recorded in U.S. Atlantic EEZ waters between South Carolina and Cape Cod (Garrison 2007). During 2010–2013, all observed interactions and estimated bycatch in the pelagic longline fishery was assigned to the short-finned pilot whale stock because the observed interactions all occurred at times and locations where available data indicated that long-finned pilot whales were very unlikely to occur. Specifically, the highest bycatch rates of undifferentiated pilot whales were observed during September–November along the mid-Atlantic coast (south of 40°N; Garrison 2007), and biopsy data collected in this area during October–November 2011 indicated that only short-finned pilot whales occurred in this region (Garrison and Rosel 2017). Similarly, all genetic data collected from interactions in the pelagic longline fishery have indicated interactions with short-finned pilot whales. However, during 2014, 4 pilot whale interactions (all serious injuries) occurred along the southern flank of Georges Bank. No samples were collected from these animals. Therefore, the logistic regression model (described above in ‘Spatial Distribution and Abundance Estimates for Globicephala melas’) was applied to estimate the probability that these 2014 interactions were from short-finned vs. long-finned pilot whales (Garrison and Rosel 2017). Due to high water temperatures (approximately 25°C) along the southern flank of Georges Bank at the time of the observed takes, these interactions were estimated to have a >80% probability of coming from short-finned pilot whales. The estimated probability was used to apportion the estimated serious injury and mortality from 2014 in the pelagic longline fishery between the short-finned and long-finned pilot whale stocks. The estimated serious injury and mortality for the short-finned pilot whale was 233 (CV=0.24), and that for long-finned pilot whales was 9.6 (CV=0.43; Garrison and Stokes 2016). See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

Northeast Bottom Trawl
In addition to takes observed by fisheries observers, the Marine Mammal Authorization Program (MMAP) (http://www.nmfs.noaa.gov/pr/interactions/mmap/) included 2 self-reported incidental takes (mortalities) in trawl gear off Maine and Rhode Island during 2011. Self-reported takes were not used in the estimation process and are not reported in Table 2. Fishery-related bycatch rates for years 2010–2014 were estimated using an annual stratified ratio-estimator (Lyssikatos 2015). These mortality estimates replace the 2008–2011 annual estimates reported in the 2013 stock assessment report that were generated using a different method described in Rossman (2010). See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

Northeast Mid-Water Trawl (Including Pair Trawl)
In September 2011, one pilot whale was taken in the northeast mid-water trawl fishery on the northern flank of Georges Bank. Another pilot whale was taken in a mid-water trawl in 2012. Three were taken in 2013 near the western edge of Georges Bank. Four were taken in 2014. Using model-based predictions and at-sea identification, these takes have all been assigned as long-finned pilot whales. Due to small sample sizes, the ratio method was used to estimate the bycatch rate (observed takes per observed hours the gear was in the water) for each year, where the paired and single northeast mid-water trawls were pooled and only hauls that targeted herring or mackerel were used. The VTR herring and mackerel data were used to estimate the total effort (NMFS unpublished data). Estimated annual fishery-related mortalities were 0 in 2010 (Table 2). Expanded estimates of fishery mortality for 2011-2014 are not available, and so for those years the raw number is provided. See Table 2 for bycatch estimates
and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

**CANADA**

Unknown numbers of long-finned pilot whales have been taken in Newfoundland, Labrador, and Bay of Fundy groundfish gillnets; Atlantic Canada and Greenland salmon gillnets; and Atlantic Canada cod traps (Read 1994).

**Table 2. Summary of the incidental mortality and serious injury of long-finned pilot whales (Globicephala melas melas.) by commercial fishery including the years sampled (Years), the type of data used (Data Type), the annual observer coverage (Observer Coverage), the observed mortalities and serious injuries recorded by on-board observers, the estimated annual mortality and serious injury, the combined annual estimates of mortality and serious injury (Estimated Combined Mortality), the estimated CV of the combined estimates (Est. CVs) and the mean of the combined estimates (CV in parentheses). These are minimum observed counts as expanded estimates are not available.**

a Observer data (Obs. Data) are used to measure bycatch rates and the data are collected within the Northeast Fisheries Observer Program (NEFOP). NEFSC collects landings data (unallocated Dealer Data and Allocated Dealer Data) which are used as a measure of total landings and mandatory Vessel Trip Reports (VTR) (Trip Logbook) are used to determine the spatial distribution of landings and fishing effort. Total landings are used as a measure of total effort for the coastal gillnet fishery.

b The observer coverages for the northeast sink gillnet fishery are ratios based on tons of fish landed. Northeast bottom trawl and northeast mid-water trawl fishery coverages are ratios based on trips. Total observer coverage reported for gillnet and bottom trawl gear in the years starting in 2010 include samples collected from traditional fisheries observers in addition to fishery at-sea monitors through the Northeast Fisheries Observer Program (NEFOP). For 2010 only the NEFOP observed data were reported in this table, since the at-sea monitoring program just started in May 2010. Both at-sea monitor and traditional fisheries observer data were used for 2011 and onwards.

c Expanded estimates for 2010–2014 are not available for this fishery.

**Other Mortality**

Pilot whales have a propensity to mass strand throughout their range, but the role of human activity in these events is unknown. From 2010 to 2014, 27 long-finned pilot whales (Globicephala melas melas), and 5 pilot whales not specified to the species level (Globicephala sp.) were reported stranded between Maine and Florida, including the EEZ (Table 3).

Long-finned pilot whales have been reported stranded as far south as Florida, where 2 long-finned pilot whales
were reported stranded in November 1998, though their flukes had been apparently cut off, so it is unclear where these animals actually may have died. One additional long-finned pilot whale stranded in South Carolina in 2003, though the confidence in the species identification at the time was only moderate. A genetic sample from this animal has subsequently been sequenced and mitochondrial DNA analysis supports the long-finned pilot whale identification.

During 2010–2014, several human and/or fishery interactions were documented in stranded pilot whales within the U.S. EEZ. Two long-finned pilot whale stranding mortalities in 2011 in Massachusetts were classified as human interaction cases, one due to onlookers trying to refloat the animal, and another with tow rope around the tail most likely tied on postmortem.

### Table 3. Pilot whale Globicephala melas melas [LF] and Globicephala sp. [Sp]) strandings along the Atlantic coast, 2010-2014. Strandings which were not reported to species have been reported as Globicephala sp. The level of technical expertise among stranding network personnel varies, and given the potential difficulty in correctly identifying stranded pilot whales to species, reports to specific species should be viewed with caution.

- Data supplied by Nova Scotia Marine Animal Response Society (pers. comm.). Strandings in 2011 include one mass stranding of 6-8 whales (one of which died) and 2 animals with ropes tied around their tail stocks. Strandings in 2013 include one fishery entanglement (bait net) and one mass stranding of 4 animals.
- One of the 2010 animals released alive.

Stranding data probably underestimate the extent of human and fishery-related mortality and serious injury, particularly for offshore species such as pilot whales, because not all of the whales that die or are seriously injured in human interactions wash ashore, or, if they do, they are not all recovered (Peltier et al. 2012; Wells et al. 2015). Additionally, not all carcasses will show evidence of human interaction, entanglement or other fishery-related interaction due to decomposition, scavenger damage, etc. (Byrd et al. 2014). Finally, the level of technical expertise among stranding network personnel varies widely as does the ability to recognize signs of human interaction.

**HABITAT ISSUES**

A potential human-caused source of mortality is from polychlorinated biphenyls (PCBs) and chlorinated pesticides (DDT, DDE, dieldrin, etc.), moderate levels of which have been found in pilot whale blubber (Taruski et al. 1975; Muir et al. 1988; Weisbrod et al. 2000). Weisbrod et al. (2000) reported that bioaccumulation levels were more similar in whales from the same stranding group than in animals of the same sex or age. Also, high levels of
toxic metals (mercury, lead, cadmium) and selenium were measured in pilot whales harvested in the Faroe Island drive fishery (Nielsen et al. 2000). Similarly, Dam and Bloch (2000) found very high PCB levels in pilot whales in the Faroes. The population effect of the observed levels of such contaminants is unknown.

STATUS OF STOCK

The long-finned pilot whale is not listed as threatened or endangered under the Endangered Species Act, but the western North Atlantic stock is considered strategic under the MMPA because the mean annual human-caused mortality and serious injury exceeds PBR. Total U.S. fishery-related mortality and serious injury for long-finned pilot whales is not less than 10% of the calculated PBR and, therefore, cannot be considered to be insignificant and approaching zero mortality and serious injury rate. The status of this stock relative to OSP in the U.S. Atlantic EEZ is unknown. There are insufficient data to determine the population trends for this stock.

SHORT-FINNED PILOT WHALE (Globicephala macrorhynchus):
Western North Atlantic Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

There are 2 species of pilot whales in the western North Atlantic - the long-finned pilot whale, Globicephala melas melas, and the short-finned pilot whale, G. macrorhynchus. These species are difficult to differentiate at sea and cannot be reliably visually identified during either abundance surveys or observations of fishery mortality without high-quality photographs (Rone and Pace 2012); therefore, the ability to separately assess the 2 species in U.S. Atlantic waters is complex and requires additional information on seasonal spatial distribution. Undifferentiated pilot whales (Globicephala sp.) in the western North Atlantic occur primarily near the continental shelf break ranging from Florida to the Nova Scotia Shelf (Mullin and Fulling 2003). Long-finned and short-finned pilot whales overlap spatially along the mid-Atlantic shelf break between New Jersey and the southern flank of Georges Bank (Payne and Heinemann 1993; Rone and Pace 2012). Long-finned pilot whales have occasionally been observed stranded as far south as South Carolina, and short-finned pilot whales have occasionally been observed stranded as far north as Massachusetts. The latitudinal ranges of the two species therefore remain uncertain, although south of Cape Hatteras, most pilot whale sightings are expected to be short-finned pilot whales, while north of ~42°N most pilot whale sightings are expected to be long-finned pilot whales (Figure 1). In addition, short-finned pilot whales are documented along the continental shelf and continental slope in the northern Gulf of Mexico (Hansen et al. 1996; Mullin and Hoggard 2000; Mullin and Fulling 2003), and they are also known from the wider Caribbean. A May 2011 mass stranding of 23 short-finned pilot whales in the Florida Keys has been considered to be Gulf of Mexico stock whales based on stranding location, yet two tagged and released individuals from this stranding travelled directly into the Atlantic (Wells et al. 2013). Studies are currently being conducted at the Southeast Fisheries Science Center to evaluate genetic population structure in short-finned pilot whales. Pending these results, the Globicephala macrorhynchus population occupying U.S. Atlantic waters is considered separate from both the northern Gulf of Mexico stock and short-finned pilot whales occupying

Figure 1. Distribution of long-finned (open symbols), short-finned (black symbols), and possibly mixed (gray symbols; could be either species) pilot whale sightings from NEFSC and SEFSC shipboard and aerial surveys during the summers of 1998, 1999, 2002, 2004, 2006, 2007 and 2011. The inferred distribution of the two species is preliminary and is valid for June-August only. Isobaths are the 100-m, 1,000-m, and 4,000-m depth contours.
Caribbean waters.

**POPULATION SIZE**

The best available estimate for short-finned pilot whales in the western North Atlantic is 21,515 (CV=0.37; Table 1; Palka 2012; Garrison 2016). This estimate is from summer 2011 surveys covering waters from central Florida to the lower Bay of Fundy. Sightings from vessel and aerial surveys were strongly concentrated along the continental shelf break; however, pilot whales were also observed over the continental slope in waters associated with the Gulf Stream (Figure 1). The best available abundance estimates are from aerial and shipboard surveys conducted during the summer of 2011 because these are the most recent surveys covering the full range of pilot whales in U.S. Atlantic waters. Because long-finned and short-finned pilot whales are difficult to distinguish at sea, sightings data are reported as *Globicephala sp.* These survey data have been combined with an analysis of the spatial distribution of the 2 species based on genetic analyses of biopsy samples to derive separate abundance estimates (Garrison and Rosel 2017).

**Earlier Estimates**

Please see Appendix IV for a summary of abundance estimates including earlier estimates and survey descriptions. Due to changes in survey methodology, these historical data should not be used to make comparisons with more current estimates. In addition, as recommended in the GAMMS II Workshop Report (Wade and Angliss 1997), estimates older than 8 years are deemed unreliable for the determination of a current PBR.

**Recent surveys and abundance estimates for *Globicephala sp.***

An abundance estimate of 11,865 (CV=0.57) *Globicephala sp.* was generated from aerial and shipboard surveys conducted during June–August 2011 between central Virginia and the lower Bay of Fundy (Palka 2012). The aerial portion covered 6,850 km of trackline over waters north of New Jersey between the coastline and the 100-m depth contour through the U.S. and Canadian Gulf of Maine, and up to and including the lower Bay of Fundy. Pilot whales were not observed during the aerial portion of the survey. The shipboard portion covered 3,811 km of trackline between central Virginia and Massachusetts in waters deeper than the 100-m depth contour out to beyond the U.S. Exclusive Economic Zone (EEZ). Both sighting platforms used a double-platform data collection procedure, which allows estimation of abundance corrected for perception bias of the detected species (Laake and Borchers 2004). Estimation of the abundance was based on the independent observer approach assuming point independence (Laake and Borchers 2004) and calculated using the mark-recapture distance sampling option in the computer program Distance (version 6.0, release 2, Thomas *et al.* 2009). The vessel portion of this survey included habitats where both short-finned and long-finned pilot whales occur. A logistic regression (see next section) was used to estimate the abundance of short-finned pilot whales from this survey as 4,569 (CV=0.57).

An abundance estimate of 16,946 (CV=0.43) *Globicephala sp.* was generated from a shipboard survey conducted concurrently (June–August 2011) in waters between central Virginia and central Florida (Garrison 2016). This shipboard survey included shelf-break and inner continental slope waters deeper than the 50-m depth contour within the U.S. EEZ. The survey employed two independent visual teams searching with 25x150 “bigeye” binoculars. A total of 4,445 km of trackline was surveyed, yielding 290 cetacean sightings. The majority of sightings occurred along the continental shelf break north of Cape Hatteras, North Carolina, with a lower number of sightings over the continental slope in the southern portion of the survey. Estimation of pilot whale abundance was based on the independent observer approach assuming point independence (Laake and Borchers 2004) and calculated using the mark-recapture distance sampling option in the computer program Distance (version 6.0, release 2, Thomas *et al.* 2009). This survey included habitats that are expected to exclusively contain short-finned pilot whales.

**Spatial Distribution and Abundance Estimates for *Globicephala macrorhynchus***

Pilot whale biopsy samples were collected during summer months (June–August) from South Carolina to the southern flank of Georges Bank between 1998 and 2007. These samples were identified to species using genetic analysis of mitochondrial DNA sequences. A portion of the mtDNA genome was sequenced from each biopsy sample collected in the field, and genetic species identification was performed through phylogenetic reconstruction of the haplotypes. Samples from stranded specimens that were morphologically identified to species were used to assign clades in the phylogeny to species and thereby identify all survey samples. The probability of a sample being from a short-finned (or long-finned) pilot whale was evaluated as a function of sea surface temperature and water depth using logistic regression. This analysis indicated that the probability of a sample coming from a short-finned pilot whale was near 0 at water temperatures <22°C, and near 1 at temperatures >25°C. The probability of a short-finned pilot whale also increased with increasing water depth. Spatially, during summer months, this regression
model predicts that all pilot whales observed in offshore waters near the Gulf Stream are most likely short-finned pilot whales. The area of overlap between the 2 species occurs primarily along the shelf break off the coast of New Jersey between 38°N and 40°N latitude (Garrison and Rosel 2017). This model was used to partition the abundance estimates from surveys conducted during the summer of 2011. The sightings from the southeast shipboard survey covering waters from Florida to central Virginia were predicted to consist entirely of short-finned pilot whales. The aerial portion of the northeast surveys covered the Gulf of Maine and the Bay of Fundy where the model predicted that only long-finned pilot whales would occur, but no pilot whales were observed. The vessel portion of the northeast survey included waters along the shelf break and waters further offshore extending to the U.S. EEZ. Pilot whales were observed in both areas during the survey. Along the shelf break, the model predicted a mixture of both species, but the sightings in offshore waters near the Gulf Stream were predicted to consist predominantly of short-finned pilot whales (Garrison and Rosel 2017). The best abundance estimate for short-finned pilot whales is thus the sum of the southeast survey estimate (16,946; CV=0.43) and the estimated number of short-finned pilot whales from the northeast vessel survey (4,569; CV=0.57). The best available abundance estimate is thus 21,515 (CV=0.37).

Table 1. Summary of recent abundance estimates for the western North Atlantic short-finned pilot whale (Globicephala macrorhynchus) by month, year, and area covered during each abundance survey, and resulting abundance estimate (Nbest) and coefficient of variation (CV).

Minimum Population Estimate
The minimum population estimate is the lower limit of the two-tailed 60% confidence interval of the log-normally distributed best abundance estimate. This is equivalent to the 20th percentile of the log-normal distribution as specified by Wade and Angliss (1997). The best estimate of abundance for western North Atlantic Globicephala macrorhynchus is 21,515 animals (CV=0.37). The minimum population estimate is 15,913.

Current Population Trend
A trend analysis has not been conducted for this stock. There are 2 abundance estimates for Globicephala spp. from summer 1998 (14,909; CV=0.26) and summer 2004 surveys (31,139; CV=0.27), and 1 abundance estimate of G. macrorhynchus from summer 2011 surveys (21,515; CV=0.37). Because the 1998 and 2004 surveys did not derive separate abundance estimates for each pilot whale species, comparisons to the 2011 estimate are inappropriate.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES
Current and maximum net productivity rates are unknown for this stock. For purposes of this assessment, the maximum net productivity rate was assumed to be 0.04. This value is based on theoretical modeling showing that cetacean populations may not grow at rates much greater than 4% given the constraints of their reproductive life history (Barlow et al. 1995).

POTENTIAL BIOLOGICAL REMOVAL
Potential Biological Removal (PBR) is the product of minimum population size, one-half the maximum productivity rate, and a “recovery” factor (MMPA Sec. 3. 16 U.S.C. 1362; Wade and Angliss 1997). The minimum population size for short-finned pilot whales is 15,913. The maximum productivity rate is 0.04, the default value for cetaceans. The “recovery” factor is 0.5 because the stock's status relative to optimum sustainable population (OSP) is unknown and the CV of the average mortality estimate is less than 0.3 (Wade and Angliss 1997). PBR for the western North Atlantic short-finned pilot whale is 159.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY
The estimated mean annual fishery-related mortality and serious injury during 2010–2014 due to the pelagic longline fishery was 192 short-finned pilot whales (CV=0.17; Table 2). The total annual fishery-related mortality and serious injury for this stock during 2010–2014 is unknown because in addition to observed takes in the pelagic
longline fishery, there was a self-reported take in the unobserved hook and line fishery in 2013.

During 2010–2013, all observed interactions and estimated bycatch was assigned to the short-finned pilot whale stock because the observed interactions all occurred at times and locations where available data indicated that long-finned pilot whales were very unlikely to occur. Specifically, the highest bycatch rates of undifferentiated pilot whales were observed during September–November along the mid-Atlantic coast (south of 40°N; Garrison 2007), and biopsy data collected in this area during October–November 2011 indicated that only short-finned pilot whales occurred in this region (Garrison and Rosel 2017). Similarly, all genetic data collected from interactions in the pelagic longline fishery have indicated interactions with short-finned pilot whales. However, during 2014, 4 pilot whale interactions (all serious injuries) occurred along the southern flank of Georges Bank. No samples were collected from these animals. Therefore, the logistic regression model (described above in 'Spatial Distribution and Abundance Estimates for *Globicephala macrorhynchus*') was applied to estimate the probability that these 2014 interactions were from short-finned vs. long-finned pilot whales (Garrison and Rosel 2017). Due to high water temperatures (approximately 25°C) along the southern flank of Georges Bank at the time of the observed takes, these interactions were estimated to have a >80% probability of coming from short-finned pilot whales. The estimated probability was used to apportion the estimated serious injury and mortality from 2014 in the pelagic longline fishery between the short-finned and long-finned pilot whale stocks. The estimated serious injury and mortality for the short-finned pilot whale was 233 (CV=0.24), and that for long-finned pilot whales was 9.6 (CV=0.43; Garrison and Stokes 2016).

In bottom trawl, mid-water trawl, and gillnet fisheries, mortalities were observed north of 40°N latitude and in areas expected to have only long-finned pilot whales. Takes and bycatch estimates for these fisheries are therefore attributed to the long-finned pilot whale stock.

**Fishery Information**

The commercial fisheries that interact, or that potentially could interact, with this stock in the Atlantic Ocean are the Category I Atlantic Ocean, Caribbean, Gulf of Mexico large pelagics longline and Atlantic Highly Migratory Species longline fisheries; and the Category III U.S. Atlantic tuna purse seine and Atlantic Ocean, Gulf of Mexico, Caribbean commercial passenger fishing vessel (hook and line) fisheries. All recent gillnet and trawl interactions have been assigned to long-finned pilot whales using model-based predictions. Detailed fishery information is reported in Appendix III.

**Earlier Interactions**

See Appendix V for information on historical takes.

**Longline**

The large pelagics longline fishery operates in the U.S. Atlantic (including Caribbean) and Gulf of Mexico EEZ, and pelagic swordfish, tunas and billfish are the target species. The estimated annual average serious injury and mortality attributable to the Atlantic Ocean large pelagics longline fishery for the 5-year period from 2010 to 2014 was 192 short-finned pilot whales (CV=0.17; Table 2). During 2010–2014, 69 serious injuries were observed in the following fishing areas of the North Atlantic: Florida East Coast, Mid-Atlantic Bight, Northeast Coastal, and South Atlantic Bight. During 2010–2014, 1 mortality was observed (in 2011) in the Mid-Atlantic Bight fishing area (Garrison and Stokes 2012a,b; 2013; 2014; 2016).

Most of the estimated marine mammal bycatch in the U.S. pelagic longline fishery was recorded in U.S. Atlantic EEZ waters between South Carolina and Cape Cod (Garrison 2007). January–March observed bycatch was concentrated on the continental shelf edge northeast of Cape Hatteras, North Carolina. During April–June, bycatch was recorded in this area as well as north of Hydrographer Canyon in water over 1,000 fathoms (1830 m) deep. During the July–September period, observed takes occurred on the continental shelf edge east of Cape Charles, Virginia, and on Block Canyon slope in over 1,000 fathoms of water. October–December bycatch occurred between the 20- and 50-fathom (37- and 92-m) isobaths between Barnegat Bay, New Jersey and Cape Hatteras, North Carolina.

The Atlantic Highly Migratory Species longline fishery operates outside the U.S. EEZ. No takes of short-finned pilot whales within high seas waters of the Atlantic Ocean have been observed or reported thus far.

See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical estimates of annual mortality and serious injury.
During 2010–2014, there was 1 self-reported take (in 2013) in which a short-finned pilot whale was hooked and entangled by a charterboat fisherman. The animal was released alive but considered seriously injured (Maze-Foley and Garrison 2016).

Other Mortality

Pilot whales have a propensity to mass strand throughout their range, but the role of human activity in these events is unknown. Between 2 and 168 pilot whales have stranded annually, either individually or in groups, along the eastern U.S. seaboard since 1980 (NMFS 1993, stranding databases maintained by NMFS NER, NEFSC and SEFSC). From 2010–2014, 45 short-finned pilot whales (Globicephala macrorhynchus) and 6 pilot whales not specified to the species level (Globicephala sp.) were reported stranded between Massachusetts and Florida, including the EEZ (Table 3).

Table 2. Summary of the incidental mortality and serious injury of short-finned pilot whales (Globicephala macrorhynchus) by the pelagic longline commercial fishery including the years sampled (Years), the number of vessels active within the fishery (Vessels), the type of data used (Data Type), the annual observer coverage (Observer Coverage), the annual observed serious injury and mortality recorded by on-board observers, the annual estimated serious injury and mortality, the combined annual estimates of serious injury and mortality (Estimated Combined Mortality), the estimated CV of the combined annual mortality estimates (Est. CVs) and the mean of the combined mortality estimates (CV in parentheses).

* Proportion of sets observed

Hook and Line

During 2010–2014, there was 1 self-reported take (in 2013) in which a short-finned pilot whale was hooked and entangled by a charterboat fisherman. The animal was released alive but considered seriously injured (Maze-Foley and Garrison 2016).

Other Mortality

Pilot whales have a propensity to mass strand throughout their range, but the role of human activity in these events is unknown. Between 2 and 168 pilot whales have stranded annually, either individually or in groups, along the eastern U.S. seaboard since 1980 (NMFS 1993, stranding databases maintained by NMFS NER, NEFSC and SEFSC). From 2010–2014, 45 short-finned pilot whales (Globicephala macrorhynchus) and 6 pilot whales not specified to the species level (Globicephala sp.) were reported stranded between Massachusetts and Florida, including the EEZ (Table 3).

Table 3. Short-finned pilot whale (Globicephala macrorhynchus [SF] and Globicephala sp. [Sp]) strandings along the Atlantic coast, 2010–2014. Strandings which were not reported to species have been reported as Globicephala sp. The level of technical expertise among stranding network personnel varies, and given the potential difficulty in correctly identifying stranded pilot whales to species, reports to specific species should be viewed with caution.

99
Short-finned pilot whales strandings (*Globicephala macrorhynchus*) have been reported as far north as Block Island, Rhode Island (2001), and Cape Cod, Massachusetts (2011), although the majority of the strandings occurred from North Carolina southward (Table 3).

During 2010–2014, several human interactions, including some that were fishery interactions, were documented in stranded pilot whales along the U.S. Atlantic coast. A short-finned pilot whale stranded in North Carolina in 2010 had evidence of longline interaction. In 2011, a short-finned pilot whale in North Carolina was classified as a fishery interaction and a short-finned pilot whale in New Jersey was found with a healed but abscessed bullet wound. In 2012, 3 short-finned pilot whales had evidence of fishery interactions, 2 of them in South Carolina and 1 in North Carolina. During 2013–2014, no evidence of human interactions was documented for stranded pilot whales.

Stranding data probably underestimate the extent of human and fishery-related mortality and serious injury, particularly for offshore species such as pilot whales, because not all of the whales that die or are seriously injured in human interactions wash ashore, or, if they do, they are not all recovered (Peltier *et al.* 2012; Wells *et al.* 2015). Additionally, not all carcasses will show evidence of human interaction, entanglement or other fishery-related interaction due to decomposition, scavenger damage, etc. (Byrd *et al.* 2014). Finally, the level of technical expertise among stranding network personnel varies widely as does the ability to recognize signs of human interaction.

**HABITAT ISSUES**

A potential human-caused source of mortality is from polychlorinated biphenyls (PCBs) and chlorinated pesticides (DDT, DDE, dieldrin, etc.), moderate levels of which have been found in pilot whale blubber (Taruski *et al.* 1975; Muir *et al.* 1988; Weisbrod *et al.* 2000). Weisbrod *et al.* (2000) reported that bioaccumulation levels were more similar in whales from the same stranding group than in animals of the same sex or age. Also, high levels of toxic metals (mercury, lead, cadmium) and selenium were measured in pilot whales harvested in the Faroe Island drive fishery (Nielsen *et al.* 2000). Similarly, Dam and Bloch (2000) found very high PCB levels in pilot whales in the Faroes. The population effect of the observed levels of such contaminants is unknown.

**STATUS OF STOCK**

The short-finned pilot whale is not listed as threatened or endangered under the Endangered Species Act, but the western North Atlantic stock is considered strategic under the MMPA because the mean annual human-caused mortality and serious injury exceeds PBR. Total U.S. fishery-related mortality and serious injury attributed to short-finned pilot whales exceeds 10% of the calculated PBR and therefore cannot be considered to be insignificant and approaching zero mortality and serious injury rate. The status of this stock relative to OSP in the U.S. Atlantic EEZ is unknown. There are insufficient data to determine the population trends for this stock.

ATLANTIC WHITE-SIDED DOLPHIN (*Lagenorhynchus acutus*): Western North Atlantic Stock

**STOCK DEFINITION AND GEOGRAPHIC RANGE**

White-sided dolphins are found in temperate and sub-polar waters of the North Atlantic, primarily in continental shelf waters to the 100-m depth contour. In the western North Atlantic the species inhabits waters from central West Greenland to North Carolina (about 35˚N) and perhaps as far east as 29˚W in the vicinity of the mid-Atlantic Ridge (Evans 1987; Hamazaki 2002; Doksaeter *et al.* 2008; Waring *et al.* 2008). Distribution of sightings, strandings and incidental takes suggest the possible existence of three stock units: Gulf of Maine, Gulf of St. Lawrence and Labrador Sea stocks (Palka *et al.* 1997). Evidence for a separation between the population in the southern Gulf of Maine and the Gulf of St. Lawrence population comes from the reduced density of summer sightings along the Atlantic side of Nova Scotia. This was reported in Gaskin (1992), is evident in Smithsonian stranding records and in Canadian/west Greenland bycatch data (Stenson *et al.* 2011) and was obvious during summer abundance surveys that covered waters from Virginia to the Gulf of St. Lawrence and during the Canadian component of the Trans-North Atlantic Sighting Survey in the summer of 2007 (Lawson and Gosselin 2009, 2011). White-sided dolphins were seen frequently in Gulf of Maine waters and in waters at the mouth of the Gulf of St. Lawrence, but only a relatively few sightings were recorded between these two regions. This trend is less obvious since 2007.

The Gulf of Maine population of white-sided dolphins is most common in continental shelf waters from Hudson Canyon (approximately 39˚N) to Georges Bank, and in the Gulf of Maine and lower Bay of Fundy. Sighting data indicate seasonal shifts in distribution (Northridge *et al.* 1997). During January to May, low numbers of white-sided dolphins are found from Georges Bank to Jeffreys Ledge (off New Hampshire), with even lower numbers south of Georges Bank, as documented by a few strandings collected on beaches of Virginia to South Carolina. From June through September, large numbers of white-sided dolphins are found from Georges Bank to the lower Bay of Fundy. From October to December, white-sided dolphins occur at intermediate densities from southern Georges Bank to southern Gulf of Maine (Payne and Heinemann 1990). Sightings south of Georges Bank, particularly around Hudson Canyon, occur year round but at low densities. The Virginia and North Carolina observations appear to represent the southern extent of the species’ range during the winter months. On 4 May 2008 a stranded 17-year old male white-sided dolphin with severe pulmonary distress and reactive lymphadenopathy stranded in South Carolina (Powell *et al.* 2012). In the absence of additional strandings or sightings, this stranding seems to be an out-of-range anomaly. The seasonal spatial distribution of this species appears to be changing during the last few years. There is evidence for an earlier distributational shift during the 1970s, from primarily offshore waters into the Gulf of Maine, hypothesized to be related to shifts in abundance of pelagic fish stocks resulting from depletion of herring by foreign distant-water fleets (Kenney *et al.* 1986).

Recent stomach-content analysis of both stranded and incidentally caught white-sided dolphins in U.S. waters determined that the predominant prey were silver hake (*Merluccius bilinearis*), spoonarm octopus (*Bathypolyalus*)...
bairdii) and haddock (Melanogrammus aeglefinus). Sand lances (Ammodytes spp.) were only found in the stomach of one stranded white-sided dolphin. Seasonal variation in diet was indicated; pelagic Atlantic herring (Clupea harengus) was the most important prey in summer, but was rare in winter (Craddock et al. 2009).

**POPULATION SIZE**

The best available current abundance estimate for white-sided dolphins in the western North Atlantic stock is 48,819 (CV= 0.61), resulting from a June–August 2011 survey.

**Earlier abundance estimates**

Please see Appendix IV for earlier abundance estimates. As recommended in the GAMMS Workshop Report (Wade and Angliss 1997), estimates older than eight years are deemed unreliable to determine the current PBR.

**Recent surveys and abundance estimates**

An abundance estimate of 48,819 (CV=0.61) white-sided dolphins was generated from a shipboard and aerial survey conducted during June–August 2011 (Palka 2012). The aerial portion that contributed to the abundance estimate covered 5,313 km of tracklines that were over waters north of New Jersey from the coastline to the 100-m depth contour through the U.S. and Canadian Gulf of Maine and up to and including the lower Bay of Fundy. The shipboard portion covered 3,107 km of tracklines that were in waters offshore of central Virginia to Massachusetts (waters that were deeper than the 100-m depth contour out to beyond the U.S. EEZ). Both sighting platforms used a double-platform data-collection procedure, which allows estimation of abundance corrected for perception bias of the detected species (Laake and Borchers, 2004). Estimation of the abundance was based on the independent-observer approach assuming point independence (Laake and Borchers 2004) and calculated using the MRDS option in the computer program Distance (version 6.0, release 2, Thomas et al. 2009).

No white-sided dolphins were detected in the aerial and ship abundance surveys that were conducted concurrently (June-August 2011) in waters between central Virginia and central Florida. This shipboard survey included shelf-break and inner continental slope waters deeper than the 50-m depth contour within the U.S. EEZ. The survey employed the double-platform methodology searching with 25x150 “bigeye” binoculars. A total of 4,445 km of tracklines was surveyed, yielding 290 cetacean sightings.

**Minimum Population Estimate**

The minimum population estimate is the lower limit of the two-tailed 60% confidence interval of the log-normally distributed best abundance estimate. This is equivalent to the 20th percentile of the log-normal distribution as specified by (Wade and Angliss 1997). The best estimate of abundance for the western North Atlantic stock of white-sided dolphins is 48,819 (CV=0.61). The minimum population estimate for these white-sided dolphins is 30,403.

**Current Population Trend**

A trend analysis has not been conducted for this stock. The statistical power to detect a trend in abundance for this stock is poor due to the relatively imprecise abundance estimates and long survey interval. For example, the power to detect a precipitous decline in abundance (i.e., 50% decrease in 15 years) with estimates of low precision (e.g., CV > 0.30) remains below 80% (alpha = 0.30) unless surveys are conducted on an annual basis (Taylor et al. 2007).

**CURRENT AND MAXIMUM NET PRODUCTIVITY RATES**

Current and maximum net productivity rates are unknown for this stock. Life history parameters that could be used to estimate net productivity include: calving interval is 2-3 years; lactation period is 18 months; gestation period is 10–12 months and births occur from May to early August, mainly in June and July; length at birth is 110 cm; length at sexual maturity is 230–240 cm for males, and 201–222 cm for females; age at sexual maturity is 8–9
years for males and 6–8 years for females; mean adult length is 250 cm for males and 224 cm for females (Evans 1987); and maximum reported age for males is 22 years and for females, 27 years (Sergeant et al. 1980).

For purposes of this assessment, the maximum net productivity rate was assumed to be 0.04. This value is based on theoretical modeling showing that cetacean populations may not grow at rates much greater than 4% given the constraints of their reproductive life history (Barlow et al. 1995).

**POTENTIAL BIOLOGICAL REMOVAL**

Potential Biological Removal (PBR) is the product of minimum population size, one-half the maximum productivity rate, and a recovery factor (MMPA Sec. 3. 16 U.S.C. 1362; Wade and Angliss 1997). The minimum population size is 30,403. The maximum productivity rate is 0.04, the default value for cetaceans. The recovery factor is 0.5, the default value for stocks of unknown status relative to OSP, and the CV of the average mortality estimate is less than 0.3 (Wade and Angliss 1997). PBR for the western North Atlantic stock of white-sided dolphin is 304.

**ANNUAL HUMAN- CAUSED MORTALITY AND SERIOUS INJURY**

Total annual estimated average fishery-related mortality or serious injury to this stock during 2010–2014 was 77 (CV=0.2) white-sided dolphins (Table 2).

**Fishery Information**

Detailed fishery information is reported in Appendix III.

**Earlier Interactions**

**U.S. Northeast Sink Gillnet**

Annual white-sided dolphin mortalities were estimated using annual ratio-estimator methods (Table 2; Orphanides 2013; Hatch and Orphanides 2014, 2015, 2016). Recently white-sided dolphin bycatch has occurred mostly in the Gulf of Maine, with a few south of Cape Cod. Bycatch occurred nearly year round, though mostly in the winter and summer. There are large inter-annual differences in the magnitude of the level of bycatch, which may be due to inter-annual differences in the number of white-sided dolphins using the Gulf of Maine, as has been seen in the series of past abundance estimates for this species. See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for long-term bycatch information.

**Northeast Bottom Trawl**

Fishery-related bycatch rates for years 2009–2013 were estimated using an annual stratified ratio-estimator (Lyssikatos 2015). Between 2008 and 2013, all white-sided dolphin bycatch occurred in the Gulf of Maine and Georges Bank eco-regions, primarily during the winter (January–April) season when sea surface temperatures are less than 10° C. See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for long-term bycatch information.

**Mid-Atlantic Bottom Trawl**

Fishery-related bycatch rates were estimated using an annual stratified ratio-estimator (Lyssikatos 2015). See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for long-term bycatch information.
Table 2. Summary of the incidental mortality of North Atlantic stock of white-sided dolphins (*Lagenorhynchus acutus*) by commercial fishery including the years sampled, the type of data used, the annual observer coverage, the serious injuries and mortalities recorded by on-board observers, the estimated annual serious injury and mortality, the estimated CV of the combined annual mortality and the mean annual mortality (CV in parentheses).

a Observer data (Obs. Data), used to measure bycatch rates, are collected within the Northeast Observer Program and At-sea Monitoring Program. NEFSC collects landings data (unallocated Dealer Data or Allocated Dealer Data) which are used as a measure of total landings and mandatory Vessel Trip Reports (VTR) (Trip Logbook) are used to determine the spatial distribution of landings and fishing effort in the sink gillnet, bottom trawl and mid-water trawl fisheries. In addition, the Trip Logbooks are the primary source of the measure of total effort (tow duration) in the mid-water and bottom trawl fisheries.

b Observer coverage is defined as the ratio of observed to total metric tons of fish landed for the gillnet fisheries, and the ratio of observed to total trips for bottom trawl and Mid-Atlantic mid-water trawl (including pair trawl) fisheries. Beginning in May 2010 total observer coverage reported for bottom trawl and gillnet gear includes samples collected from the at-sea monitoring program in addition to traditional observer coverage through the Northeast Fisheries Observer Program (NEFOP).

c After 1998, a weighted bycatch rate was applied to effort from both pingered and non-pingered hauls within the stratum where white-sided dolphins were observed taken. During the years 1997, 1999, 2001, 2002, and 2004, respectively, there were 2, 1, 1, 1, and 1 observed white-sided dolphins taken on pingered trips. No takes were observed on pinger trips during 1995, 1996, 1998, 2000, 2005 through 2007. Three of the 2008 takes were on non-pingered hauls and the fourth take was recorded as pinger condition unknown. Of the six 2010 observed takes, 4 were in pingered nets and 2 in non-pingered nets. Four of the 2011 takes were in pingered nets. The 2012 take was in a non-pingered net. The 2013 take was in a pingered net. In 2010, both observed mortalities were in pingered nets.

**CANADA**

There is little information available that quantifies fishery interactions involving white-sided dolphins in Canadian waters. Two white-sided dolphins were reported caught in groundfish gillnet sets in the Bay of Fundy during 1985 to 1989, and 9 were reported taken in West Greenland between 1964 and 1966 in the now non-operational salmon drift nets (Gaskin 1992). Several (number not specified) were also taken during the 1960s in the now non-operational Newfoundland and Labrador groundfish gillnets. A few (number not specified) were taken in an experimental drift gillnet fishery for salmon off West Greenland which took place from 1965 to 1982 (Read 1994).

Hooker *et al.* (1997) summarized bycatch data from a Canadian fisheries observer program that placed
observers on all foreign fishing vessels operating in Canadian waters, on 25-40% of large Canadian fishing vessels (greater than 100 feet long), and on approximately 5% of smaller Canadian fishing vessels. Bycaught marine mammals were noted as weight in kilos rather than by the numbers of animals caught. Thus the number of individuals was estimated by dividing the total weight per species per trip by the maximum recorded weight of each species. During 1991 through 1996, an estimated 6 white-sided dolphins were observed taken. One animal was from a longline trip south of the Grand Banks (43° 10'N 53° 08'W) in November 1996 and the other 5 were taken in the bottom trawl fishery off Nova Scotia in the Atlantic Ocean; 1 in July 1991, 1 in April 1992, 1 in May 1992, 1 in April 1993, 1 in June 1993 and 0 in 1994 to 1996.

Estimation of small cetacean bycatch for Newfoundland fisheries using data collected during 2001 to 2003 (Benjamins et al. 2007) indicated that, while most of the estimated 862 to 2,228 animals caught were harbor porpoises, a few were white-sided dolphins caught in the Newfoundland nearshore gillnet fishery and offshore monkfish/skate gillnet fisheries.

**Herring Weirs**

Previously only one white-sided dolphin was released alive and unharmed from a herring weir in the Bay of Fundy (A. Westgate, pers. comm.). Due to the formation of a cooperative program between Canadian fishermen and biologists, it is expected that most dolphins and whales will be able to be released alive. Fishery information is available in Appendix III.

**Other Mortality**

**U.S.**

During 2010–2014 there were 130 documented Atlantic white-sided dolphin strandings on the U.S. Atlantic coast (Table 3; NOAA National Marine Mammal Health and Stranding Response Database unpublished data, accessed 08 October 2015). Thirty of these animals were released alive. Human interaction was indicated in 5 records during this period. Of these, one was classified as a fishery interaction.

Mass strandings involving up to a hundred or more animals at one time are common for this species. The causes of these strandings are not known. Because such strandings have been known since antiquity, it could be presumed that recent strandings are a normal condition (Gaskin 1992). It is unknown whether human causes, such as fishery interactions and pollution, have increased the number of strandings. In an analysis of mortality causes of stranded marine mammals on Cape Cod and southeastern Massachusetts between 2000 and 2006, Bogomolni et al. (2010) found 69% (46 of 67) of stranded white-sided dolphins were involved in mass-stranding events with no significant cause determined, and 21% (14 of 67) were classified as disease-related.

Stranding data probably underestimate the extent of fishery-related mortality and serious injury because all of the marine mammals that die or are seriously injured may not wash ashore, nor will all of those that do wash ashore necessarily show signs of entanglement or other fishery-interaction. Finally, the level of technical expertise among stranding network personnel varies widely as does the ability to recognize signs of fishery interaction.

*a* Records of mass strandings in Massachusetts during this period are: March 2010 - 7 animals (one dead calf, 6 adults released alive), 16 animals (5 dead, 11 released alive) and 3 animals (one released alive); April 2010 - 2 animals (released alive); July 2010 - 2 animals (released alive); March 2011 - 4 animals (2 released alive), 2 animals (released alive); April 2013 - 2 animals (one released alive); December 2013 - 3 animals (all released alive).

*b* In 2010, 2 animals in Massachusetts were classified as human interactions, 1 of them a fishery interaction. In 2011, 1 animal in Massachusetts was classified as human interaction due to post-mortem mutilation. In 2014, 1 animal in Massachusetts was classified as human interaction due to attempts by public to return animal to sea. In 2014, 1 animal in Maine was classified as human interaction due to plastics ingestion.

*c* Data supplied by Nova Scotia Marine Animal Response Society (pers. comm.). 2014 data include a mass stranding of 7 animals all released alive and a single animal released alive.

**STATUS OF STOCK**

White-sided dolphins are not listed as threatened or endangered under the Endangered Species Act. The Western North Atlantic stock of white-sided dolphins is not considered strategic under the Marine Mammal Protection Act. The estimated average annual human-related mortality does not exceed PBR but is not less than 10% of the calculated PBR; therefore, it cannot be considered to be insignificant and approaching zero mortality and serious injury rate. The status of white-sided dolphins, relative to OSP, in the U.S. Atlantic EEZ is unknown. A trend analysis has not been conducted for this species.

COMMON DOLPHIN (*Delphinus delphis delphis*): Western North Atlantic Stock

**STOCK DEFINITION AND GEOGRAPHIC RANGE**

The common dolphin (*Delphinus delphis delphis*) may be one of the most widely distributed species of cetaceans, as it is found world-wide in temperate and subtropical seas. In the North Atlantic, common dolphins are commonly found along the shoreline of Massachusetts in mass-stranding events (Bogomolni et al. 2010; Sharp et al. 2014), as well as found over the continental shelf between the 100-m and 2000-m isobaths and over prominent underwater topography and east to the mid-Atlantic Ridge (29°W) (Doksæter et al. 2008; Waring et al. 2008) and are associated with Gulf Stream features (CETAP 1982; Selzer and Payne 1988; Waring et al. 1992; Hamazaki 2002). The species is less common south of Cape Hatteras, although schools have been reported as far south as the Georgia/South Carolina border (32°N) (Jefferson et al. 2009). They have seasonal movements where they are found from Cape Hatteras northeast to Georges Bank (35° to 42°N) during mid-January to May (Hain et al. 1981; CETAP 1982; Payne et al. 1984) though some animals tagged and released after stranding in winters of 2010-2012 used habitat in the Gulf of Maine north to almost 44° (Sharp et al. 2016). Common dolphins move onto Georges Bank, Gulf of Maine, and the Scotian Shelf from mid-summer to autumn. Selzer and Payne (1988) reported very large aggregations (greater than 3,000 animals) on Georges Bank in autumn. Common dolphins were occasionally found in the Gulf of Maine (Selzer and Payne 1988), more often in the last few years (Figure 1). Migration onto the Scotian Shelf and continental shelf off Newfoundland occurs during summer and autumn when water temperatures exceed 11°C (Sergeant et al. 1970; Gowans and Whitehead 1995).

Westgate (2005) tested the proposed one-population-stock model using a molecular analysis of mitochondrial DNA (mtDNA), as well as a morphometric analysis of cranial specimens. Both genetic analysis and skull morphometrics failed to provide evidence (p>0.05) of more than a single population in the western North Atlantic, supporting the proposed one-stock model. However, when western and eastern North Atlantic common dolphin mtDNA and skull morphology were compared, both the cranial and mtDNA results showed evidence of restricted gene flow (p<0.05) indicating that these two areas are not panmictic. Cranial specimens from the two sides of the North Atlantic differed primarily in elements associated with the rostrum. These results suggest that common dolphins in the western North Atlantic are composed of a single panmictic group whereas gene flow between the western and eastern North Atlantic is limited (Westgate 2005, 2007).

**POPULATION SIZE**

The current best abundance estimate for common dolphins off the U.S. Atlantic coast is 70,184 (CV=0.28). This estimate, derived from 2011 shipboard and aerial surveys, is the only current estimate available. This estimate
is substantially lower than the estimate from the previous (2015) SAR. This is because the previous estimate included data from the 2007 TNASS surveys of Canadian waters. For the purposes of this SAR, as recommended in the GAMMS II Workshop Report (Wade and Angliss 1997), estimates older than eight years are deemed unreliable, so this new estimate must not include data from the 2007 TNASS survey. This new estimate should not be interpreted as a decline in abundance of this stock, as previous estimates are not directly comparable.

Earlier estimates
Please see Appendix IV for a summary of abundance estimates, including earlier estimates and survey descriptions. As recommended in the GAMMS II Workshop Report (Wade and Angliss 1997), estimates older than eight years are deemed unreliable to determine a current PBR.

Recent surveys and abundance estimates
An abundance estimate of 67,191 (CV=0.29) common dolphins was generated from a shipboard and aerial survey conducted during June–August 2011 (Palka 2012). The aerial portion that contributed to the estimate covered 5,313 km of tracklines that were over waters north of New Jersey from the coastline to the 100-m depth contour through the U.S. and Canadian Gulf of Maine and up to and including the lower Bay of Fundy. The shipboard portion covered 3,107 km of tracklines between central Virginia and Massachusetts in waters deeper than the 100-m depth contour out to beyond the U.S. EEZ. Both sighting platforms used a double-platform data-collection procedure, which allows estimation of abundance corrected for perception bias of the detected species (Laake and Borchers 2004). Estimation of the abundance was based on the independent-observer approach assuming point independence (Laake and Borchers 2004) and calculated using the MRDS option in the computer program Distance (version 6.0, release 2, Thomas et al. 2009).

An abundance estimate of 2,993 (CV=0.87) common dolphins was generated from a shipboard survey conducted concurrently (June–August 2011) in waters between central Virginia and central Florida. This shipboard survey included shelf-break and inner continental slope waters deeper than the 50-m depth contour within the U.S. EEZ. The survey employed a double-platform visual team procedure searching with 25×150 “bigeye” binoculars. A total of 4,445 km of tracklines was surveyed, yielding 290 cetacean sightings. The majority of sightings occurred along the continental shelf break with generally lower sighting rates over the continental slope. Estimation of the abundance was based on the independent-observer approach assuming point independence (Laake and Borchers 2004) and calculated using the mark-recapture distance sampling option in the computer program Distance (version 6.0, release 2, Thomas et al. 2009).

Minimum Population Estimate
The minimum population estimate is the lower limit of the two-tailed 60% confidence interval of the log-normally distributed best abundance estimate. This is equivalent to the 20th percentile of the log-normal distribution as specified by Wade and Angliss (1997). The best estimate of abundance for common dolphins is 70,184 animals (CV=0.28), derived from the 2011 aerial and shipboard surveys. The minimum population estimate for the western North Atlantic common dolphin is 55,690.

Current Population Trend
A trend analysis has not been conducted for this stock. The statistical power to detect a trend in abundance for this stock is poor due to the relatively imprecise abundance estimates and long survey interval. For example, the power to detect a precipitous decline in abundance (i.e., 50% decrease in 15 years) with estimates of low precision (e.g., CV > 0.30) remains below 80% (alpha = 0.30) unless surveys are conducted on an annual basis (Taylor et al.
CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Current and maximum net productivity rates are unknown for this stock. Life history parameter information that could be used to estimate net productivity are there is a peak in parturition during July and August with an average birth day of 28 July. Gestation lasts about 11.7 months and lactation lasts at least a year. Given these results western North Atlantic female common dolphins are likely on a 2-3 year calving interval. Females become sexually mature earlier (8.3 years and 200 cm) than males (9.5 years and 215 cm) as males continue to increase in size and mass. There is significant sexual dimorphism present with males being on average about 9% larger in body length (Westgate 2005; Westgate and Read 2007).

For purposes of this assessment, the maximum net productivity rate was assumed to be 0.04. This value is based on theoretical modeling showing that cetacean populations may not grow at rates much greater than 4% given the constraints of their reproductive life history (Barlow et al. 1995).

POTENTIAL BIOLOGICAL REMOVAL

Potential Biological Removal (PBR) is the product of minimum population size, one-half the maximum productivity rate, and a recovery factor (MMPA Sec. 3. 16 U.S.C. 1362; Wade and Angliss 1997). The minimum population size is 55,690 animals. The maximum productivity rate is 0.04, the default value for cetaceans. The recovery factor is 0.5, the default value for stocks of unknown status and the CV of the average mortality estimate is less than 0.3 (Wade and Angliss 1997). PBR for the western North Atlantic stock of common dolphin is 557.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

Total annual estimated average fishery-related mortality or serious injury to this stock during 2010–2014 was 409 (CV=0.10) common dolphins.

Fishery information

Detailed fishery information is reported in Appendix III.

Earlier Interactions

Historically, US fishery interactions have been documented with common dolphins in the northeast and mid-Atlantic gillnet fisheries, northeast and mid-Atlantic bottom trawl fisheries, northeast and mid-Atlantic mid-water trawl fishery, and the pelagic longline fishery. See Appendix V for more information on historical takes.

Northeast Sink Gillnet

In 1990, an observer program was started by NMFS to investigate marine mammal takes in the northeast sink gillnet fishery (Appendix III). Common dolphin bycatch in the northern Gulf of Maine occurs primarily from June to September, while in the southern Gulf of Maine, bycatch occurs from January to May and September to December. Annual common dolphin mortalities were estimated using annual ratio-estimator methods (Orphanides 2013; Hatch and Orphanides 2014, 2015, 2016). See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

A study of the effects of two different hanging ratios in the bottom-set monkfish gillnet fishery on the bycatch of cetaceans and pinnipeds was conducted by NEFSC in 2009 and 2010 with 100% observer coverage. Commercial fishing vessels from Massachusetts and New Jersey were used for the study, which took place south of the Harbor Porpoise Take Reduction Team Cape Cod South Management Area (south of 40° 40’N) in February–April. Researchers purposely picked an area of historically high bycatch rates in order to have a chance of finding a significant difference. Eight research strings of fourteen nets each were fished and 159 hauls were completed during the course of the 2009–2010 study. Results showed that while a 0.33 mesh performed better at catching commercially important finfish than a 0.50 mesh, there was no statistical difference in cetacean or pinniped bycatch rates between the two hanging ratios. One common dolphin was caught in this study south of New England in 72 hauls during 2009 and one animal was caught in 72 hauls during the 2010 experiment in the mid-Atlantic (A.I.S., Inc. 2010). The 2010 take is in the time period of this report and is included in the observed interactions and added to the total estimates in Table 2, although these animals and the fishing effort from this experiment were not included in the estimation of the bycatch rate that was expanded to the rest of the fishing effort.

Mid-Atlantic Gillnet

Common dolphins were taken in observed trips during most years. Annual common dolphin mortalities were
estimated using annual ratio-estimator methods (Orphanides 2013; Hatch and Orphanides 2014, 2015, 2016). See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

A study of the effects of tie-downs and bycatch rates of Atlantic Sturgeon (Acipenser oxyrinchus oxyrinchus) in both control and experimental gillnet gear operating in Statistical Area 612 (off New York and New Jersey) between 14 November and 18 December 2010 had 100% observer coverage. This experimental fishery captured 6 common dolphins and 3 unidentified dolphins (unidentified due to lack of photos) during this time period (Fox et al. 2011). These 6 takes are included in the observed interactions and added to the total estimates, though these interactions and their associated fishing effort were not included in bycatch rate calculations that was expanded to the rest of the fishery (Table 2).

**Northeast Bottom Trawl**

This fishery is active in New England waters in all seasons. Annual common dolphin mortalities were estimated using annual stratified ratio-estimator methods (Lyssikatos 2015). See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

**Mid-Atlantic Bottom Trawl**

Annual common dolphin mortalities were estimated using annual stratified ratio-estimator methods (Lyssikatos 2015). See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

**Northeast Mid-water Trawl Fishery (Including Pair Trawl)**

A common dolphin mortality was observed in this fishery in 2010, and another in 2012 (Table 2). An expanded bycatch estimate has not been calculated so the minimum raw count is reported.

Table 2. Summary of the incidental serious injury and mortality of North Atlantic common dolphins (Delphinus delphis delphis) by commercial fishery including the years sampled, the type of data used, the annual observer coverage, the serious injuries and mortalities recorded by on-board observers, the estimated annual serious injury and mortality, the combined serious injury and mortality estimate, the estimated CV of the annual combined serious injury and mortality and the mean annual serious injury and mortality estimate (CV in parentheses).
Observer data (Obs. Data), used to measure bycatch rates, are collected within the Northeast Fisheries Observer Program and At-sea Monitoring Program. NEFSC collects landings data (unallocated Dealer Data or Allocated Dealer Data) which are used as a measure of total landings and mandatory Vessel Trip Reports (VTR) (Trip Logbook) are used to determine the spatial distribution of landings and fishing effort.

Observer coverage is defined as the ratio of observed to total metric tons of fish landed for the gillnet fisheries, and the ratio of observed to total trips for bottom trawl and Mid-Atlantic mid-water trawl (including pair trawl) fisheries. Beginning in May 2010 total observer coverage reported for bottom trawl and gillnet gear includes samples collected from the at-sea monitoring program in addition to traditional observer coverage through the Northeast Fisheries Observer Program (NEFOP).

Fishery related bycatch rates for years 2010-2014 were estimated using an annual stratified ratio-estimator (Lyssikatos 2015).

One common dolphin was incidentally caught in 2010 in the mid-Atlantic gillnet fishery as part of a NEFSC hanging ratio study to examine the impact of gillnet hanging ratio on harbor porpoise bycatch. Six common dolphins were caught in a study of the effects of tie-downs on Atlantic Sturgeon bycatch rates conducted in the mid-Atlantic gillnet fishery in 2010. All research takes are included in the observed interactions and added to the total estimates, though these interactions and their associated fishing effort were not included in bycatch rate calculations that was expanded to the rest of the fishery.

Serious injuries were evaluated for the 2010–2014 period using new guidelines and include both at-sea monitor and traditional observer data (Waring et al. 2014, 2015; Wenzel et al. 2015, 2016).

### CANADA
Between January 1993 and December 1994, 36 Spanish deep-water trawlers, covering 74 fishing trips (4,726 fishing days and 14,211 sets), were observed in NAFO Fishing Area 3 (off the Grand Banks) (Lens 1997). A total of 47 incidental catches was recorded, which included one common dolphin. The incidental mortality rate for common dolphins was 0.007/set. One common dolphin was reported as a bycatch mortality in Canadian bottom otter trawl fishing on Georges Bank in 2012 (pers. comm. Marine Animal Response Society, Nova Scotia).

### Other Mortality
From 2010 to 2014, 698 common dolphins were reported stranded between Maine and Florida (Table 3). The total includes mass-stranded common dolphins in Massachusetts during 2010 (a total of 30 in 8 events), 2011 (a total of 30 animals in 5 events), 2012 (23 group stranding events), 2013 (a total of 9 in 3 events), and 2014 (a total of 14 in 4 events), one mass stranding in North Carolina in 2011 (4 animals), and 2 mass strandings in Virginia in 2013 (a total of 6 in 2 events). Eleven animals in 2010, 15 animals in 2011, 71 animals in 2012, 13 in 2013 and 12 in 2014 were released or last sighted alive. In 2010, 7 animals were classified as human interactions, 2 of which were fishery interactions (all Massachusetts mass-stranded animals) and 2 of which (Rhode Island) involved animals last sighted free-swimming. In 2011, 3 animals were classified as having human interactions, 2 of which were fishery interactions (one of these was satellite-tagged and released). Twelve human interaction cases were reported in 2012 (7 in Massachusetts, 3 in New York and 2 in New Jersey), 6 of which (2 in Massachusetts, 2 in New York and 1 in New Jersey) were classified as fisheries interactions. In 2013, 10 cases were classified as human interaction, 4 of which were fishery interactions. In 2014, 5 cases were classified as human interaction, 1 of which was a fishery interaction. In an analysis of mortality causes of stranded marine mammals on Cape Cod and southeastern Massachusetts between 2000 and 2006, Bogomolni (2010) reported that 61% of stranded common dolphins were
involved in mass-stranding events, and 37% of all the common dolphin stranding mortalities were disease-related.

The Marine Animal Response Society of Nova Scotia reported one common dolphin stranded in 2010 (released alive), 2 (one a fisheries interaction) in 2011, 0 in 2012 and 2013, and 3 in 2014 (Tonya Wimmer, pers. comm.).

b. Seven HI cases in 2010 (4 mortalities in MA, 2 released alive in RI, and 1 mortality in New Jersey), 2 of which (Massachusetts) were classified as fishery interactions. Three HI cases in 2011, all in Massachusetts, 2 of which were classified as fishery interactions (but one of those fishery interaction animals was released alive). Twelve HI cases in 2012 (7 in Massachusetts, 3 in New York and 2 in New Jersey), 6 of which (2 in Massachusetts, 2 in New York and 1 in New Jersey) were classified as fisheries interactions. Ten records with indications of human interactions in 2013 (3 in New York, 1 in Rhode Island and 6 in Massachusetts), 4 of which (1 in Massachusetts and 3 in New York) were classified as fishery interactions. Five records of human interaction in 2014 (1 fisheries interaction in Rhode Island, 2 other human interactions in Massachusetts and 2 in Rhode Island). Two of the human interactions in 2014 (1 Massachusetts and 1 Rhode Island) involved live animals.

Stranding data probably underestimate the extent of fishery-related mortality and serious injury because all of the marine mammals that die or are seriously injured may not wash ashore, nor will all of those that do wash ashore necessarily show signs of entanglement or other fishery interaction. Finally, the level of technical expertise among stranding network personnel varies widely as does the ability to recognize signs of fishery interaction. However a recently published human interaction manual (Barco and Moore 2013) and case criteria for human interaction determinations (Moore *et al.* 2013) should help with this.

**STATUS OF STOCK**

Common dolphins are not listed as threatened or endangered under the Endangered Species Act, and the Western North Atlantic stock is not considered strategic under the Marine Mammal Protection Act. The 2010–2014 average annual human-related mortality does not exceed PBR. The total U.S. fishery-related mortality and serious injury for this stock is not less than 10% of the calculated PBR and, therefore, cannot be considered to be insignificant and approaching zero mortality and serious injury rate. The status of common dolphins, relative to
OSP, in the U.S. Atlantic EEZ is unknown. Population trends for this species have not been investigated.

COMMON BOTTLENOSE DOLPHIN (Tursiops truncatus truncatus):
Western North Atlantic Offshore Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

There are two morphologically and genetically distinct common bottlenose dolphin morphotypes (Duffield et al. 1983; Mead and Potter 1995; Rosel et al. 2009) described as the coastal and offshore forms in the western North Atlantic (Hersh and Duffield 1990; Mead and Potter 1995; Curry and Smith 1997; Rosel et al. 2009). The two morphotypes are genetically distinct based upon both mitochondrial and nuclear markers (Hoelzel et al. 1998; Rosel et al. 2009). The offshore form is distributed primarily along the outer continental shelf and continental slope in the Northwest Atlantic Ocean from Georges Bank to the Florida Keys (Figure 1; CETAP 1982; Kenney 1990), where dolphins with characteristics of the offshore type have stranded. However, common bottlenose dolphins have occasionally been sighted in Canadian waters, on the Scotian Shelf (e.g., Baird et al. 1993; Gowans and Whitehead 1995), and these animals are thought to be of the offshore form.

North of Cape Hatteras, there is separation of the two morphotypes across bathymetry during summer months. Aerial surveys flown during 1979–1981 indicated a concentration of common bottlenose dolphins in waters < 25 m deep corresponding to the coastal morphotype, and an area of high abundance along the shelf break corresponding to the offshore stock (CETAP 1982; Kenney 1990). Biopsy tissue sampling and genetic analysis demonstrated that common bottlenose dolphins concentrated close to shore were of the coastal morphotype, while those in waters > 40 m depth were from the offshore morphotype (Garrison et al. 2003). However, south of Cape Hatteras, North Carolina, the ranges of the coastal and offshore morphotypes overlap to some degree. Torres et al. (2003) found a statistically significant break in the distribution of the morphotypes at 34 km from shore based upon the genetic analysis of tissue samples collected in nearshore and offshore waters from New York to central Florida. The offshore morphotype was found exclusively seaward of 34 km and in waters deeper than 34 m. Within 7.5 km of shore, all animals were of the coastal morphotype. More recently, offshore morphotype animals have been sampled as close as 7.3 km from shore in water depths of 13 m (Garrison et al. 2003). Systematic biopsy collection surveys were conducted coast-wide during the summer and winter between 2001 and 2005 to evaluate the degree of spatial overlap between the two morphotypes. Over the continental shelf south of Cape Hatteras, North Carolina, the two morphotypes overlap spatially, and the probability of a sampled group being from the offshore morphotype increased with increasing depth based upon a logistic regression analysis (Garrison et al. 2003). Hersh and Duffield (1990) examined common bottlenose dolphins that stranded along the southeast coast of Florida and found four that had hemoglobin profiles matching that of the offshore morphotype. These strandings suggest the offshore form occurs as far south as southern Florida. The range of the offshore form...
common bottlenose dolphin includes waters beyond the continental slope (Kenney 1990), and also waters beyond the U.S. EEZ, and therefore the offshore stock is a transboundary stock (Figure 1). Offshore common bottlenose dolphins may move between the Gulf of Mexico and the Atlantic (Wells et al. 1999).

The western North Atlantic Offshore Stock of common bottlenose dolphins is being considered separate from the Gulf of Mexico Oceanic Stock of common bottlenose dolphins for management purposes. One line of evidence to support this decision comes from Baron et al. (2008), who found that Gulf of Mexico common bottlenose dolphin whistles (collected from oceanic waters) were significantly different from those in the western North Atlantic Ocean (collected from continental shelf and oceanic waters) in duration, number of inflection points and number of steps.

**POPULATION SIZE**

The best available estimate for the offshore stock of common bottlenose dolphins in the western North Atlantic is 77,532 (CV=0.40; Table 1; Palka 2012; Garrison 2016). This estimate is from summer 2011 surveys covering waters from central Florida to the lower Bay of Fundy.

**Earlier abundance estimates**

Please see Appendix IV for a summary of abundance estimates, including earlier estimates and survey descriptions. As recommended in the GAMMS II Workshop Report (Wade and Angliss 1997), estimates older than 8 years are deemed unreliable for the determination of the current PBR.

**Recent surveys and abundance estimates**

An abundance estimate of 26,766 (CV=0.52) offshore common bottlenose dolphins was generated from aerial and shipboard surveys conducted during June–August 2011 between central Virginia and the lower Bay of Fundy (Palka 2012). The aerial portion covered 6,850 km of trackline over waters north of New Jersey between the coastline and the 100-m depth contour through the U.S. and Canadian Gulf of Maine, and up to and including the lower Bay of Fundy. The shipboard portion covered 3,811 km of trackline between central Virginia and Massachusetts in waters deeper than the 100-m depth contour out to beyond the U.S. EEZ. Both sighting platforms used a double-platform data-collection procedure, which allows estimation of abundance corrected for perception bias of the detected species (Laake and Borchers 2004). Estimation of the abundance was based on the independent observer approach assuming point independence (Laake and Borchers 2004) and calculated using the mark-recapture distance sampling option in the computer program Distance (version 6.0, release 2, Thomas et al. 2009).

An abundance estimate of 50,766 (CV=0.55) offshore common bottlenose dolphins was generated from a shipboard survey conducted concurrently (June–August 2011) in waters between central Virginia and central Florida (Garrison 2016). This shipboard survey included shelf-break and inner continental slope waters deeper than the 50-m depth contour within the U.S. EEZ. The survey employed two independent visual teams searching with 25x150 “bigeye” binoculars. A total of 4,445 km of trackline was surveyed, yielding 290 cetacean sightings. The majority of sightings occurred along the continental shelf break with generally lower sighting rates over the continental slope. Estimation of the abundance was based on the independent observer approach assuming point independence (Laake and Borchers 2004) and calculated using the mark-recapture distance sampling option in the computer program Distance (version 6.0, release 2, Thomas et al. 2009).

**Minimum Population Estimate**

The minimum population estimate is the lower limit of the two-tailed 60% confidence interval of the log-normally distributed best abundance estimate. This is equivalent to the 20th percentile of the log-normal distribution as specified by Wade and Angliss (1997). The best abundance estimate is 77,532 (CV=0.40). The minimum
population estimate for western North Atlantic offshore common bottlenose dolphin is 56,053.

**Current Population Trend**
A trend analysis has not been conducted for this stock. There are 3 abundance estimates from: 1) summer 1998 surveys (29,774; CV=0.25); 2) summer 2002/2004 surveys (81,588; CV=0.17); and 3) summer 2011 surveys (77,532; CV=0.40). Methodological differences between the estimates need to be evaluated before quantifying trends.

**CURRENT AND MAXIMUM NET PRODUCTIVITY RATES**
Current and maximum net productivity rates are unknown for this stock. For purposes of this assessment, the maximum net productivity rate was assumed to be 0.04. This value is based on theoretical modeling showing that cetacean populations may not grow at rates much greater than 4% given the constraints of their reproductive life history (Barlow *et al.* 1995).

**POTENTIAL BIOLOGICAL REMOVAL**
Potential biological removal (PBR) is the product of minimum population size, one-half the maximum productivity rate, and a “recovery” factor (MMPA Sec. 3. 16 U.S.C. 1362; Wade and Angliss 1997). The minimum population size for offshore common bottlenose dolphins is 56,053. The maximum productivity rate is 0.04, the default value for cetaceans. The “recovery” factor is 0.5 because the stock's status relative to optimum sustainable population (OSP) is unknown and the CV of the average mortality estimate is less than 0.3 (Wade and Angliss 1997). PBR for the western North Atlantic offshore common bottlenose dolphin is therefore 561.

**ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY**
The estimated mean annual fishery-related mortality and serious injury of offshore common bottlenose dolphins during 2010–2014 was 39.4 (CV=0.29; Table 2) due to interactions with the northeast sink gillnet, northeast bottom trawl, mid-Atlantic bottom trawl, and pelagic longline fisheries. The total annual fishery-related mortality and serious injury for this stock during 2010–2014 is unknown because in addition to observed takes, there was a self-reported take in the unobserved mid-Atlantic tuna hook and line fishery during 2010.

**Fisheries Information**
The commercial fisheries that interact, or that potentially could interact, with this stock in the Atlantic Ocean are the Category I Atlantic Highly Migratory Species longline; Atlantic Ocean, Caribbean, Gulf of Mexico large pelagics longline; mid-Atlantic gillnet; and northeast sink gillnet fisheries; the Category II mid-Atlantic bottom trawl and northeast bottom trawl fisheries; and the Category III Gulf of Maine, U.S. mid-Atlantic tuna, shark, swordfish hook and line/harpoon fishery. Detailed fishery information is reported in Appendix III.

**Earlier Interactions**
Historically, U.S. fishery interactions have been documented with common bottlenose dolphins in the pelagic drift gillnet fishery, pelagic pair trawl fishery, northeast and mid-Atlantic bottom trawl fisheries, and the northeast and mid-Atlantic gillnet fisheries. See Appendix V for more information on historical takes.

**Longline**
The large pelagics longline fishery operates in the U.S. Atlantic (including Caribbean) and Gulf of Mexico EEZ, and pelagic swordfish, tunas and billfish are the target species. The estimated annual average mortality and serious injury attributable to the Atlantic Ocean pelagics longline fishery for the 5-year period from 2010 to 2014 was 12.4 common bottlenose dolphins (CV=0.68; Table 2). During 2010–2014, 3 serious injuries to common bottlenose dolphins were observed: 2 during quarter 1 of 2012 in the South Atlantic Bight (SAB) region, and 1 during quarter 3 of 2012 in the Northeast Coastal (NEC) region (Garrison and Stokes 2013; see also Garrison and Stokes 2012a,b; 2014; 2016). During 2010 (1 animal), 2011 (2 animals), 2012 (2 animals), and 2013 (2 animals), a total of 7 common bottlenose dolphins were observed entangled and released alive in the SAB, Mid-Atlantic Bight (MAB) and NEC regions (Garrison and Stokes 2012a,b; 2013; 2014; 2016). These animals were presumed to have no serious injuries.

Historically in the large pelagics longline fishery, no common bottlenose dolphin mortalities or serious injuries were observed between 2002 and 2008 (Garrison 2003; Garrison and Richards 2004; Garrison 2005; Fairfield Walsh and Garrison 2006; Fairfield-Walsh and Garrison 2007; Fairfield and Garrison 2008; Garrison *et al.* 2009). However, 1 common bottlenose dolphin serious injury was observed during quarter 4 of 2009 in the MAB region.
(Garrison and Stokes 2010), and 1 common bottlenose dolphin was observed entangled and released alive, presumed
to have no serious injuries, in 2005 in the SAB region (Fairfield Walsh and Garrison 2006).

The Atlantic Highly Migratory Species longline fishery operates outside the U.S. EEZ. No takes of common
bottlenose dolphins within high seas waters of the Atlantic Ocean have been observed or reported thus far.

See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and
Appendix V for historical estimates of annual mortality and serious injury.

Through the Marine Mammal Authorization Program (MMAP), there were 2 self-reported incidental takes
(mortalities) of common bottlenose dolphins during 2014 off Rhode Island by fishers trawling for Illex squid.

### Table 2. Summary of the incidental mortality and serious injury of Atlantic Ocean offshore common bottlenose
dolphins (*Tursiops truncatus truncatus*) by commercial fishery including the years sampled (Years), the type of
data used (Data Type), the annual observer coverage (Observer Coverage), the observed mortalities and serious
injuries recorded by on-board observers, the estimated annual mortality and serious injury, the combined annual
estimates of mortality and serious injury (Estimated Combined Mortality), the estimated CV of the combined
estimates (Estimated CVs) and the mean of the combined estimates (CV in parentheses).

*a* Observer data (Obs. Data) are used to measure bycatch rates, and the data are collected within the Northeast Fisheries Observer Program. Mandatory logbook data were used to measure total effort for the longline fishery. These data are collected at the Southeast Fisheries Science Center (SEFSC).

*b* Proportion of sets observed (for Pelagic Longline).

*c* Fishery related bycatch rates for 2010–2014 were estimated using an annual stratified ratio-estimator following the methodology described in Lyssikatos (2015).

**Northeast Sink Gillnet**

During 2010–2014, 1 mortality was observed (in 2013) in the northeast sink gillnet fishery (Orphanides 2013; Hatch and Orphanides 2014; 2015; 2016). No takes were observed during 2010–2012 and 2014. There were no observed injuries of common bottlenose dolphins in the Northeast region during 2010–2014 to assess using new serious injury criteria. See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

**Northeast Bottom Trawl**

During 2010–2014, 5 mortalities were observed in the northeast bottom trawl fishery (Lyssikatos 2015). There were no observed injuries of common bottlenose dolphins in the northeast region during 2010–2014 to assess using new serious injury criteria. See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

Through the Marine Mammal Authorization Program (MMAP), there were 2 self-reported incidental takes (mortalities) of common bottlenose dolphins during 2014 off Rhode Island by fishers trawling for *Illex* squid.
Mid-Atlantic Bottom Trawl

During 2010–2014, 11 mortalities were observed in the mid-Atlantic bottom trawl fishery (Lyssikatos 2015). There were no observed injuries of common bottlenose dolphins in the mid-Atlantic region during 2010–2014 to assess using new serious injury criteria. See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

Through the MMAP, there were 2 self-reported incidental takes (mortalities) involving 3 common bottlenose dolphins in total during 2011 off Rhode Island and New Jersey by fishers trawling for *Loligo* squid.

U.S. Mid-Atlantic Tuna Hook and Line

Through the MMAP, there was 1 self-reported incidental take (serious-injury) of a common bottlenose dolphin during 2010 off North Carolina by a fisher using hook and line targeting tuna.

Other Mortality

Common bottlenose dolphins are among the most frequently stranded small cetaceans along the Atlantic coast. Many of the animals show signs of human interaction (i.e., net marks, mutilation, etc.); however, it is unclear what proportion of these stranded animals is from the offshore stock because most strandings are not identified to morphotype, and when they are, animals of the offshore form are uncommon. For example, only 19 of 185 *Tursiops* strandings in North Carolina were genetically assigned to the offshore form (Byrd *et al.* 2014).

An Unusual Mortality Event (UME) of bottlenose dolphins and other cetaceans occurred along the mid-Atlantic coast from New York to Brevard County, Florida, from 1 July 2013 to 1 March 2015. The total number of stranded bottlenose dolphins was ~1650. Morbillivirus has been determined to be a primary cause of the event. Post-UME monitoring of bottlenose dolphins will continue over the next few years, and work continues to determine the effect of this event on bottlenose dolphin stocks in the Atlantic.

STATUS OF STOCK

The common bottlenose dolphin in the western North Atlantic is not listed as threatened or endangered under the Endangered Species Act, and the offshore stock is not considered strategic under the MMPA. Total U.S. fishery-related mortality and serious injury for this stock is less than 10% of the calculated PBR and, therefore, can be considered to be insignificant and approaching the zero mortality and serious injury rate. The status of this stock relative to OSP in the U.S. Atlantic EEZ is unknown. There are insufficient data to determine the population trends for this stock.

HARBOR PORPOISE (*Phocoena phocoena phocoena*): Gulf of Maine/Bay of Fundy Stock

**STOCK DEFINITION AND GEOGRAPHIC RANGE**

This stock is found in U.S. and Canadian Atlantic waters. The distribution of harbor porpoises has been documented by sighting surveys, strandings and takes reported by NMFS observers in the Sea Sampling Programs. During summer (July to September), harbor porpoises are concentrated in the northern Gulf of Maine and southern Bay of Fundy region, generally in waters less than 150 m deep (Gaskin 1977; Kraus et al. 1983; Palka 1995), with a few sightings in the upper Bay of Fundy and on Georges Bank (Palka 2000). During fall (October–December) and spring (April–June), harbor porpoises are widely dispersed from New Jersey to Maine, with lower densities farther north and south. They are seen from the coastline to deep waters (>1800 m; Westgate et al. 1998), although the majority of the population is found over the continental shelf. During winter (January to March), intermediate densities of harbor porpoises can be found in waters off New Jersey to North Carolina, and lower densities are found in waters off New York to New Brunswick, Canada. There does not appear to be a temporally coordinated migration or a specific migratory route to and from the Bay of Fundy region. However, during the fall, several satellite-tagged harbor porpoises did favor the waters around the 92-m isobath, which is consistent with observations of high rates of incidental catches in this depth range (Read and Westgate 1997). There were two stranding records from Florida during the 1980s (Smithsonian strandings database) and one in 2003 (NE Regional Office/NMFS strandings and entanglement database).

Gaskin (1984, 1992) proposed that there were four separate populations in the western North Atlantic: the Gulf of Maine/Bay of Fundy, Gulf of St. Lawrence, Newfoundland, and Greenland populations. Analyses involving mtDNA (Wang et al. 1996; Rosel et al. 1999a; 1999b), organochlorine contaminants (Westgate et al. 1997; Westgate and Tolley 1999), heavy metals (Johnston 1995), and life history parameters (Read and Hohn 1995) support Gaskin’s proposal. Genetic studies using mitochondrial DNA (Rosel et al. 1999a) and contaminant studies using total PCBs (Westgate and Tolley 1999) indicate that the Gulf of Maine/Bay of Fundy females were distinct from females from the other populations in the Northwest Atlantic. Gulf of Maine/Bay of Fundy males were distinct from Newfoundland and Greenland males, but not from Gulf of St. Lawrence males according to studies comparing mtDNA (Palka et al. 1996; Rosel et al. 1999a) and CHLORs, DDTs, PCBs and CHBs (Westgate and Tolley 1999). Nuclear microsatellite markers have also been applied to samples from these four populations, but this analysis failed to detect significant population sub-division in either sex (Rosel et al. 1999a). These patterns may be indicative of female philopatry coupled with dispersal of males. Both mitochondrial DNA and microsatellite

---

**Figure 1. Distribution of harbor porpoises from NEFSC and SEFSC shipboard and aerial surveys during the summers of 1995, 1998, 1999, 2002, 2004, 2006, 2007, 2008, 2010, and 2011 and DFO’s 2007 TNASS survey. Isobaths are the 100-m, 1000-m, and 4000-m depth contours.**
analyses indicate that the Gulf of Maine/Bay of Fundy stock is not the sole contributor to the aggregation of porpoises found off the mid-Atlantic states during winter (Rosel et al. 1999a; Hiltunen 2006). Mixed-stock analyses using twelve microsatellite loci in both Bayesian and likelihood frameworks indicate that the Gulf of Maine/Bay of Fundy is the largest contributor (~60%), followed by Newfoundland (~25%) and then the Gulf of St. Lawrence (~12%), with Greenland making a small contribution (<3%). For Greenland, the lower confidence interval of the likelihood analysis includes zero. For the Bayesian analysis, the lower 2.5% posterior quantiles include zero for both Greenland and the Gulf of St. Lawrence. Intervals that reach zero provide the possibility that these populations contribute no animals to the mid-Atlantic aggregation.

This report follows Gaskin's hypothesis on harbor porpoise stock structure in the western North Atlantic, where the Gulf of Maine and Bay of Fundy harbor porpoises are recognized as a single management stock separate from harbor porpoise populations in the Gulf of St. Lawrence, Newfoundland, and Greenland.

**POPULATION SIZE**

The best current abundance estimate of the Gulf of Maine/Bay of Fundy harbor porpoise stock is from the 2011 survey: 79,883 (CV=0.32).

**Earlier abundance estimates**

Please see Appendix IV for a summary of abundance estimates, including earlier estimates and survey descriptions. As recommended in the GAMMS II Workshop Report (Wade and Angliss 1997), estimates older than eight years are deemed unreliable for the determination of the current PBR.

**Recent surveys and abundance estimates**

An abundance estimate of 79,883 (CV=0.32) harbor porpoises was generated from a shipboard and aerial survey conducted during June–August 2011 (Palka 2012). The aerial portion that contributed to the abundance estimate covered 5,313 km of tracklines that were over waters north of New Jersey from the coastline to the 100-m depth contour through the U.S. and Canadian Gulf of Maine and up to and including the lower Bay of Fundy. The shipboard portion covered 3,107 km of tracklines that were in waters offshore of central Virginia to Massachusetts (waters that were deeper than the 100-m depth contour out to beyond the U.S. EEZ). Both sighting platforms used a double-platform team data-collection procedure, which allows estimation of abundance corrected for perception bias of the detected species (Laake and Borchers 2004). Estimation of the abundance was based on the independent-observer approach assuming point independence (Laake and Borchers 2004) and calculated using the mark-recapture distance sampling option in the computer program Distance (version 6.0, release 2, Thomas et al. 2009).

No harbor porpoises were detected in an abundance survey that was conducted concurrently (June–August 2011) in waters between central Virginia and central Florida. This shipboard survey included shelf-break and inner continental slope waters deeper than the 50-m depth contour within the U.S. EEZ. The survey employed the double-platform methodology searching with 25x150 “bigeye” binoculars. A total of 4,445 km of tracklines was surveyed, yielding 290 cetacean sightings.

| Table 1. Summary of recent abundance estimates for the Gulf of Maine/Bay of Fundy harbor porpoise (*Phocoena phocoena phocoena*) by month, year, and area covered during each abundance survey and the resulting abundance estimate (N_{best}) and coefficient of variation (CV). |
|---|---|---|
| Month/Year | Area | N_{best} | CV |
| Jul-Aug 2011 | Central Virginia to lower Bay of Fundy | 79,883 | 0.32 |

**Minimum Population Estimate**

The minimum population estimate is the lower limit of the two-tailed 60% confidence interval of the log-normal distributed best abundance estimate. This is equivalent to the 20th percentile of the log-normal distribution as specified by Wade and Angliss (1997). The best estimate of abundance for harbor porpoises is 79,883 (CV=0.32). The minimum population estimate for the Gulf of Maine/Bay of Fundy harbor porpoise is 61,415.

**Current Population Trend**

A trend analysis has not been conducted for this stock. The statistical power to detect a trend in abundance for this stock is poor due to the relatively imprecise abundance estimates and long survey interval. For example, the power to detect a precipitous decline in abundance (i.e., 50% decrease in 15 years) with estimates of low precision...
(e.g., CV > 0.30) remains below 80% (alpha = 0.30) unless surveys are conducted on an annual basis (Taylor et al. 2007).

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Several attempts have been made to estimate potential population growth rates. Barlow and Boveng (1991), who used a re-scaled human life table, estimated the upper bound of the annual potential growth rate to be 9.4%. Woodley and Read (1991) used a re-scaled Himalayan tahr life table to estimate a likely annual growth rate of 4%. In an attempt to estimate a potential population growth rate that incorporates many of the uncertainties in survivorship and reproduction, Caswell et al. (1998) used a Monte Carlo method to calculate a probability distribution of growth rates. The median potential annual rate of increase was approximately 10%, with a 90% confidence interval of 3–15%. This analysis underscored the considerable uncertainty that exists regarding the potential rate of increase in this population. Moore and Read (2008) conducted a Bayesian population modeling analysis to estimate the potential population growth of harbor porpoise in the absence of bycatch mortality. Their method used fertility data, in combination with age-at-death data from stranded animals and animals taken in gillnets, and was applied under two scenarios to correct for possible data bias associated with observed bycatch of calves. Demographic parameter estimates were ‘model averaged’ across these scenarios. The Bayesian posterior median estimate for potential natural growth rate was 0.046. This last, most recent, value will be the one used for the purpose of this assessment.

POTENTIAL BIOLOGICAL REMOVAL

Potential Biological Removal (PBR) is the product of minimum population size, one-half the maximum productivity rate, and a recovery factor (MMPA Sec. 3. 16 U.S.C. 1362; Wade and Angliss 1997). The minimum population size is 61,415. The maximum productivity rate is 0.046. The recovery factor is 0.5 because stock's status relative to OSP is unknown and the CV of the average mortality estimate is less than 0.3 (Wade and Angliss 1997). PBR for the Gulf of Maine/Bay of Fundy harbor porpoise is 706.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

The total annual estimated average human-caused mortality is 437 harbor porpoises per year. This is derived from two components: 394 harbor porpoise per year (CV=0.18) from U.S. fisheries using observer and MMAP data, and 43 per year (unknown CV) from Canadian fisheries using observer data.

Fishery Information

Recently, Gulf of Maine/Bay of Fundy harbor porpoise takes have been documented in the U.S. northeast sink gillnet, mid-Atlantic gillnet, and northeast bottom trawl fisheries and in the Canadian herring weir fisheries (Table 2). Detailed U.S. fishery information is reported in Appendix III.

Earlier Interactions

One harbor porpoise was observed taken in the Atlantic pelagic drift gillnet fishery during 1991–1998; the fishery ended in 1998. This observed bycatch was notable because it occurred in continental shelf edge waters adjacent to Cape Hatteras (Read et al. 1996). See Appendix V for more information on historical takes.

U.S. Northeast Sink Gillnet

Harbor porpoise bycatch in the northern Gulf of Maine occurs primarily from June to September, while in the southern Gulf of Maine, bycatch occurs from January to May and September to December. Annual bycatch is estimated using ratio estimator techniques that account for the use of pingers (Orphanides 2013; Hatch and Orphanides 2014, 2015, 2016). See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

There appeared to be no evidence of differential mortality in U.S. or Canadian gillnet fisheries by age or sex in animals collected before 1994, although there was substantial inter-annual variation in the age and sex composition of the bycatch (Read and Hohn 1995). Using observer data collected during 1990–1998 and a logit regression model, females were 11 times more likely to be caught in the offshore southern Gulf of Maine region, males were more likely to be caught in the south Cape Cod region, and the overall proportion of males and females caught in a gillnet and brought back to land were not significantly different from 1:1 (Lamb 2000).

Scientific experiments that demonstrated the effectiveness of pingers in the Gulf of Maine were conducted during 1992 and 1993 (Kraus et al. 1997). After the scientific experiments, experimental fisheries were allowed in
the general fishery during 1994 to 1997 in various parts of the Gulf of Maine and south of Cape Cod areas. During these experimental fisheries, bycatch rates of harbor porpoises in pingered nets were less than in non-pingered nets.

A study on the effects of two different hanging ratios in the bottom-set monkfish gillnet fishery on the bycatch of cetaceans and pinnipeds was conducted by NEFSC in 2009 and 2010 with 100% observer coverage which took place in both the Northeast and mid-Atlantic gillnet fisheries. Commercial fishing vessels from Massachusetts and New Jersey were used for the study, which took place south of the Harbor Porpoise Take Reduction Cape Cod South Management Area (south of 40° 40’N) in February–April. Researchers purposely picked an area of historically high bycatch rates in order to have a chance of finding a significant difference. Eight research strings of fourteen nets each were fished and 159 hauls were completed during the course of the 2009–2010 study. Results showed that while a 0.33 mesh performed better at catching commercially important finfish than a 0.50 mesh, there was no statistical difference in cetacean or pinniped bycatch rates between the two hanging ratios. Twelve harbor porpoises were caught in this project in 79 hauls during 2009 and one animal was caught in 72 hauls during the 2010 experiment in the Northeast (A.I.S., Inc. 2010). The 2010 animal was included in the observed interactions and added into the total estimates (Table 2), though these animals and the fishing effort from this experiment were not included in the estimation of the bycatch rate that was expanded to the rest of the fishing effort. The 2009 takes were included in earlier editions of this report.

Mid-Atlantic Gillnet

Annual bycatch is estimated using ratio estimator techniques (Orphanides 2013; Hatch and Orphanides 2014, 2015, 2016). See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

In the northeast gillnet fishery section above, see the description of the study on the effects of two different hanging rations in the bottom-set gillnet fishery which took place in both the northeast and mid-Atlantic gillnet fisheries. Ten harbor porpoises were caught in 8 hauls in the mid-Atlantic in 2010 as part of this experiment (A.I.S., Inc. 2010). Harbor porpoises that were caught in this study were included in the observed interactions and added into the total estimates (Table 2), though these animals and the fishing effort from this experiment were not included in the estimation of the bycatch rate that was expanded to the rest of the fishing effort.

Northeast Bottom Trawl

Since 1989, harbor porpoise mortalities have been observed in the northeast bottom trawl fishery, but many of these were not attributable to this fishery because decomposed animals are presumed to have been dead prior to being taken by the trawl. New serious injury criteria were applied to all observed interactions retroactive back to 2007 (Waring et al. 2014, 2015, Wenzel et al. 2015, 2016). Fishery-related bycatch rates for years since 2008 were estimated using an annual stratified ratio-estimator (Lyssikatos 2015). These estimates replace the 2008–2010 annual estimates reported in the 2013 stock assessment report that were generated using a different method. See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

CANADA

Bay of Fundy Sink Gillnet

The earlier estimated annual mortality estimates were 38 for 1998, 32 for 1999, 28 for 2000, and 73 for 2001 (Trippel and Shepherd 2004). Estimates of variance are not available. However, since 2002 there has been no observer program in the Bay of Fundy region, but the fishery is still active. Bycatch for these years is unknown. The annual average of the most recent five years with available data (1997–2001) was 43 animals, so this value is used to estimate the annual average for more recent years. In 2011 there was little gillnet effort in New Brunswick waters in the summer; thus the Canadian porpoise by-catch estimates could have been near zero. The fishermen that sought groundfish went into the mid-Bay of Fundy where traditionally bycatch levels were extremely low, though current bycatch levels are unknown. Trippel (pers. comm.) estimated that fewer than 10 porpoises were bycaught in the Canadian fisheries in the Bay of Fundy in 2011. Analysis of port catch records might allow estimation of bycatch for more recent times, however, it would be difficult to also accurately account for the changes in the spatial distribution of the harbor porpoises and fisheries.

Herring Weirs

Harbor porpoises are taken in Canadian herring weirs, but there have been no recent efforts to observe takes in the U.S. component of this fishery. Smith et al. (1983) estimated that in the 1980s approximately 70 harbor
porpoises became trapped annually and, on average, 27 died annually. In 1990, at least 43 harbor porpoises were trapped in Bay of Fundy weirs (Read et al. 1994). In 1993, after a cooperative program between fishermen and Canadian biologists was initiated, over 100 harbor porpoises were released alive (Read et al. 1994). Between 1992 and 1994, this cooperative program resulted in the live release of 206 of 263 harbor porpoises caught in herring weirs. Mortalities (and releases) were 11 (50) in 1992, 33 (113) in 1993, and 13 (43) in 1994 (Neimanis et al. 1995).

Since that time, additional harbor porpoises have been documented in Canadian herring weirs: mortalities (releases and unknowns) were 5 (60, 0) in 1995, 2 (4, 0) in 1996, 2 (24, 0) in 1997, 2 (26, 0) in 1998, 3 (89, 0) in 1999, 0 (13, 0) in 2000 (A. Read, pers. comm.), 14 (296, 0) in 2001, 3 (46, 4) in 2002, 1 (26, 3) in 2003, 4 (53, 2) in 2004, 0 (19, 5) in 2005, 2 (14, 0) in 2006, 3 (9, 3) in 2007, 0 (8, 6) in 2008, 0 (3,4) in 2009, 1 in 2010 (7, 0), 0 (2, 3) in 2011, 0 (2, 3) in 2012, 0 (2,0) in 2013 and 0 (9, 2) in 2014 (Neimanis et al. 2004; H. Koopman and A. Westgate, pers. comm.).

See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

NA = Not available.

Observer data (Obs. Data) are used to measure bycatch rates; the U.S. data are collected by the Northeast...
Fisheries Science Center (NEFSC) Sea Sampling Program and At-Sea Monitoring Program; the Canadian data are collected by DFO. NEFSC collects Weighout (Weighout) landings data that are used as a measure of total effort for the U.S. gillnet fisheries. The Canadian DFO catch and effort statistical system collected the total number of trips fished by the Canadians (Can. Trips), which was the measure of total effort for the Canadian groundfish gillnet fishery. Mandatory vessel trip report (VTR) (Trip Logbook) data are used to determine the spatial distribution of fishing effort in the northeast sink gillnet fishery. Observed mortalities from herring weirs are collected by a cooperative program between fishermen and Canadian biologists (Coop. Data).

b. Observer coverage for the U.S. Northeast and mid-Atlantic coastal gillnet fisheries is based on tons of fish landed. Northeast bottom trawl fishery coverages are ratios based on trips. Total observer coverage reported for bottom trawl gear and gillnet gear in the year 2010 includes only samples collected from traditional fisheries observer, but not the fishery monitors. Monitor trips were incorporated starting in 2011, the first full year of monitor coverage.

c. Since 2002 in the Northeast gillnet fishery, harbor porpoises were taken on pingered strings within strata that required pingers but that stratum also had observed strings without pingers. For estimates made during 1998 and after, a weighted bycatch rate was applied to effort from both pingered and non-pingered hauls within a stratum. The weighted bycatch rate was:

\[
\frac{\text{# porpoises harvested}}{\text{# total hauls}} \times \frac{\text{# pingered hauls}}{\text{# non-pingered hauls}}
\]

There were 10, 33, 44, 0, 11, 0, 2, 8, 6, 2, 26, 2, 4, 12, 2, 9, 6, 11, 23, 11, 30, 20, and 27 observed harbor porpoise takes on pinger trips from 1992 to 2014, respectively, that were included in the observed mortality column.

d. There were 255 licenses for herring weirs in the Canadian Bay of Fundy region.

e. Data provided by H. Koopman pers. comm.

f. The Canadian gillnet fishery was not observed during 2002 and afterwards, but the fishery is still active; thus, the current bycatch estimate for this fishery is assumed to be the average estimate using last five years that the fishery was observed in (1997–2001).

g. Fishery related bycatch rates for years 2010–2014 were estimated using an annual stratified ratio-estimator.

h. One harbor porpoise in the Northeast area and 10 in the mid-Atlantic area were incidentally caught in 2010 as part of a 2009-2010 NEFSC gillnet hanging ratio study to examine the impact of hanging ratio on harbor porpoise bycatch in gillnets. These animals were included in the observed interactions and added to the total estimates, though these interactions and their associated fishing effort were not included in the estimation of the bycatch rate that was expanded to the rest of the fishery.

i. Serious injuries were evaluated for the 2010–2014 period using new guidelines and include both at-sea monitor and traditional observer data (Waring et al. 2014, 2015, Wenzel et al. 2015, 2016)

**Other Mortality**

**U.S.**

There is evidence that harbor porpoises were harvested by natives in Maine and Canada before the 1960s, and the meat was used for human consumption, oil, and fish bait (NMFS 1992). The extent of these past harvests is unknown, though it is believed to have been small. Up until the early 1980s, small kills by native hunters (Passamaquoddy Indians) were reported. In recent years it was believed to have nearly stopped (Polacheck 1989) until media reports in September 1997 depicted a Passamaquoddy tribe member dressing out a harbor porpoise. Further articles describing use of porpoise products for food and other purposes were timed to coincide with ongoing legal action in state court.

During 2010, 82 harbor porpoises were reported stranded on Atlantic U.S. beaches. Of these, six stranding mortalities were reported as having signs of human interaction, three of which were reported to be fishery interactions.

During 2011, 164 harbor porpoises were reported stranded on Atlantic U.S. beaches. Of these, nine stranding mortalities were reported as having signs of human interaction, three of which were reported to be fishery interactions.
interactions.

During 2012, 45 harbor porpoises were reported stranded on Atlantic U.S. beaches. Of these, four stranding mortalities were reported as having signs of human interaction, one of which was reported to be a fishery interaction.

During 2013, 102 harbor porpoises were reported stranded on Atlantic U.S. beaches. Of these, nine stranding mortalities were reported as having signs of human interaction, three of which were reported to be fishery interactions.

During 2014, 39 harbor porpoises were reported stranded on Atlantic U.S. beaches. Of these, one stranding mortality was reported as having signs of human interactions, which was also reported to have been a fishery interaction.

Stranding data probably underestimate the extent of fishery-related mortality and serious injury because all of the marine mammals that die or are seriously injured may not wash ashore, nor will all of those that do wash ashore necessarily show signs of entanglement or other fishery-interaction. Finally, the level of technical expertise among stranding network personnel varies widely as does the ability to recognize signs of fishery interaction.

a. In Massachusetts in 2011, 5 animals were released alive and one taken to rehab. One Maine animal was taken to rehab in 2012. Three Massachusetts live strandings were taken to rehab in 2013 and 1 Maine animal was released alive.

b. In Rhode Island in 2011, one animal classified as human interaction due to fluke amputation.

c. One of the 2012 New York strandings classified as human interaction due to interaction with marine debris.

d. In 2014, one harbor porpoise in Virginia was classified as a fishery interaction.

e. Six total HI cases in 2010; 2 in Massachusetts, 1 in Maine, 1 in North Carolina and 2 in New Jersey. One of the New Jersey records, one of the North Carolina records, and the Maine record were fishery interactions.

f. Nine total HI cases in 2011; 5 in Massachusetts, 1 in Rhode Island, 2 in New York and 1 in Virginia. Two of these Massachusetts animals and the Virginia animal were fishery interactions.
g. Four HI cases in 2012. One of these was a fishery interaction (Massachusetts).
h. Ten total HI cases in 2013 (MA-3, ME-2, NY-3, NJ-1, CT-1), including one released alive (ME). Three of these were considered fishery interactions, including one entangled in gear in Maine.
i. Data supplied by Nova Scotia Marine Animal Response Society (pers. comm.). One of the 2012 animals trapped in mackerel net. Not included in count for 2014 are at least 8 animals released alive from weirs.

CANADA

Whales and dolphins stranded on the coast of Nova Scotia are recorded by the Marine Animal Response Society and the Nova Scotia Stranding Network, including 5 (1 released alive) in 2010, 13 (4 released alive) in 2011, 6 in 2012, 21 in 2013 and 9 in 2014; Table 3).

One dead stranded harbor porpoise was reported in 2010 by the Newfoundland and Labrador Whale Release and Strandings Program, 0 in 2011 and 2012, 3 in 2013, and 0 in 2014 (Ledwell and Huntington 2010, 2011, 2012a, 2012b, 2013, 2014; Table 3).

STATUS OF STOCK

Harbor porpoise in the Gulf of Maine/Bay of Fundy are not listed as threatened or endangered under the Endangered Species Act, and this stock is not considered strategic under the MMPA. The total U.S. fishery-related mortality and serious injury for this stock is not less than 10% of the calculated PBR and, therefore, cannot be considered to be insignificant and approaching zero mortality and serious injury rate. The status of harbor porpoises, relative to OSP, in the U.S. Atlantic EEZ is unknown. Population trends for this species have not been investigated.

HARBOR SEAL (Phoca vitulina vitulina):
Western North Atlantic Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE
The harbor seal (Phoca vitulina) is found in all nearshore waters of the North Atlantic and North Pacific Oceans and adjoining seas above about 30°N (Burns 2009; Desportes et al. 2010). In the western North Atlantic, they are distributed from the eastern Canadian Arctic and Greenland south to southern New England and New York, and occasionally to the Carolinas (Mansfield 1967; Boulva and McLaren 1979; Katona et al. 1993; Baird 2001; Desportes et al. 2010). Although the stock structure of the western North Atlantic subspecies (P. v. concolor) is unknown, it is thought that harbor seals found along the eastern U.S. and Canadian coasts represent one population (Temte et al. 1991; Andersen and Olsen 2010). In U.S. waters, breeding and pupping normally occur in waters north of the New Hampshire/Maine border, although breeding occurred as far south as Cape Cod in the early part of the twentieth century (Temte et al. 1991; Katona et al. 1993).

Harbor seals are year-round inhabitants of the coastal waters of eastern Canada and Maine (Katona et al. 1993), and occur seasonally along the southern New England to New Jersey coasts from September through late May (Schneider and Payne 1983; Schroeder 2000). Scattered sightings and strandings have been recorded as far south as Florida (NOAA National Marine Mammal Health and Stranding Response Database, accessed 08 October 2015). A general southward movement from the Bay of Fundy to southern New England waters occurs in autumn and early winter (Rosenfeld et al. 1988; Whitman and Payne 1990; Jacobs and Terhune 2000). A northward movement from southern New England to Maine and eastern Canada occurs prior to the pupping season, which takes place from mid-May through June along the Maine Coast (Richardson 1976; Wilson 1978; Whitman and Payne 1990; Waring et al. 2006). Earlier research identified no pupping areas in southern New England (Payne and Schneider 1984); however, more recent anecdotal reports suggest that some pupping is occurring at high-use haulout sites off Manomet, Massachusetts and the Isles of Shoals, Maine.

Prior to the spring 2001 live-capture and radio-tagging of adult harbor seals (Waring et al. 2006), it was believed that the majority of seals moving into southern New England and mid-Atlantic waters were subadults and juveniles (Whitman and Payne 1990; Katona et al. 1993). The 2001 study established that adult animals also made this migration. Seventy-five percent (9/12) of the seals tagged in March in Chatham Harbor were detected at least once during the May/June 2001 abundance survey along the Maine coast (Gilbert et al. 2005; Waring et al. 2006). Similar findings were made in spring 2011 and 2012 work (Waring et al. 2015a).
POPULATION SIZE

The best current abundance estimate of harbor seals is 75,834 (CV=0.15) which is from a 2012 survey (Waring et al. 2015).

Earlier abundance estimates

Please see Appendix IV for earlier abundance estimates. As recommended in the GAMMS Workshop Report (Wade and Angliss 1997), estimates older than eight years are deemed unreliable for determination of the current PBR.

Recent surveys and abundance estimates

The 2001 survey (Gilbert et al. 2005), conducted in May/June, included replicate surveys and radio-tagged seals to obtain a correction factor for animals not hauled out. The 2012 survey was designed (Waring et al. 2015a) to sample bay units using a single aircraft, and it also included a radio-tracking aircraft and obtained a correction factor. The corrected estimates (pups in parenthesis) for 2001 and 2012, respectively, were 99,340 (23,722) and 75,834 (23,830) (Table 1). The 2001 observed count of 38,014 was 28.7% greater than the 1997 count, whereas the 2012 corrected estimate was 24% lower than the 2001 estimate. In addition, the CV of the 2012 estimate is 0.153 compared to 0.091 in 2001.

Although the 2012 population estimate was lower than the 2001 estimate, Waring et al. (2015a) did not consider the population to be declining because the two estimates are not significantly different and because the actual estimate was lower is because some fraction of the population was not in the survey area. Evidence for this is that the 31.4% of the count were pups, a percentage that is biologically unlikely. The estimated number of harbor seal pups did not differ significantly between 2001 and 2012. In 2001, there were an estimated 23,722 (CV=0.096) pups in the study area (Gilbert et al. 2005); in 2012 there were an estimated 23,830 (CV=0.159) pups in the study area. Therefore it is likely that there were some non-pups in the population that were not available to be counted because it was not in the study area of Coastal Maine. Some number of seals could have remained farther south in New England, more northerly in Canada, or offshore. Currently there is some uncertainty in the patterns of harbor seal abundance and distribution in the northeastern U.S. Johnston et al. (2015) document a decline in stranding and bycatch rates of harbor seals, providing support for an apparent decline in abundance. However, much of the data examined centered in southern New England and did not cover the center of the population in Maine. There has been very little systematic research conducted on fine-scale changes in habitat use, particularly in relation to the sympatric population of gray seals, although Russell et al. (2015) found little impact of the presence of gray seals on harbor seal time budgets.

Minimum Population Estimate

The minimum population estimate is the lower limit of the two-tailed 60% confidence interval of the log-normally distributed best abundance estimate. This is equivalent to the 20th percentile of the log-normal distribution as specified by Wade and Angliss (1997). The best estimate of abundance for harbor seals is 75,834 (CV=0.15). The minimum population estimate is 66,884 based on corrected available counts along the Maine coast in 2012.

Current Population Trend

A trend analysis has not been conducted for this stock. The statistical power to detect a trend in abundance for this stock is poor due to the relatively imprecise abundance estimates and long survey interval. For example, the power to detect a precipitous decline in abundance (i.e., 50% decrease in 15 years) with estimates of low precision (e.g., CV > 0.30) remains below 80% (alpha = 0.30) unless surveys are conducted on an annual basis (Taylor et al. 2007).

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Current and maximum net productivity rates are unknown for this stock. For purposes of this assessment, the
maximum net productivity rate was assumed to be 0.12. This value is based on theoretical modeling showing that pinniped populations may not grow at rates much greater than 12% given the constraints of their reproductive life history (Barlow et al. 1995).

**POTENTIAL BIOLOGICAL REMOVAL**

Potential Biological Removal (PBR) is the product of minimum population size, one-half the maximum productivity rate, and a recovery factor (MMPA Sec. 3. 16 U.S.C. 1362; Wade and Angliss 1997). The minimum population size is 66,884 animals. The maximum productivity rate is 0.12, the default value for pinnipeds. The recovery factor ($F_R$) is 0.5, the default value for stocks of unknown status relative to optimum sustainable population (OSP), and the CV of the average mortality estimate is less than 0.3 (Wade and Angliss 1997). PBR for the western North Atlantic stock of harbor seals is 2,006.

**ANNUAL HUMAN-CAUSED SERIOUS INJURY AND MORTALITY**

For the period 2010-2014 the total human caused mortality and serious injury to harbor seals is estimated to be 389 per year. The average was derived from three components: 1) 377 (CV=0.13; Table 2) from 2010-2014 observed fisheries; 2) 12 from average 2010-2014 non-fishery-related, human interaction stranding and direct interaction mortalities (NOAA National Marine Mammal Health and Stranding Response Database, accessed 08 October 2015); and 3) 0.2 from U.S. research mortalities. Analysis of bycatch rates from fisheries observer program records likely underestimates lethal (Lyle and Willcox 2008), and greatly under-represents sub-lethal, fishery interactions.

**Fishery Information**

Detailed fishery information is given in Appendix III.

**U.S. Northeast Sink Gillnet:**

Harbor seal bycatch is observed year round where they are most frequently observed in the summer in groundfish trips occurring between Boston, MA and Maine in the coastal Gulf of Maine waters. Williams (1999) aged 261 harbor seals caught in this fishery from 1991 to 1997, and 93% were juveniles (i.e., less than four years old). Since 1997, unidentified seals have not been prorated to a species. This is consistent with the treatment of other unidentified mammals that do not get prorated to a specific species. Revised serious injury guidelines were applied for this period (Waring et al. 2014, 2015; Wenzel et al. 2015, 2016). See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information. Analysis methodology and results can be found in Hatch and Orphanides (2014, 2015, 2016).

**Mid-Atlantic Gillnet**

Harbor seal bycatch has been observed in this fishery in waters off Massachusetts and New Jersey and rarely further south. A study on the effects of two different hanging ratios in the bottom-set monkfish gillnet fishery on the bycatch of cetaceans and pinnipeds was conducted by NEFSC in 2009 and 2010 with 100% observer coverage. Commercial fishing vessels from Massachusetts and New Jersey were used for the study, which took place south of the Harbor Porpoise Take Reduction Team Cape Cod South Management Area (south of 40° 40’) in February, March and April. Eight research strings of fourteen nets each were fished, and 159 hauls were completed during the course of the study. Results showed that while a 0.33 mesh performed better at catching commercially important finfish than a 0.50 mesh. There was no statistical difference in cetacean or pinniped bycatch rates between the two hanging ratios. Four harbor seals (3 in mid-Atlantic gillnet and 1 in NE gillnet) were caught in this project during 2010 (AIS 2010).

See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information. Analysis methodology and results can be found in Hatch and Orphanides (2014, 2015, 2016).

**Northeast Bottom Trawl**

Harbor seals are occasionally observed taken in this fishery. See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

**Mid-Atlantic Bottom Trawl**

Harbor seals are rarely observed taken in this fishery. Annual harbor seal mortalities were estimated using
annual stratified ratio-estimator methods (Lyssikatos 2015). See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

**Northeast Mid-water Trawl Fishery (Including Pair Trawl)**

Harbor seals are occasionally observed taken in this fishery. An extended bycatch rate has not been calculated for the current 5-year period. Until this bycatch estimate can be developed, the average annual fishery-related mortality and serious injury for 2010–2014 is calculated as 0.8 animal (4 animals /5 years). See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

**Mid-Atlantic Mid-water Trawl Fishery (Including Pair Trawl)**

A harbor seal mortality was observed in this fishery in 2010. An expanded bycatch estimate has not been generated. Until this bycatch estimate can be developed, the average annual fishery-related mortality and serious injury for 2010–2014 is calculated as 0.2 animals (1 animal/5 years). See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

**Gulf of Maine Atlantic Herring Purse Seine Fishery**

The Gulf of Maine Atlantic Herring Purse Seine Fishery is a Category III fishery. This fishery was not observed until 2003. No mortalities have been observed, but 3 harbor seals were captured and released alive in 2011, 1 in 2012, 1 in 2013 and 0 in 2014. In addition, 8 seals of unknown species were captured and released alive in 2011, and 0 in 2012–2014. One harbor seal and two unknown species in were designated as serious injuries/mortalities in 2011, based on fisheries monitoring logs (Waring et al. 2014). An expanded bycatch estimate has not been generated. Until this bycatch estimate can be developed, the average annual fishery-related mortality and serious injury for 2010-2014 is calculated as 0.2 animals (1 animal/5 years). See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

**CANADA**

Currently, scant data are available on bycatch in Atlantic Canada fisheries due to limited observer programs (Baird 2001). An unknown number of harbor seals have been taken in Newfoundland, Labrador, Gulf of St. Lawrence and Bay of Fundy groundfish gillnets; Atlantic Canada and Greenland salmon gillnets; Atlantic Canada cod traps; and in Bay of Fundy herring weirs (Read 1994; Cairns et al. 2000). Furthermore, some of these mortalities (e.g., seals trapped in herring weirs) are the result of direct shooting under nuisance permits.

| Table 2. Summary of the incidental mortality of harbor seals (Phoca vitulina vitulina) by commercial fishery including the years sampled (Years), the number of vessels active within the fishery (Vessels), the type of data used (Data Type), the annual observer coverage (Observer Coverage), the mortalities recorded by on-board observers (Observed Mortality), the estimated annual mortality (Estimated Mortality), the estimated CV of the annual mortality (Estimated CVs) and the mean annual mortality (CV in parentheses). |

### Other Mortality

#### U.S.

Historically, harbor seals were bounty-hunted in New England waters, which may have caused a severe decline of this stock in U.S. waters (Katona et al. 1993; Lelli et al. 2009). Bounty-hunting ended in the mid-1960s.

Other sources of harbor seal mortality include human interactions, storms, abandonment by the mother, disease (Anthony et al. 2012), and predation (Katona et al. 1993; NOAA National Marine Mammal Health and Stranding Response Database, accessed 08 October 2015; Jacobs and Terhune 2000). Mortalities caused by human interactions include research mortalities, boat strikes, fishing gear interactions, oil spill/exposure, harassment, and shooting.

Harbor seals strand each year throughout their migratory range. Stranding data provide insight into some of
these sources of mortality. From 2010 to 2014, 1,368 harbor seal stranding mortalities were reported between Maine and Florida (Table 3; NOAA National Marine Mammal Health and Stranding Response Database, accessed 08 October 2015). Seventy-five (5.4%) of the dead harbor seals stranded during this five-year period showed signs of human interaction (20 in 2010, 20 in 2011, 9 in 2012, 15 in 2013, and 11 in 2014), with 15 (1.0%) having some sign of fishery interaction (6 in 2010, 2 in 2011, 2 in 2012, 3 in 2013, and 2 in 2014). Five harbor seals during this period were reported as having been shot.

An Unusual Mortality Event (UME) was declared for harbor seals in northern Gulf of Maine waters in 2003 and continued into 2004. No consistent cause of death could be determined. The UME was declared over in spring 2005 (MMC 2006). NMFS declared another UME in the Gulf of Maine in autumn 2006 based on infectious disease. A UME was declared in November of 2011 that involved 567 harbor seal stranding mortalities between June 2011 and October 2012 in Maine, New Hampshire, and Massachusetts. The UME was declared closed in February 2013.

Stobo and Lucas (2000) have documented shark predation as an important source of natural mortality at Sable Island, Nova Scotia. They suggest that shark-inflicted mortality in pups, as a proportion of total production, was less than 10% in 1980-1993, approximately 25% in 1994–1995, and increased to 45% in 1996. Also, shark predation on adults was selective towards mature females. The decline in the Sable Island population appears to result from a combination of shark-inflicted mortality on both pups and adult females and inter-specific competition with the much more abundant gray seal for food resources (Stobo and Lucas 2000; Bowen et al. 2003).

**CANADA**

Aquaculture operations in eastern Canada are licensed to shoot nuisance seals, but the number of seals killed is unknown (Jacobs and Terhune 2000; Baird 2001). Small numbers of harbor seals are taken in subsistence hunting in northern Canada (DFO 2011).

### Table 3. Harbor seal (*Phoca vitulina vitulina*) stranding mortalities along the U.S. Atlantic coast (2010-2014) with subtotals of animals recorded as pups in parentheses.

a. Unusual Mortality event (UME) declared for harbor seals in southern Maine to northern Massachusetts in 2011.
STATUS OF STOCK

Harbor seals are not listed as threatened or endangered under the Endangered Species Act, and the western North Atlantic stock is not considered strategic under the Marine Mammal Protection Act. The 2010–2014 average annual human-caused mortality and serious injury does not exceed PBR. The status of the western North Atlantic harbor seal stock, relative to OSP, in the U.S. Atlantic EEZ is unknown. Total fishery-related mortality and serious injury for this stock is not less than 10% of the calculated PBR and, therefore, cannot be considered to be insignificant and approaching zero mortality and serious injury rate.

REFERENCES CITED

GRAY SEAL (*Halichoerus grypus atlantica*): Western North Atlantic Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

The gray seal (*Halichoerus grypus atlantica*) is found on both sides of the North Atlantic, with three major populations: eastern Canada, northwestern Europe and the Baltic Sea (Katona *et al.* 1993). The western North Atlantic stock is equivalent to the eastern Canada population, and ranges from New Jersey to Labrador (Davies 1957; Mansfield 1966; Katona *et al.* 1993; Lesage and Hammill 2001). This stock is separated by geography, differences in the breeding season, and mitochondrial and nuclear DNA variation from the northeastern Atlantic stocks (Bonner 1981; Boskovic *et al.* 1996; Lesage and Hammill 2001; Klimova *et al.* 2014). There are three breeding aggregations in eastern Canada: Sable Island, Gulf of St. Lawrence, and along the coast of Nova Scotia (Laviguer and Hammill 1993). Outside the breeding period, there is overlap in the distribution of animals from the three colonies (Laviguer and Hammill 1993; Harvey *et al.* 2008; Breed *et al.* 2006, 2009) and they are considered a single population based on genetic similarity (Boskovic *et al.* 1996; Wood *et al.* 2011). In the mid-1980s, small numbers of animals and pupping were observed on several isolated islands along the Maine coast and in Nantucket-Vineyard Sound, Massachusetts (Katona *et al.* 1993; Rough 1995: Gilbert *et al.* 2005). In December 2001, NMFS initiated aerial surveys to monitor gray seal pup production on Muskeget Island and adjacent sites in Nantucket Sound, and Green and Seal Islands off the coast of Maine (Wood *et al.* 2007). Tissue samples collected from Canadian and US populations were examined for genetic variation using microsatellite loci (Wood *et al.* 2011). All individuals were identified as belonging to one population, confirming that recolonization by Canadian gray seals is the source of the U.S. population.

POPULATION SIZE

Current estimates of the total western Atlantic gray seal population are not available; although estimates of portions of the stock are available for select time periods. The Canadian gray seal stock assessment (DFO 2014) reports gray seal pup production in 2014 for the three Canadian aggregations (Gulf of St. Lawrence, Sable Island, and Nova Scotia) as 93,000 (95% CI=48,000-137,000) animals; these are projected using population models to total population levels of 505,000 (95% CI=329,000-682,000) animals.

In U.S. waters, gray seals primarily pup at four established colonies: Muskeget and Monomoy islands in Massachusetts, and Green and Seal islands in Maine. Since 2010 pupping has also been observed at Noman’s Island in Massachusetts and Wooden Ball and Matinicus Rock in Maine. Although white-coated pups have stranded on eastern Long Island beaches, no pupping colonies have been detected in that region. Gray seals have been observed using the historic pupping site on Muskeget Island in Massachusetts since 1988. Pupping has taken place on Seal and Green Islands in Maine since at least the mid-1990s. Aerial survey data from these sites indicate that pup

---

**Figure 1.** Approximate coastal range of gray seals. Isobaths are the 100-m, 1000-m, and 4000-m depth contours.
production is increasing (Table 2), although aerial survey quality and coverage has varied significantly among surveys. A minimum of 2,620 pups (Muskeget= 2,095, Green= 59, Seal= 466) were born in the U.S. in 2008 (Wood LaFond 2009). Table 2 summarizes single-day pup counts from three of the U.S. pupping colonies from 2001/2002 to 2007/2008 pupping periods.

There are several published counts of gray seals in the Northeast U.S. outside of the pupping season. In April–May 1994 a maximum count of 2,010 was obtained for Muskeget Island and Monomoy Island combined (Rough 1995). Maine coast-wide surveys conducted during summer estimated 597 and 1,731 gray seals in 1993 and 2001, respectively (Gilbert et al. 2005). In March 1999 a maximum count of 5,611 was obtained in the region south of Maine (between Isles of Shoals, Maine and Woods Hole, Massachusetts) (Barlas 1999).

Minimum Population Estimate

Based on modeling, the total Canadian gray seal population was estimated to be 505,000 (95% CI = 329,000-682,000; DFO 2014). Present data are insufficient to calculate the minimum population estimate for U.S. waters.

Current Population Trend

Gray seal abundance is likely increasing in the U.S. Atlantic Exclusive Economic Zone (EEZ), but the rate of increase is unknown. An increasing trend in abundance in U.S. waters is supported by analysis of trends in gray seal strandings and bycatch records from the Northeastern U.S. (Johnston et al. 2015).

The population in eastern Canada was greatly reduced by hunting and bounty programs, and in the 1950s the gray seal was considered rare (Lesage and Hammill 2001). The Sable Island, Nova Scotia, population was less affected and has been increasing for several decades. Pup production on Sable Island increased exponentially at a rate of 12.8% per year between the 1970s and 1997 (Stobo and Zwanenburg 1990; Mohn and Bowen 1996; Bowen et al. 2003; Trzcinski et al. 2005; Bowen et al. 2007; DFO 2011). Recent population modeling indicates that the combined population increased at an annual rate of 5.2% between 2007 and 2010, and since then has continued to grow at a rate of 4.5% per year (DFO 2011, 2014). The non-Sable Island population increased from approximately 25,000 in the mid-1980s to a peak of 112,000 in 2014 (Thomas et al. 2011; DFO 2014). Modeling estimates of pup production increased from approximately 6,000 in 1985 to 21,500 in 2014 (Thomas et al. 2011; DFO 2014). Approximately 75% of the western North Atlantic population is from the Sable Island stock. In the early 1990s...
pupping was established on Hay Island, off the Cape Breton coast (Lesage and Hammill 2001; Hammill et al. 2007, Hamill and Stenson 2010).

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Current and maximum net productivity rates are unknown for this stock. Recent studies estimated the current annual rate of increase at 4.5% for the combined breeding aggregations in Canada (DFO 2014), continuing a decline in the rate of increase (Trzcinski et al. 2005; Bowen et al. 2007; Thomas et al. 2011; DFO 2014). For purposes of this assessment, the maximum net productivity rate was assumed to be 0.12. This value is based on theoretical modeling showing that pinniped populations may not grow at rates much greater than 12% given the constraints of their reproductive life history (Barlow et al. 1995).

POTENTIAL BIOLOGICAL REMOVAL

Potential Biological Removal (PBR) is the product of minimum population size, one-half the maximum productivity rate, and a recovery factor (MMPA Sec. 3. 16 U.S.C. 1362; Wade and Angliss 1997). The minimum population size is unknown. The maximum productivity rate is 0.12, the default value for pinnipeds. The recovery factor ($F_R$) for this stock is 1.0, the value for stocks of unknown status, but which are known to be increasing. PBR for the portion of the western North Atlantic gray seal stock in U.S. waters is unknown.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

For the period 2010–2014, the average annual estimated human caused mortality and serious injury to gray seals was 4,937 per year. The average was derived from six components: 1) 1,162 (CV=0.10) (Table 3) from the 2010–2014 U.S. observed fishery; 2) 7.8 from average 2010–2014 non-fishery related, human interaction stranding mortalities; 136 from average 2010–2014 kill in the Canadian hunt; 4) 82 from DFO scientific collections (DFO 2011); 5) 3,549 removals of nuisance animals in Canada (DFO 2014); and 6) 0.4 from U.S. research mortalities. Analysis of bycatch rates from fisheries observer program records likely underestimates lethal (Lyle and Willcox 2008), and greatly under-represents sub-lethal, fishery interactions.

Fishery Information

Detailed fishery information is given in Appendix III.

U.S.

Northeast Sink Gillnet

Gray seal bycatch in the northeast sink gillnet fishery were usually observed in the first half of the year in waters to the east and south of Cape Cod, Massachusetts in 12-inch gillnets fishing for skates and monkfish (Orphanides 2013; Hatch and Orphanides 2014, 2015, 2016). There were 7, 9, 1, 8, and 8 unidentified seals observed during 2010–2014, respectively. Since 1997 unidentified seals have not been prorated to a species. This is consistent with the treatment of other unidentified mammals that do not get prorated to a specific species. See Table 3 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

Mid-Atlantic Gillnet

Gray seal interactions were first observed in this fishery in 2010, since then, when they are observed, it is usually in waters off New Jersey in gillnets that have mesh sizes $\geq 7$ in (Orphanides 2013; Hatch and Orphanides 2014, 2015, 2016). See Table 3 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

Northeast Mid-Water Trawl

One gray seal mortality was observed in 2012 and one in 2013 in this fishery. An expanded bycatch estimate has not been generated. Until this bycatch estimate can be developed, the average annual fishery-related mortality and serious injury for 2010–2014 is calculated as 0.4 animals (2 animals /5 years). See Table 3 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

Mid-Atlantic Mid-Water Trawl

One gray seal mortality was observed in 2010 in this fishery. An expanded bycatch estimate has not been
generated. Until this bycatch estimate can be developed, the average annual fishery-related mortality and serious injury for 2010–2014 is calculated as 0.2 animals (1 animal /5 years). See Table 3 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

**Gulf of Maine Atlantic Herring Purse Seine Fishery**

The Gulf of Maine Atlantic Herring Purse Seine Fishery is a Category III fishery. This fishery was not observed until 2003, and was not observed in 2006. No mortalities have been observed, but during this time period 4 gray seals were captured and released alive in 2010, 34 in 2011, 33 in 2012, 1 in 2013, and 2 in 2014. In addition, during this time period 8 seals of unknown species were captured and released alive in 2011. See Table 3 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

**Northeast Bottom Trawl**

Vessels in the North Atlantic bottom trawl fishery, a Category III fishery under MMPA, were observed in order to meet fishery management, rather than marine mammal management needs. No mortalities were observed prior to 2005, when four mortalities were attributed to this fishery. See Table 2 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

**Mid-Atlantic Bottom Trawl**

Three gray seal mortalities were observed in this fishery in 2011, 1 in 2012, 2 in 2013, and 1 in 2014 (Table 2). See Table 3 for bycatch estimates and observed mortality and serious injury for the current 5-year period, and Appendix V for historical bycatch information.

**CANADA**

Historically, an unknown number of gray seals has been taken in Newfoundland and Labrador, Gulf of St. Lawrence, and Bay of Fundy groundfish gillnets; Atlantic Canada and Greenland salmon gillnets; Atlantic Canada cod traps, and Bay of Fundy herring weirs (Read 1994).

### Table 3. Summary of the incidental serious injury and mortality of gray seal (Halichoerus grypus atlantica) by commercial fishery including the years sampled, the type of data used, the annual observer coverage, the serious injuries and mortalities recorded by on-board observers, the estimated annual mortality, the estimated CV of the annual mortality and the mean annual combined mortality (CV in parentheses).

TOTAL 1,162 (0.10)

a. Observer data (Obs. Data) are used to measure bycatch rates, and the data are collected within the Northeast Fisheries Observer Program. The Northeast Fisheries Observer Program collects landings data (Weighout), and total landings are used as a measure of total effort for the sink gillnet fishery. Mandatory logbook (Logbook) data are used to determine the spatial distribution of fishing effort in the Northeast multispecies sink gillnet fishery.

b. The observer coverages for the northeast sink gillnet fishery and the mid-Atlantic gillnet fisheries are ratios based on tons of fish landed. North Atlantic bottom trawl mid-Atlantic bottom trawl, and mid-Atlantic mid-water trawl fishery coverages are ratios based on trips. Total observer coverage reported for bottom trawl gear and gillnet gear in the years 2010–2014 includes traditional fisheries observers in addition to fishery monitors through the Northeast Fisheries Observer Program (NEFOP).

c. Since 1998, takes from pingered and non-pingered nets within a marine mammal time/area closure that required pingers, and takes from pingered and non-pingered nets not within a marine mammal time/area closure were pooled. The pooled bycatch rate was weighted by the total number of samples taken from the stratum and used to estimate the mortality. In 2010–2014, respectively, 17, 125, 54, 38, and 85 takes were observed in nets with pingers. In 2010-2014, respectively, 39, 90, 97, 10, 31, and 74 takes were observed in nets without pingers.

d. Fishery related bycatch rates for years 2010–2014 were estimated using an annual stratified ratio-estimator. These estimates replace the 2008-2011 annual estimates reported in the 2013 stock assessment report that were generated using a different method (Lyssikatos et al. 2015).

e. Serious injuries were evaluated for the 2010–2014 period using new guidelines (Waring et al. 2014, 2015; Wenzel et al. 2015, 2016)

Other Mortality

U.S. Gray seals, like harbor seals, were hunted for bounty in New England waters until the late 1960s (Katona et al. 1993; Lelli et al. 2009). This hunt may have severely depleted this stock in U.S. waters (Rough 1995; Lelli et al. 2009). Other sources of mortality include human interactions, storms, abandonment by the mother, disease, and shark predation. Mortalities caused by human interactions include research mortalities, boat strikes, fishing gear interactions, power plant entrainment, oil spill/exposure, harassment, and shooting. Seals entangled in netting have been reported at several major haul-out sites in the Gulf of Maine.

From 2010 to 2014, 521 gray seal stranding mortalities were recorded, extending from Maine to North Carolina (Table 4; NOAA National Marine Mammal Health and Stranding Response Database, accessed 08 October 2015). Most stranding mortalities were in Massachusetts, which is the center of gray seal abundance in U.S. waters. Sixty-one (12%) of the total stranding mortalities showed signs of human interaction (12 in 2010, 20 in 2011, 4 in 2012, and 17 in 2013, and 8 in 2014), 22 of which had some indication of fishery interaction (4 in 2010, 5 in 2011, 2 in 2012, 9 in 2013 and 2 in 2014). Ten gray seals are recorded in the stranding database during the 2010 to 2014 period as having been shot—one in Maine and 2 in Massachusetts in 2010, 6 in Massachusetts in 2011, and none in 2012–2014.

STATUS OF STOCK

Gray seals are not listed as threatened or endangered under the Endangered Species Act, and the western North Atlantic stock is not considered strategic under the Marine Mammal Protection Act. The level of human-caused mortality and serious injury in the U.S. Atlantic EEZ is low relative to the total stock size. The status of the gray seal population relative to OSP in U.S. Atlantic EEZ waters is unknown, but the stock’s abundance appears to be increasing in Canadian and U.S. waters. The total U.S. fishery-related mortality and serious injury for this stock is low relative to the stock size in Canadian and U.S. waters and can be considered insignificant and approaching zero mortality and serious injury rate.

COMMON BOTTLENOSE DOLPHIN (*Tursiops truncatus truncatus*): Northern Gulf of Mexico Bay, Sound, and Estuary Stocks

NOTE – NMFS is in the process of writing individual stock assessment reports for each of the 31 bay, sound and estuary stocks of common bottlenose dolphins that are included in this report. Until this effort is completed and this report is replaced by 31 individual reports, basic information for all individual bay, sound and estuary stocks will remain in this report: “Northern Gulf of Mexico Bay, Sound and Estuary Stocks”. To date, four stocks have individual reports completed (Barataria Bay Estuarine System; Mississippi Sound, Lake Borgne, Bay Boudreau; Choctawhatchee Bay; St. Joseph Bay) and the remaining 27 stocks are assessed in this report.

STOCK DEFINITION AND GEOGRAPHIC RANGE

Common bottlenose dolphins are distributed throughout the bays, sound and estuaries of the Gulf of Mexico (Mullin 1988). The identification of biologically-meaningful “stocks” of bottlenose dolphins in these waters is complicated by the high degree of behavioral variability exhibited by this species (Shane *et al.* 1986; Wells and Scott 1999; Wells 2003), and by the lack of requisite information for much of the region.

Distinct stocks are delineated in each of 31 areas of contiguous, enclosed or semi-enclosed bodies of water adjacent to the northern Gulf of Mexico (i.e., U.S. Gulf of Mexico; Table 1; Figure 1). The genesis of the delineation of these stocks was work initiated in the 1970s in Sarasota Bay, Florida (Irvine *et al.* 1981), and in bays in Texas (Shane 1977; Gruber 1981). These studies documented year-round residency of individual bottlenose dolphins in estuarine waters. As a result, the expectation of year-round resident populations was extended to bay, sound and estuary (BSE) waters across the northern Gulf of Mexico when the first stock assessment reports were established in 1995. Since these early studies, long-term (year-round, multi-year) residency has been reported from nearly every site where photographic identification (photo-ID) or tagging studies have been conducted in the Gulf of Mexico. In Texas, long-term resident dolphins have been reported in the Matagorda-Espiritu Santo Bay area (Gruber 1981; Lynn and Würsig 2002), Aransas Pass (Shane 1977; Weller 1998), San Luis Pass (Maze and Würsig 1999; Irwin and Würsig 2004), and Galveston Bay (Bräger 1993; Bräger *et al.* 1994; Fertl 1994). In Louisiana, Miller (2003) concluded the bottlenose dolphin population in the Barataria Basin was relatively closed. Hubard *et al.* (2004) reported sightings of dolphins in Mississippi Sound that were known from tagging efforts there 12–15 years prior. In Florida, long-term residency has been reported from Tampa Bay (Wells 1986; Wells *et al.* 1996b; Urian *et al.* 2009), Sarasota Bay (Irvine and Wells 1972; Irvine *et al.* 1981; Wells 1986; 1991; 2003; 2014; Wells *et al.* 1987; Scott *et al.* 1990; Wells 1991; 2003), Lemon Bay (Wells *et al.* 1996a; Bassos-Hull *et al.* 2013), Charlotte Harbor/Pine Island Sound (Shane 1990; Wells *et al.* 1996a; Wells *et al.* 1997; Shane 2004; Bassos-Hull *et al.* 2013) and Gasparilla Sound (Bassos-Hull *et al.* 2013). In Sarasota Bay, which has the longest research history, at least 5 concurrent generations of identifiable residents have been identified, including some of those first identified in 1970 (Wells 2014). Maximum immigration and emigration rates of about 2–3% have been estimated (Wells and Scott 1990).

Genetic data also support the concept of relatively discrete BSE stocks. Analyses of mitochondrial DNA haplotype distributions indicate the existence of clinal variations along the Gulf of Mexico coastline (Duffield and Wells 2002). Differences in reproductive seasonality from site to site also suggest genetic-based distinctions between communities (Urian *et al.* 1996). Mitochondrial DNA analyses suggest finer-scale structural levels as well. For example, dolphins in Matagorda Bay, Texas, appear to be a localized population, and differences in haplotype frequencies distinguish among adjacent communities in Tampa Bay, Sarasota Bay and Charlotte Harbor/Pine Island Sound, along the central west coast of Florida (Duffield and Wells 1991; 2002). Additionally, Sellas *et al.* (2005) examined population subdivision among dolphins sampled in Sarasota Bay, Tampa Bay, Charlotte Harbor, Matagorda Bay, and the coastal Gulf of Mexico (1–12 km offshore) from just outside Tampa Bay to the southern end of Lemon Bay, and found evidence of significant population structure among all areas on the basis of both mitochondrial DNA control region sequence data and 9 nuclear microsatellite loci. The Sellas *et al.* (2005) findings support the separate identification of BSE populations from those occurring in adjacent Gulf coastal waters.

In many cases, residents occur primarily in BSE waters, with limited movements through passes to the Gulf of Mexico (Shane 1977; 1990; Gruber 1981; Irvine *et al.* 1981; Maze and Würsig 1999; Lynn and Würsig 2002; Fazioli *et al.* 2006). These habitat use patterns are reflected in the ecology of the dolphins in some areas; for
example, residents of Sarasota Bay, Florida, lacked squid in their diet, unlike non-resident dolphins stranded on nearby Gulf beaches (Barros and Wells 1998). However, in some areas year-round residents may co-occur with non-resident dolphins. For example, about 14–17% of group sightings involving resident Sarasota Bay dolphins include at least 1 non-resident as well (Wells et al. 1987; Fazioli et al. 2006). Mixing of inshore residents and non-residents has been seen at San Luis Pass, Texas (Maze and Würsig 1999), Cedar Keys, Florida (Quintana-Rizzo and Wells 2001), and Pine Island Sound, Florida (Shane 2004). Non-residents exhibit a variety of movement patterns, ranging from apparent nomadism recorded as transience to a given area, to apparent seasonal or non-seasonal migrations. Passes, especially the mouths of the larger estuaries, serve as mixing areas. For example, dolphins from several different areas were documented at the mouth of Tampa Bay, Florida (Wells 1986), and most of the dolphins identified in the mouths of Galveston Bay and Aransas Pass, Texas, were considered transients (Heningsen 1991; Bräger 1993; Weller 1998).

Seasonal movements of dolphins into and out of some of the bays, sounds and estuaries have also been documented. In Sarasota Bay, Florida, and San Luis Pass, Texas, residents have been documented moving into Gulf coastal waters in fall/winter, and returning inshore in spring/summer (Irvine et al. 1981; Maze and Würsig 1999). Fall/winter increases in abundance have been noted for Tampa Bay (Scott et al. 1989) and are thought to occur in Matagorda Bay (Gruber 1981; Lynn and Würsig 2002) and Aransas Pass (Shane 1977; Weller 1998). Spring/summer increases in abundance occur in Mississippi Sound (Hubard et al. 2004) and are thought to occur in Galveston Bay (Heningsen 1991; Bräger 1993; Fertl 1994).

Spring and fall increases in abundance have been reported for St. Joseph Bay, Florida. Mark-recapture abundance estimates were highest in spring and fall and lowest in summer and winter (Table 1; Balmer et al. 2008). Individuals with low site-fidelity indices were sighted more often in spring and fall, whereas individuals sighted during summer and winter displayed higher site-fidelity indices. In conjunction with health assessments, 23 dolphins were radio tagged during April 2005 and July 2006. Dolphins tagged in spring 2005 displayed variable utilization areas and variable site fidelity patterns. In contrast, during summer 2006 the majority of radio tagged individuals displayed similar utilization areas and moderate to high site-fidelity patterns. The results of the studies suggest that during summer and winter St. Joseph Bay hosts dolphins that spend most of their time within this region, and these may represent a resident community. In spring and fall, St. Joseph Bay is visited by dolphins that range outside of this area (Balmer et al. 2008).

The current BSE stocks are delineated as described in Table 1. There are some estuarine areas that are not currently part of any stock’s range. Many of these are areas that dolphins cannot readily access. For example, the marshlands between Galveston Bay and Sabine Lake and between Sabine Lake and Calcasieu Lake are fronted by long, sandy beaches that prohibit dolphins from entering the marshes. The region between the Calcasieu Lake and Vermilion Bay/Atchafalaya Bay stocks has some access, but these marshes are predominantly freshwater rather than saltwater marshes, making them unsuitable for long-term survival of a viable population of bottlenose dolphins. In other regions, there is insufficient estuarine habitat to harbor a demographically independent population, for instance between the Matagorda Bay and West Bay Stocks in Texas, and/or sufficient isolation of the estuarine habitat from coastal waters. The regions between the south end of the Estero Bay Stock area to just south of Naples and between Little Sarasota Bay and Lemon Bay are highly developed and contain little appropriate habitat. South of Naples to San Marco Island and Gullivant Bay is also not currently covered in a stock boundary. This region may reasonably contain bottlenose dolphins, but the relationship of any dolphins in this region to other BSE stocks is unknown. They may be members of the Gullivant to Chokoloskee Bay stock as there is passage behind San Marco Island that would allow dolphins to move north. The regions between Apalachee Bay and Cedar Key/Waccasassa Bay, between Crystal Bay and St. Joseph Sound and between Chokoloskee Bay and Whitewater Bay are comprised of thin strips of marshland with no barriers to adjacent coastal waters. Further work is necessary to determine whether year-round resident dolphins use these thin marshes or whether dolphins in these areas are members of the coastal stock that use the fringing marshland as well. Finally, the region between the eastern border of the Barataria Bay Stock and the Mississippi Delta Stock to the east may harbor dolphins, but the area is small and work is necessary to determine whether any dolphins utilizing this habitat come from an adjacent BSE stock.

As more information becomes available, combination or division of these stocks, or alterations to stock boundaries, may be warranted. Recent research based on photo-ID data collected by Bassos-Hull et al. (2013) recommended combining B21, Lemon Bay, with B22–23, Gasparilla Sound, Charlotte Harbor, Pine Island Sound. Therefore, these stocks have been combined (see Table 1). However, it should be noted this change was made in the absence of genetic data and could be revised again in the future when genetic data are available. Additionally, a number of geographically and socially distinct subgroupings of dolphins in regions such as Tampa Bay, Charlotte Harbor, Pine Island Sound, Aransas Pass and Matagorda Bay have been identified, but the importance of these distinctions to stock designations remains undetermined (Shane 1977; Gruber 1981; Wells et al. 1996a; 1996b;
1997; Lynn and Würsig 2002; Urian 2002). For Tampa Bay, Urian et al. (2009) described 5 discrete communities (including the adjacent Sarasota Bay community) that differed in their social interactions and ranging patterns. Structure was found despite a lack of physiographic barriers to movement within this large, open embayment. Urian et al. (2009) further suggested that fine-scale structure may be a common element among bottlenose dolphins in the southeastern U.S. and recommended that management should account for fine-scale structure that exists within current stock designations.

Table 1. Most recent common bottlenose dolphin abundance (N_{BEST}), coefficient of variation (CV) and minimum population estimate (N_{MIN}) in northern Gulf of Mexico bays, sounds and estuaries. Because they are based on data collected more than 8 years ago, most estimates are considered unknown or undetermined for management purposes. Blocks refer to aerial survey blocks illustrated in Figure 1. PBR – Potential Biological Removal; UNK – unknown; UND – undetermined.

West)

Notes:

a During earlier surveys (Scott et al. 1989), the range of seasonal abundances was as follows: B57, 0–2 (CV=0.38); B58, 0–6 (0.34); B59, 0–0; B30, 0–182 (0.14); B07, 0–0; B21, 0–15 (0.43); and B36, 0–0.

b Block not surveyed during surveys reported in Blaylock and Hoggard (1994).

c The individual SAR for this stock has not been updated yet to reflect this change.

†An individual stock assessment report is available for this stock.

Figure 1. Northern Gulf of Mexico bays, sounds and estuaries. Each of the alpha-numerically designated blocks corresponds to one of the NMFS Southeast Fisheries Science Center logistical aerial survey areas listed in Table 1. The common bottlenose dolphins inhabiting each bay, sound or estuary are considered to comprise a unique stock for purposes of this assessment. Four stocks have their own stock assessment report (see Table 1).

POPULATION SIZE

Population size estimates for most of the stocks are greater than 8 years old and therefore the current population sizes for all but 3 of these stocks are considered unknown (Wade and Angliss 1997). However, a capture-mark-recapture population size estimate for 2015 is available for Sarasota Bay, Little Sarasota Bay (Tyson and Wells 2016). Recent aerial survey line-transect population size estimates are available for Mississippi River Delta and Mississippi Sound, Lake Borgne, Bay Boudreau (Garrison 2017; Table 1). Population size estimates for many stocks were generated from preliminary analyses of line-transect data collected during aerial surveys conducted in September-October 1992 in Texas and Louisiana and in September-October 1993 in Louisiana, Mississippi, Alabama and the Florida Panhandle (Blaylock and Hoggard 1994; Table 1). Standard line-transect perpendicular sighting distance analytical methods (Buckland et al. 1993) and the computer program DISTANCE (Laake et al. 1993) were used.

Minimum Population Estimate

The population sizes for all but 3 stocks are currently unknown and the minimum population estimates are given for those 3 stocks in Table 1. The minimum population estimate is the lower limit of the two-tailed 60% confidence interval of the log-normally distributed abundance estimate. This is equivalent to the 20th percentile of the log-normal distribution as specified by Wade and Angliss (1997). The minimum population estimate was calculated for each block from the estimated population size and its associated coefficient of variation.
Current Population Trend

The data are insufficient to determine population trends for most of the Gulf of Mexico BSE common bottlenose dolphin stocks.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Current and maximum net productivity rates are not known for these stocks. The maximum net productivity rate was assumed to be 0.04. This value is based on theoretical modeling showing that cetacean populations may not grow at rates much greater than 4% given the constraints of their reproductive life history (Barlow et al. 1995).

POTENTIAL BIOLOGICAL REMOVAL

Potential Biological Removal (PBR) is the product of minimum population size, one-half the maximum productivity rate and a recovery factor (Wade and Angliss 1997). The recovery factor is 0.5 because these stocks are of unknown status. PBR is undetermined for all but 3 stocks because the population size estimates are more than 8 years old. PBR for those stocks with population size estimates less than 8 years old is given in Table 1.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

The total annual human-caused mortality and serious injury for these stocks during 2010–2014 is unknown because these stocks interact with unobserved fisheries (see below). Five-year unweighted mean mortality estimates for 2007–2011 for the commercial shrimp trawl fishery were calculated at the state level (see Shrimp Trawl section below).

Fishery Information

The commercial fisheries that interact, or that potentially could interact, with these stocks in the Gulf of Mexico are the Category II Southeastern U.S. Atlantic, Gulf of Mexico shrimp trawl; Gulf of Mexico menhaden purse seine; Southeastern U.S. Atlantic, Gulf of Mexico stone crab trap/pot; and Gulf of Mexico gillnet fisheries; and the Category III Gulf of Mexico blue crab trap/pot; Florida spiny lobster trap/pot; and Atlantic Ocean, Gulf of Mexico, Caribbean commercial passenger fishing vessel (hook and line) fisheries (Appendix III).

In the following sections the number of documented interactions of common bottlenose dolphins with each of these fisheries during 2010–2014 is reported. The likely stock(s) of origin for each interaction has been inferred based on the location of the interaction and distribution of the fishery.

Shrimp Trawl

During 2010–2014, there were no documented mortalities or serious injuries of common bottlenose dolphins from Gulf of Mexico BSE stocks by commercial shrimp trawls because observer coverage of this fishery does not include BSE waters. Between 1997 and 2011, 5 common bottlenose dolphins and 7 unidentified dolphins, which could have been either common bottlenose dolphins or Atlantic spotted dolphins, became entangled in the lazy line, turtle excluder device or tickler chain gear in the commercial shrimp trawl fishery in the Gulf of Mexico. All dolphin bycatch interactions resulted in mortalities except for 1 unidentified dolphin that was released alive in 2009. Soldevilla et al. (2015) provided mortality estimates calculated from analysis of shrimp fishery effort data and NMFS’s Observer Program bycatch data. Observer program coverage does not extend into BSE waters; time-area stratified bycatch rates were extrapolated into inshore waters to estimate bycatch mortalities from inshore fishing effort. Annual mortality estimates were calculated for the years 1997–2011 from stratified annual fishery effort and bycatch rates, and a 5-year unweighted mean mortality estimate for 2007–2011 was calculated for Gulf of Mexico dolphin stocks. The 4-area (Texas, Louisiana, Mississippi/Alabama, Florida) stratification method was chosen because it best approximates how fisheries operate (Soldevilla et al. 2015). The BSE stock mortality estimates were aggregated at the state level as this was the spatial resolution at which fishery effort is modeled (e.g., Nance et al. 2008). The mean annual mortality estimates for the BSE stocks were as follows: Texas BSE (from Galveston Bay, East Bay, Trinity Bay south to Laguna Madre): 0; Louisiana BSE (from Sabine Lake east to Barataria Bay): 88 (CV=1.01); Mississippi/Alabama BSE (from Mississippi River Delta east to Mobile Bay, Bonsecour Bay): 41 (CV=0.67); and Florida BSE (from Perdido Bay east and south to the Florida Keys): 3.4 (CV=0.99). These estimates do not include skimmer trawl effort, which may represent up to 50% of shrimp fishery effort in Louisiana, Alabama, and Mississippi inshore waters, because observer program coverage of skimmer trawls is limited. Limitations and biases of annual bycatch mortality estimates are described in detail in Soldevilla et al. (2015).

One mortality (2009) and 1 live release without serious injury (2012) occurred in Alabama bays during non-
commercial shrimp trawling (see "Other Mortality" below for details).

**Menhaden Purse Seine**

During 2010–2014, there were 2 mortalities and 1 animal released alive without serious injury documented within BSE waters involving the menhaden purse seine fishery. All 3 interactions occurred within the waters of the Mississippi Sound, Lake Borgne, Bay Boudreau Stock (also reported in that SAR).

There is currently no observer program for the Gulf of Mexico menhaden purse seine fishery; however, recent incidental takes have been reported via two sources. First, during 2011, a pilot observer program operated from May through September, and observers documented 3 dolphins trapped within purse seine nets. All 3 were released alive without serious injury (Maze-Foley and Garrison 2016a). Two of the 3 dolphins were trapped within a single purse seine within waters of the Western Coastal Stock. The third animal was trapped in waters of the Mississippi Sound, Lake Borgne, Bay Boudreau Stock. Second, through the Marine Mammal Authorization Program (MMAP), there have been 13 self-reported incidental takes (all mortalities) of common bottlenose dolphins in northern Gulf of Mexico coastal and estuarine waters by the menhaden purse seine fishery during 2000–2014. Specific self-reported takes under the MMAP likely involving BSE stocks are as follows: 2 dolphins were reported taken in a single purse seine during 2012 in Mississippi Sound (Mississippi Sound, Lake Borgne, Bay Boudreau Stock); 1 take of a single bottlenose dolphin was reported in Louisiana waters during 2004 that likely belonged to the Mississippi River Delta Stock; 1 take of a single unidentified dolphin reported during 2002 likely belonged to the Mississippi Sound, Lake Borgne, Bay Boudreau Stock; 1 take of a single bottlenose dolphin was reported in Louisiana waters during 2001 that likely belonged to Mississippi River Delta Stock or Northern Coastal Stock; during 2000, 1 take of a single bottlenose dolphin was reported in Louisiana waters that likely belonged to Mississippi River Delta Stock or Northern Coastal Stock; and also in 2000, 3 bottlenose dolphins were reported taken in a single purse seine in Mississippi waters that likely belonged to Mississippi Sound, Lake Borgne, Bay Boudreau Stock.

Without an ongoing observer program, it is not possible to obtain statistically reliable information for this fishery on the incidental take and mortality rates, and the stocks from which bottlenose dolphins are being taken.

**Blue Crab, Stone Crab and Florida Spiny Lobster Trap/Pot**

During 2010–2014 there were 4 documented interactions with trap/pot fisheries and BSE stocks. During 2013, 1 animal was disentangled and released alive from Florida spiny lobster trap/pot gear (it could not be determined if the animal was seriously injured following mitigation (disentanglement) efforts; the initial determination (pre-mitigation) was seriously injured [Maze-Foley and Garrison 2016c]). This animal likely belonged to the Florida Keys Stock. During 2011, 1 mortality occurred and 1 live animal was disentangled and released (it could not be determined if the animal was seriously injured [Maze-Foley and Garrison 2016a]). The BSE stocks involved were likely Waccasassa Bay, Withlacoochee Bay, Crystal Bay and Galveston Bay, East Bay, Trinity Bay, respectively. In 2010, a calf likely belonging to the Copano Bay, Aransas Bay, San Antonio Bay, Redfish Bay, Espiritu Santo Bay Stock was disentangled by stranding network personnel from a crab trap line wrapped around its peduncle. The animal swam away with no obvious injuries, but was considered seriously injured because it is unknown whether it was reunited with its mother (Maze-Foley and Garrison 2016a). The specific fishery could not be identified for the trap/pot gear involved in the 2011 and 2010 interactions. All mortalities and animals released alive were included in the stranding database (NOAA National Marine Mammal Health and Stranding Response Database unpublished data, accessed 15 June 2015) and are included in the stranding totals in Table 1. Because there is no systematic observer program, it is not possible to estimate the total number of interactions or mortalities associated with crab traps/pots.

**Gillnet**

No marine mammal mortalities associated with gillnet fisheries have been reported or observed in recent years, but stranding data suggest that gillnet and marine mammal interactions do occur, causing mortality and serious injury. During 2010–2014, a total of 12 entanglements in research-related gillnets were reported in BSE stocks: 8 dolphins in Texas, 2 in Louisiana and 2 in Florida. Three of the 12 entanglements resulted in mortalities, and 1 in a serious injury (see “Other Mortality” below for details on recent and historical research-related entanglements).

There has been no observer coverage of this fishery in federal waters. Beginning in November 2012, NMFS began placing observers on commercial vessels in the coastal waters of Alabama, Mississippi and Louisiana (state waters only). No takes have been observed to date (Mathers et al. 2016). In 1995, a Florida state constitutional amendment banned gillnets and large nets from bays, sounds, estuaries and other inshore waters. Commercial and recreational gillnet fishing is also prohibited in Texas state waters.
Hook and Line (Rod and Reel)

During 2010–2014 there were 29 documented interactions (entanglements or ingestions) with hook and line gear and BSE stocks—20 mortalities and 9 live animals for which disentanglement efforts were made. Available evidence from stranding data was examined for the 20 mortalities. For 12 of these mortalities, evidence suggested the hook and line gear interaction contributed to the cause of death. For 4 mortalities, evidence suggested the hook and line gear interaction was incidental and was not a contributing factor to cause of death. For 4 mortalities, it could not be determined if the hook and line gear interaction contributed to cause of death. Attempts were made to disentangle 9 live animals from hook and line gear, 2 of which were considered seriously injured by the gear based on observations during mitigation (disentanglement) efforts. Four live animals were considered seriously injured by the gear prior to mitigation efforts, but based on observations during mitigations, they were considered not seriously injured post-mitigation. For the remaining 3 live animals, it could not be determined if the animals were seriously injured (Maze-Foley and Garrison 2016a,b,c,d). In summary, the evidence available from stranding data suggested that at least 12 mortalities and 2 serious injuries to animals from BSE stocks were a result of interactions with rod and reel hook and line gear.

Interactions by year with hook and line gear were as follows: During 2010 there were 3 mortalities, and 1 live animal was disentangled and released, considered seriously injured (Maze-Foley and Garrison 2016a). During 2011, there were 2 mortalities, and 2 live animals were disentangled from hook and line gear. One of the live animals was considered seriously injured, and 1 was not seriously injured (Maze-Foley and Garrison 2016a). During 2012 there were 8 mortalities, and 2 live animals were disentangled from hook and line gear (1 considered not seriously injured, 1 could not be determined if it was seriously injured) (Maze-Foley and Garrison 2016b). During 2013 there were 3 mortalities and 3 live animals disentangled from hook and line gear. One of the live animals was considered not seriously injured and for the other 2, it could not be determined whether they were seriously injured (Maze-Foley and Garrison 2016c). Finally, during 2014 there were 4 mortalities and 1 live animal disentangled from hook and line gear considered not seriously injured (Maze-Foley and Garrison 2016d).

The mortalities and serious injuries likely involved animals from the following BSE stocks: Pensacola Bay, East Bay; Waccasassa Bay, Withlacoochee Bay, Crystal Bay; Tampa Bay; Sarasota Bay, Little Sarasota Bay; Pine Island Sound, Charlotte Harbor, Gasparilla Sound, Lemon Bay; Caloosahatchee River; Estero Bay; Chokoloskee Bay, Ten Thousand Islands, Gullivian Bay; Galveston Bay, East Bay, Trinity Bay; West Bay; Copano Bay, Aransas Bay, San Antonio Bay, Redfish Bay, Espiritu Santo Bay; and Neuces Bay, Corpus Christi Bay.

All mortalities and live entanglements were included in the stranding database (NOAA National Marine Mammal Health and Stranding Response Database unpublished data, accessed 15 June 2015) and are included in the stranding totals presented in Table 1. It should be noted that, in general, it cannot be determined if rod and reel hook and line gear originated from a commercial (i.e., charter boat and headboat) or recreational angler because the gear type used by both sources is typically the same. Also, it is not possible to estimate the total number of interactions with hook and line gear because there is no systematic observer program.

Strandings

A total of 564 common bottlenose dolphins were found stranded within bays, sounds and estuaries of the northern Gulf of Mexico from 2010 through 2014 (Table 2; NOAA National Marine Mammal Health and Stranding Response Database unpublished data, accessed 15 June 2015). It could not be determined if there was evidence of human interaction for 452 of these strandings. For 27 dolphins, no evidence of human interaction was detected. Evidence of human interactions was detected for 85 of these dolphins. Human interactions were from numerous sources, including 29 entanglements with hook and line gear, 4 entanglements with trap/pot gear, 12 incidental takes in research gillnet gear, 1 stabbing with a screwdriver, 2 animals shot by arrow and 1 with gunshot, 1 entanglement in a non-commercial shrimp trawl, 1 entanglement in research longline gear, 2 strandings with visible, external oil, and 1 entrapment between oil booms (see Table 1). Strandings with evidence of fishery-related interactions are reported above in the respective gear sections. Bottlenose dolphins are known to become entangled in, or ingest recreational and commercial fishing gear (Wells and Scott 1994; Gorzelany 1998; Wells et al. 1998, 2008), and some are struck by vessels (Wells and Scott 1997; Wells et al. 2008).

There are a number of difficulties associated with the interpretation of stranding data. Except in rare cases, such as Sarasota Bay, Florida, where residency can be determined, it is possible that some or all of the stranded dolphins may have been from a nearby coastal stock. However, the proportion of stranded dolphins belonging to another stock cannot be determined because of the difficulty of determining from where the stranded carcasses originated. Stranding data probably underestimate the extent of human and fishery-related mortality and serious injury because not all of the dolphins that die or are seriously injured in human interactions wash ashore, or, if they do, they are not all recovered (Peltier et al. 2012; Wells et al. 2015). Additionally, not all carcasses will show evidence of human...
interaction, entanglement or other fishery-related interaction due to decomposition, scavenger damage, etc. (Byrd et al. 2014). Finally, the level of technical expertise among stranding network personnel varies widely as does the ability to recognize signs of human interaction.

Since 1990, there have been 13 bottlenose dolphin die-offs or Unusual Mortality Events (UMEs) in the northern Gulf of Mexico (Litz et al. 2014; http://www.nmfs.noaa.gov/pr/health/mmume/events.html, accessed 11 January 2016). 1) From January through May 1990, a total of 344 bottlenose dolphins stranded in the northern Gulf of Mexico. Overall this represented a two-fold increase in the prior maximum recorded number of strandings for the same period, but in some locations (i.e., Alabama) strandings were 10 times the average number. The cause of the 1990 mortality event could not be determined (Hansen 1992), however, morbillivirus may have contributed to this event (Litz et al. 2014). 2) A UME was declared for Sarasota Bay, Florida, in 1991 involving 31 bottlenose dolphins. The cause was not determined, but it is believed biotoxins may have contributed to this event (Litz et al. 2014). 3) In March and April 1992, 119 bottlenose dolphins stranded in Texas - about 9 times the average number. The cause of this event was not determined, but low salinity due to record rainfall combined with pesticide runoff and exposure to morbillivirus were suggested as potential contributing factors (Duignan et al. 1996; Colbert et al. 1999; Litz et al. 2014). 4) In 1993–1994 a UME of bottlenose dolphins caused by morbillivirus started in the Florida Panhandle and spread west with most of the mortalities occurring in Texas (Lipscomb 1993; Lipscomb et al. 1994; Litz et al. 2014). From February through April 1994, 236 bottlenose dolphins were found dead on Texas beaches, of which 67 occurred in a single 10-day period. 5) In 1996 a UME was declared for bottlenose dolphins in Mississippi when 31 bottlenose dolphins stranded during November and December. The cause was not determined, but a Karenia brevis (red tide) bloom was suspected to be responsible (Litz et al. 2014). 6) Between August 1999 and May 2000, 150 bottlenose dolphins died coincident with K. brevis blooms and fish kills in the Florida Panhandle (additional strandings included 3 Atlantic spotted dolphins, Stenella frontalis, 1 Risso’s dolphin, Grampus griseus, 2 Blainville’s beaked whales, Mesoplodon densirostris, and 4 unidentified dolphins). Brevetoxin was determined to be the cause of this event (Twiner et al. 2012; Litz et al. 2014). 7) In March and April 2004, in another Florida Panhandle UME attributed to K. brevis blooms, 105 bottlenose dolphins and 2 unidentified dolphins stranded dead (Litz et al. 2014). Although there was no indication of a K. brevis bloom at the time, high levels of brevetoxin were found in the stomach contents of the stranded dolphins (Flewelling et al. 2005; Twiner et al. 2012). 8) In 2005, a particularly destructive red tide (K. brevis) bloom occurred off central west Florida. Manatee, sea turtle, bird and fish mortalities were reported in the area in early 2005 and a manatee UME had been declared. Dolphin mortalities began to rise above the historical averages by late July 2005, continued to increase through October 2005, and were then declared to be part of a multi-species UME. The multi-species UME extended into 2006, and ended in November 2006. In total, 190 dolphins were involved, primarily bottlenose dolphins (plus strandings of 1 Atlantic spotted dolphin, S. frontalis, and 23 unidentified dolphins). The evidence suggests a red tide bloom contributed to the cause of this event (Litz et al. 2014). 9) A separate UME was declared in the Florida Panhandle after elevated numbers of dolphin strandings occurred in association with a K. brevis bloom in September 2005. Dolphin strandings remained elevated through the spring of 2006 and brevetoxin was again detected in the tissues of most of the stranded dolphins and determined to be the cause of the event (Twiner et al. 2012; Litz et al. 2014). Between September 2005 and April 2006 when the event was officially declared over, a total of 88 bottlenose dolphin strandings occurred (plus strandings of 5 unidentified dolphins). 10) During February and March of 2007 an event was declared for northeast Texas and western Louisiana involving 64 bottlenose dolphins and 2 unidentified dolphins. Decomposition prevented conclusive analyses on most carcasses (Litz et al. 2014). 11) During February and March of 2008 an additional event was declared in Texas involving 111 bottlenose dolphin strandings (plus strandings of 1 unidentified dolphin and 1 melon-headed whale, Peponocephala electra). Most of the animals recovered were in a decomposed state. The investigation is closed and a direct cause could not be identified. However, there were numerous, co-occurring harmful algal bloom toxins detected during the time period of this UME which may have contributed to the mortalities (Fire et al. 2011). 12) A UME was declared for cetaceans in the northern Gulf of Mexico beginning 1 February 2010 and ending 31 July 2014 (Litz et al. 2014; http://www.nmfs.noaa.gov/pr/health/mmume/cetacean_gulfofmexico.htm, accessed 1 June 2016). The UME began a few months prior to the Deepwater Horizon (DWH) oil spill, however most of the strandings prior to May 2010 were in Lake Pontchartrain, Louisiana, and western Mississippi and were likely a result of low salinity and cold temperatures (Venn Watson et al. 2015a). The largest increase in strandings (compared to historical data) occurred after May 2010 following the DWH spill, and strandings were focused in areas exposed to DWH oil. Investigations to date have determined that the DWH oil spill is the primary underlying cause of the elevated stranding numbers in the northern Gulf of Mexico after the spill (e.g., Schwacke et al. 2014; Venn-Watson et al. 2015b). 13) A UME occurred from November 2011 to March 2012 across 5 Texas counties and included 126 bottlenose dolphin strandings. The strandings were coincident with a harmful algal bloom of K. brevis, but researchers have not
determined that was the cause of the event. During 2011, 6 animals from BSE stocks were considered to be part of the UME; during 2012, 24 animals.

Table 2. Common bottlenose dolphin strandings occurring in bays, sounds and estuaries in the northern Gulf of Mexico from 2010 to 2014, as well as number of strandings for which evidence of human interaction was detected and number of strandings for which it could not be determined (CBD) if there was evidence of human interaction. Data are from the NOAA National Marine Mammal Health and Stranding Response Database (unpublished data, accessed 15 June 2015). Please note human interaction does not necessarily mean the interaction caused the animal’s death. Please also note that this table does not include strandings from Barataria Bay Estuarine System; Mississippi Sound, Lake Borgne, Bay Boudreau; Choctawhatchee Bay; or St. Joseph Bay.

a This total includes animals that are part of the Northern Gulf of Mexico UME.
b This total includes animals that are part of the Northern Gulf of Mexico UME, and also includes 6 animals that were part of the 2011–2012 UME in Texas.
c This total includes animals that are part of the Northern Gulf of Mexico UME, and also includes 24 animals that were part of the 2011–2012 UME in Texas.
d This total includes animals that are part of the Northern Gulf of Mexico UME.
e This total includes animals that are part of the Northern Gulf of Mexico UME.
f Includes 4 entanglement interactions with hook and line gear (3 mortalities and 1 animal released alive seriously injured); 1 entanglement interaction with unidentified trap/pot gear (released alive seriously injured); 2 entanglement interactions with research gillnet gear (1 released alive without serious injury, 1 released alive that could not be determined if seriously injured or not); 1 live release without serious injury following entrapment between oil booms (animal was initially seriously injured, but due to mitigation efforts, was released without serious injury); 1 animal visibly oiled (mortality); and 1 entanglement interaction with unknown gear (released alive without serious injury [animal was initially seriously injured, but due to mitigation efforts, was released without serious injury]).
g Includes 4 entanglement interactions with hook and line gear (2 mortalities, 1 animal released alive seriously injured, 1 released alive without serious injury [this animal was initially seriously injured, but due to mitigation efforts, was released without serious injury]); 2 entanglement interactions with research gillnet gear (1 mortality, 1 released alive without serious injury); 2 entanglement interactions with trap/pot gear (1 mortality, 1 released alive that could not be determined if seriously injured or not); and 1 animal visibly oiled (mortality).
h Includes 10 entanglement interactions with hook and line gear (8 mortalities, 1 released alive without serious injury [animal was initially seriously injured, but due to mitigation efforts, was released without serious injury], 1 released alive that could not be determined if seriously injured or not); 4 entanglement interactions with research gillnet gear (1 released alive seriously injured, 3 released alive without serious injury); 1 entanglement in a non-commercial shrimp trawl net (released alive without serious injury); 1 stabbing (mortality); and 1 entanglement interaction with unknown fishing gear (released alive without serious injury [animal was initially seriously injured, but due to mitigation efforts, was released without serious injury]).
i Includes 6 entanglement interactions with hook and line gear (3 mortalities, 1 animal released alive without serious injury [animal was initially seriously injured, but due to mitigation efforts, was released without serious injury], 2 animals released alive that could not be determined if seriously injured or not); 4 entanglement interactions with research gillnet gear (2 mortalities, 1 animal released alive without serious injury, 1 animal released alive that could not be determined if seriously injured or not); 1 interaction with Florida spiny lobster trap/pot gear (released alive, could not be determined if seriously injured or not [this animal was initially seriously injured, but mitigation efforts were made]); 1 interaction with research longline gear (released alive, seriously injured); and 1 animal that was gunshot (mortality).
j Includes 5 entanglement interactions with hook and line gear (4 mortalities, 1 released alive without serious injury [animal was initially seriously injured, but due to mitigation efforts, was released without serious injury]) and 2 animals shot by arrow (mortalities).
Other Mortality

There were 3 live dolphins included in the stranding database during 2010–2014 that were entangled in unidentified fishing gear or unidentified gear. One animal was seriously injured in 2013 in the Pine Island Sound, Charlotte Harbor, Gasparilla Sound, Lemon Bay Stock area (Maze-Foley and Garrison 2016c). Two animals were initially considered seriously injured, but following mitigation efforts, were released alive without serious injury in 2010 (Sarasota Bay, Little Sarasota Bay Stock) and 2012 (Pine Island Sound, Charlotte Harbor, Gasparilla Sound, Lemon Bay Stock) (Maze-Foley and Garrison 2016a,b). In addition, during 2012 in Alabama (Perdido Bay Stock), a dolphin was disentangled from a shrimp trawling net being used in a local ecotour. The animal was considered not seriously injured (Maze-Foley and Garrison 2016b), and was also included in the stranding database (NOAA National Marine Mammal Health and Stranding Response Database unpublished data, accessed 15 June 2015).

In addition to animals included in the stranding database, during 2010–2014, there were 20 at-sea observations in BSE stock areas of common bottlenose dolphins entangled in fishing gear or unidentified gear (hook and line, crab trap/pot and unidentified gear/line/rope). In 8 of these cases the animals were seriously injured, in 1 case the animal was not seriously injured, and for the remaining 11 cases, it could not be determined (CBD) if the animals were seriously injured (Maze-Foley and Garrison 2016a,b,c,d; see Table 3).

Table 3. At-sea observations of common bottlenose dolphins entangled in fishing gear or unidentified gear during 2010–2014, including the serious injury determination (mortality, serious injury, not a serious injury, or could not be determined (CBD) if seriously injured) and stock to which each animal likely belonged based on sighting location. Further details can be found in Maze-Foley and Garrison (2016a,b,c,d).

Common bottlenose dolphins are also known to interact with research-fishery gear. During 2010–2014, a dolphin was seriously injured during a research longline survey (Maze-Foley and Garrison 2016c; see Table 4) and 12 dolphins were entangled in research-related gillnets—in Texas (8), Louisiana (2) and Florida (2). Three of the 12 entanglements resulted in mortalities; 1 entanglement resulted in a serious injury; 6 entanglements were released alive without serious injury; and for 2 entanglements, it could not be determined if the animals were seriously injured (Maze-Foley and Garrison 2016a,b,c,d; see Table 4). All of the interactions with research gear were included in the stranding database (NOAA National Marine Mammal Health and Stranding Response Database unpublished...
Table 4. Research-related takes of common bottlenose dolphins during 2010–2014, including the serious injury determination for each animal (mortality, serious injury, not a serious injury, or could not be determined (CBD) if seriously injured) and stock to which each animal likely belonged based on location of the interaction. All of these interactions were included in the stranding database (NOAA National Marine Mammal Health and Stranding Response Database unpublished data, accessed 15 June 2015). Further details on injury determinations can be found in Maze-Foley and Garrison (2016a,b,c,d).

The problem of dolphin depredation of fishing gear is increasing in Gulf of Mexico coastal and estuary waters. There was a recent case within BSE waters of a shrimp fisherman illegally taking a common bottlenose dolphin in Mississippi Sound (Mississippi Sound, Lake Borgne, Bay Boudreaux Stock) during summer 2012. In December 2013 the fisherman was convicted under the MMPA for knowingly shooting a dolphin with a shotgun while shrimping.

In addition to the above case where it was confirmed the fisherman retaliated against depredation by dolphins, there have been several other documented shootings of BSE common bottlenose dolphins in recent years, both by arrows and guns. During 2014 in Cow Bayou, Texas (Sabine Lake Stock), a dolphin was shot with a compound bow resulting in mortality. In 2014 near Orange Beach, Alabama (Perdido Bay Stock), a dolphin was shot with a hunting arrow. In the arrow cases, there was no evidence the acts were committed due to dolphin depredation of fishing gear. In 2014 within Choctawhatchee Bay, Florida (Choctawhatchee Bay Stock), a pregnant bottlenose dolphin was found dead with a bullet lodged in its lung. Necropsy results indicated the dolphin died of the gunshot wound. Two individual bottlenose dolphins were shot with buckshot-like ammunition in Louisiana waters: 1 in 2014 within Barataria Bay (Barataria Bay Stock), and 1 in 2013 in a canal off Terrebonne Bay (Terrebonne Bay, Timbalier Bay Stock). In 2013 in Mississippi Sound, a dolphin was found with a bullet lodged in its lung. Necropsy results indicated the bullet had been there for several months and likely was not the cause of death. In the gunshot cases, it is unknown whether the animals were shot due to depredation of fishing gear, but it is possible one or more of these acts was related to depredation. All of these shootings were included in the stranding database and in Table 2. During 2012 a dolphin was observed swimming in Perdido Bay with a screwdriver protruding from its melon and was found dead the next day. This stabbing was included in the stranding database and in Table 2.

Illegal feeding or provisioning of wild bottlenose dolphins has been documented in Florida, particularly near Panama City Beach in the Panhandle (Samuels and Bejder 2004) and in and near Sarasota Bay (Cunningham-Smith et al. 2006; Powell and Wells 2011), and also in Texas near Corpus Christi (Bryant 1994). Feeding wild dolphins is defined under the MMPA as a form of ‘take’ because it can alter their natural behavior and increase their risk of injury or death. Nevertheless, a high rate of provisioning was observed near Panama City Beach in 1998 (Samuels...
and Bejder 2004), and provisioning has been observed south of Sarasota Bay since 1990 (Cunningham-Smith et al. 2006; Powell and Wells 2011). There are emerging questions regarding potential linkages between provisioning and predation of recreational fishing gear and associated entanglement and ingestion of gear, which is increasing through much of Florida. During 2006, at least 2% of the long-term resident dolphins of Sarasota Bay died from ingestion of recreational fishing gear (Powell and Wells 2011).

Swimming with wild bottlenose dolphins has also been documented in Florida in Key West (Samuels and Engleby 2007) and near Panama City Beach (Samuels and Bejder 2004). Near Panama City Beach, Samuels and Bejder (2004) concluded that dolphins were amenable to swimmers due to illegal provisioning. Swimming with wild dolphins may cause harassment, and harassment is illegal under the MMPA.

As noted previously, bottlenose dolphins are known to be struck by vessels (Wells and Scott 1997; Wells et al. 2008). During 2010–2014, 19 stranded bottlenose dolphins (of 564 total strandings) showed signs of a boat collision (NOAA National Marine Mammal Health and Stranding Response Database unpublished data, accessed 15 June 2015). It is possible some of the instances were post-mortem collisions. In addition to vessel collisions, the presence of vessels may also impact bottlenose dolphin behavior in bays, sounds and estuaries. Nowacek et al. (2001) reported that boats pass within 100 m of each bottlenose dolphin in Sarasota Bay once every 6 minutes on average, leading to changes in dive patterns and group cohesion. Buckstaff (2004) noted changes in communication patterns of Sarasota Bay dolphins when boats approached. Miller et al. (2008) investigated the immediate responses of bottlenose dolphins to “high-speed personal watercraft” (i.e., boats) in Mississippi Sound. They found an immediate impact on dolphin behavior demonstrated by an increase in traveling behavior and dive duration, and a decrease in feeding behavior for non-traveling groups. The findings suggested dolphins attempted to avoid high-speed personal watercraft. It is unclear whether repeated short-term effects will result in long-term consequences like reduced health and viability of dolphins. Further studies are needed to determine the impacts throughout the Gulf of Mexico.

As part of its annual coastal dredging program, the Army Corps of Engineers conducts sea turtle relocation trawling during hopper dredging as a protective measure for marine turtles. No interactions have been documented during the most recent 5 years, 2010–2014, that fall within BSE stocks in this report; however, 1 interaction occurred within the boundaries of the Mississippi Sound, Lake Borgne, Bay Boudreau Stock (please see that SAR for details). In earlier years, 5 interactions, including 4 mortalities (2003, 2005, 2006, 2007), were documented in the Gulf of Mexico involving bottlenose dolphins and relocation trawling activities. It is likely that 2 of these animals belonged to BSE stocks (2003, 2006).

There have been documented mortalities of common bottlenose dolphins during health-assessment research projects in the Gulf of Mexico, but none have occurred during the most recent 5 years, 2010–2014. Historically, 1 mortality occurred within Sarasota Bay in 2002, and 1 mortality occurred in St. Joseph Bay in 2006.

Some of the BSE communities were the focus of a live-capture fishery for bottlenose dolphins which supplied dolphins to the U.S. Navy and to oceanaria for research and public display for more than 2 decades (Reeves and Leatherwood 1984; Scott 1990). Between 1973 and 1988, 533 bottlenose dolphins were removed from Southeastern U.S. waters (Scott 1990). The impact of these removals on the stocks is unknown. In 1989, the Alliance of Marine Mammal Parks and Aquariums declared a self-imposed moratorium on the capture of bottlenose dolphins in the Gulf of Mexico (Corkeron 2009).

HABITAT ISSUES
The DWH MC252 drilling platform, located approximately 50 miles southeast of the Mississippi River Delta in waters about 1500 m deep, exploded on 20 April 2010. The rig sank, and over 87 days up to ~4.9 million barrels of oil were discharged from the wellhead until it was capped on 15 July 2010 (McNutt et al. 2012). During the response effort dispersants were applied extensively at the seafloor and at the sea surface (Lehr et al. 2010; OSAT 2010). In-situ burning, or controlled burning of oil at the surface, was also used extensively as a response tool (Lehr et al. 2010). The oil, dispersant and burn residue compounds present ecological concerns (Buist et al. 1999; NOAA 2011). The magnitude of this oil spill was unprecedented in U.S. history, causing impacts to wildlife, natural habitats and human communities along coastal areas from western Louisiana to the Florida Panhandle (NOAA 2011). It could be years before the entire scope of damage is ascertained (NOAA 2011).

A substantial number of beaches and wetlands along the Louisiana coast experienced heavy or moderate oiling (OSAT-2 2011; Michel et al. 2013). The heaviest oiling in Louisiana occurred west of the Mississippi River on the Mississippi Delta and in Barataria and Terrebonne Bays, and to the east of the river on the Chandeleur Islands. Some heavy to moderate oiling occurred on Alabama and Florida beaches, with the heaviest stretch occurring from Dauphin Island, Alabama, to Gulf Breeze, Florida. Light to trace oil was reported along the majority of Mississippi’s mainland coast, from Gulf Breeze to Panama City, Florida, and outside of Atchafalaya and Vermilion Bays in western Louisiana. Heavy to light oiling occurred on Mississippi’s barrier islands (Michel et al. 2013). Thus, it is
likely that some BSE stocks were exposed to oil. Dolphins were observed with tar balls attached to them and seen swimming through oil slicks close to shore and inland bays. The effects of oil exposure on marine mammals depend on a number of factors including the type and mixture of chemicals involved, the amount, frequency and duration of exposure, the route of exposure (inhaled, ingested, absorbed, or external) and biomedical risk factors of the particular animal (Geraci 1990; Helm et al. 2015). In general, direct external contact with petroleum compounds or dispersants with skin may cause skin irritation, chemical burns and infections. Inhalation of volatile petroleum compounds or dispersants may irritate or injure the respiratory tract, which could lead to pneumonia or inflammation. Ingestion of petroleum compounds may cause injury to the gastrointestinal tract, which could affect an animal’s ability to digest or absorb food. Absorption of petroleum compounds or dispersants may damage kidney, liver and brain function in addition to causing immune suppression and anemia. Long term chronic effects such as lowered reproductive success and decreased survival may occur (Geraci 1990; Helm et al. 2015).

Shortly after the oil spill, the Natural Resource Damage Assessment (NRDA) process was initiated under the Oil Pollution Act of 1990. A variety of NRDA research studies are being conducted to determine potential impacts of the spill on marine mammals. These studies have focused on identifying the type, magnitude, severity, length and impact of oil exposure to oceanic, continental shelf, coastal and estuarine marine mammals. The research is ongoing. For coastal and estuarine dolphins, the NOAA-led efforts include: active surveillance to detect stranded animals in remote locations; aerial surveys to document the distribution, abundance, species and exposure relative to oil from the DWH spill; assessment of sublethal and chronic health impacts on coastal and estuarine bottlenose dolphins in Barataria Bay, Louisiana, Mississippi Sound, and a reference site in Sarasota Bay, Florida; and assessment of injuries to dolphin stocks in Barataria Bay and Chandeleur Sound, Louisiana, Mississippi Sound, and as a reference site, St. Joseph Bay, Florida.

The nearshore habitat occupied by many of these stocks is adjacent to areas of high human population, and in some bays, such as Mobile Bay in Alabama and Galveston Bay in Texas, is highly industrialized. The area surrounding Galveston Bay, for example, has a coastal population of over 3 million people. More than 50% of all chemical products manufactured in the U.S. are produced there, and 17% of the oil produced in the Gulf of Mexico is refined there (Henningsen and Würsig 1991). Many of the enclosed bays in Texas are surrounded by agricultural lands which receive periodic pesticide applications.

Concentrations of chlorinated hydrocarbons and metals were examined in conjunction with an anomalous mortality event of bottlenose dolphins in Texas bays in 1990 and found to be relatively low in most; however, some had concentrations at levels of possible toxicological concern (Varanasi et al. 1992). No studies to date have determined the amount, if any, of indirect human-induced mortality resulting from pollution or habitat degradation.

Analyses of organochlorine concentrations in the tissues of bottlenose dolphins in Sarasota Bay, Florida, have found that the concentrations in male dolphins exceeded toxic threshold values that may result in adverse effects on health or reproductive rates (Schwacke et al. 2002). Studies of contaminant concentrations relative to life history parameters showed higher levels of mortality in first-born offspring, and higher contaminant concentrations in these calves and in primiparous females (Wells et al. 2005). While there are no direct measurements of adverse effects of pollutants on estuarine dolphins, the exposure to environmental pollutants and subsequent effects on population health are areas of concern and active research.

STATUS OF STOCKS

The status of these stocks relative to OSP is unknown and this species is not listed as threatened or endangered under the Endangered Species Act. The occurrence of 13 Unusual Mortality Events (UMEs) among common bottlenose dolphins along the northern Gulf of Mexico coast since 1990 (Litz et al. 2014; http://www.nmfs.noaa.gov/pr/health/mmume/events.html, accessed 11 January 2016) is cause for concern. Notably, stock areas in Louisiana, Mississippi, Alabama and the western Florida panhandle have been impacted by a UME of unprecedented size and duration (began 1 February 2010, and as of December 2015, the event is under consideration for closure). However, the effects of the mortality events on stock abundance have not yet been determined, in large part because it has not been possible to assign mortalities to specific stocks due to a lack of empirical information on stock identification.

Human-caused mortality and serious injury for each of these stocks is not known. Considering the evidence from stranding data (Table 2) and the low PBRs for stocks with recent abundance estimates, the total fishery-related mortality and serious injury likely exceeds 10% of the total known PBR or previous PBR, and therefore, it is probably not insignificant and not approaching the zero mortality and serious injury rate. NMFS considers each of these stocks to be strategic because most of the stock sizes are currently unknown, but likely small and relatively few mortalities and serious injuries would exceed PBR.

ROUGH-TOOTHED DOLPHIN (Steno bredanensis): Northern Gulf of Mexico Stock

STOCK DEFINITION AND GEOGRAPHIC RANGE

The rough-toothed dolphin is distributed worldwide in tropical to warm temperate waters (Leatherwood and Reeves 1983; Miyazaki and Perrin 1994; West et al. 2011). Rough-toothed dolphins occur in oceanic and to a lesser extent continental shelf waters in the northern Gulf of Mexico (i.e., U.S. Gulf of Mexico) (Figure 1; Fulling et al. 2003; Mullin and Fulling 2004; Maze-Foley and Mullin 2006). Rough-toothed dolphins were seen in all seasons during GulfCet aerial surveys of the northern Gulf of Mexico between 1992 and 1998 (Hansen et al. 1996; Mullin and Hoggard 2000). Four dolphins from a mass stranding of 62 animals in the Florida Panhandle in December 1997 were rehabilitated and released in 1998, and satellite-linked transmitters on 3 of these were tracked for 4 to 112 days. A report after 5 months indicated that the animals returned to, and remained in, northeastern Gulf waters averaging about 195 m deep offshore of the original stranding site (Wells et al. 1999).

Although there are only a few records from Gulf of Mexico waters beyond U.S. boundaries (e.g., Jefferson and Schiro 1997, Ortega Ortiz 2002), rough-toothed dolphins almost certainly occur throughout the oceanic Gulf of Mexico (Jefferson et al. 2008), which is also composed of waters belonging to Mexico and Cuba where there is currently little information on cetacean species abundance and distribution. U.S. waters comprise only about 40% of the entire Gulf of Mexico and 35% of the oceanic (i.e., >200 m) Gulf of Mexico. The Gulf of Mexico population is being considered 1 stock for management purposes, although there is currently no information to differentiate this stock from the Atlantic Ocean stock(s), nor information on whether more than 1 stock may exist in the Gulf of Mexico. Additional morphological, genetic and/or behavioral data are needed to provide further information on stock delineation.

POPULATION SIZE

The current population size for the rough-toothed dolphin in the northern Gulf of Mexico is 624 (CV=0.99; Table 1; Garrison 2016). This estimate is from a summer 2009 oceanic survey covering waters from the 200-m isobath to the seaward extent of the U.S. Exclusive Economic Zone (EEZ).

Earlier abundance estimates

Estimates of abundance were derived through the application of distance sampling analysis (Buckland et al. 2001) and the computer program DISTANCE (Thomas et al. 1998) to line-transect survey data. During summer 2003 and spring 2004, ship surveys dedicated to estimating cetacean abundance were conducted in oceanic waters along a grid of uniformly-spaced transect lines from a random start. The abundance estimate for rough-toothed dolphins in oceanic waters, pooled from 2003 to 2004, was 1,508 (CV=0.39) (Mullin 2007).

Please see Appendix IV for a summary of abundance estimates, including earlier estimates and survey descriptions.
Recent surveys and abundance estimates

During summer 2009, a line-transect shipboard survey dedicated to estimating the abundance of oceanic cetaceans was conducted in the northern Gulf of Mexico covering waters depths from the 200-m isobath to the seaward extent of the U.S. EEZ (Garrison 2016). Survey lines were stratified in relation to depth and the location of the Loop Current. In total, 4,600 km of trackline were surveyed using a single visual observation team. The abundance estimate for rough-toothed dolphins in oceanic waters during 2009 was 624 (CV=0.99; Table 1; Garrison 2016). This is the most reliable current estimate for the northern Gulf of Mexico but it is probably an underestimate. This estimate does not include Gulf of Mexico continental shelf waters where an estimate based on 1998–2001 surveys was over 1,000 rough-toothed dolphins (Fulling et al. 2003). There is not a recent estimate for continental shelf waters.

Table 1. Most recent abundance estimates ($N_{\text{best}}$) and coefficient of variation (CV) of rough-toothed dolphins in the northern Gulf of Mexico oceanic waters (200 m to the offshore extent of the EEZ) during spring/summer 2003–2004 and summer 2009.

Minimum Population Estimate

The minimum population estimate is the lower limit of the two-tailed 60% confidence interval of the log-normal distributed abundance estimate. This is equivalent to the 20th percentile of the log-normal distributed abundance estimate as specified by Wade and Angliss (1997). The best estimate of abundance for rough-toothed dolphins is 624 (CV=0.99). The minimum population estimate for northern Gulf of Mexico rough-toothed dolphins is 311.

Current Population Trend

A trend analysis has not been conducted for this stock. Two point estimates of rough-toothed dolphin abundance have been made based on data from oceanic surveys during 2003–2004 and 2009 (Table 1). The estimates vary by a factor of more than two. To determine whether changes in oceanic abundance have occurred over this period, an analysis of all the survey data needs to be conducted which incorporates covariates (e.g., survey conditions, season) that could potentially affect estimates. It should be noted that since this is a transboundary stock and the abundance estimates are for U.S. waters only, it will be difficult to interpret any detected trends. Additionally, the extent to which rough-toothed dolphins inhabit continental shelf waters and whether there is movement between these waters and oceanic waters needs to be resolved.

CURRENT AND MAXIMUM NET PRODUCTIVITY RATES

Current and maximum net productivity rates are unknown for this stock. For purposes of this assessment, the maximum net productivity rate was assumed to be 0.04. This value is based on theoretical modeling showing that cetacean populations may not grow at rates much greater than 4% given the constraints of their reproductive history (Barlow et al. 1995).

POTENTIAL BIOLOGICAL REMOVAL

Potential Biological Removal (PBR) is the product of the minimum population size, one half the maximum net productivity rate and a recovery factor (MMPA Sec. 3.16 U.S.C. 1362; Wade and Angliss 1997). The minimum population size is 311. The maximum productivity rate is 0.04, the default value for cetaceans. The recovery factor is 0.40 because the CV of the average mortality estimate is greater than 0.8 (Wade and Angliss 1997). PBR for the northern Gulf of Mexico rough-toothed dolphin is 2.5.

ANNUAL HUMAN-CAUSED MORTALITY AND SERIOUS INJURY

The estimated mean annual fishery-related mortality and serious injury for this stock during 2010–2014 was 0.8 rough-toothed dolphins (CV=1.0; Table 2) due to interactions with the pelagic longline fishery.

New Serious Injury Guidelines

NMFS updated its serious injury designation and reporting process, which uses guidance from previous serious
injury workshops, expert opinion, and analysis of historic injury cases to develop new criteria for distinguishing serious from non-serious injury (Angliss and DeMaster 1998; Andersen et al. 2008; NMFS 2012). NMFS defines serious injury as an “injury that is more likely than not to result in mortality”. Injury determinations for stock assessments revised in 2013 or later incorporate the new serious injury guidelines, based on the most recent 5-year period for which data are available.

Fisheries Information

The commercial fishery that interacts, or that potentially could interact, with this stock in the Gulf of Mexico is the Atlantic Ocean, Caribbean, Gulf of Mexico large pelagics longline fishery (Appendix III). Pelagic swordfish, tunas and billfish are the targets of the large pelagics longline fishery operating in the northern Gulf of Mexico. For the 5-year period 2010–2014, the estimated annual combined serious injury and mortality attributable to the large pelagics longline fishery in the northern Gulf of Mexico was 0.8 (CV=1.0) rough-toothed dolphins (Table 2). During the second quarter of 2014, 2 serious injuries were observed (Garrison and Stokes 2016). There were no reports of mortality or serious injury to rough-toothed dolphins by this fishery in the northern Gulf of Mexico during 1998–2013 (Yeung 1999; Yeung 2001; Garrison 2003; Garrison and Richards 2004; Garrison 2005; Fairfield Walsh and Garrison 2006; Fairfield-Walsh and Garrison 2007; Fairfield and Garrison 2008; Garrison et al. 2009; Garrison and Stokes 2010; 2012a,b; 2013; 2014; 2016).

During the second quarters (15 April – 15 June) of 2010–2014, observer coverage in the Gulf of Mexico large pelagics longline fishery was greatly enhanced (approaching 55%) to collect more robust information on the interactions between pelagic longline vessels and spawning bluefin tuna. Therefore, the high annual observer coverage rates during 2010–2014 (Table 2) primarily reflect high coverage rates during the second quarter of each year. During the second quarter, this elevated coverage results in an increased probability that relatively rare interactions will be detected. Species within the oceanic Gulf of Mexico are presumed to be resident year-round; however, it is unknown if the bycatch rate observed during the second quarter is representative of that which occurs throughout the year.

Table 2. Summary of the incidental mortality and serious injury of northern Gulf of Mexico rough-toothed dolphins in the pelagic longline commercial fishery including the years sampled (Years), the number of vessels active within the fishery (Vessels), the type of data used (Data Type), the annual observer coverage (Observer Coverage), the annual observed serious injury and mortality recorded by on-board observers, the annual estimated serious injury and mortality, the combined annual estimates of serious injury and mortality (Estimated Combined Mortality), the estimated CV of the combined annual mortality estimates (Est. CVs) and the mean of the combined mortality estimates (CV in parentheses).

a Number of vessels in the fishery is based on vessels reporting effort to the pelagic longline logbook.
b Observer data (Obs. Data) are used to measure bycatch rates, and the data are collected within the Northeast Fisheries Observer Program. Mandatory logbook data were used to measure total effort for the longline fishery. These data are collected at the Southeast Fisheries Science Center (SEFSC). Observer coverage in the GOM is dominated by very high coverage rates during April–June associated with efforts to improve estimates of bluefin tuna bycatch.
c Proportion of sets observed.

Other Mortality

There were 4 stranded rough-toothed dolphins in the northern Gulf of Mexico during 2010–2014 (NOAA National Marine Mammal Health and Stranding Response Database unpublished data, accessed 15 June 2015). No evidence of human interaction was detected for 2 stranded animals, and for the remaining 2, it could not be determined if there was evidence of human interaction. Stranding data probably underestimate the extent of human and fishery-related mortality and serious injury because not all of the dolphins that die or are seriously injured in human interactions wash ashore, or, if they do, they are not all recovered (Peltier et al. 2012; Wells et al. 2015).
Additionally, not all carcases will show evidence of human interaction, entanglement or other fishery-related interaction due to decomposition, scavenger damage, etc. (Byrd et al. 2014). Finally, the level of technical expertise among stranding network personnel varies widely as does the ability to recognize signs of human interaction.

An Unusual Mortality Event (UME), involving primarily bottlenose dolphins, was declared for cetaceans in the northern Gulf of Mexico beginning 1 February 2010 and ending 31 July 2014 (Litz et al. 2014; http://www.nmfs.noaa.gov/pr/health/mmume/cetacean_gulfofmexico.htm, accessed 1 June 2016). Investigations to date have determined that the DWH oil spill is the primary underlying cause of the elevated stranding numbers in the northern Gulf of Mexico after the spill (e.g., Schwacke et al. 2014; Venn-Watson et al. 2015). During 2010–2014, 1 animal from this stock was considered to be part of the UME, a 2013 stranding in Destin, Florida.

HABITAT ISSUES

The DWH MC252 drilling platform, located approximately 50 miles southeast of the Mississippi River Delta in waters about 1500 m deep, exploded on 20 April 2010. The rig sank, and over 87 days up to ~4.9 million barrels of oil were discharged from the wellhead until it was capped on 15 July 2010 (McNutt et al. 2012). During the response effort dispersants were applied extensively at the seafloor and at the sea surface (Lehr et al. 2010; OSAT 2010). In-situ burning, or controlled burning of oil at the surface, was also used extensively as a response tool (Lehr et al. 2010). The oil, dispersant and burn residue compounds present ecological concerns (Buist et al. 1999; NOAA 2011). The magnitude of this oil spill was unprecedented in U.S. history, causing impacts to wildlife, natural habitats and human communities along coastal areas from western Louisiana to the Florida Panhandle (NOAA 2011). It could be years before the entire scope of damage is ascertained (NOAA 2011).

Shortly after the oil spill, the Natural Resource Damage Assessment (NRDA) process was initiated under the Oil Pollution Act of 1990. A variety of NRDA research studies are being conducted to determine potential impacts of the spill on marine mammals. These studies have focused on identifying the type, magnitude, severity, length and impact of oil exposure to oceanic, continental shelf, coastal and estuarine marine mammals. For continental shelf and oceanic cetaceans, the NOAA-led efforts include: aerial surveys to document the distribution, abundance, species and exposure relative to oil from the DWH spill; and ship surveys to evaluate exposure to oil and other chemicals and to assess changes in animal behavior and distribution relative to oil exposure through visual and acoustic surveys, deployment of passive acoustic monitoring systems, collection of tissue samples, and deployment of satellite-linked tags on sperm and Bryde’s whales.

Vessel and aerial surveys documented common bottlenose dolphins, Atlantic spotted dolphins, rough-toothed dolphins, spinner dolphins, pantropical spotted dolphins, risso's dolphins, striped dolphins, sperm whales, dwarf/pygmy sperm whales and a Cuvier's beaked whale swimming in oil or potentially oil-derived substances (e.g., sheen, mousse) in offshore waters of the northern Gulf of Mexico following the DWH oil spill. The effects of oil exposure on marine mammals depend on a number of factors including the type and mixture of chemicals involved, the amount, frequency and duration of exposure, the route of exposure (inhaled, ingested, absorbed, or external) and biomedical risk factors of the particular animal (Geraci 1990; Helm et al. 2015). In general, direct external contact with petroleum compounds or dispersants with skin may cause skin irritation, chemical burns and infections. Inhalation of volatile petroleum compounds or dispersants may irritate or injure the respiratory tract, which could lead to pneumonia or inflammation. Ingestion of petroleum compounds may cause injury to the gastrointestinal tract, which could affect an animal’s ability to digest or absorb food. Absorption of petroleum compounds or dispersants may damage kidney, liver and brain function in addition to causing immune suppression and anemia. Long term chronic effects such as lowered reproductive success and decreased survival may occur (Geraci 1990; Helm et al. 2015).

STATUS OF STOCK

Rough-toothed dolphins are not listed as threatened or endangered under the Endangered Species Act, and the northern Gulf of Mexico stock is not considered strategic under the MMPA. Total fishery-related mortality and serious injury for this stock is not less than 10% of the calculated PBR and therefore cannot be considered to be insignificant and approaching zero mortality and serious injury rate. The status of rough-toothed dolphins in the northern Gulf of Mexico, relative to OSP, is unknown. There are insufficient data to determine the population trends for this stock.

Appendix III
Fishery Descriptions

This appendix is broken into two parts: Part A describes commercial fisheries that have documented interactions with marine mammals in the Atlantic Ocean; and Part B describes commercial fisheries that have documented interactions with marine mammals in the Gulf of Mexico. A complete list of all known fisheries for both oceanic regions, the List of Fisheries, is published in the Federal Register annually. Each part of this appendix contains three sections: I. data sources used to document marine mammal mortality/entanglements and commercial fishing effort trip locations, II. links to fishery descriptions for Category I, II and some category III fisheries that have documented interactions with marine mammals and their historical level of observer coverage, and III. historical fishery descriptions.

Part A. Description of U.S Atlantic Commercial Fisheries

I. Data Sources

Items 1-5 describe sources of marine mammal mortality, serious injury or entanglement data; items 6-9 describe the sources of commercial fishing effort data used to summarize different components of each fishery (i.e. active number of permit holders, total effort, temporal and spatial distribution) and generate maps depicting the location and amount of fishing effort.

1. Northeast Region Fisheries Observer Program (NEFOP)

In 1989 a Fisheries Observer Program was implemented in the Northeast Region (Maine-Rhode Island) to document incidental bycatch of marine mammals in the Northeast Region Multi-species Gillnet Fishery. In 1993 sampling was expanded to observe bycatch of marine mammals in Gillnet Fisheries in the Mid-Atlantic Region (New York-North Carolina). The Northeast Fisheries Observer Program (NEFOP) has since been expanded to sample multiple gear types in both the Northeast and Mid-Atlantic Regions for documenting and monitoring interactions of marine mammals, sea turtles and finfish bycatch attributed to commercial fishing operations. At sea observers onboard commercial fishing vessels collect data on fishing operations, gear and vessel characteristics, kept and discarded catch composition, bycatch of protected species, animal biology, and habitat (NMFS-NEFSC 2003).

2. Southeast Region Fishery Observer Programs

Three Fishery Observer Programs are managed by the Southeast Fisheries Science Center (SEFSC) that observe commercial fishery activity in U.S. Atlantic waters. The Pelagic Longline Observer Program (POP) administers a mandatory observer program for the U.S. Atlantic Large Pelagics Longline Fishery. The program has been in place since 1992 and randomly allocates observer effort by eleven geographic fishing areas proportional to total reported effort in each area and quarter. Observer coverage levels are mandated under the Highly Migratory Species Fisheries Management Plan (HMS FMP, 50 CFR Part 635). The second program is the Shark Gillnet Observer Program that observes the Southeastern U.S. Atlantic Shark Gillnet Fishery. The Observer Program is mandated under the HMS FMP, the Atlantic Large Whale Take Reduction Plan (ALWTRP) (50 CFR Part 229.32), and the Biological Opinion under Section 7 of the Endangered Species Act. Observers are deployed on any active fishing vessel reporting shark drift gillnet effort. In 2005, this program also began to observe sink gillnet fishing for sharks along the southeastern U.S. coast. The observed fleet includes vessels with an active directed shark permit and fish with sink gillnet gear (Carlson and Bethea 2007). The third program is the Southeastern Shrimp Otter Trawl Fishery Observer Program. Prior to 2007, this was a voluntary program administered by SEFSC in cooperation with the Gulf and South Atlantic Fisheries Foundation. The program was funding and project dependent, therefore observer coverage is not necessarily randomly allocated across the fishery. In 2007, the observer program was expanded, and it became mandatory for fishing vessels to take an observer if selected. The program now includes more systematic sampling of the fleet based upon reported landings and effort patterns. The total level of observer coverage for this program is approximately 1% of the total fishery effort. In each Observer Program, the observers record information on the total target species catch, the number and type of interactions with protected species (including both marine mammals and sea turtles), and biological information on species caught.

3. Regional Marine Mammal Stranding Networks

The Northeast and Southeast Region Stranding Networks are components of the Marine Mammal Health and Stranding Response Program (MMHSRP). The goals of the MMHSRP are to facilitate collection and dissemination
of data, assess health trends in marine mammals, correlate health with other biological and environmental parameters, and coordinate effective responses to unusual mortality events (Becker et al. 1994). Since 1997, the Northeast Region Marine Mammal Stranding Network has been collecting and storing data on marine mammal strandings and entanglements that occur from Maine through Virginia. The Southeast Region Strandings Program is responsible for data collection and stranding response coordination along the Atlantic coast from North Carolina to Florida, along the U.S. Gulf of Mexico coast from Florida through Texas, and in the U.S. Virgin Islands and Puerto Rico. Prior to 1997, stranding and entanglement data were maintained by the New England Aquarium and the National Museum of Natural History, Washington, D.C. Volunteer participants, acting under a letter of agreement, collect data on stranded animals that include: species; event date and location; details of the event (i.e., signs of human interaction) and determination on cause of death; animal disposition; morphology; and biological samples. Collected data are reported to the appropriate Regional Stranding Network Coordinator and are maintained in regional and national databases.

4. Marine Mammal Authorization Program
Commercial fishing vessels engaging in Category I or II fisheries are automatically registered under the Marine Mammal Authorization Program (MMAP) in order to lawfully take a non-endangered/threatened marine mammal incidental to fishing operations. These fishermen are required to carry an Authorization Certificate onboard while participating in the listed fishery, must be prepared to carry a fisheries observer if selected, and must comply with all applicable take reduction plan regulations. All vessel owners, regardless of the category of fishery they are operating in, are required to report, within 48 hours of the incident and even if an observer has recorded the take, all incidental injuries and mortalities of marine mammals that have occurred as a result of fishing operations (NMFS-OPR 2003). Events are reported by fishermen on the Marine Mammal Mortality/Injury forms then submitted to and maintained by the NMFS Office of Protected Resources. The data reported include: captain and vessel demographics; gear type and target species; date, time and location of event; type of interaction; animal species; mortality or injury code; and number of interactions. Reporting forms are available online at http://www.nmfs.noaa.gov/pr/pdfs/interactions/mmap_reporting_form.pdf.

5. Other Data Sources for Protected Species Interactions/Entanglements/Ship Strikes
In addition to the above, data on fishery interactions/entanglements and vessel collisions with large cetaceans are reported from a variety of other sources including the New England Aquarium (Boston, Massachusetts); Provincetown Center for Coastal Studies (Provincetown, Massachusetts); U.S. Coast Guard; whale watch vessels; Canadian Department of Fisheries and Oceans (DFO); and members of the Atlantic Large Whale Disentanglement Network. These data, photographs, etc. are maintained by the Protected Species Division at the Greater Atlantic Regional Fisheries Office (GARFO), the Protected Species Branch at the Northeast Fisheries Science Center (NEFSC) and the Southeast Fisheries Science Center (SEFSC).

6. Northeast Region Vessel Trip Reports
The Northeast Region Vessel Trip Report Data Collection System is a mandatory, but self-reported, commercial fishing effort database (Wigley et al. 1998). The data collected include: species kept and discarded; gear types used; trip location; trip departure and landing dates; port; and vessel and gear characteristics. The reporting of these data is mandatory only for vessels fishing under a federal permit. Vessels fishing under a federal permit are required to report in the Vessel Trip Report even when they are fishing within state waters.

7. Southeast Region Fisheries Logbook System
The Fisheries Logbook System (FLS) is maintained at the SEFSC and manages data submitted from mandatory Fishing Vessel Logbook Programs under several FMPs. In 1986 a comprehensive logbook program was initiated for the Large Pelagics Longline Fishery and this reporting became mandatory in 1992. Logbook reporting has also been initiated since the 1990s for a number of other fisheries including: Reef Fish Fisheries; Snapper-Grouper Complex Fisheries; federally managed Shark Fisheries; and King and Spanish Mackerel Fisheries. In each case, vessel captains are required to submit information on the fishing location, the amount and type of fishing gear used, the total amount of fishing effort (e.g., gear sets) during a given trip, the total weight and composition of the catch, and the disposition of the catch during each unit of effort (e.g., kept, released alive, released dead). FLS data are used to estimate the total amount of fishing effort in the fishery and thus expand bycatch rate estimates from observer data to estimates of the total incidental take of marine mammal species in a given fishery. More information is available at http://www.sefsc.noaa.gov/fisheries/logbook.htm.
8. Northeast Region Dealer Reported Data
The Northeast Region Dealer Database houses trip level fishery statistics on fish species landed by market category, vessel ID, permit number, port location and date of landing, and gear type utilized. The data are collected by both federally permitted seafood dealers and NMFS port agents. Data are considered to represent a census of both vessels actively fishing with a federal permit and total fish landings. It also includes vessels that fish with a state permit (excluding the state of North Carolina) that land a federally managed species. Some states submit the same trip level data to the Northeast Region, but contrary to the data submitted by federally permitted seafood dealers, the trip level data reported by individual states does not include unique vessel and permit information. Therefore, the estimated number of active permit holders reported within this appendix should be considered a minimum estimate. It is important to note that dealers were previously required to report weekly in a dealer call in system. However, in recent years the NER regional dealer reporting system has instituted a daily electronic reporting system. Although the initial reports generated from this new system did experience some initial reporting problems, these problems have been addressed and the new daily electronic reporting system is providing better real time information to managers.

9. Northeast At Sea Monitoring Program
At-sea monitors collect scientific, management, compliance, and other fisheries data onboard commercial fishing vessels through interviews of vessel captains and crew, observations of fishing operations, photographing catch, and measurements of selected portions of the catch and fishing gear. At-sea monitoring requirements are detailed under Amendment 16 to the NE Multispecies Fishery Management Plan with a planned implementation date of May 1st, 2010. At-sea monitoring coverage is an integral part of catch monitoring to ensure that Annual Catch Limits are not exceeded. At-sea monitors collect accurate information on catch composition and the data are used to estimate total discards by sectors (and common pool), gear type, and stock area. Coverage levels are expected around 30%.

II. Marine Mammal Protection Act’s List of Fisheries
The List of Fisheries (LOF) classifies U.S. commercial fisheries into one of three Categories according to the level of incidental mortality or serious injury of marine mammals:

I. frequent incidental mortality or serious injury of marine mammals
II. occasional incidental mortality or serious injury of marine mammals
III. remote likelihood of/no known incidental mortality or serious injury of marine mammals

The Marine Mammal Protection Act (MMPA) mandates that each fishery be classified by the level of mortality or serious injury and mortality of marine mammals that occurs incidental to each fishery as reported in the annual Marine Mammal Stock Assessment Reports for each stock. A fishery may qualify as one Category for one marine mammal stock and another Category for a different marine mammal stock. A fishery is typically categorized on the LOF according to its highest level of classification (e.g., a fishery that qualifies for Category III for one marine mammal stock and Category II for another marine mammal stock will be listed under Category II). The fisheries listed below are linked to classification based on the most current LOF published in the Federal Register.

IV. Historical Fishery Descriptions

Atlantic Foreign Mackerel

Prior to 1977, there was no documentation of marine mammal bycatch in DWF activities off the Northeast coast of the U.S. With implementation of the Magnuson Fisheries Conservation and Management Act (MFCMA) in that year, an Observer Program was established which recorded fishery data and information on incidental bycatch of marine mammals. DWF effort in the U.S. Atlantic Exclusive Economic Zone (EEZ) had been directed primarily towards Atlantic Mackerel and Squid. From 1977 through 1982, an average mean of 120 different foreign vessels per year (range 102-161) operated within the U.S. Atlantic EEZ. In 1982, there were 112 different foreign vessels; 16%, or 18, were Japanese Tuna longline vessels operating along the U.S. east coast. This was the first year that the Northeast Regional Observer Program assumed responsibility for observer coverage of the longline vessels. Between 1983 and 1991, the numbers of foreign vessels operating within the U.S. Atlantic EEZ each year were 67, 52, 62, 33, 27, 26, 14, 13, and 9 respectively. Between 1983 and 1988, the numbers of DWF vessels included 3, 5, 7, 6, 8, and 8 respectively, Japanese longline vessels. Observer coverage on DWF vessels was 25-35% during 1977-1982, and increased to 58%, 86%, 95% and 98%, respectively, in 1983-1986. One hundred percent observer coverage was maintained during 1987-1991. Foreign fishing operations for Squid ceased at the end of the 1986 fishing season and for Mackerel at the end of the 1991 season. Documented interactions with white sided dolphins were reported in this fishery.

Pelagic Drift Gillnet

In 1996 and 1997, NMFS issued management regulations which prohibited the operation of this fishery in 1997. The fishery operated during 1998. Then, in January 1999 NMFS issued a Final Rule to prohibit the use of drift net gear in the North Atlantic Swordfish Fishery (50 CFR Part 630). In 1986, NMFS established a mandatory self-reported fisheries information system for Large Pelagic Fisheries. Data files are maintained at the SEFSC. The
estimated total number of hauls in the Atlantic Pelagic Drift Gillnet Fishery increased from 714 in 1989 to 1,144 in 1990; thereafter, with the introduction of quotas, effort was severely reduced. The estimated number of hauls from 1991 to 1996 was 233, 243, 232, 197, 164, and 149 respectively. Fifty-nine different vessels participated in this fishery at one time or another between 1989 and 1993. In 1994 to 1998 there were 11, 12, 10, 0, and 11 vessels, respectively, in the fishery. Observer coverage, expressed as percent of sets observed, was 8% in 1989, 6% in 1990, 20% in 1991, 40% in 1992, 42% in 1993, 87% in 1994, 99% in 1995, 64% in 1996, no fishery in 1997, and 99% coverage during 1998. Observer coverage dropped during 1996 because some vessels were deemed too small or unsafe by the contractor that provided observer coverage to NMFS. Fishing effort was concentrated along the southern edge of Georges Bank and off Cape Hatteras, North Carolina. Examination of the species composition of the catch and locations of the fishery throughout the year suggest that the Drift Gillnet Fishery was stratified into two strata: a southern, or winter, stratum and a northern, or summer, stratum. Documented interactions with North Atlantic right whales, humpback whales, sperm whales, pilot whale spp., Mesoplodon spp., Risso’s dolphins, common dolphins, striped dolphins and white sided dolphins were reported in this fishery.

Atlantic Tuna Purse Seine

The Tuna Purse Seine Fishery occurring between the Gulf of Maine and Cape Hatteras, North Carolina is directed at large medium and giant Bluefin Tuna (BFT). Spotter aircraft are typically used to locate fish schools. The official start date, set by regulation, is 15 July of each year. Individual Vessel Quotas (IVQs) and a limited access system prevent a derby fishery situation. Catch rates for large medium and giant Tuna can be high and consequently, the season can last only a few weeks, however, over the last number of years, effort expended by this sector of the BFT fishery has diminished dramatically due to the unavailability of BFT on the fishing grounds.

The regulations allocate approximately 18.6% of the U.S. BFT quota to this sector of the fishery (5 IVQs) with a tolerance limit established for large medium BFT (15% by weight of the total amount of giant BFT landed.

Limited observer data is available for the Atlantic Tuna Purse Seine Fishery. Out of 45 total trips made in 1996, 43 trips (95.6%) were observed. Forty-four sets were made on the 43 observed trips and all sets were observed. A total of 136 days were covered. No trips were observed during 1997 through 1999. Two trips (seven hauls) were observed in October 2000 in the Great South Channel Region. Four trips were observed in September 2001. No marine mammals were observed taken during these trips. Documented interactions with pilot whale spp. were reported in this fishery.

Atlantic Tuna Pelagic Pair Trawl

The Pelagic Pair Trawl Fishery operated as an experimental fishery from 1991 to 1995, with an estimated 171 hauls in 1991, 536 in 1992, 856 in 1993, 407 in 1994, and 440 in 1995. This fishery ceased operations in 1996 when NMFS rejected a petition to consider pair trawl gear as an authorized gear type in the Atlantic Tuna Fishery. The fishery operated from August to November in 1991, from June to November in 1992, from June to October in 1993 (Northridge 1996), and from mid-summer to December in 1994 and 1995. Sea sampling began in October of 1992 (Gerrior et al. 1994) where 48 sets (9% of the total) were sampled. In 1993, 102 hauls (17% of the total) were sampled. In 1994 and 1995, 52% (212) and 55% (238), respectively, of the sets were observed. Nineteen vessels have operated in this fishery. The fishery operated in the area between 35N to 41N and 69W to 72W. Approximately 50% of the total effort was within a one degree square at 39N, 72W, around Hudson Canyon, from 1991 to 1993. Examination of the 1991-1993 locations and species composition of the bycatch, showed little seasonal change for the six months of operation and did not warrant any seasonal or areal stratification of this fishery (Northridge 1996). During the 1994 and 1995 Experimental Pelagic Pair Trawl Fishing Seasons, fishing gear experiments were conducted to collect data on environmental parameters, gear behavior, and gear handling practices to evaluate factors affecting catch and bycatch (Goudy 1995, 1996), but the results were inconclusive. Documented interactions with pilot whale spp., Risso’s dolphin and common dolphins were reported in this fishery.

Part B. Description of U.S. Gulf of Mexico Fisheries

1. Data Sources

   Items 1 and 2 describe sources of marine mammal mortality, serious injury or entanglement data, and item 3 describes the source of commercial fishing effort data used to generate maps depicting the location and amount of fishing effort and the numbers of active permit holders. In general, commercial fisheries in the Gulf of Mexico have had little directed observer coverage and the level of fishing effort for most fisheries that may interact with marine mammals is either not reported or highly uncertain.
1. Southeast Region Fishery Observer Programs

Two fishery observer programs are managed by the SEFSC that observe commercial fishery activity in the U.S. Gulf of Mexico. The Pelagic Longline Observer Program (POP) administers a mandatory observer program for the U.S. Atlantic Large Pelagics Longline Fishery. The program has been in place since 1992, and randomly allocates observer effort by eleven geographic fishing areas proportional to total reported effort in each area and quarter. Observer coverage levels are mandated under the Highly Migratory Species FMP (HMS FMP, 50 CFR Part 635). The second is the Southeastern Shrimp Otter Trawl Fishery Observer Program. Prior to 2007, this was a voluntary program administered by SEFSC in cooperation with the Gulf and South Atlantic Fisheries Foundation. The program was funding and project dependent, therefore observer coverage is not necessarily randomly allocated across the fishery. In 2007, the observer program was expanded, and it became mandatory for fishing vessels to take an observer if selected. The program now includes more systematic sampling of the fleet based upon reported landings and effort patterns. The total level of observer coverage for this program is ~1% of the total fishery effort. In each Observer Program, the observers record information on the total target species catch, the number and type of interactions with protected species (including both marine mammals and sea turtles), and biological information on species caught. In each Observer Program, the observers record information on the total target species catch, the number and type of interactions with protected species including both marine mammals and sea turtles, and biological information on species caught.

2. Regional Marine Mammal Stranding Networks

The Southeast Regional Stranding Network is a component of the Marine Mammal Health and Stranding Response Program (MMHSRP). The goals of the MMHSRP are to facilitate collection and dissemination of data, assess health trends in marine mammals, correlate health with other biological and environmental parameters, and coordinate effective responses to unusual mortality events (Becker et al. 1994). The Southeast Region Strandings Program is responsible for data collection and stranding response coordination along the U.S. Gulf of Mexico coast from Florida through Texas. Prior to 1997, stranding and entanglement data were maintained by the New England Aquarium and the National Museum of Natural History, Washington, D.C. Volunteer participants, acting under a letter of agreement with NOAA Fisheries, collect data on stranded animals that include: species; event date and location; details of the event including evidence of human interactions; determinations of the cause of death; animal disposition; morphology; and biological samples. Collected data are reported to the appropriate Regional Stranding Network Coordinator and are maintained in regional and national databases.

3. Southeast Region Fisheries Logbook System

The FLS is maintained at the SEFSC and manages data submitted from mandatory fishing vessel logbook programs under several FMPs. In 1986, a comprehensive logbook program was initiated for the Large Pelagics Logline Fisheries, and this reporting became mandatory in 1992. Logbook reporting has also been initiated since the early 1990s for a number of other fisheries including: reef fish fisheries; snapper-grouper complex fisheries; federally managed shark fisheries; and king and Spanish mackerel fisheries. In each case, vessel captains are required to submit information on the fishing location, the amount and type of fishing gear used, the total amount of fishing effort (e.g., gear sets) during a given trip, the total weight and composition of the catch, and the disposition of the catch during each unit of effort (e.g., kept, released alive, released dead). FLS data are used to estimate the total amount of fishing effort in the fishery and thus expand bycatch rate estimates from observer data to estimates of the total incidental take of marine mammal species in a given fishery.

4. Marine Mammal Authorization Program

Commercial fishing vessels engaging in Category I or II fisheries are automatically registered under the Marine Mammal Authorization Program (MMAP) in order to lawfully take a non-endangered/threatened marine mammal incidental to fishing operations. These fishermen are required to carry an Authorization Certificate onboard while participating in the listed fishery, must be prepared to carry a fisheries observer if selected, and must comply with all applicable take reduction plan regulations. All vessel owners, regardless of the category of fishery they are operating in, are required to report, within 48 hours of the incident even if an observer has recorded the take, all incidental injuries and mortalities of marine mammals that have occurred as a result of fishing operations (NMFS-OPR 2003). Events are reported by fishermen on the Marine Mammal Mortality/Injury forms then submitted to and maintained by the NMFS Office of Protected Resources. The data reported include: captain and vessel demographics; gear type and target species; date, time and location of event; type of interaction; animal species; mortality or injury code; and number of interactions. Reporting forms are available online at http://www.nmfs.noaa.gov/pr/pdfs/interactions/mmap_reporting_form.pdf.

</table>

This abundance estimate is from 2000-2001 surveys only (from Fulling et al. 2003). Current best population size estimate is unknown because data from the continental shelf portion of this species’ range are more than 8 years old.

Procedures for Issuing Manuscripts in the Northeast Fisheries Science Center Reference Document (CRD) Series

Clearance

All manuscripts submitted for issuance as CRDs must have cleared the NEFSC’s manuscript/abstract/webpage review process. If any author is not a federal employee, he/she will be required to sign an “NEFSC Release-of-Copyright Form.” If your manuscript includes material from another work which has been copyrighted, then you will need to work with the NEFSC’s Editorial Office to arrange for permission to use that material by securing release signatures on the “NEFSC Use-of-Copyrighted-Work Permission Form.”

For more information, NEFSC authors should see the NEFSC’s online publication policy manual, “Manuscript/abstract/webpage preparation, review, and dissemination: NEFSC author’s guide to policy, process, and procedure,” located in the Publications/Manuscript Review section of the NEFSC intranet page.

Organization

Manuscripts must have an abstract and table of contents, and (if applicable) lists of figures and tables. As much as possible, use traditional scientific manuscript organization for sections: “Introduction,” “Study Area” and/or “Experimental Apparatus,” “Methods,” “Results,” “Discussion,” “Conclusions,” “Acknowledgments,” and “Literature/References Cited.”

Style

The CRD series is obligated to conform with the style contained in the current edition of the United States Government Printing Office Style Manual. That style manual is silent on many aspects of scientific manuscripts. The CRD series relies more on the CSE Style Manual. Manuscripts should be prepared to conform with these style manuals.

The CRD series uses the American Fisheries Society’s guides to names of fishes, mollusks, and decapod crustaceans, the Society for Marine Mammalogy’s guide to names of marine mammals, the Biosciences Information Service’s guide to serial title abbreviations, and the ISO’s (International Standardization Organization) guide to statistical terms.

For in-text citation, use the name-date system. A special effort should be made to ensure that all necessary bibliographic information is included in the list of cited works. Personal communications must include date, full name, and full mailing address of the contact.

Preparation

Once your document has cleared the review process, the Editorial Office will contact you with publication needs – for example, revised text (if necessary) and separate digital figures and tables if they are embedded in the document. Materials may be submitted to the Editorial Office as files on zip disks or CDs, email attachments, or intranet downloads. Text files should be in Microsoft Word, tables may be in Word or Excel, and graphics files may be in a variety of formats (JPG, GIF, Excel, PowerPoint, etc.).

Production and Distribution

The Editorial Office will perform a copy-edit of the document and may request further revisions. The Editorial Office will develop the inside and outside front covers, the inside and outside back covers, and the title and bibliographic control pages of the document.

Once both the PDF (print) and Web versions of the CRD are ready, the Editorial Office will contact you to review both versions and submit corrections or changes before the document is posted online.

A number of organizations and individuals in the Northeast Region will be notified by e-mail of the availability of the document online.
Publications and Reports of the Northeast Fisheries Science Center

The mission of NOAA’s National Marine Fisheries Service (NMFS) is “stewardship of living marine resources for the benefit of the nation through their science-based conservation and management and promotion of the health of their environment.” As the research arm of the NMFS’s Northeast Region, the Northeast Fisheries Science Center (NEFSC) supports the NMFS mission by “conducting ecosystem-based research and assessments of living marine resources, with a focus on the Northeast Shelf, to promote the recovery and long-term sustainability of these resources and to generate social and economic opportunities and benefits from their use.” Results of NEFSC research are largely reported in primary scientific media (e.g., anonymously-peer-reviewed scientific journals). However, to assist itself in providing data, information, and advice to its constituents, the NEFSC occasionally releases its results in its own media. Currently, there are three such media:

NOAA Technical Memorandum NMFS-NE -- This series is issued irregularly. The series typically includes: data reports of long-term field or lab studies of important species or habitats; synthesis reports for important species or habitats; annual reports of overall assessment or monitoring programs; manuals describing program-wide surveying or experimental techniques; literature surveys of important species or habitat topics; proceedings and collected papers of scientific meetings; and indexed and/or annotated bibliographies. All issues receive internal scientific review and most issues receive technical and copy editing.

Northeast Fisheries Science Center Reference Document -- This series is issued irregularly. The series typically includes: data reports on field and lab studies; progress reports on experiments, monitoring, and assessments; background papers for, collected abstracts of, and/or summary reports of scientific meetings; and simple bibliographies. Issues receive internal scientific review and most issues receive copy editing.

Resource Survey Report (formerly Fishermen’s Report) -- This information report is a regularly-issued, quick-turnaround report on the distribution and relative abundance of selected living marine resources as derived from each of the NEFSC’s periodic research vessel surveys of the Northeast’s continental shelf. This report undergoes internal review, but receives no technical or copy editing.

TO OBTAIN A COPY of a NOAA Technical Memorandum NMFS-NE or a Northeast Fisheries Science Center Reference Document, either contact the NEFSC Editorial Office (166 Water St., Woods Hole, MA 02543-1026; 508-495-2350) or consult the NEFSC webpage on “Reports and Publications” (http://www.nefsc.noaa.gov/nefsc/publications/). To access Resource Survey Report, consult the Ecosystem Surveys Branch webpage (http://www.nefsc.noaa.gov/femad/ecosurvey/mainpage/).

ANY USE OF TRADE OR BRAND NAMES IN ANY NEFSC PUBLICATION OR REPORT DOES NOT IMPLY ENDORSEMENT.

NEW PRINCIPLES FOR
THE CONSERVATION OF
WILD LIVING RESOURCES

by

SIDNEY J. HOLT AND LEE M. TALBOT

APRIL 1978

No. 59
FRONTISPIECE. Humpback whale, Pacific Ocean off Hawaii. Protected for periods ranging from 12 years in the northern Pacific Ocean to 23 years in the northwestern Atlantic Ocean. The remaining humpback whale stocks are roughly estimated at about 10 percent of their original populations, with no clear evidence of recovery. Whales represent the classic case of mismanagement of wild living resources, one with stock after stock overharvested to commercial, and occasionally, biological extinction. However, the International Whaling Commission has now adopted most of the new principles for management that this paper recommends. (Credit: John Dominis, Time-Life Inc.)

² President's Council on Environmental Quality, Washington, D.C. 20006.
Preface

There is growing international concern with the depletion of stocks of many wild animal resources—fishes, marine mammals, reptiles, invertebrates, and terrestrial wildlife—in the face of increasing demands on those resources for food and other values. That concern led to development of a program to critically examine the basis for management of those resources and to prepare appropriate recommendations for improvement in their management. The program was sponsored by the President’s Council on Environmental Quality, the World Wildlife Fund—U.S., the Ecological Society of America, the Smithsonian Institution, and the International Union for the Conservation of Nature and Natural Resources.

The financial support for the program and publication of this monograph was provided by the World Wildlife Fund—U.S., and very considerable secretarial and other staff assistance was furnished by the Washington Office of the Fund and the Council on Environmental Quality. The program was organized by Lee M. Talbot.

Preliminary consultations and meetings were held in 1974, followed by two workshops at Airlie House, Virginia, in February and April 1975. This report is the final result.

The participants in the workshops first critically reviewed the scientific basis of existing goals of conservation. They examined both the theory and the practice of aquatic and terrestrial wildlife management, insofar as it is directed to sustaining the values of resources for future realization on a continuing basis. They concluded that a new statement of principles was urgently needed to meet modern needs in the light of current knowledge, particularly of ecology. They prepared such a statement, redefining the primary goal of renewable resource management and formulating four general principles for its implementation.

The participants in the workshops also prepared a detailed interpretation of the new principles, with respect to marine resources now under consideration by the United Nations Conference on the Law of the Sea (Appendix 4). Lastly, they suggested that resource management institutions—international, national, state, and local—should incorporate the new principles in their charters, and further, that those institutions should be evaluated with respect to their capacities to implement and achieve the basic goal as defined.

The participants (Appendix 1) were invited on the basis of outstanding expertise and experience in research and management of wild terrestrial or aquatic living resources. They were drawn from a broad spectrum of disciplines and all had focussed on the theory or practice of conservation and exploitation of the resources involved.

The objective of the meetings and workshops was to produce a written report intended to present the “state of the art” as perceived by the participants. The procedure followed was to start with individual working papers, and carry them through successive reviews, revisions, and redrafts. The text is the final report of the workshops, assembled and edited by Sidney Holt and Lee Talbot. To assure that it accurately reflected the participants’ views, the final draft was circulated to all participants for correction and approval.

Introduction

Man is making ever-increasing demands on the world’s wild living resources—fishes, aquatic invertebrates, reptiles, marine and terrestrial mammals, and birds—for food, other animal products, and other values. The United Nations Conference on the Human Environment in 1972, the World Conferences on Food and on Population in 1974, and the fisheries aspects of current Law of the Sea negotiations, attest to the growing international recognition of the problems thereby created. At the same
time, it is clear that past attempts to manage those resources, or the failure to manage their exploitation on a rational basis, have allowed gross depletion of many of them, rather than assuring sustained or improved yields and values.

The absence of rational management policy, or the application of a policy that results in overutilization or other abuse of a resource, results in the loss of the full range of benefits to both present and future generations. Effective management policy, on the other hand, can result in an equitable distribution of benefits between present and future users of the resource.

Considering the world as a whole, we can say that most exploitation of wild living resources has not been managed in the strict or scientific sense of the word. Where management has been attempted, the concept of maximum sustainable yield (MSY) or some related single species approach most often has been adopted as the basic concept (Appendix 3). A number of other factors have been involved in past failures to achieve rational management of wild living resources. In view of the significance of those resources to human welfare, it is timely to redefine the scientific principles that should underlie their conservation and management.

The term “conservation” has been used with such a variety of meanings, and often without definition, that it is tempting to avoid using it here. Yet it does have the specific meaning we need of “wise use,” involving “keeping for future use,” for which concept there is no better word in the English language. Therefore we have retained it (Appendix 2).

The maintenance of resource systems in desirable states is an essential part of scientific, ecologically sound management, and should be the primary goal of conservation policy. Such states can provide continuing social benefits and cultural values. Benefits and values may be tangible or intangible, realized or potential. A resource system in a desirable state would have the capacity to accommodate changing human values and to persist in the face of changing environmental conditions. Of particular importance is the need to avoid irreversible changes in the system as a result of human actions.

Effective management and successful conservation requires the existence of legal and institutional arrangements to implement scientifically based principles. While different resource users may have widely differing objectives, those objectives, and the corresponding legal and institutional arrangements to attain them are not the main concern of this report. However, the above primary goal is consistent with the aims of most national and international institutions concerned with the management of living resources. To achieve our primary goal requires a sophisticated approach to conservation that takes into account the ecosystem as well as the selected species or stocks considered to have special value at some particular time. Ecologically simplistic concepts such as maximum sustainable yield are not adequate for that purpose. More comprehensive concepts and procedures are suggested below.

**THE CHALLENGE**

The approaches to conservation measures, to secure future values, have varied from one situation to another. One approach is an ad hoc one—simply to try to find agreement on a collective action that enhances future values for all present participants. To achieve this, some inequities usually must be accepted; some users will have greater potential benefit than others and that can lead, and has sometimes led, to the failure of such an approach.

Another approach has been to define a specific goal of conservation. The most usual goal has been the maintenance of the resource in such condition that it is capable of supplying a maximum sustainable yield, and that has been the basis for regulating the exploitation of many wild species (Appendix 3). Strictly, maximum
sustainable yield has applied only to some consumptive uses of the resource, but by referring to "values" instead of "yields," the concept could be generalized. The apparent simplicity of the maximum sustainable yield approach has appealed to legislators. It has been incorporated in many international instruments as well as in national and local legislation to regulate fish and game harvest. The concept has sometimes been advocated so forcefully as to imply that a maximum yield not only could be taken but should be taken; a policy of so-called "full utilization" leads to the view that a resource is in some ways being "wasted" if a maximum sustainable yield is not being taken. Such a view can be grossly misleading.

Where maximum sustainable yield has been applied, it has ensured recognition of the renewable nature of the resource as well as its vulnerability, and undoubtedly has sometimes served the purpose of restraining exploitation. Some failures in maximum sustainable yield management must be ascribed more to failures in application than to weakness in the concept. On the other hand, such a simplistic concept has a number of deficiencies and problems (Fig. 1). For example, it:

FIG. 1. Pribilof fur seals (bulls, cows, and pups), St. Paul Islands, Alaska. Brought back from a seriously depleted population to the point where they have provided an annual harvest of tens of thousands of animals, the Pribilof fur seals were long regarded as the classic example of the success of single species management according to the concept of maximum sustainable yield. However, in recent years there has been a decrease in productivity of the population, and it is clear that there are factors involved other than direct harvest. Those factors probably include competition for food (pollock) from commercial fishing operations, deaths caused by seals becoming entangled in discarded fish nets and binding materials, physiological impact from pesticides and heavy metals, and possibly changes in social structure when the seals are ashore on the islands. (Credit: National Oceanic and Atmospheric Administration)
— focuses attention on the dynamics of particular species or stocks without explicit regard to the interactions between those species or stocks and other components of the ecosystem;
— concerns only the quantity and not the quality of potential yield or other value from the resource;
— depends on a degree of stability and resilience of the resource that may not exist;
— focuses attention on the output from resource use, without regard to the input of energy, of other natural resources, and of human skill and labor required to secure the output;
— may admit, and even encourage, overexploitation.

There are, of course, certain fundamental differences in conservation objectives when a resource is managed for commercial exploitation rather than for recreational use. Those differences are particularly evident when we compare the problems associated with managing some terrestrial vertebrate resources with those of marine fisheries. The maximum sustainable yield concept has not often been the explicit basis for the former. Small game management often is based on the annual production of a seasonal surplus being harvested down to a threshold density that will maintain what is believed to be a reproductive population in a steady state. Some avian species with high potentials for increase have been managed successfully on that basis in favorable localities with good habitat conditions. Allowable harvests of large ungulates (Fig. 2), on the other hand, are conceptually based more on the concept of limited carrying capacity of the environment, as presumably determined by the impact of the species on the vegetation in its habitat. In theory, surveys are made of vegetational conditions as an index of population pressure and the annual harvest is adjusted accordingly. In practice, other considerations often prevail. In the case of waterfowl (Fig. 3), harvest limits are set on the basis of surveys of aquatic conditions, breeding pairs, and indexes of production of young, with the objective of maintaining an adequate breeding population for the following year. Successful management of terrestrial vertebrates has often relied on habitat protection and restrictions on harvest methods.

In terrestrial situations, detailed observations of behavior, ecological relationships, and habitat response are often possible (Figs. 2, 4), whereas those factors usually are inferred indirectly from samples in aquatic situations. Terrestrial species provide greater opportunity than aquatic ones for rapid detection of response to management mistakes and to natural changes, and for control of harvest by species, sex, and age. Most of the harvested terrestrial species are herbivores so that the relationship between abundance of the species and its food supply not only can be observed directly, but is usually fairly simple and well understood. On the other hand, the bulk of the harvested aquatic species are carnivorous, so that the relationship between harvested species and food supply is not only much more difficult to observe, but is also likely to be quite complex.

Such differences do not mean that maximum sustainable yield is necessarily a more useful concept in the management of terrestrial wildlife than in marine fisheries—it is not (Fig. 5). They do illustrate the particular difficulty in obtaining accurate data for the effective management of aquatic resources, and emphasize the need for more sophisticated procedures. Present procedures usually consider only the effects of exploiting an individual species or group of species in isolation, and fail to recognize any need for predicting the effects on other components of the ecosystem or reciprocal relationships between the species and its environment. Those effects may include changes (1) in the populations of competing or symbiotic species within the functional group of the exploited species,
FIG. 2. Aerial survey of pronghorns, Sheldon Antelope Refuge, California. In management of such terrestrial species, direct observations of numbers, behavior, ecological relationships, and habitat condition are often possible, whereas those factors usually must be inferred from samples in aquatic situations.

FIG. 3. Trapping and banding waterfowl (Canada geese and mallards) at the Blackwater National Wildlife Refuge, Maryland, in the course of studies on the population dynamics and migration routes. The resulting information is basic to management of this resource for both consumptive and nonconsumptive purposes. (Credit: U.S. Fish and Wildlife Service)

(2) in the vegetational structure and carnivore populations where the exploited species is a herbivore, and (3) in prey numbers where the exploited species is a carnivore. These are only first-order responses, and consequent changes in more remote parts of the system are probable.

No species exists in isolation. Exploitation of one species has some impact on other components of the ecosystem (Fig. 6), and valid principles for conservation would take due account of that fact. A truly ecological approach will, however, go further. Just as it is necessary, especially under conditions of intensifying use, to
view the species and stocks of immediate interest to man in the context of the ecosystems as a whole, so now those natural systems are seen in the context of their relationships with human institutions. Historically, many renewable resource stocks—especially marine animals—were exploited as common property resources, with little or no form of effective regulation (Fig. 7). Such exploitation often resulted in the depletion of stocks, not only economically but also biologically. Such depletion—or the threat of it—has led to the establishment of institutions that have attempted to control exploitation. In practice, such institutions occasionally have been successful in controlling biological depletion at least temporarily, but much less successful in reducing economic overexploitation. One factor cited is that under such conditions, resource rents may have remained at a low level, and the corresponding overcapacity of industry has often led to continuing difficulties even in controlling biological overexploitation.

A more sophisticated management approach might attempt explicitly to achieve economic efficiency in resource exploitation in the long run. One theory postulates that such regulation could generate economic rents that could in turn be utilized—reinvested—so as further to improve the effectiveness of management. Unfortunately, that approach has not been attempted at the international level, in part at least because of a continuing failure to recognize the magnitude of the potential benefits, and in part, because of the problems of distribution of benefits to new participants or nations in a fishery. The failure to apply effective management results in the loss of the values that could be realized from the resource.

Fig. 4. African elephants, Tanzania, Africa. The herd matriarch comes forward to protect her family, and often is the first shot. Elephant studies have shown the necessity of considering the social and behavioral factors in any management program. (Credit: Ianian and Oria Douglas-Hamilton, World Wildlife Fund)
Newly defined principles of conservation need to be applied in such a way as to facilitate securing and sustaining such benefits.

THE PRINCIPLES OF CONSERVATION

The embodiment of simplistic formulations in legislation has reinforced a belief that hypotheses, such as that the size of a stock essentially determines the yield it can sustain in perpetuity, have in fact been validated, and that the desirable state of a resource system can be exactly specified in terms of a single criterion. That belief does not survive scrutiny, and attempts to apply simple criteria can hinder attempts to use renewable resources wisely. At the same time, man's uses of natural resources are continually intensifying and becoming more widespread, and as a result more demands are put on our ability to understand and predict the consequences of such uses. Although present and near-future needs for increased food supplies might partially and temporarily be met by increased exploitation, conservation for the long term must take precedence in defining new guiding principles to meet the criticisms described in the previous section.

The particular patterns of resource use will, of course, vary from place to place and time to time, but this means only that the new general principles would be applied in a different style, and with differ-
FIG. 6. Purse seiner in the eastern tropical Pacific Ocean fishing "on porpoise" for yellowfin tuna. The net is deployed around a school of porpoise because the tuna are often found in association with them. Unless care is taken when the seine net is pursed, the porpoises may be drowned. Such "incidental take" has represented a gross waste of living resources, ranging from around a quarter of a million to well over a half million dolphins per year. Regulations under the Marine Mammal Protection Act of 1972, enforced for the first time in 1977, reduced that loss to about 24,000 animals. In the photograph, porpoises may be seen escaping from the seine, assisted by fishermen in the skiff. (Credit: Naval Undersea Center)

ing emphasis, from one situation to another. Since there is a growing appreciation of the fact that effective conservation, even of a particular species, must take into account interactions between that species and its living and nonliving environment, the formulation of principles here includes the ecosystem within which the species exists.

The consequences of resource utilization and the implementation of principles of resource conservation are the responsibility of the parties having jurisdiction over the resource or, in the absence of clear jurisdiction, with those having jurisdiction over the users of the resource. The privilege of utilizing a resource carries with it the obligation to adhere to the following four general principles:

1. The ecosystem should be maintained in a desirable state such that
   a. consumptive and nonconsumptive values could be maximized on a continuing basis,
   b. present and future options are ensured, and
   c. risk of irreversible change or long-term adverse effects as a result of use is minimized.
2. Management decisions should include a safety factor to allow for the facts that knowledge is limited and institutions are imperfect.

3. Measures to conserve a wild living resource should be formulated and applied so as to avoid wasteful use of other resources.

4. Survey or monitoring, analysis, and assessment should precede planned use and accompany actual use of wild living resources. The results should be made available promptly for critical public review.

Principle 1 recognizes the necessity of maintaining each of the world's ecosystems in a desirable state in which potential users of resources within a system may realize a diversity of values in perpetuity. The three criteria of Principle 1, taken together, cover the main features of the desirable size and structure of the living resource, its natural change in time, and its relation with the varying physical environment. Criterion 1a is a more ecologically valid development from the maximum sustainable yield concept since it specifies a wider range of benefits to
be maximized rather than simply specifying a particular maximum yield as a primary goal. Options should be kept open (Criterion 1b) since values are diverse and can be expected to change. Further, advances in scientific knowledge and the ensuing technology will provide new uses and new perceptions that may well call for different treatments of living resources. Our understanding of diversity, organization, and dynamics of ecosystems, as well as of the genetic basis and evolutionary development of various forms of life, can be expected to improve. We must thus strive to maintain any given ecosystem in a state that permits changing values to be appreciated and new knowledge to be applied.

Adjustments to changing values and needs, and correction for the results of previous actions, may also require the capacity to reverse the outcomes of previous actions (Criterion 1c). Thus, it is desirable to avoid those actions that alter ecosystems in such a way that the return of the system to its previous state is impossible or unlikely. The extinction of a species and destruction of habitat are examples of irreversible outcomes. Often, the outcomes of proposed actions cannot be adequately predicted, and in such cases the apparent relative potential of actions to lead to undesirable effects may serve as a basis for their selection or rejection. Actions that are spatially or temporally limited are less likely to lead to large-scale irreversible outcomes than similar actions that are widespread or persistent.

The several criteria for a desirable state may not always appear to be wholly compatible, and defining the desirable state will then involve compromises. In applying Principle 1, fulfillment of its Criteria 1b and 1c may, strictly, involve acceptance of somewhat less than the maximum of a particular single yield that could possibly be realized on a continuing basis as provided in Criterion 1a. Such “sacrifice” will, however, be relatively small and will be compensated for in other ways. Specifically, it will contribute to safety (Principle 2) and to the avoidance of waste of other resources (Principle 3). It may also increase the net benefits to each user in realizing consumptive values. Further, it should be recognized that Criterion 1a refers to values, not simply to yields. Value, in this context, implies more than economic yield.

Ideally, resource conservation measures should be based on a thorough understanding of the biological characteristics of the resource and its environment. Principle 2 recognizes that both our knowledge and our arrangements for applying that knowledge will always have shortcomings, and that they should be allowed for so present management does not inadvertently prejudice future values.

In practice, our knowledge is often seriously inadequate, and predictions are uncertain. Uncertainty may arise from ignorance of such things as biological growth rates, interactions with other species, effects of the species on its habitat, and unpredictable environmental events. Similarly, the imperfection of institutional arrangements can lead to errors and delays in the implementation of policy decisions. To reduce the risk of irreversible changes or other long-term adverse effects, an appropriate safety factor should be included in all conservation measures. The magnitude of the safety factor should be proportional to the magnitude of the risk. The greater our ignorance of the resource—particularly of its capacity to respond to changed conditions—and/or the weaker the management institutions, the greater the safety factor must be.

Any use of a living resource must involve use of other resources, such as capital and energy. It is well known that the conduct of many fisheries, including some supposedly managed on the maximum sustainable yield principle, has involved an overcommitment of resources such as capital, labor, and fuel (Fig. 8). Specific measures for conserving a particular resource should be chosen and applied in such a way that they do not encourage undesired and unnecessary waste.
or misuse of other natural resources. The conservation of other resources will nearly always require utilization at a level appreciably less than the supposed maximum sustainable yield. The safety factor will thus often result in a net economic gain in both the short and long term. This should not be taken to imply that consideration should not be given to noneconomic values. Where recreational or nonconsumptive values are of primary concern, consideration of economic efficiency may be inapplicable. A further waste to be avoided or minimized may occur through incidental destruction of "nontarget species," i.e., species other than those primarily valued and sought, such as porpoises in the yellowfin tuna fishery (Fig. 6).

Principle 4 concerns the needs and duties of information gathering, interpreting and explaining, that are an essential part of resource management. Timely and accurate scientific information is an essential component of a conservation program (Fig. 9). The amount of investment in such assessment should be related to the intensity of use, the complexity of the problem, and the vulnerability of the system to adverse impact.

Data collection—in principle by all those who exercise or claim a right to use a resource—is itself extremely important, but of equal importance is continual improvement in our understanding of processes in ecosystems and of methods to measure and predict the directions and rates of those processes. Such improved
information is necessary to improve and correct management approaches and to adjust them to changing conditions. Critical public review is necessary both to provide for accountability for data and decisions, and to ensure the opportunity for normal scientific peer review. Thus, Principle 4 implies both strengthening and some reorientation of research and research procedures.

APPLICATIONS

Obviously, it will not be easy to develop the techniques needed to put the four proposed principles into effect. It will take much time and considerable effort. If, as is hoped, the principles are widely accepted, high priority should be given to working out interpretations of them for particular cases, and suitable procedures for their implementation.

Clearly, the complexity of the problems involved is now being more widely appreciated. This is attested by the attempts to understand ecosystems as functioning units, as in the Biome Projects of the International Biological Program. In the management of aquatic and terrestrial resources, several institutions already have acknowledged the need to move beyond management based on the maximum sustainable yield concept toward broader goals. Some have considered cer-
tain aspects of the general principles outlined in this document.

The need to limit the rate of development of fisheries on newly exploited species in order to permit adequate assessment of the effects of fishing has been recognized and applied by the International Commission for the Northwest Atlantic Fisheries (ICNAF). Also, the concept of including interspecific effects has been incorporated by setting limits on the total harvest of all species from an area. The protocol of the International Commission for the Northwest Atlantic Fisheries stipulates that regulations may be proposed on the basis of scientific, economic, and technical considerations.

Available reports about the anchoveta fishery in Peru now reflect consideration not only of conventional and improved stock production models, but also determinations of the optimal number of fishing boats, the best capacity for processing plants, discussion of social effects of modifying the labor costs, and the phasing of some of the overcapacity into new fishing endeavors.

Some experimental management studies of warmwater recreational fisheries in the United States have recognized the importance of maintaining satisfactory age and size structures of fish populations in order to sustain fishing quality. Conservation and sustained benefits can be accomplished by programs that maintain the satisfactory qualities of ecosystems—both habitat and community structure.

In the International Whaling Commission (IWC), most of the principles are beginning to play a role in the establishment of harvest quotas. At its 1974 meeting, the Commission agreed that management of whale stocks should eventually be based on some “optimum” rather than simple numerical maximum sustainable yield, the Scientific Advisory Committee of the International Whaling Commission having recommended that “Scientific advice for management of whale stocks should be based not only on the concept of sustainable yield and numbers, but should also include considerations such as total whale weight rather than numbers, interactions within the marine ecosystem, and the health of the ecosystem as this concept is quantified.” The “New Management Procedures” now in effect, provide for a safety factor, and the scientific analysis and assessments have been much improved, with publication required.

In the management of fur seals in South Africa, attention is now being given to the balance between the fur seal and the pilchard populations on which they prey, both species being of economic value in their own right.

There are examples of harvesting of wild ungulate populations in African nations where management policies emphasize balanced harvesting of several species simultaneously in the context of the condition of the environment.

The Marine Mammal Protection Act of 1972 is the first national legislation to place maintenance of the health of the ecosystem as the primary objective of management. Its declaration of policy states that:

“Species and population stocks should not be permitted to diminish beyond the point at which they cease to be a significant functional element of the ecosystem of which they are a part . . . . The primary objective of their management should be to maintain the health and stability of the marine ecosystem. Wherever consistent with the primary objective, it should be the goal to obtain an optimum sustainable population, keeping in mind the optimum carrying capacity of the habitat.”

These examples serve to demonstrate how the need for new approaches has already brought some institutions to adopt certain aspects of the principles defined here. The following steps are now needed:

(1) The charters of resource management institutions should be amended as necessary to embody the four general principles, and

(2) The institutions should be evaluat-
ed with respect to their capacities to implement the principles.

APPENDIX 2

Conservation

The term “conservation” has been used with the meaning of “wise use” involving among other things, “keeping for future use.” In its broad definition, it includes management measures, and means the collection and application of biological information for the purposes of increasing and maintaining the number of animals within species and populations at some optimum level with respect to their habitat. Used in this way, conservation refers to the entire scope of activities that constitute a modern scientific resource program, including but not limited to research, census, law enforcement, and habitat acquisition and improvement, and periodic or total protection as well as regulated taking.

Conservation may refer to a set of measures intended to maintain a resource in a desirable state, or to designate the process of attaining such a state. In a narrow context, conservation can refer to the application of measures that in some way restrain the otherwise free use of a resource in order to ensure that it retains certain desirable natural properties. Used in this way, conservation can be considered as one facet of rational resource management, which may also cover activities intended to improve the resource or ameliorate damage resulting from previous misuse of it. (Of course, in its broader context, conservation includes all those activities.)

The need for conservation arises from a combination of two conditions:

(1) that the use of the resource is sufficiently intensive to significantly affect it, and
(2) that the pressure of present use is such that unless restrained or otherwise regulated it will prejudice future uses and values.

The development of technology and the increase of human populations now ensure that practically all wild living resources are accessible to, and vulnerable to change—sometimes drastic change—by human agency. The second condition might, in theory, apply to an individual man, owning and subsisting on a wild resource who decides to limit his hunting now so that he has food for next year and the year after. Noncompetitive groups may also impose restraints on themselves in the expectation of providing better for the future of their members and their kin. In practice, however, in the modern world, the need for conservation measures arises essentially because any group of users usually will give relatively
greater weight to present values with respect to future values, than does the larger group of which the user group is a part. Conservation measures are the means to correct such an imbalance by adding more weight to future values than would be accorded to them by the separate users of the resource.

Each resource user's relatively short-term view is enhanced by his uncertainty of future benefit. This arises from the expected behavior of contemporary competitors and insecurity of his future access to the resource. Societies, therefore, often seek to establish a longer-term view by eliminating or reducing the risks of exclusion and detrimental competition. Thus, indefinite or long-term rights of use may be granted, competition regulated through allocations, and conflicts in different kinds of use of the same resource resolved by applying some formula. Such actions are not considered to be included among the conservation measures to which attention is here directed, but they are complementary to them. Experience has shown the need for both types of social action at all levels—from the control of individual users by local authorities to the self-regulation of national activities through international mechanisms.

APPENDIX 3

The Concept of Maximum Sustainable Yield

The maximum sustainable yield (MSY) is the greatest harvest that can be taken from a self-regenerating stock of animals year after year while still maintaining a constant average size of the stock. It is derived from the hypothesis—supported to a certain extent by observations—that a population of animals, in growing from an initial small number, at first increases more or less geometrically (exponentially) but that the rate of increase slows down as the population gets larger. The graph of population size against time is thus an S-shaped curve that eventually approaches or reaches a “final” size, that reflects the carrying capacity of the habitat of the population (Fig. 10). At that level, the death rate is balanced by recruitment, and a “steady state” is attained. The simple theory then postulates that the final size is actually the initial size of the renewable resource before man begins exploitation, and that when he begins to take an annual harvest the stock is reduced. According to the theory, the potential of the stock for increase is assumed to be determined by its size, and it presumably can be held steady at a certain size by removing each year a catch equal to that potential rate of increase; this is a “sustainable yield.” So if the population growth curve is S-shaped, the greatest yield can be sustained from a stock of intermediate size, corresponding with the turning point (inflection) of the population growth curve. Study of such curves suggests that the intermediate stock level to be expected in many cases would be between about 40 and 60 percent of the level at “carrying capacity,” although for some species the level may be higher.

The simple conceptual model outlined above, and also some more complex mathematical models, exhibit the property of a single maximum yield as a function of stock size. According to certain commonly used theoretical models of population growth, maximum sustainable yield should be obtainable from a stock level about half the level at “carrying capacity” (Fig. 11). Such models involve a number of assumptions, the most important of which may be summarized as follows:

— the stock is more or less self-contained;
— the stock has attained, before exploitation began, a steady state, at the carrying capacity;
— there are no significant trends in carrying capacity during the period of exploitation;
— the nature of the implied density de-
FIG. 10. The population curve is S-shaped because increments to the population are slow when the population is at a low level, with few individuals reproducing; the increments increase steeply when the population is higher and all individuals are reproducing at maximum rate; and the increments level off when the carrying capacity of the environment is reached, and mortality or other loss balances recruitment.

It is in practice usually very difficult to test any of those assumptions. Stocks have occasionally been reduced to less than half their initial size, and then recovered under full or partial protection (as in the case of the North Pacific halibut). In other cases, severely reduced stocks have never recovered, in spite of receiving total protection (such as the
Figure 11. The maximum sustainable yield concept is based on the assumption that an unexploited population exists at an equilibrium density, maintained by density dependent factors—i.e., it is at the carrying capacity. When the population is reduced and the density lowered, recruitment rates increase and exceed rates of loss. The difference between the recruitment and loss represents the number of animals that can be removed through exploitation, without reducing the population further, and if that number is removed annually, it is assumed that the population will be stabilized at the new, artificially induced equilibrium density. Under a strict abstract logistic curve condition, the population density producing the greatest harvestable surplus—the maximum sustainable yield—is one-half the "original level."

In some cases, reduction of one species has led to the increase of another, unexploited species, and a change in the composition of the ecosystem (such as in the case of the California sardine and anchovy). We have as yet no sure means of predicting such consequences. Although a number of methods have been devised and used to estimate the parameters of the models described, they all depend on assumptions that are both overly simplistic and unproven. For example, the effect of exploitation on the age composition of a population has often been ignored, or it has been assumed that a reduction of the proportion of old individuals will result in an increase in reproduction. Under exploitation, the age composition usually is truncated, with the younger age groups comprising a higher proportion of the total. This occurs where exploitation is nonselective as well as where there is selection for larger—usually older—individuals. If, in a given species, the older age groups have higher reproductive rates—and particu-
larly if the youngest several age groups constitute a prereproductive stage in the life history—an exploited population with truncated age structure will have a lower relative reproductive rate than would a population in which all individuals had an equivalent reproductive potential.

The social organization of the wild population is another factor to which far too little attention has been given in development of the concept of maximum sustainable yield. Dominance patterns, involving the supremacy of one or a few males that accomplish all or most of the breeding, exist in many species. Those patterns may rather delicately control the reproduction of a population, and if the patterns are destroyed, that control can be upset, in some cases, reducing the reproductive rate. Another aspect of concern is the effect that loss of group leaders experienced in foraging or migration, may have on group survival (Fig. 4).

From an ecological point of view, the major problems associated with maximum sustainable yield involve its concentration on the stock involved to the exclusion of factors such as:

- relationships within a trophic level (e.g., competition);
- relationships between trophic levels;
- impacts on symbiotic or commensal relationships; and
- changes in carrying capacity due to factors such as climate, pollution, and other human influences.

In sum, the concept of maximum sustainable yield as a simple function of stock size was developed to provide a generalized approximate description of the response of a stock or species to exploitation. It has served a useful evolutionary function, as a means of generalized description, and as an elementary teaching aid for students and for administrators. It has provided a preliminary conservation goal where it has been used to try to avoid or correct overexploitation. It has played a significant role in the evolution of understanding of wild populations. However, like some other simplified concepts, maximum sustainable yield has become institutionalized in a more absolute and precise role than intended by the biologists who were responsible for its original formulation. It is being expected to perform functions for which it was never intended, serving for example, as the sole conceptual basis for or goal of management in some cases. Once a concept has been adopted and institutionalized, it is difficult to change it. In this case, because of its institutionalization, the concept of maximum sustainable yield is now an obstacle to the acceptance of concepts that derive from present ecological knowledge, and that would provide a more adequate basis for management. A more adequate basis is especially necessary at this time when the overall impact of man on the biosphere is increasing and diversifying as never before.

**APPENDIX 4**

**Application to the Law of the Sea**

**Summary**

The Workshop prepared a statement of principles for the conservation of wild living resources that could meet modern needs. The statement redefines the primary goal of renewable resource management and the conditions for effective application of the principles. In this Appendix to the report of the workshops the statement is adapted to specific problems concerning the living resources of the sea, particularly, but not exclusively, those that are or may be internationally managed. The document explains the reasoning behind this endeavor, and annexed to it is a form of words that it is suggested might usefully be included in the text of instruments now being prepared by the United Nations Conference on the Law of the Sea.

**Text**

Man is making ever-increasing demands on renewable natural resources, for food and for other products and val-
ues. The United Nations Conference on the Human Environment in 1972, the United Nations Conferences on Population and Food in 1974, and the current United Nations Conference on the Law of the Sea (UNCLOS) all attest to rising international awareness of the global problems created thereby. With respect to the wild living resources, including fishes and other marine organisms, it is evident that although much progress has been made in the past three decades, some attempts to manage those resources have nevertheless permitted gross depletion of several of them, rather than assuring continuing, high and improved yields. Absence of an effective policy for rational management, or the application of a policy that results in overutilization or other abuse of a resource, results in the loss of potential benefits to both present and future generations. Losses with respect to marine resources have been estimated roughly in the order of several hundreds of millions of dollars annually. Such losses will increase unless appropriate policies are implemented soon. An effective policy would, on the other hand, secure great benefits and ensure that they are distributed equitably both among nations and existing users, and between present and future generations.

The United Nations Conference on the Law of the Sea has concentrated on the equitable distribution of fisheries resources among states, and hence of potential benefits from their use, rather than on the problem of balancing present and future uses. Proposals submitted to the Conference to date address more the question of rights, access, and jurisdictional limits than the formulation of overall long-term objectives. This is understandable, in view of the urgent need to resolve existing and potential conflicts among nations and among different users of the ocean. The two questions are, however, linked. The task of the Workshops was limited to close examination of the latter and to suggest new approaches to its solution. It is hoped that the suggestions made will be useful to those persons engaged in preparing new legislation covering those matters.

Management failures are attributable at least as much to institutional weaknesses as to shortcomings in the formulation of objectives. Those aspects are, however, also linked; in particular, attempts to apply unsound objectives lead to the sharpening of conflicts and to stress and failure in management institutions, and hence to less than optimal use of resources.

If management as a whole is concerned primarily with the allocation of values among interested parties who use or may use a resource, conservation is that component of management which regulates the relationship between current and potential values (Appendixes 1 and 2). The primary goal of conservation policy is the maintenance of resource systems in desirable states. Such a goal is consistent with the perceived evolutionary direction of international institutions.

The Workshops agreed on a set of Principles for the conservation of wild living resources. Those Principles provide guidelines for achieving the primary goal; they represent, inter alia, an attempt to specify what are desirable states in this context. In addition, a number of criteria were agreed that should be met in applying the Principles. For this, a sophisticated approach to management is necessary, taking into account the basic characteristics of ecosystems as well as the properties of selected species and resource stocks that may be of interest to certain users at particular times. Simplistic goals of conservation, including the widely adopted one of assuring “maximum sustainable yield,” prove to be inadequate.

The desirable state of a resource system is defined as one that fulfills the following three conditions:

1. physical yields, or other derived values, could be maximized on a continuing basis;
2. diversity of present and future options in using it are ensured; and
CONSERVATION OF WILD LIVING RESOURCES—Holt and Talbot

(3) risk of irreversible change or of long-term adverse effects resulting from use is minimized.

These three conditions do not contradict each other, but they are not always wholly compatible. Where the desired state is some compromise between them, Conditions 2 and 3 may be fulfilled by foregoing some of the continuing yield the potential for which Condition 1 seeks to maximize. Such sacrifice will, however, be relatively small, and compensated for by other benefits to present and future users.

The set of Principles prepared by the Workshop are generally applicable to terrestrial, marine, and freshwater situations. With respect specifically to the marine environment, it is suggested that the instruments to be prepared by the United Nations Conference on the Law of the Sea should refer explicitly to those Principles and to the necessary conditions for their application in various circumstances. This might best be done by including an appropriate definition of "conservation" and specification of the main conditions. Accordingly, an annotated draft text is offered in the Annex to this Appendix. It includes valid ideas expressed in existing texts but reflects the better understanding of the nature of marine resources we now possess, as well as being responsive to modern fishing conditions.

The draft is divided into three paragraphs. These could, if necessary, be used separately, in articles, in a preamble, or in a Conference resolution, depending on the eventual form of the instruments now being prepared. They might serve to specify the general criteria for international management of fisheries in waters beyond national jurisdictions, and as guidelines to coastal states in exercising their authority in waters falling within their jurisdictions. Similar wording might be used to define the conditions for exercise of authority entrusted to any state, group of states, or international machinery.

“Conservation” is defined in Paragraph A of the Annex. The introductory words, and Subparagraph 1, are identical in form with, and similar in content to, Article 2 of the 1958 Geneva Convention on Fishing and Conservation of the Living Resources of the High Seas. Similar wording has been included in a number of draft articles submitted by states to the United Nations Conference on the Law of the Sea, several of which acknowledge the need for more effective conservation programs and would impose a conservation obligation on coastal states as well as on international organizations established to manage fishery resources. Two small, but nevertheless significant, additions have been made here. Firstly, the definition refers both to the resources themselves and to their environment, which together constitute the marine ecosystem. Secondly, Subparagraph 1 indicates the need for supplies of food to be stable as well as maximal; the population levels of many stocks of fish and other marine animals are naturally variable, but under intensive use that variability can be increased, to the detriment of the fishing industry and, in some cases, endangering the survival of the stock. The intention of Subparagraph 1 is to ensure that stocks will generally be maintained at levels not lower, and possibly substantially higher, than the levels required to meet the definition in the 1958 convention, insofar as such levels can be determined.

Subparagraphs 2 and 3 introduce new principles. These are called for by changes in the nature of fisheries that have occurred in the 20 years since a United Nations Technical Conference prepared the earlier definition. Marine fisheries have, in that time, expanded greatly. They have diversified, and many more nations are participating in them. Although the world catch has continued to increase, the rate of increase has slowed—despite continuing increase in fishing effort—and occasionally in recent years the total annual catch has declined. Some of the resources on which large and
valuable fisheries were based have proved unable to withstand the intensity of fishing to which they have been subjected, resulting in considerable distress to some fishing industries, social disruption, and financial losses. Although no species are known yet to have become totally extinct as a result of this fishing pressure, the adverse effects will in some cases endure for many years and some may be irreversible. Over the same period, shifts in the nature of interest in the marine resources have reminded us that values can and do change, often unpredictably. Thus, wise use of resources involves regulating the impact of current exploitation so as to provide for continuation of current types of use but at the same time not to foreclose use of the resource for other purposes in the future. This is particularly desirable for a resource the exploitation of which is regulated internationally, because those who use it in the future may not always be the descendents of those who use it now. Application of Subparagraph 2 is a necessary—but not in itself sufficient—action to preserve options. This will be achieved generally by limiting the impact of fishing, and probably more effectively by encouraging a pattern of resource utilization such that a given total yield is secured as a balanced mixture of species from various trophic levels in the ecosystem, rather than comprising one or a few species taken mainly or entirely from one trophic level.

As pointed out earlier, simultaneous fulfillment of all criteria laid down in the three subparagraphs may in practice involve some compromise, but should by its nature give compensatory benefits. In particular, by taking yields on a continuing basis at levels somewhat less than the maximum possible, some unintended wasteful expenditure of other natural resources used by fishery industries (e.g., fuel used to obtain the catch or materials and energy used in constructing excess vessels and gear), will be avoided, and the net benefits accruing to each participant in the fishery will often be increased. The problem of wasteful use of other resources is addressed in Subparagraph 1 of Paragraph B in the Annex. It has long been recognized that the benefits of conservation may lie as much in avoiding excessive fishing effort, as in enhancing the value of sustained catches. Application of the Principles embodied in the definition of conservation would of course restrain effort, but it is not alone sufficient; there are numerous cases where the benefits from conservation measures have been largely dissipated through intensified competition among participants for shares of the regulated catches. At a time when it is becoming widely accepted that there are overall limits to natural resources, it seems appropriate that the instruments of the United Nations Conference on the Law of the Sea should be explicit on this matter by recognizing that the conservation of living marine resources while having special aspects, is nevertheless a part of the general problem of resource husbandry.

Subparagraph 2 may be read to cover also the need to act, in the process of applying conservation measures, so as to ensure that catches of fishes and other animals that may be taken incidentally with those most prized, are not wasted. While some ecological concepts are rather well founded and generally accepted by the scientific community, there are weaknesses in current theory, data, models, and analytical and computational procedures. Furthermore, as fishing continues to intensify and diversify, the nature of its impact is changing so that, notwithstanding scientific advances of the past two decades, we are still far from

---

1 This biological term describes the feeding relationships of organisms. Some—the green plants, including phytoplankton—are primary producers, constructing living material from inorganic nutrients in the sea by photosynthesis; others are herbivorous; primary carnivores feed on the herbivores, and they in turn form the diet of secondary carnivores. These several categories (producers, herbivores, primary carnivores, etc.) constitute trophic levels.
being able to predict in detail, or at long-range, changes in marine ecosystems—particularly qualitative changes—that may profoundly affect man's use of those resources. Furthermore, although the machinery for decision making may be improved; there will always be some delay in implementing decisions, some likelihood of mistakes having significant consequences, and perhaps some shortcomings in enforcement of regulations. Good management calls for appropriate allowance for these inevitabilities. Again, natural changes in many characteristics of living systems and of their physical environment cannot yet be predicted, and some may never be predictable. These facts all call for the inclusion of safety factors in conservation measures, the margin of safety provided being based on reasonable assessments of the degree of uncertainty and the magnitude of the risk. This is provided for in Paragraph B, Subparagraph 2.

The wording of Subparagraph 3 is taken straight from the 1958 Convention. It favors a priority of resource use that is now even more relevant than it was in 1958, or than in 1966 when that convention came into force. The wording does not, in our interpretation, exclude products for indirect human consumption, but would nevertheless tend to favor direct use where possible. Since that time, some other aspects of "product quality" have also been recognized as important, such as the presence of heavy metals, pesticides, and other contaminants in marine organisms. This is in part covered by other draft articles before the United Nations Conference on the Law of the Sea that deal with pollution of the sea, but perhaps calls for explicit cross-reference in the articles on conservation and allocation of fisheries resources.

The 1958 Convention provides for conservation measures to be based on scientific evidence. This is a necessary, but not a sufficient, provision for successful application of new international law. Data must not only be adequate, but they and the derived results must be promptly disseminated so that critical review of them is possible. The application of conservation measures should be constantly modulated by feedback of data, and their effects continuously monitored. Furthermore, pertinent environmental properties need to be monitored concurrently, and the observed or anticipated effects of changes in them—whether natural or caused by man—taken into account through appropriate changes in the conservation measures.

A most important need is to locate unambiguously the responsibility for collecting and analyzing data, and generally for conducting research and monitoring. Practical considerations dictate that specific duties must be firmly, though not necessarily exclusively, assigned to those entities that have the right to utilize the resources, and particularly to those that exercise that right. Not only can they benefit economically from their right, but much of the data essential for the formulation of conservation measures comes from the catches and the records of fishing operations. Those who utilize a resource are, further, likely to be the ones with the means, or access to the means, to conduct the necessary research, and also with the possibilities, under international law, of conducting certain kinds of research—whether from commercial or research vessels or from other platforms—in areas over which jurisdiction is exercised. One of the main causes of past failures has been that data have not been promptly available, nor contributed by all participants in the fisheries, and have not always been of adequate scope. Furthermore, the means to analyze and interpret the data and materials that have been collected have frequently been inadequate, and the results have not been promptly disseminated. The provisions of Paragraph B are intended to correct those faults.

ANNEX

A. "Conservation of the living resources of the sea is that aggregate
of measures required to maintain those resources and their environment in a state such that

(b) (1) a maximum and stable supply of food and other marine products may be taken from them on a continuing basis;

(c) (2) there is minimal likelihood of irreversible or long-term adverse effects of exploitation on particular resources or on the marine ecosystem as a whole; and

(g) (3) a wide diversity of options for future use is ensured.

B. “Conservation measures shall be formulated with a view to

(f) (1) avoiding wasteful use of other natural resources expended to secure the supply of food and other marine products;

(2) providing a margin of safety to allow for unpredicted variations and characteristics of marine resources and their environment, and for the fact that the application of measures may be subject to delay or be otherwise imperfect; and

(h) (3) securing in the first place a supply of food for human consumption.”

C. “The party or parties having jurisdiction over a living marine resource shall ensure that such continuing scientific research is conducted, and that such data are regularly collected and analyzed and results promptly disseminated, as are necessary for the formulation of conservation measures and for monitoring the effects of their application. The scope of the necessary research and data is such as to reveal the state and dynamics of the stocks being or to be exploited, the effects of exploitation on them, their interactions with other elements of the marine ecosystem to which they belong, and their dependence on environmental processes.”

“In meeting this responsibility the party having jurisdiction shall ensure that entities acting under its authority collect the necessary data, including information about the utilized and the discarded catches, and about the fishing operations.”

Notes

(a) The 1958 Geneva Convention on Fishing and Conservation of the Living Resources of the High Seas refers in its Article 1, Paragraph 2, to “conservation” as the process of reaching a defined state of the resources. Article 2, on the other hand, defines “conservation” as “the aggregate of measures” required for attainment of such a state. Here, the latter approach is followed, for convenience.

(b) We would have preferred not to use the technical term “maximum” in such a text but recognize that it has found acceptance in many international treaties as a legal term [see (e) below].

(c) Values may be attached to properties of living marine resources other than their ability to yield “food and products”; examples are the recreational value of sport fishing, and aesthetic, ecological, and scientific values. Under present conditions, these other values pertain more to resources that are, or may become, under the exclusive jurisdiction of certain coastal states than to resources of international interest; for the latter, that are the primary concern of the draft here offered, we retain the overriding interest in “products,” noting that possible shifts of interests are taken care of in Subparagraph 3.

(d) Irreversible effects include the extinction of species, tribes, or races of plants or animals, or the reduction of them to levels from which they may not recover their former order of abundance even if exploitation of them were to cease entirely. The term also includes any irreversible consequences of such a reduc-
tion to other components of the ecosystem. This criterion can strictly only be expressed in terms of a change in a probability. There are now available (as there were not in 1958) case histories and some biological models relevant to this criterion, adoption of which would ensure that the danger was recognized and due caution exercised.

(e) Whereas the concept of maximum sustainable yield in the 1958 Convention was formulated as a sufficient criterion of conservation, a cohesive set of criteria is now required. The 1958 formulation becomes, as amended, one of the set. Different elements of such a set may be only partially compatible. From the scientific point of view, several interconnected variables cannot, in general, simultaneously be maximized or minimized. Such incoherence is, however, not unusual in legal documents, and the practice has been followed here, rather than attempting to define precisely the mathematical conditions for singular states.

(f) The set of desirable qualities to be maintained in the resource can be expanded to meet economic and social criteria other than those recognized explicitly in the definition of conservation. Not all of them will necessarily be fully compatible with the three contained in the definition. They concern, inter alia, the relations of input to output of the industry and its continuity and stability; and the nature and quality of the products. Input–output relations can be expressed formally in the language of economic theory, but for the present purposes, especially in an international context, a more general reference to the ways of using some natural resources to secure values from others seems more appropriate. (Subparagraph 1). This consideration might also be taken into account in the application of the provision of Subparagraph 3.

(g) Data concerning quantities, composition, and other characteristics of catches are among the most important information required for resource assessment. Most catches are retained and utilized, but frequently parts of the catches are discarded. Such discards may include unwanted catches of valued species—undersized ones, for example—or other species of lower market value or for which there is no market. It is always desirable and sometimes essential, to have information about them, for monitoring the effect of certain conservation measures, for assessing the overall impact of fishing, for studying how resource waste might be avoided, and because in the future species now discarded may be valued more highly than now.

(h) Notwithstanding the recent development of some independent methods of assessing marine fishery resources, measures of “fishing effort” remain essential for this purpose. In any case, appropriate conservation resources can neither be formulated nor their effects adequately monitored without a rather detailed knowledge of the intensity, efficiency, and deployment of fishing operations. Data needed include the distribution of different kinds of fishing effort in time and space, and information about technical, environmental, and other factors that determine the level of performance of fishing units.

REFERENCES

This paper is the report of a program of workshops, and the text does not contain literature citations. However, it was felt that the inclusion of titles for further reference would be useful. The following references do not represent the full body of literature on which the report was based; instead, they are presented as a representative selection of important sources of further information on the subject of the report.

Preface

This year's Annual Report contains materials from the 46th Annual Commission and Scientific Committee Meetings held in Puerto Vallarta, Mexico in 1994.

The final section of the volume contains scientific papers from the annual Scientific Committee meeting all of which have been anonymously peer reviewed and revised since their presentation to the Scientific Committee. Ten of the papers submitted to that meeting were reviewed and published in the latest volume in our special issue series (Perrin, W.F., Donovan, G.P. and Barlow, J. (eds). 1994. *Gillnets and Cetaceans*, Reports of the International Whaling Commission (special issue 15): i-ix+629pp.). A number of others will be considered for forthcoming special issues. A *Guide for Authors* is included at the back of this volume.

The references in this volume have again been compiled using the *Papyrus* Bibliography System (Research Software Design, Portland, Oregon 97201, USA). Keywords have been assigned to each paper. The keywords used are the standard ones used in the IWC database. In conjunction with RSD we are offering the *Papyrus* software package plus a database containing all published and unpublished IWC papers (over 4,000 references). Details can be obtained from the Office of the Commission.

Production of a volume of this size is a major task and I would particularly like to thank the following: Helen Sharp (nee Coulson), who keeps track of the manuscripts and who types in and prepares many of the revised manuscripts; Julie Creek who keys in and prepares the tables for publication; Stella Duff, who oversees the proof reading; Helen Richardson, who helps with proof reading and artwork; Cherry Allison of the computing department; and the staff of Black Bear Press.

As in recent years, Résumés of those papers presented to the Scientific Committee but not published in full are included in the final section of the volume. These do not constitute a publication and are included for information only. They must not be cited without permission of the author. Copies of the full versions of these papers as presented to the Scientific Committee can be obtained from the Office of the Commission at cost price.

## RESUME SECTION

439

## GUIDE FOR AUTHORS

459

This report records the activities of the Commission in the year following the 45th Annual Meeting held in Kyoto, Japan, 10–14 May 1993, under the Chairmanship of Dr L. Fleischer (Mexico). The Chairman’s Report of that meeting was published in the Forty-fourth Annual Report of the Commission (Rep. int. Whal. Commn 44:11–39).

STOCK CLASSIFICATIONS

Catch limits for the killing for commercial purposes of whales from all stocks for the 1986 coastal and 1985/86 pelagic seasons and thereafter were set at zero at the 34th (1982) Annual Meeting. The Commission has made no changes to the stock classifications adopted at the 37th (1985) Annual Meeting, which are shown on pages 26–27 of Rep. int. Whal. Commn 37.

CATCHES

The Government of Japan issued a Special Permit to take 300 (or 330 if required to implement the research) minke whales, excluding dwarf minke whales, in Antarctic Area IV (south of 55°S, east of 70°E and west of 130°E, excluding the 200 mile zones of foreign countries) in its programme to collect new bias-free data on natural mortality and recruitment.

The Government of Norway issued a Permit for the take of 110 minke whales in the northeastern Atlantic, to provide information on feeding ecology for incorporation into a model for future multi-species management of the area.

In addition, the Government of Norway also resumed commercial whaling operations on the northeastern Atlantic stock of minke whales under objections it lodged in 1985 to the classification of this stock as a Protection Stock, and in 1982 to the ban on commercial whaling from 1986.

The catches taken under Special Permit and objection are shown in Table 1.

ABORIGINAL SUBSISTENCE CATCHES

The prohibition of commercial whaling does not affect catches by, or on behalf of, native peoples for subsistence purposes. The catches taken under the regulations governing such aboriginal subsistence whaling by IWC members are also shown in Table 1.

INFRINGEMENTS

Infractions of the Commission’s regulations reported in the aboriginal subsistence whaling operations in 1993 are summarised in Table 2.

SCIENTIFIC RESEARCH

The 16th Antarctic Minke Whale Sightings Cruise was carried out in part of Area I (from 110°W-80°W) as a contribution to the Commission’s Second International Decade of Cetacean Research. Six scientists – from Argentina, Australia, Chile, Japan, New Zealand and the USA – carried out the survey from 23 December 1993 to 21 February 1994 aboard two research vessels provided by the Government of Japan.

The Commission has also provided partial funding in support of research projects concerning humpback whales on the west coast of South Africa, humpback whale stock identity in the southern Ocean, the stock identity of fin

whales in the Gulf of St Lawrence and off Greenland, and DNA analysis of tissue samples from Bryde's whales collected in the Philippines.

**SCIENTIFIC COMMITTEE**

The Scientific Committee completed its specification for the calculation of catch limits in a Revised Management Procedure for baleen whales for the Commission's 45th Annual Meeting. The Secretariat has continued the documentation of the relevant computer programs, as well as the work on data entry of whale records into machine-readable format. The latter includes post-War whale marking and recovery data, and pre-War African and Australian catches. A database of sightings records is also being created under contract.

Trials to implement the RMP for North Pacific minke whales have been specified and an initial set of results produced for consideration by the Scientific Committee.

The Commission last year endorsed the plans of the Scientific Committee to establish an intersessional Steering Group to identify objectives for research on Southern Hemisphere blue whales. The Government of Japan hosted a meeting of the Steering Group in Tokyo, 11–13 October 1993. The Commission has afforded this activity high priority and will examine mechanisms to finance the implementation of the research programme.

**IWC ACTIVITIES**

An intersessional Working Group met at the invitation of the Government of Australia on Norfolk Island, South Pacific, 20–24 February 1994, to address the outstanding issues raised by the proposal put forward by the Government of France at the 44th Annual Meeting for the establishment of a whale sanctuary in the Southern Ocean. The concept was endorsed at the 45th Annual Meeting and the Working Group formulated recommendations with a view to enabling the Commission to take a full decision at the 46th Annual Meeting.

At the 45th Annual Meeting the Commission requested the Secretary to prepare a consolidated report about whalewatching, including estimates of its economic and scientific value and potential. A questionnaire was sent to member governments to assess the extent and value of whalewatching activities in their countries, and to obtain regulations affecting whalewatching. A Working Group will consider the report and make recommendations to the 46th Annual Meeting.

During the year the Secretary has contacted all non-member states to collect information on actual or planned whaling activities, to investigate their reasons for remaining outside the IWC and inviting them to accede to the Convention.

**COOPERATION WITH OTHER ORGANISATIONS**

The Commission was represented in an Observer capacity at meetings of:

- NAMMCO, Reykjavik, Iceland, July 1993; and Tromsø, Norway, February 1994;
- ICES, Dublin, Ireland, September/October 1993;
- ASCOBANS, Cambridge, UK, October 1993;
- CCAMLR, Hobart, Tasmania, October/November 1993;
- ICCAT, Madrid, Spain, November 1993;

**FINANCE**

The budget approved for the financial year 1993/94 amounted to £1,000,035, including an allocation of £152,035 for research. It is shown on page 36 of the 44th Annual Report (Rep. int. Whal. Commn 44).

Contributions from Contracting Governments were set at £886,080, making allowance for a projected shortfall which in the event amounted to £106,080 due to the failure of seven governments to pay in full: Costa Rica, Ecuador, Kenya, Peru, Senegal, Seychelles and Venezuela.

A further sum of £996,623 representing non-payments from previous years together with interest was still outstanding from these governments and from Antigua & Barbuda and Argentina. The sanctions of withholding Commission documentation and the suspension of the right to vote for a Government more than three months in arrears with its annual payments continued from previous years for six Governments - Costa Rica, Ecuador, Kenya, Peru, Senegal and Venezuela. Argentina and Antigua & Barbuda have made arrangements to repay their arrears by instalments, in consideration of which the Commission has lifted these sanctions.

The penalty of the addition of 10% interest for failure to pay their 1993/94 contributions by the due date was applied in March 1994 to the Governments of Dominica, Netherlands, St Kitts & Nevis, St Lucia, Seychelles and the Solomon Islands as well as to the six Governments with existing arrears.
The four former members Belize, Egypt, Philippines and Uruguay still owe £168,568 for unpaid contributions and interest.

Dr R. Gambell, Secretary to the Commission, 31 August 1994
Financial Statements for the year ended 31 August 1994

Report of the Auditors to the Commission

We have audited the financial statements which have been prepared under the accounting policies set out below.

Respective responsibilities of the Secretary and auditors
As described below, the Secretary is responsible for the preparation of financial statements. It is our responsibility to form an independent opinion, based on our audit, on those statements and to report our opinion to you.

Basis of opinion
We conducted our audit in accordance with Auditing Standards issued by the Auditing Practices Board. An audit includes examination, on a test basis, of evidence relevant to the amounts and disclosures in the financial statements. It also includes an assessment of the significant estimates and judgements made by the Secretary in the preparation of the financial statements, and of whether the accounting policies are appropriate to the Commission's circumstances, consistently applied and adequately disclosed.

We planned and performed our audit so as to obtain all the information and explanations which we considered necessary in order to provide us with sufficient evidence to give reasonable assurance that the financial statements are free from material misstatement, whether caused by fraud or other irregularity or error. In forming our opinion, we also evaluated the overall adequacy of the presentation of information in the financial statements.

Opinion
In our opinion the financial statements have been properly prepared in accordance with the accounting policies and present a true and fair statement of the transactions of the Commission for the year ended 31 August 1994.

Touche Ross & Co, Chartered Accountants.

Statement of the Secretary's Responsibilities

The financial responsibilities of the Secretary to the Commission are set out in its Rules of Procedure and Financial Regulations. Fulfillment of those responsibilities requires the Secretary to prepare financial statements for each financial year which give a true and fair view of the state of affairs of the Commission as at the end of the financial year and of the surplus or deficit of the Commission for that period. In preparing those financial statements, the Secretary should select suitable accounting policies and then apply them consistently; make judgements and estimates that are reasonable and prudent; prepare the financial statements on the going concern basis unless it is inappropriate to presume that the Commission will continue in operation.

The Secretary is responsible for keeping proper accounting records which disclose with reasonable accuracy at any time the financial position of the Commission. He is also responsible for safeguarding the assets of the Commission and hence for taking reasonable steps for the prevention and detection of fraud and other irregularities.

Accounting Policies

The accounting policies adopted by the Commission in the preparation of these financial statements are as set out below. The departures from generally accepted accounting practice are considered not to be significant for the reasons stated.

Convention
These financial statements are prepared under the historical cost convention.

Fixed Assets
The full cost of office furniture and equipment is written off in the Income and Expenditure Account in the year in which it is incurred. The total cost of equipment owned by the Commission is some £70,000 and its value after allowing for depreciation is not significant. Proposed expenditure on new items is included in budgets and raised by contributions for the year of expenditure.

Publications
The full cost of printing publications is written off in the year. No account is taken of stocks which remain unsold at the balance sheet date. Most sales occur shortly after publication and so stocks held are unlikely to result in many sales; consequently their net realisable value is not significant.

Severance Pay Provision
In accordance with the practice of other intergovernmental organisations, the Commission provides for an indemnity to all full time members of staff in the event of their appointment being terminated on the abolition of their posts. The indemnity varies according to length of service and therefore an annual provision is made to bring the total provision up to the maximum liability. This liability is calculated after adjusting for staff assessments, since they would not form part of the Commission's liability.

Interest on overdue contributions
Interest is included in the Income and Expenditure Account on the accruals basis and provision is made where its recoverability is in doubt.

Leases
The costs of operating leases are charged to the income and expenditure account as they accrue. Equipment held under finance leases is not capitalised and no provision is made for future instalments as expenditure on fixed assets is expensed as incurred. This is in line with the treatment of other fixed assets.

Foreign Exchange
Transactions denominated in foreign currencies are translated into sterling at rates ruling at the date of the transactions. Monetary assets and liabilities denominated in foreign currencies at the balance sheet date are translated at the rates ruling at that date. These translation differences are dealt with in the Income and Expenditure account.

Notes to the Accounts

1. **Publications Fund**
   - Interest receivable: £2,525, £4,065
   - Sales of sponsored publications: £7,914, £2,491
   - Expenditure on publications: (£10,556), (£6,151)

2. **Research Fund**
   - Allocation for research: £117,235, £96,250
   - Value added tax recoverable: £3,513, £ -
   - Voluntary contributions received: £7,437, £ -
   - Profit on sale of promotional items: £91, £307
   - Interest receivable: £4,053, £2,889
   - Research expenditure: (£136,961), (£75,982)

3. **General Fund**
   - Net transfers from (to) Income and Expenditure Account: (£4,632), £23,464
   - Opening balances at 1 September: £35,608, £12,144
   - Closing balances at 31 August: £30,976, £35,608

4. **Provision for Severance Pay**
   - Opening balances at 1 September: £202,414, £179,812
   - Transfer from Income and Expenditure being: Allocation: £10,623, £12,584
   - Interest received: £9,077, £10,018
   - Closing balances at 31 August: £222,114, £202,414

5. **Creditors**: amounts falling due within 1 year
   - Deferred contributions income: £157,745, £146,933
   - Amounts received in advance:
     - Sponsored Gillnet publication: £4,994, £4,994
     - Scientific data: £ - , £3,793
     - Yonah project: £ - , £18,937
     - Other creditors and accruals: £24,918, £11,469
   - Closing balances at 31 August: £187,657, £186,126

6. **Reconciliation of Movement in Funds**
   - Excess of income over expenditure: £146,031, £3,309
   - Opening funds: £477,665, £474,356
   - Closing funds: £623,696, £477,665

7. **Financial Commitments**
   - The Commission had annual commitments at 31 August 1994 under non-cancellable operating leases for office equipment as set out below and which expire:
     - within one year: £885, £ -
     - within 2 to 5 years: £1,486, £ -
     - after 5 years: £17,137, £16,725
   - Closing balances at 31 August: £18,623, £17,610
46th Annual Meeting: May 1994, Puerto Vallarta

Agenda of the 46th Annual Meeting

1. ADDRESS OF WELCOME

2. OPENING STATEMENTS
   (Papers IWC/46/OS —)

3. ARRANGEMENTS FOR THE MEETING

4. ADOPTION OF AGENDA

5. APPOINTMENT OF COMMITTEES
   (Rules of Procedure, Rule M.1.)

6. HUMANE KILLING
   (Chairman’s Report of the 45th Meeting, paragraph 7 and Appendix 1)
   6.1 Report of Humane Killing Working Group
      (Paper IWC/46/18)
      6.1.1 Terms of reference
      6.1.2 Action arising from the 1992 Workshop
         on Humane Killing Methods
      6.1.3 Preparations to reconvene the Workshop
         on Humane Killing Methods
      6.1.3.1 Terms of reference
      6.1.3.2 Practical arrangements
      6.1.4 Other matters
   6.2 Action arising
      (Any provisions adopted may require amendment of the Schedule)

7. SOCIO-ECONOMIC IMPLICATIONS AND SMALL-TYPE WHALING
   (Chairman’s Report of the 45th Meeting, paragraph 8 and Appendix 3)
   7.1 Report of Working Group
      (Paper IWC/46/16)
      7.1.1 Action on 1993 Resolution
   7.2 Action arising
      (Changes of categories of whaling or definitions may
       require amendment of the Schedule)

8. INFRACTIONS, 1993 SEASON
   (Chairman’s Report of the 45th Meeting, paragraph 9)
   8.1 Report of Infractions Sub-committee
      (Paper IWC/46/7)
      8.1.1 Infractions reports from Contracting Governments
         (Paper IWC/46/6)
      8.1.2 Other matters
   8.2 Action arising
      (Changes to the observer schemes may require
       amendment of the Schedule, paragraph 21; changes in the
       information required under Section VI of the Schedule
       may require amendment of that Section.)

9. MECHANISM TO ADDRESS SMALL CETACEANS IN THE COMMISSION
   (Chairman’s Report of the 45th Meeting, paragraphs 10 & 11 and Appendix 4)
   9.1 Report of Working Group
      (Paper IWC/46/17)
   9.2 Action arising
      (Any provisions adopted may require amendment of the Schedule)

10. ABORIGINAL SUBSISTENCE WHALING
    (Chairman’s Report of the 45th Meeting, paragraph 12)
    10.1 Report of the Scientific Committee
        (Paper IWC/46/4)
    10.2 Report of Aboriginal Subsistence Whaling Sub-committee
        (Paper IWC/46/13)
        10.2.1 Management objectives and procedure
            for aboriginal subsistence whaling
        10.2.2 Bering-Chukchi-Beaufort Seas stock of
            bowhead whales
        10.2.3 North Pacific eastern stock of gray
            whales
        10.2.4 West Greenland stock of fin whales
        10.2.5 West Greenland stock of minke whales
        10.2.6 North Atlantic Central stock of minke
            whales
        10.2.7 North Atlantic humpback whales
    10.3 Action arising
        (Changes to the management procedure, catch limits or
         other regulations will require amendment of the Schedule
         including paragraphs 12, 13 and Table 1)

11. COMPREHENSIVE ASSESSMENT OF WHALE STOCKS
    (Chairman’s Report of the 45th Meeting, paragraph 13)
    11.1 Report of the Scientific Committee
        (Paper IWC/46/4)
    11.1.1 Revised Management Procedure
    11.1.2 Southern Hemisphere baleen whales
    11.1.3 North Pacific minke whales
    11.1.4 North Atlantic minke whales
    11.1.5 Southern Hemisphere minke whales
    11.1.6 North Pacific Bryde’s whales
    11.1.7 Other stocks
    11.1.8 Future work plans
    11.2 Review of Schedule paragraph 10(e) and other
        related paragraphs
    11.3 Proposed new system of supervision and control
        (Paper IWC/46/29)
    11.4 Adoption of the Revised Management
        Procedure
        (Paper IWC/46/29)
11.5 Proposed data standards (Paper IWC/46/29)
11.6 Proposed survey guidelines (Paper IWC/46/29)

11.7 Action arising
(Changes to the management procedure, classification and catch limits of stocks, areas or sub-areas will require amendment of the Schedule including paragraphs 9, 10, 11, 12 and Tables 1, 2 and 3. Changes to the data requirements, survey guidelines, inspection and observer schemes will require amendment of the Schedule including Chapters 5 and 6).

12. WHALE SANCTUARY IN THE SOUTHERN OCEAN
(Chairman’s Report of the 45th Meeting, paragraph 16 and Appendix 6)
12.1 Report of intersessional Working Group (Paper IWC/46/19)
12.2 Proposal by France, Australia, Brazil, Ireland, Monaco, Netherlands, New Zealand, Spain, UK and USA (Paper IWC/46/25)

12.3 Action arising
(Any provisions adopted may require amendment of the Schedule, including Chapter III Capture)

13. ADOPTION OF REPORT OF THE TECHNICAL COMMITTEE
(to be circulated as Paper IWC/46/5)

14. SCIENTIFIC PERMITS
(Chairman’s Report of the 45th Meeting, paragraph 18 and Appendices 7 and 8)
14.1 Report of the Scientific Committee (Paper IWC/46/4)
14.2 Action arising

15. SECOND INTERNATIONAL DECADE OF CETACEAN RESEARCH
(Chairman’s Report of the 45th Meeting, paragraph 19)
15.1 Report of the Scientific Committee (Paper IWC/46/4)
15.2 Action arising

16. CONSERVATION OF WHALE STOCKS
(Chairman’s Report of the 45th Meeting, paragraph 15 and Appendix 5)
16.1 Report of the Scientific Committee (Paper IWC/46/4)
16.2 Mechanisms to finance research programme
16.3 Action arising

17. RESEARCH ON THE ENVIRONMENT AND WHALE STOCKS
(Chairman’s Report of the 45th Meeting, paragraph 23 and Appendices 12 and 13)
17.1 Report of the Scientific Committee (Paper IWC/46/4)
17.2 Action arising

18. THE RESPONSIBILITY OF IWC FOR THE CONSERVATION AND SUSTAINABLE USE OF WHALE RESOURCES
(Chairman’s Report of the 45th Meeting, paragraph 21)

19. WHALEWATCHING
(Chairman’s Report of the 45th Meeting, paragraph 20 and Appendix 9)

19.1 Report of Working Group (Paper IWC/46/22)
19.2 Action arising

20. THE RESIGNATION OF THE CHAIRMAN OF THE SCIENTIFIC COMMITTEE
(Paper IWC/46/27)

21. CO-OPERATION WITH OTHER ORGANISATIONS
21.1 Observers’ Reports (Paper IWC/46/10)
21.1.1 NAMMCO
21.1.2 ICES
21.1.3 ASCOBANS
21.1.4 CCAMLR
21.1.5 ICCAT

21.2 Other
21.2.1 IOMAC
21.2.2 IWC observers

22. ADOPTION OF REPORT OF THE SCIENTIFIC COMMITTEE
(to be circulated as Paper IWC/46/4)

23. FINANCIAL STATEMENTS AND BUDGET ESTIMATES
(Chairman’s Report of the 45th Meeting, paragraph 24)
23.1 Review of provisional financial statement, 1993/94 (Paper IWC/46/8A)
23.2 Consideration of estimated basic budget, 1994/95 (Paper IWC/46/8B)
23.3 Consideration of advance budget estimates for 1995/96 (Paper IWC/46/8B)
23.4 Observer fees
23.5 Action arising

24. AMENDMENT OF THE RULES OF PROCEDURE AND DEBATE
(Chairman’s Report of the 45th Meeting, paragraph 25)
24.1 Amendment of the Rules of Procedure (Papers IWC/46/14, 15 and 23)
24.2 Amendment of the Financial Regulations (Paper IWC/46/20)
24.3 Amendment of the Rules of Debate (Paper IWC/46/21)
24.4 Action arising
(Changes are proposed to the Commission’s Rule of Procedure M; the Financial Regulations E.2 and F.1; the Scientific Committee’s Rule of Procedure E.7; and other Rules)

25. DATE AND PLACE OF ANNUAL MEETINGS
(Rules of Procedure, Rule B.1.)
25.1 47th Annual Meeting, 1995
25.2 48th Annual Meeting, 1996

26. ADOPTION OF REPORT OF FINANCE AND ADMINISTRATION COMMITTEE
(to be circulated as Paper IWC/46/9)

27. REGISTER OF WHALING VESSELS
(Chairman’s Report of the 45th Meeting, paragraph 28)
(Paper IWC/46/12)
28. WHALING ACTIVITIES BY NON-MEMBER STATES  
(Chairman's Report of the 45th Meeting, paragraph 30 and Appendix 18)  
(Paper IWC/46/30)

29. FORTY-FIFTH ANNUAL REPORT  
(Paper IWC/46/11 Draft)

30. ELECTION OF CHAIRMAN  
(Rule of Procedure F.1)

31. ELECTION OF VICE-CHAIRMAN  
(Rule of Procedure G.1)

32. ANY OTHER BUSINESS
Chairman’s Report of the Forty-Sixth Annual Meeting

1. DATE AND PLACE
The 46th Annual Meeting of the Commission was held in Puerto Vallarta, Mexico, 23–27 May 1994, at the kind invitation of the Government of Mexico. Dr L. Fleischer (Mexico) chaired the proceedings.

2. REPRESENTATION
Commissioners, experts and advisors were present from 33 of the 40 Contracting Governments, together with observers from 5 non-member governments, 8 intergovernmental organisations and 94 non-governmental organisations.

3. ADDRESS OF WELCOME
Following a welcome from the Governor of the State of Jalisco, Mr Carlos Rivera Aceves, an address was given by Mr Guillermo Jimenez Morales, Secretary of the Fisheries Department, on behalf of the Government of Mexico. He emphasised the importance of cooperation in managing and preserving biodiversity and the role of responsible fishing. Mexico has incorporated such actions in its own legislation and mention was made of the tuna/dolphin situation, its actions on the vaquita and sea lions, and the establishment of whale refuges for gray whales. Mexico will support the IWC moratorium until the Revised Management Scheme is finished. It also supported the Antarctic sanctuary and looked for decisions which respect national sovereignty and are based on scientific evidence.

4. OPENING STATEMENTS
Opening statements from member and non-member governments and observer organisations were distributed as meeting documents. Austria, as a newly joined member, spoke of its interest in environmental and wildlife protection whilst South Africa was applauded for its new standing.

5. ADOPTION OF AGENDA
The agenda circulated in advance of the meeting was adopted. Mexico gave notice that it would raise under Item 32. Any Other Business, the question of the operation of the Convention.

The Chairman indicated that Items 10, 11 and 12 would be considered first in Technical Committee under the Chairmanship of Dr P. Bridgewater (Australia).

6. HUMANE KILLING
6.1 Report of Humane Killing Working Group
The Working Group met under the chairmanship of Mr H.P. Johansen (Norway).

6.1.1 Terms of reference
The 45th Annual Meeting had charged the Working Group with considering its mandate further this year. The discussion revealed that the Working Group was in the same position as the previous year and, on the Chairman’s proposal, the meeting agreed to proceed on the basis of the terms of reference proposed in 1993 – to review information and documentation available with a view to advising the Commission on promoting the development of humane methods of killing whales. The objection of Japan to this change, and the interpretation of Denmark and Norway that this referred to whales covered by the Convention, were taken into account.

Japan also raised the further issue concerning the name and title of the Working Group, since ‘humane’ is not defined. It suggested a more objective name should be sought, such as ‘Killing Methods of Whales’. This matter was referred to the Commission for its consideration.

6.1.2 Action arising from the 1992 Workshop on Humane Killing Methods
A number of papers were submitted to the Working Group and presented by the respective delegations.

Norway introduced its paper on hunting methods in Norway, a report from the 1993 scientific and traditional catch. This indicated a substantial decrease in the median (72 seconds to 0) and mean (334 to 228 seconds) survival times compared with the latest data collected from the traditional catch during 1984-86, and an increase (from 44.8% to 53.5%) in the percentage of animals that died and lost consciousness instantaneously.

The USA gave an account of the hunting efficiency and recovery methods developed and employed by native Alaskans in the subsistence hunt for the bowhead whale. The development of the pentrite projectile and the benefits of the AEWC’s focus on efficiency are evident in the statistics of the 1993 hunt when close to 80% of the whales struck were landed, which represents a dramatic improvement over the 50% efficiency rate found in this hunt historically.

New Zealand presented a report on its preliminary investigation of techniques for killing whales, focusing on anatomical studies and basic work on the euthanasia of stranded animals. Multiple projectiles fired from a 12-gauge shotgun were ideal for small cetaceans and explosive pentrite charges for larger animals. It also had preliminary evidence that electric lancing is likely to cause unnecessary pain and suffering to a whale already harpooned.

Japan reported on the humane killing of Antarctic minke whales for the 1993/94 season. This recalled the development of the pentrite grenade harpoon used since 1983 and efforts to reduce the kill time while ensuring crew safety. The median time to death was calculated as four minutes. It also presented a paper setting out the reasons why it thought comparison with cases of other animals is essential, since comparative studies, particularly with terrestrial animals, will offer direct information on time to death and assessment of stress which may inspire improvement in the presently used methods.

Japan also reported on a bilateral meeting with Norway to exchange information for refinement of the design of the pentrite grenade harpoon.

The UK offered a compilation of figures on times to death and struck-and-lost rates in recent Norwegian scientific and commercial whaling operations derived from Norwegian Government reports, in the belief that it might assist discussion.

Denmark outlined the ways the 1993 Greenland action plan on whale hunting methods implemented the IWC’s 1992 Action Plan. This included provisions concerning
overhaul and repairs of harpoon guns, training, the use of the detonating grenade harpoon and establishment of a Working Group to examine the rifle hunt. Time to death is now also required to be reported.

Discussion of these papers ranged over a number of topics where delegates held different views, including the use of rifles and the electric lance for secondary killing, as well as appreciation of the new material presented.

6.1.3 Preparations to reconvene the Workshop on Humane Killing Methods

6.1.3.1 Terms of reference

The UK had prepared a discussion paper reviewing the areas on which the Workshop could focus and proposing terms of reference. It noted that the proposal is to reconvene the 1992 Workshop, with no substantial changes other than updating to take account of the Action Plan and new data.

At the conclusion of the ensuing debate the Working Group agreed that the terms of reference for the 1995 Workshop would be to:

(i) consider all methods of killing currently in use in whaling or known to be in development;
(ii) assess the methods, their efficacy and physiological effects;
(iii) evaluate the time to death achieved by the various methods;
(iv) review and evaluate all data, relevant to the Workshop, available through the IWC or held by national governments or organisations;
(v) complete a comparative analysis of the methods and consider revision of the Action Plan as appropriate, with a view to improving the humanness of whale killing techniques while paying proper regard to the safety of the crew.

The Working Group referred to the Commission for final clarification the question of which animals, including comparisons of hunting methods of terrestrial species, should be considered by the Workshop and agreed that every document submitted to the Workshop should be endorsed by a member government.

6.1.3.2 Practical arrangements

A number of delegations supported the proposal by Norway that, since this Workshop was a reconvening of the 1992 Workshop, it should, wherever possible, reflect the same arrangements as for the earlier workshop. Following discussion of the various aspects, the Working Group made the following proposals.

The Working Group agreed to recommend to the Commission that, if possible, the Workshop be held in conjunction with the IWC's 1995 Annual Meeting.

On the question of who should chair the Workshop, Denmark observed that, since this is a reconvening of the 1992 Workshop, there is already an existing chairman and vice-chairman and that other approaches be made only if these are unavailable. The relevant governments agreed to approach the respective chairman and vice-chairman to ascertain if they would be available for the 1995 Workshop.

Some delegations believed that national governments should be responsible for providing funding for their own experts to attend while others suggested that there was a case for provision to be made for a small number of recognised experts to be invited by the Commission to attend as the Commission's experts.

It was agreed to report these two views to the Commission for its final decision.

The Working Group recommended that participants be technical experts but recognised that it was the decision of member governments as to who they sent.

Since it had been agreed that the 1995 Workshop is a reconvening of the 1992 Workshop, the arrangements for the admission of observers should be on the same basis as in 1992.

In the Plenary, Japan reiterated its position that humane killing does not fall within the competence of the IWC, but it was prepared to cooperate on a voluntary basis. It thought there was general recognition that the explosive harpoon is the best method available and that this issue had been fully addressed. It was concerned over the direction being taken by the Commission, since it seemed that the more information it provided the more it was criticised. It believed that the electric lance was humane. Japan restated its views that the name of the Working Group and Workshop should be 'Killing Methods' and, on the terms of reference, the desirability of including comparisons with terrestrial hunting methods.

Australia acknowledged the pragmatic stance of Japan on this matter. It preferred to retain the existing name and was unconvinced of the need to consider land animals. It also advocated a sparing use of IWC funds. The UK agreed with Australia on many points and was concerned over the effect of removing 'humane' from the name. New Zealand echoed these thoughts and believed that changing the name would send a wrong signal. It would be disappointed if there were no improvements in techniques and expressed particular concern over the continuing use of the electric lance.

The USA supported continued use of the name Humane Killing Working Group and Norway spoke in favour of the arrangements for the Workshop including a full review and evaluation of comparative data, in which other large mammals could be useful.

6.1.4 Other matters

Last year the Commission adopted a Resolution inviting the Danish Government to encourage the Faroese Government to provide all additional information on its pilot whale hunt to the 46th Annual Meeting and the forthcoming Workshop preceding the 47th Annual Meeting. The Faroese representative advised that it is the opinion of his Government that the IWC does not have legal competence on this issue and that questions concerning those species are more efficiently dealt with on a regional basis through organisations such as NAMMCO. There is no need to repeat the work of NAMMCO, but the Faroese Government is willing to discuss such matters on a bilateral basis. The UK hoped the Faroes would be able to participate in the 1995 Workshop.

6.2 Action arising

Following interventions from the UK, Japan, USA, Denmark, New Zealand and Norway on various points of clarification and interpretation, the Chairman summarised the conclusions on reconvening the 1992 Workshop, leaving the detailed arrangements to the Secretary and the Convenor of the Working Group. The Workshop will be held immediately prior to the next Annual Meeting; the terms of reference are those proposed by the Working Group; the same name will be retained; technical experts from different specialities will attend, some nominated by member governments and others invited by the
7. SOCIO-ECONOMIC IMPLICATIONS AND SMALL-TYPE WHALING

7.1 Report of the Working Group on Socio-economic Implications and Small-type Whaling

The Working Group met with Mr E. Lemeche (Denmark) in the chair.

7.1.1 Action on 1993 Resolution

The Commission adopted a Resolution last year in which it recognised the socio-economic and cultural needs of the four small coastal whaling communities in Japan and the distress to these communities which has resulted from the cessation of minke whaling; and resolved to work expeditiously to alleviate the distress to these communities which has resulted from the cessation of minke whaling at its next Annual Meeting.

Japan summarised the issue concerning Japanese small-type whaling since the adoption by the IWC of the moratorium on commercial whaling in 1982. It held the view that its small-type whaling had the same characteristics as aboriginal subsistence whaling, hence a similar treatment should be considered. Its case in 1987 was ignored and the following year an international group of socio-anthropological scientists started comprehensive research which concluded that there were characteristics overlapping with those inherent in aboriginal subsistence whaling, and the Japanese small-type coastal whaling should be recognised as a distinctive third category to which the moratorium should not be applied. Japan's requests for an interim relief allocation of 30 minke whales had been denied every year since 1988. The mayor of one whaling community, Oshiko Town, and the Chairman of the Japan Small-type Whaling Association made supporting statements.

Japan then presented a series of documents in support of its case. These papers examined the concepts of 'commercial', 'subsistence' and 'aboriginal people' to show that the distinction between aboriginal subsistence and commercial whaling is untenable: listed 33 submissions since 1986 from 23 social scientists from 8 countries to show the depth of work carried out; discussed the small scale and localised nature of the operations and emphasised the importance of the diversified regional minke whale-based cuisine in northern Japan; and updated the Action Plan presented last year.

The Action Plan proposes to utilise a non-market distribution system to remove profit motivation from production and distribution of whale products; ensures that the edible whale products would be exclusively consumed in the local communities specified; organises the distribution and consumption of whale products so as to maximise benefits for social communities.

To achieve this the Action Plan proposes that small-type whalers shall catch no more than 50 minke whales in a given season. This restriction will be reinforced by Japanese domestic laws and regulations; the catches will be landed at special ports; the small-type whales shall flense the landed carcasses and hand over all the whale products to the local management council.

Japan further explained how the local management council established to manage minke whaling would operate.

Various questions were raised and answered in the Working Group, including whether the Scientific Committee in 1990 had established a replacement yield for North Pacific minke whales; none has been accepted by the Scientific Committee.

There was extensive discussion of the proposal for community-based whaling in the Working Group. Arguments in favour included: the fact that the time has come for the IWC to agree on solutions; that small-type whaling is of high importance to many smaller communities to satisfy their socio-economic, cultural and traditional needs; it was only reasonable that customary trade in the modern world must include limited exchanges for cash; subsistence users cannot live in a modern cash economy without some cash exchange; certain cash transactions and marketing exist in the Greenland aboriginal subsistence whaling; a permissive regime is easier to control than a prohibitory one; cultural and social needs have been well documented; these needs bear similarities to those underlying the acceptance of aboriginal subsistence whaling; the IWC's credibility depends on finding a solution to this problem; the Japanese proposal should be considered as there would be no adverse effect on the stock; and the unrealistic biological hypothesis of there being seven sub-stocks in this small fishery.

Arguments against the Action Plan were: that it allows the sale of whale meat for profit; there were no controls to prevent resale or mixing with meat from other sources; a non-commercial harvest could not coexist with a well developed high value market for the same product; until the moratorium ends commerce in whale meat should be prohibited; the IWC's credibility would be affected if it allowed an exception to the moratorium without being sure of the recovery of the stock in question, without having a new whaling regulation in place and without evidence that such an expensive commodity could be distributed non-commercially in parallel with a commercial market for similar products; not all commercial elements had been eliminated from the proposed plan, and indeed whether they could be eliminated; and the Scientific Committee's apparent inability to provide reassurance about the effects on the stock.

The Chairman noted that the Working Group was under instruction from the Commission to work expeditiously to alleviate distress to the four small coastal whaling communities in Japan. Only one proposal to this end had been received, from Japan; 15 of the 19 delegations had
spoken in the meeting and the majority were not disposed to accept it, either because they found specific problems or had general doubts. However, no delegation had suggested amendments which would facilitate its acceptability.

The Working Group considered the options open to it and recommended beginning bilateral talks with Japan, which could lead to convening an ad hoc committee.

Finally, the Working Group left with the Plenary the question of whether or not it should reconvene next year.

7.2 Action arising
An extensive discussion ensued in the Plenary. Denmark thought the Working Group should continue and, noting the way Japan has tried to accommodate within its Action Plan the concerns expressed, was sympathetic. Norway was also supportive of the Japanese proposal. However, the UK could make no commitment to change the moratorium and had concerns about the practicality of a non-commercial operation running alongside a commercial one. The USA also recognised the effort put into this plan by Japan but had a fundamental objection to the sale of the whale meat.

Japan pointed out that it had revised the Action Plan submitted last year in response to the comments made then, and emphasised the religious, cultural and food aspects. It also interpreted the analyses of the Scientific Committee to conclude that a take of 50 animals would not cause an adverse impact on the minke whale population around Japan.

St Vincent and The Grenadines noted the present rigour in sticking to the Convention when there is no definition of commercial whaling, called for flexibility and considered this a demeaning exercise. Grenada also noted that the Commission is not making any effort to comply with the Convention in catching whales. The RMP would allow a take greater than 50 animals and it commented on the colonial destruction of cultures. It requested accommodation on this issue.

The Republic of Korea recalled that it had accepted the moratorium since 1986 and noted the Scientific Committee’s Comprehensive Assessment, particularly with respect to the need for extra information on mixing of the stocks. If Japan is given a catch it too will demand a quota and thought the IWC should respond to all coastal communities’ needs. The best way to do this is to implement the RMP and RMS.

The Netherlands appreciated the efforts of Japan, but still only recognised two types of whaling and thought any decision should wait until the moratorium is lifted. Chile indicated it would abstain because the action requested implies a partial lifting of the moratorium.

Japan responded to these comments. It noted in particular that the minke whale stock around Korea is classified as a Protection Stock, and offered technical and scientific assistance for further studies. It preferred to stay inside the Commission to argue its case, even though community-based whaling was conducted by Indonesia and others outside the IWC. Before the UK and the Netherlands had ended their commercial whaling activities it had been oil and not whale meat that they had sought, which had no community or social significance. It commented on the ban by Brazil in the joint venture operations with Japan for minke whales and thought replacement of the whale meat might result in deforestation of the Amazon or utilisation of dolphin meat.

Brazil responded that it had taken into account that its whaling operation occurred in a significant breeding area for minke whales with many pregnant females. Protein is available from other sources, but it does not have exact information on direct takes of dolphins.

The People’s Republic of China was sympathetic to the distress and hardship caused in the Japanese communities and hoped that consideration can be given to the needs of tradition, culture and religion. It appreciated the efforts made by Japan and at the same time called for IWC observers to monitor the implementation of the management measures.

Switzerland realised that there is no formal definition for small-type coastal whaling and that the establishment of any quotas outside aboriginal subsistence whaling requires lifting the moratorium. It had increasing difficulties in recognising any factual differences between aboriginal subsistence whaling and small-type coastal whaling as organised in the Japanese Action Plan, and therefore would abstain in any vote. It urged an in-depth analysis of the similarities and differences between these forms of whaling.

Argentina stated that it could not support the Japanese proposal because of its commitment to the commercial moratorium and thought the needs of these communities quite different from hunting for subsistence.

The Japanese submission was formally presented and seconded by Norway in three documents. A proposed amendment to the Schedule was to insert after paragraph 13 a new paragraph

Notwithstanding the provisions of paragraph 10, the taking of 50 minke whales from the Oshokotak Sea-West Pacific stock of the North Pacific in the 1994 season is permitted in order to alleviate the hardship in the Community-based Whaling communities.

A supporting Resolution on Japanese community-based minke whaling identified the allocation and utilisation of these 50 whales according to the arrangements set out in the Action Plan for Japanese Community-based Whaling: Distribution and consumption of whale products document. The first two documents were proposed by Japan, Norway, St Lucia, St Vincent and The Grenadines, Dominica, Grenada and the Solomon Islands. All three submissions were put to the vote together, but were defeated with 9 votes in favour, 14 against and 7 abstentions.

After the vote Sweden expressed its view that the Action Plan still does not fully meet all that is required and hoped for further progress next year. Australia suggested that the Working Group should continue next year and this was agreed.

8. INFRACTIONS

8.1 Report of the Infractions sub-committee
The Infractions sub-committee met under the chairmanship of Mr D. Taylor (Australia).

Japan, supported by Norway, noted that the sub-committee considered some of the most sensitive issues before the Commission, such as those relating to enforcement, legal and criminal proceedings. As a result they were of the view that NGOs should, in principle, be denied access. Japan advised that NGO participation might not be granted next year. Other delegations stressed the importance of IWC discussions being open, particularly in the case of this sub-committee and discussion of the development of a credible observation and inspection scheme.
8.1.1 Infractions reports from Contracting Governments

No infractions were reported from aboriginal subsistence whaling operations and no commercial whaling infractions reports were received for 1993 (the only commercial whaling was that carried out by Norway).

Discussion of the case considered last year from St Vincent and The Grenadines involving a small animal led to the suggestion that the Technical Committee should consider whether the Schedule should include definition of a calf.

Responding to requests for information on reports of large quantities of whale meat discovered in Vladivostok, apparently from Taiwan and intended for illegal shipment to Japan, the Russian Federation outlined its investigations into this matter. With the assistance of the USA authorities, DNA analyses were being conducted to determine the species of whale meat involved and the results would be provided when available. Japan also described the strenuous efforts it was undertaking to investigate this matter and, more generally, to prevent the illegal smuggling of whale meat into its territory. It stressed it would continue to enforce anti-smuggling laws and regulations strictly in collaboration among the government agencies concerned and to report all relevant information to the Commission.

Norway reported that a seizure of whale meat at Oslo airport in October 1993 was still under investigation and represented a violation of domestic law, not IWC regulations. The Republic of Korea said it had no specific information on this matter, but it has a long record of being strict on enforcing its anti-smuggling laws and in cooperating with other governments on such issues.

Japan stated that it was presently collecting information on a sperm whale head reported washed ashore, but it seemed most likely that the whale had either been caught accidentally in a coastal set-net fishery or had become stranded.

8.1.2 Surveillance of whaling operations

Norway introduced a revised proposal to amend Section V of the Schedule, based on discussions since its 1993 proposal to establish an observation and inspection system. These revised proposals would provide for national inspectors and IWC observers, for their qualifications and responsibilities, and for certain obligations of Contracting Governments relevant to observation and inspection of whaling operations.

Several delegations commended Norway for submitting this revised proposal which, in their estimation, represented an improvement over the 1993 proposal. They noted, however, that it still fell short in many respects. The USA, UK and New Zealand made particular comments, including the need for 100% observer coverage but costs borne by the whaling nation and real-time reporting. Following further comments from Denmark, Spain and Sweden and responses, Norway suggested the establishment of a formal Working Group to continue work on this matter. The sub-committee agreed to draw this to the attention of the Technical Committee.

New Zealand introduced a proposal on the development of molecular genetic methods for the identification of whale products. It suggested that this technique be brought to the attention of the Technical Committee as representing a potential technology for the detection of infractions and for consideration in developing a comprehensive system for the inspection and observation of commercial whaling operations.

Japan commented that it found grave problems with the New Zealand proposal from both a conceptual and a practical perspective. The inspection and observation scheme in the RMS is not intended to verify the source of whale meat after landing. There are also many problems in this new technique and the interpretation of the results of analyses.

8.1.3 Checklist of information required or requested under Section VI of the Schedule

Checklists were submitted by Denmark and the USA, and Norway had submitted the required information to the Secretariat.

8.1.4 Submission of national laws and regulations

The Secretariat provided a summary of the latest submissions of national legislation supplied to the IWC.

8.1.5 Soviet catches in previous years

The Scientific Committee had received information that an examination of original catch records from past USSR whaling operations in the Southern Hemisphere from 1949/50 was revealing considerable falsification of the records submitted by the Soviet authorities to the Bureau of International Whaling Statistics and now held in the IWC Secretariat database. The Russian Federation indicated that it would provide additional information when it becomes available.

8.1.6 Other matters

The USA reported on a piece of whale blubber that washed ashore near Homer, Alaska.

The USA also proposed that delegations enter into formal discussions with the aim of amending the name of the sub-committee and its terms of reference to reflect better the actual work undertaken. The sub-committee agreed to draw this to the attention of the Technical Committee.

New Zealand introduced an excerpt from a formal communique issued by the South Pacific Forum in August 1993 relevant to the IWC.

Japan drew attention to the fact that it was not solely the responsibility of the `destination' country to investigate allegations of whale meat smuggling and urged other member countries to investigate the source of this illegal trade.

8.2 Action arising

In the Plenary, Japan commented on the new USSR data now becoming available. In particular it mentioned the under-reporting of catches of blue and pygmy blue whales, but the over-reporting of some other species. It noted that most of these falsifications occurred before 1972 when the International Observer Scheme was implemented. It asked the Russian Federation to provide the true records as fully and as soon as possible.

The USA believed that it is not possible to verify if the data provided after 1972 are correct and it would take up this matter in discussion of the Comprehensive Assessment. The USA also indicated that discussions on the name and terms of reference of the sub-committee were not finished and proposed that these discussions should be resumed next year.
9. MECHANISM TO ADDRESS SMALL CETACEANS IN THE COMMISSION

9.1 Report of Working Group on a Mechanism to Address Small Cetaceans in the Commission
The Report of the Working Group was presented by its Chairman, Mr C.J. Llewelyn (UK), which considered the four main items constituting its terms of reference.

9.1.1 Examination of the way in which the Scientific Committee's sub-committee on small cetaceans identifies stocks for review
The Chairman of the Scientific Committee explained that the sub-committee had in the past given priority to stocks or species subject to direct harvest or incidental mortality from fishery operations. The 1990 and 1991 IWC Resolutions on small cetaceans confirmed that this conformed with the priorities of the Commission and provided further guidelines. Examples of three types of priority topics proposed after 1990 were: a species or stock(s) that was or might be influenced by exploitation; a geographical area where there were indications or evidence of incidental or direct exploitation on populations of small cetaceans but where information on takes or impact on specific stocks is limited; a global review of a species or taxonomic group.
Each year, recommendations by the sub-committee were put forward to the full Scientific Committee and, after approval, forwarded to the Commission. The Scientific Committee already selected topics for research for a number of years ahead.

Summing up discussion on this Item, the Chairman concluded that the Working Group was generally content with the sub-committee's current criteria for the selection of topics for review. There seemed to be general agreement that priority should be given to:

(i) endangered species;
(ii) species or stocks under specific threat from direct or indirect take or from such effects as pollution or habitat degradation;
(iii) global and regional reviews, bearing in mind the need to give due attention to regions in which little research had yet been done, or little information is available.

There was also general agreement that coastal states should be closely involved in the selection process.

9.1.2 Mechanisms for encouraging and ensuring coastal state participation in small cetaceans research and review, including from non-member countries
The Working Group agreed on the importance of involving coastal states as fully and effectively as possible in research and cooperation. The Secretariat should be asked to explore ways of achieving this.

9.1.3 Mechanism for improving availability and reliability of data and information for the sub-committee on small cetaceans
The Working Group noted that different regions, countries and local communities had different characteristics. In some countries a voluntary reporting scheme by fishermen was desirable. In countries which had advanced scientific research capability and were able to obtain the cooperation of their fishermen, observer schemes and monitoring programmes for collecting reliable data and information should be implemented and managed by relevant national or regional organisations. Such data could be made available to the IWC on a voluntary and cooperative basis.

Any review of the status of small cetaceans must be based on sound first hand data credible to both the organisation and the coastal state. In the absence of such data, assessments should not proceed.

A cooperative dialogue with relevant states should be promoted. Range states might be requested to provide information on direct takes; incidental takes; threats from degradation of the marine environment (e.g. die-offs, organochloride levels); etc. Statistically reliable observer schemes were the only reliable way of providing accurate data on bycatch.

The Scientific Committee already obtained Progress Reports from member states; some are extremely complete and well documented and have been particularly useful. The repeated request by the Scientific Committee to all Contracting Governments to use this information mechanism to the fullest extent was recalled.

It was agreed that the points made in this discussion should be brought to the attention of the sub-committee on small cetaceans through the Scientific Committee Chairman.

9.1.4 Options for developing voluntary funding mechanisms to facilitate participation of coastal states on relevant small cetaceans matters
The Working Group recommended that the Commission set up a voluntary fund, to enable scientists in coastal states who would otherwise be unable to participate in the work of the Scientific Committee to do so. This voluntary mechanism would take account of the provision of assistance in kind, as well as financial contributions.

The Commission should also explore ways of providing practical and technical forms of assistance, in order to facilitate the participation of coastal states in the work of the sub-committee on small cetaceans and the Scientific Committee.

9.1.5 Examination of the roles of the IWC and international and regional organisations which, in the opinion of many states, have a crucial role to play with respect to small cetaceans
In discussion of this item it was pointed out that the Convention on Migratory Species (CMS) covered small cetaceans. The IWC and CMS had a complex relationship and it was suggested that the Secretariat should be encouraged to work closely with the Secretariat of CMS and related regional organisations, such as ASCOBANS.
Views were expressed that the IWC did valuable work that could not be left solely to regional states and that the IWC should concentrate on areas which were not covered by an appropriate regional organisation, on the model of the FAO. It was also noted that UNEP's Global Action Plan provided a helpful reference point for coastal state participation in the IWC sub-committee on small cetaceans and vice versa.

Actions arising from regional organisations had been demonstrated to be effective specifically concerning management issues, as illustrated in the case of Mexico/IATTC/USA on the reduction of dolphin bycatch and vaquita. It was also stated that the IWC should only give scientific advice and that the management of small cetaceans should be under the purview of the regional organisations or coastal states as stipulated in UNCED Agenda 21 (paragraph 17.61 in Chapter 19).

In conclusion there seemed to be general agreement on the need to ensure close cooperation between the IWC and appropriate regional organisations.
9.1.6 Interim arrangements
The Working Group on small cetaceans had an important confidence-building role. It was important that the sub-committee on small cetaceans worked closely with the Working Group and it might be possible to arrange for the sub-committee convener to attend.

There was general agreement that the Working Group should meet again next year and that close liaison with the sub-committee on small cetaceans was desirable.

9.2 Action arising
A Resolution based on the discussions in the Working Group and reinforcing the conclusions was co-sponsored by 14 delegations – Argentina, Australia, Brazil, Finland, Germany, Ireland, Monaco, Netherlands, New Zealand, Russian Federation, Sweden, Switzerland, UK and USA. This was adopted by the Commission and is shown in Appendix 2.

A voluntary contribution of $5,000 to the voluntary fund established under the Resolution was intimated by the Environmental Investigation Agency.

A further Resolution on the biosphere reserve of the Upper Gulf of California and the Colorado River delta was introduced by Australia and co-sponsored by Argentina, Finland, France, Germany, India, Ireland, Republic of Korea, Netherlands, New Zealand, Russian Federation, South Africa, Spain, Sweden, Switzerland, UK and USA. This congratulated Mexico on its conservation efforts concerning the vaquita, and invited expeditious development of a management plan and offers of assistance for its implementation. This Resolution was adopted, as shown in Appendix 3.

10. ABORIGINAL SUBSISTENCE WHALING

10.1 Report of the Scientific Committee
10.2 Report of the Aboriginal Subsistence Whaling sub-committee

The Reports of the Scientific Committee and the Aboriginal Subsistence Whaling sub-committee were taken together with respect to the following items and considered first in the Technical Committee.

10.2.1 Management objectives and procedure for aboriginal subsistence whaling

The Scientific Committee repeated its request that the Commission consider the question of objectives and provide advice that could be used in the development of a new Aboriginal subsistence whaling scheme. In the absence of this advice the Scientific Committee was not in a position to discuss the item.

Similarly, until such information was provided, the Scientific Committee was unable to offer advice on the carryover of catch limits or strikes in the context of a new Aboriginal Whaling Scheme.

10.2.2 Bering-Chukchi-Beaufort Seas stock of bowhead whales

The Scientific Committee had no new information on stock identification, migration or distribution. It reviewed the catch history of commercial catches, abundance and trend estimates and estimation procedures. The Scientific Committee agreed that the 1988 Bayes Empirical Bayes estimate of 7,500 (with 95% probability interval 6,400–9,200) was the best estimate to use for assessment purposes. The best available estimate of current population size in 1993 was approximately 8,000 (95% confidence interval 6,900–9,200). The Scientific Committee agreed that the Bayesian synthesis approach takes full account of the evidence and uncertainty about bowhead life history, abundance and age distribution, so that the consequent assessment could be accepted as a basis for advice. The Scientific Committee agreed on a median value of 199 for replacement yield (95% probability interval 97, 300 and the 5th percentile, 104).

The Scientific Committee agreed that the current improved estimates of abundance and the view that the population is increasing towards MSY meant that there is no scientific reason to recommend the take of smaller animals and avoidance of older animals and reproductive females as in the past.

Under the Aboriginal Whaling Scheme, the Committee is required to provide advice on the size of the stock in relation both to the MSY level and a minimum level below which whales shall not be taken.

The Bering-Chukchi-Beaufort Seas stock of bowhead whales is clearly well above the latter minimum level, given that it has been increasing under a regime of catches of some 15–50 animals since 1978. Although it was unable to provide an estimate for the MSY level in terms of mature females, the Committee agreed that on the assumption that the level lies between 0.4 and 0.8, there is a very high probability that the number of mature females as a proportion of the pre-exploitation number is currently below that level. As long as annual removals are below 104, the stock will, with 95% probability, continue to move towards the MSY level, at a rate depending on the annual level of catch.

The Technical Committee endorsed a series of technical recommendations made by the Scientific Committee.

There was extensive discussion within the Aboriginal Subsistence Whaling sub-committee on a presentation from the USA on the cultural and subsistence needs of the Alaska Eskimo population, based on updated census data. The estimated annual population growth rate for the ten whaling villages (now including Little Diomede) was 4.7% between 1990 and 1992.

On the basis of the information submitted, the USA requested the sub-committee to endorse its request for a need of 51 landed whales. This would result from an annual total of 68 strikes, which is well within the figure for sustainable yield of 104 animals per year given by the Scientific Committee and would enable the bowhead population to increase in line with the IWC’s mandate.

10.2.3 North Pacific eastern stock of grey whales

The Scientific Committee was informed that there had been no Russian catch from this stock in 1992 or 1993. Abundance and trend estimates from shore-based censuses led to an estimated annual rate of increase of 2.57% (SE=0.4%). The Scientific Committee considered the indirect effects of human activities, particularly for the grey whale breeding lagoons in Baja California and took special note of Mexico’s recognition of and actions to conserve these critical habitats.

The Scientific Committee had no cause to alter its conclusions reached when the stock was last assessed in 1992 that:

(1) this stock is not a Protection Stock;
(2) given lack of information on MSY, no conclusion could be reached on whether the stock was a Sustained (SMS) or Initial (IMS) Management Stock;
(3) given the recent history of increase under a regime of constant catches, the stock did not fall within the alternative definition of a Sustained Management Stock.
(4) although the Committee was unable to determine the minimum level below which catches should not be taken, as required under the Aboriginal Whaling Scheme (Schedule para. 13), it agreed that the stock was well above such a level.

The Scientific Committee estimated the mean replacement yield for this stock as 611, which is well over the mean catch of 159 whales over the period 1968–93.

The Technical Committee endorsed a number of internal technical recommendations from the Scientific Committee.

The Aboriginal Subsistence Whaling sub-committee considered a paper from the Russian Federation which set out the nutritional needs for a proposed annual catch of 140 gray whales. This is less than recent catches because of more efficient use of the products.

In the Technical Committee there was some discussion of the cultural need for this take since there had been no catches for the last two years due to the difficulties of repairing the last whaling vessel. Seals and reindeer had been utilised instead. Mexico considered there was no need for a gray whale catch at the former level, although the USA and Spain could both accept the proposal from the Russian Federation.

10.2.4 West Greenland stock of fin whales
The most recent estimate of the number of fin whales off West Greenland by the Scientific Committee was 1,096 animals (95% CI 520–2,106). It is unlikely that the West Greenland fin whales constitute a separate stock but the Scientific Committee was unable to provide any new evidence on stock identity.

The Technical Committee endorsed recommendations for stock identity studies and further aerial surveys.

10.2.5 West Greenland stock of minke whales
The Scientific Committee had an abundance estimate of 8,371 (95% CI 2,414–16,929) for the West Greenland coastal area. It believed that these whales do not comprise a separate stock but could give no evidence on the size of catches which would allow the stock to move towards MSYL.

The Technical Committee endorsed recommendations to continue stock identity studies and aerial surveys.

10.2.6 North Atlantic Central stock of minke whales
The most recent estimate of stock size is 28,000 (approximate 95% CI 21,600–31,400) obtained in 1990.

The Aboriginal Subsistence Whaling sub-committee considered four papers from Denmark covering all the above fin and minke whale stocks. It identified sustainable and equitable whaling practices as applied to the Greenland situation. It concluded that whaling was an important component of sustainable development strategies for Greenlandic communities requiring continued monitoring of whale stocks and active cooperation between hunters and government authorities. It confirmed that the present quota for fin and minke whales was equivalent to 420 tonnes compared with the accepted need of 670 tonnes in West Greenland.

10.2.7 North Atlantic humpback whales
No whales were struck in the 1994 season and the Scientific Committee agreed that a catch of three whales would be unlikely to harm the stock. The Technical Committee endorsed the recommendation that, if whales are taken, every effort should be made to collect as much information as possible, in particular photographs of the ventral surface of the flukes and tissue samples for genetic studies.

The Aboriginal Subsistence Whaling sub-committee received a document from St Vincent and The Grenadines which included information on the value and distribution of products.

10.3 Action arising
10.3.1 Aboriginal Whaling Management Scheme
The Technical Committee forwarded the views from the Aboriginal Subsistence Whaling sub-committee that the Commission should instruct the Scientific Committee to begin work on an aboriginal whaling management scheme before the completion of the RMS. Some delegations expressed the opinion that some of the 1982 guidelines were unsatisfactory and the Commission should provide guidance to the Scientific Committee to enable it to begin its review straight away. Other delegations did not share this opinion regarding the 1982 guidelines, but agreed that the Scientific Committee might begin a review of possible alternative management regimes. A proposal from Spain to facilitate this process (slightly amended) was forwarded for consideration by the Plenary.

In the Plenary, Spain spoke in support of a Resolution submitted by the USA, Denmark and the Russian Federation for the Scientific Committee to begin a review of aboriginal subsistence management procedures. The USA pointed out that while the sponsors feel that the existing aboriginal subsistence regime is adequate, it agreed it would be appropriate for the Scientific Committee to review alternatives. The Netherlands expressed its support now that the work of the Scientific Committee on the RPM for commercial whaling has been completed. The Resolution (Appendix 4) was adopted by consensus.

10.3.2 Bering-Chukchi-Beaufort Seas stock of bowhead whales
The USA introduced its proposal and explanation for catch limits for the years 1995, 1996 and 1997 of 51 landed whales which, with a 75% efficiency, requires 68 strikes each year. There was a measure of support within the Technical Committee but a number of delegations identified areas of concern and expressed their reservations. The Technical Committee therefore was not able to put forward a firm recommendation but encouraged further discussion between delegations and the USA.

Subsequently, in the Plenary, the USA introduced a revised proposal. It proposed that the total of whales landed in the four years 1995–98 should not exceed 204, with a maximum number of 68 strikes in 1995, 67 in 1996, 66 in 1997 and 65 in 1998. Any unused strikes can be carried over to the following years, with a maximum of 10 added to any one year.

Denmark, the Russian Federation, St Vincent and The Grenadines, Spain and Sweden expressed their support. The Netherlands felt unease over the increased catch proposed. It would have preferred a more cautious approach and was concerned to know more about the meat yield these catches represent. It also raised the question of an observer scheme for this operation and the need for an annual review. This position was shared by the UK and Ireland, while Australia emphasised the need for annual review and close contact with the fishery to be maintained. Switzerland had the same concerns as the Netherlands and
wondered why an increase in catch from the numbers taken from 1848 to 1993 was needed. Argentina had a similar reservation.

The proposal, as an amendment to paragraph 13(b)(1) of the Schedule shown in Appendix 21, was nevertheless adopted unanimously. Australia asked that the strike carried over element should be reviewed next year when it was clarified that there was no limit to the number that could be carried forward from any season.

10.3.3 North Pacific eastern stock of gray whales
The Russian Federation referred to its document setting out the basis of the claim for a reduced catch limit of 140 gray whales per year. Discussion of this request demonstrated broad support within the Technical Committee for such a quota but it was noted that some discussions may still occur on replacement of whale meat from other food sources.

In the Plenary, the Russian Federation asked for support for its proposal, which was given by the USA and Spain. Australia spoke of its close and critical examination of issues of need and stock levels arising from its dedication to concern for traditional cultures and peoples, and in this context also agreed to this particular quota. France, Denmark, Sweden and Germany also voiced their support, and the Commission agreed to amend Schedule paragraph 13(b)(ii)(1) and Table 1 to set the catch limit for this stock for each of the three years 1995, 1996 and 1997 at 140 whales, as shown in Appendix 21.

10.3.4 Greenland stocks of fin and minke whales
Denmark spoke of the need recognised by the IWC for 670 tonnes of whale meat which has been supported by much documentation in recent years. It proposed that for the years 1995, 1996 and 1997 the East Greenland minke whale catch should remain at 12 animals a year; the West Greenland catch of fin whales should be maintained at 21 animals a year; but that the West Greenland minke whale quota should be increased to 165 whales struck a year with a total of 450 in the three year period.

This proposal received a measure of support within the Technical Committee, but a number of delegations wished to see the proposal in writing before they could commit themselves to the increase in the West Greenland minke whale catch proposed.

In the Plenary, Denmark introduced a revised proposal to take account of the comments it had received. This reduced the West Greenland fin whale figure to 19, and increased the West Greenland minke whale three year total to 465 with a limit of 165 a year. The East Greenland minke whale quota remains unchanged at 12 for the new three year period.

Support for this amended proposal was given by Spain, Sweden, Finland, St Vincent and The Grenadines, France, Brazil, Germany, Republic of Korea and the USA, and it was then agreed by consensus. The resulting amendments to the Schedule Table 1, the footnotes and paragraph 13(b)(iii) are given in Appendix 21.

11. COMPREHENSIVE ASSESSMENT OF WHALE STOCKS

11.1 Report of the Scientific Committee
The Chairman of the Scientific Committee presented the relevant parts of the report of his Committee to the Technical Committee, as summarised below.

11.1.1 Revised Management Procedure
The Scientific Committee noted the report of an independent panel appointed by the USA to review the RMP, considered the issues arising where appropriate and concluded they had been adequately addressed.

The Scientific Committee considered a number of matters directly related to the calculation of catch limits, including the documentation of RMP-related computer programs, questions of process error and the progress on standard analysis programs for estimating absolute abundance.

In considering further trials of the CLA, the Scientific Committee agreed that the CLA was robust to a wide range of uncertainty, including the question of multispecies effects and performance in the presence of environmental degradation.

There was discussion of the presentation of the trial results, the effects of under-reporting of historical catches and documentary performance in combination trials.

Matters not directly related to the calculation of catch limits included monitoring and data requirements, and consideration of six principles concerning the role of science in resource management. The Scientific Committee agreed that these principles had all been taken into account in developing the RMP, with great weight being given to taking account of uncertainty.

The Scientific Committee reiterated its recommendation of last year that the Commission adopt the specifications of the RMP and endorse the annotations, including the minor amendments proposed this year and adopt the guidelines for conducting surveys and analysing data within the RMS. In addition, it recommended adoption of the guidelines for data collection and analysis under the RMS other than those required as direct input for the CLA.

Methodology – Estimation of g(0)
The Scientific Committee reviewed in detail the sources of differences in the estimation of g(0) – the probability of sighting a whale on the trackline – in northeastern Atlantic minke whale sighting surveys. A new estimate of 0.587 (CV 0.063) based on a sub-set of the data had been presented; this compared with 0.36 (CV 0.079) used previously by the Committee. It identified five potential factors which contribute to the differences. The underlying causes raise a number of important issues which will be fully addressed at next year’s meeting.

In the Technical Committee, the Netherlands asked whether this problem would have an effect on the existing estimates of North Atlantic and Southern Hemisphere minke whales. In response the Chairman of the Scientific Committee clarified that in the case of North Atlantic minke whales this may indeed have consequences for the estimate. If g(0) is re-estimated for Southern Hemisphere and North Pacific minke whales, where at present it is assumed that g(0)=1, then, the estimated g(0) shall be <1. Upon a question from Norway the Chairman of the Scientific Committee pointed out that no new estimates of abundance had been suggested in the Scientific Committee for the northeastern Atlantic minke whale stock. The USA emphasised the importance of the g(0) issue.

The Scientific Committee also commented on its recognition of the problems of investigating avoidance or attraction behaviour which could bias shipboard line transect estimates for North Atlantic minke whales.

In the Plenary, there was extensive questioning of the Chairman of the Scientific Committee by the Commissioners on the details of the g(0) issue and its
implications for the assessment of the northeast Atlantic minke whale stock. Ireland sought clarification of the Report of the Scientific Committee, while the Netherlands refuted the claim by Norway that the estimate made at the Glasgow meeting in 1992 is still valid, believing that the questions over g(0) mean that there is no generally accepted abundance estimate. The UK associated itself with these remarks. Germany noted that a special working group will address the problem and received confirmation that until the Scientific Committee has resolved the issue, the exact status of the stock is not known. Spain also noted the uncertainty involved. Ireland received confirmation that if the alternative value of g(0) is correct, the estimate of numbers would be dramatically reduced.

Norway expressed surprise at these questions, pointing to the statements that the Scientific Committee had no business to discuss on this stock and no new estimate of abundance had been suggested. The Chairman of the Scientific Committee reiterated that there is an estimate of g(0) from two years ago, and a new analysis and estimate this year. It was not possible to resolve the cause of the difference this year and it was not deemed appropriate to take the next step to make a new estimate of abundance while there is uncertainty over the value of g(0) to use. The Netherlands repeated its intervention, concluding that the most important issue was the consequential effect on the abundance estimate, which could result in very different catch limits if the RMP is applied, possibly even zero if the revised estimate of g(0) is nearer the new value calculated. Norway maintained that the original abundance estimate has not been challenged in the Scientific Committee and still stands until a different result is produced, but Ireland understood that additional data and analysis now indicates uncertainty about g(0).

11.1.2 Southern Hemisphere baleen whales
The Scientific Committee has as its priority species the humpback whale. It reviewed genetic information on stock identity, possible sex-segregated migration and estimates of abundance. The best estimates from the IDCR cruise data south of 60°S were 4,500 (CV 0.23) for the 1978/79–1983/84 surveys and 5,600 (CV 0.28) for the 1985/86–1990/91 surveys. These estimates pertain to only part of the range of humpback whales at the time of the surveys. The Scientific Committee was not in a position to attempt to carry out assessments at this meeting.

The Scientific Committee reviewed the implications of the catch history revisions of past USSR whaling records now available. It noted that it only uses estimates of current abundance based on direct methods such as sightings surveys or other methods that do not depend on catch data, so revisions to past records have no effect on its estimates of current abundance.

The level of depletion of stocks will be underestimated if catches are under-reported and the reverse for over-reporting, which both occur in the USSR records. Under-reported catches may be sufficient to explain an apparent failure of a stock/species to recover when protected.

The RMP uses estimates of recent abundance together with a time series of recorded or estimated historic catches to determine the appropriate catch limits. It is robust to underestimations of total historic catches by up to 50% and implementation is only being considered for minke whales where the level of misreporting is small and certainly less than 50%.

Estimates of abundance for other species than minke and humpback whales based on the first thirteen IDCR cruises (1978/79–1990/91) south of 60°S represented only partial stock estimates, except for blue whales. This was reported to the Plenary under Item 16.

11.1.3 North Pacific minke whales
The Scientific Committee considered the preparations for implementation of the RMS for North Pacific minke whales.

11.1.4 North Atlantic minke whales
The Scientific Committee had no business to discuss under this item.

11.1.5 Southern Hemisphere minke whales
Sighting data and genetic information were considered by the Scientific Committee.

11.1.6 North Pacific Bryde's whales
The Scientific Committee agreed that it should begin the Comprehensive Assessment process for North Pacific Bryde's whales at its next meeting.

11.1.7 Other stocks
Time did not permit review by the Scientific Committee of abundance estimates for eastern North Atlantic fin whales, eastern tropical Pacific humpback whales and North Pacific minke whales.

11.1.8 Future work plans
The Scientific Committee identified six specific topics that should be considered for discussion at the 47th Annual Meeting.

11.2 Review of Schedule paragraph 10(e) and other related paragraphs
This item was referred directly to the Plenary.

In the Plenary, the UK observed that one Contracting Government has resumed commercial whaling, taking 157 minke whales in the northeast Atlantic. It deplored Norway's action which in its view weakens the credibility and reputation of the IWC and urged it to reconsider its decision to exercise its objection to the IWC's moratorium on commercial whaling. This statement was supported by the Netherlands, New Zealand, Ireland, Germany, France, Brazil, Australia, Argentina and Spain.

11.3 Proposed new system of supervision and control
Norway suggested the establishment of an ad hoc Working Group to consider questions of supervision and control of whaling operations as proposed in the paper it had submitted. The USA and Japan expressed their support and the USA expected that NGOs could attend this Working Group. The Working Group was therefore established to report directly to Plenary on this Item.

The Plenary subsequently received the report of the Working Group on Supervision and Control, chaired by Mr E. Lemche (Denmark). The Technical Committee had decided that observers would be admitted to the Working Group, but it was unclear whether this meant that the normal rules for observers' participation would apply, or if all observers would automatically participate. This question was referred to the Commission.

The Working Group took as a starting point that their discussions should be governed by the 1992 Resolution on the Revised Management Scheme, which noted that the additional steps required to complete the RMS included
agreement upon a fully effective inspection and observation programme. Norway had presented a proposal on an inspection and observation programme, but a number of delegations felt that this, while a useful starting point, was not nearly comprehensive enough.

Some delegations preferred terms of reference worked out and an agenda agreed upon at the outset, and had produced a list to this end. The Chairman stated that terms of reference would have to be given by a higher body, i.e. the Technical Committee and in the absence of an agenda he produced a list of talking points which was accepted by the Working Group as a starting point for its work.

The Working Group agreed that the work on the inspection and observation programme is based on the assumption that IWC rules will be as amended by the adoption of the RMP/RMS and noted that any future changes to the RMS may require further changes to the inspection and observation programme.

Despite the difficulties of embarking on these discussions, the following points were addressed.

**Aim of programme of Inspection and Observation**

There was agreement that the objective of the Working Group should be to develop a fully effective inspection and observation programme which would ensure that whaling operations under jurisdiction of Member Governments comply with IWC rules (Convention and Schedule).

Furthermore, there was agreement that the Working Group should focus its work to an inspection and observation programme for commercial whaling in accordance with the Commission's priority of work on Management Procedures for commercial and aboriginal subsistence whaling.

The UK referred to the 1992 Resolution which states that among the additional steps required to complete the Revised Management Scheme are ‘... arrangements to ensure that total catch limits over time are within the limits set under the Revised Management Scheme ...’. In view of this there would need to be a linkage between enforcement under inspection and observation of commercial whaling and scientific whaling programmes.

Discussion took place over the possible application of an agreed scheme for observation and inspection to scientific research under a special permit. There was consensus that such research was a sovereign right of Contracting Governments, guaranteed by Article VIII of the Convention. Such research by member countries would have to comply with IWC rules.

**Focus of work**

Some delegations held the view that this Working Group should concentrate on the international rules, i.e IWC rules, noting that member governments may have to transform IWC-rules into national law. The rules to be complied with should be the international rules.

Some delegations underlined that the international inspection and observation programme of the IWC will be the regulations as adopted in the Schedule. In addition national regulations for implementing the IWC rules, should be examined to ensure their effectiveness.

There was agreement that the Working Group should aim at a system that will be generally applicable, but would concentrate on such whaling operations which might be permitted by the IWC in the foreseeable future.

Some delegations stated that international observers may not have enforcement jurisdiction. Other delegations held the view that certain enforcement powers might be given to international observers by agreement with the flag or coastal state.

**Inspection and observation programmes in other international agreements**

Delegates and observers present provided information on a number of observer programmes operating under other treaties. These included the Observer Programme in the South Pacific, Inter-American Tropical Tuna Commission and European Community Inspectors in fisheries conducted by member states.

It was proposed that other IWC member countries may bring forward information on other programmes of this nature. The Working Group agreed to propose that the Commission through the Secretariat ask member countries to provide such information.

**Role of inspectors and observers, etc.**

**NATIONAL INSPECTORS**

Norway presented the roles and duties of national inspectors as proposed in its paper. Some delegations held the view that more enforcement powers ought to be given to the national inspector.

There was agreement that it is the duty of member governments to impose penalties for infractions. National inspectors should be given enforcement powers. If prosecution or legal actions would be required, that would be the responsibility of national judicial or administrative systems.

There was disagreement over whether the possibility of IWC sanctions should be considered or multilateral agreements in respect of sanctions along IATTC lines.

**INTERNATIONAL OBSERVERS**

Norway presented the roles and duties of international observers as proposed in its paper. Observers shall observe the whaling activity to ensure transparency, be it on board or on shore, and report to the IWC.

The Working Group concluded that observers should report on the whaling activity, including possible infractions and give copies of the reports to the captain of the vessel, the national inspector and the IWC. The Working Group also reached agreement on a number of points such as that the report should be sent to national authorities whose whaling operations were being observed, as the observers will also report on the efficiency of the national system on inspection and control.

There was agreement in the Working Group that the observers duties represented at least the above mentioned points. Some delegations stated that the list of duties for the observers would have to be more extensive.

There were divergent views in the Working Group as to the necessity and advantage of providing real time reporting.

Some delegations held the view that if vessels could not accommodate both national inspectors and international observers, the national inspector should yield to the international observer. Other delegations could not accept that enforcement of jurisdiction be transferred to international observers.

A discussion also took place on the possible role of international inspectors.

It was noted that the IWC can only set catch limits for a species in an area and this may represent a problem to be addressed when more than one member state is involved in catching in that area.
Further items
Because of time limitation, inspector and observer coverage, the administration aspects and Schedule provisions relating to penalties were not discussed, although consideration of them is essential in drawing up a new observation and control system.

The Working Group also compiled a list of additional points. It was agreed that all these points should be discussed, but not necessarily have implications for the inspection and observation programme.

Proposed terms of reference for Working Group on Supervision and Control
The Working Group agreed to recommend the following terms of reference for future work:

The Working Group shall provide advice to the Commission on a comprehensive inspection and observation programme for adoption as a component of the Revised Management Scheme for commercial whaling. The purpose of the programme is to ensure that whaling operations under the jurisdiction of Contracting Governments comply with IWC regulations and national rules implementing such regulations.

In providing that advice, the Working Group will take into account, as necessary, relevant international and national observer systems, and the potential usefulness of elements of those systems to the inspection and observation programme.

The Working Group shall provide draft text for Schedule amendments and may, within a general framework, propose different rules for different forms of whaling to which the programme would apply.

Possible timetable
The Working Group agreed that it should continue its work and expected such work to be a time consuming 3–4 days.

The Working Group agreed that it should meet in the week(s) preceding the 47th Annual Meeting, either coinciding with the Scientific Committee, or the Working Groups and sub-committees immediately before the 47th Annual Meeting. Some delegations noted the importance of NGO participation in meetings on this topic.

Some delegations proposed an intersessional meeting of the Working Group well in advance of the 47th Annual Meeting. Norway offered to host such a meeting. Other delegations foresaw difficulties as to participation in such an intersessional meeting.

11.4 Adoption of the Revised Management Procedure
11.5 Proposed data standards
11.6 Proposed survey guidelines
Norway suggested that these items should be referred directly to the Plenary, since the text of the Norwegian proposals on these agenda items was taken directly from the Scientific Committee report. This was agreed. In the Plenary, Norway proposed to reintroduce its proposals next year, given that some items are also covered in a Resolution on the RMS.

11.7 Action arising
The Technical Committee and the Commission endorsed the internal recommendations of the Scientific Committee concerning future studies, research activities and analyses. Concerning the RMP, the Technical Committee took note of the specific recommendations and passed them on to the Plenary for action.

11.7.1 Revised Management Scheme
Australia introduced a Resolution co-sponsored by Finland, Germany, Netherlands, South Africa, Spain and the USA on the Revised Management Scheme. Sweden also wished to co-sponsor what it regarded as an important step forward. Similarly Switzerland wished to be listed as a co-sponsor, noting the view that the RMP is the most rigorously tested management procedure for a resource yet designed and which it believed should be adopted and not just accepted together with finalising the RMS.

The USA recalled that the Scientific Committee had again unanimously recommended that the Commission adopt the specification of the RMP and endorse the annotations. It also recommended adopting the guidelines for conducting surveys and analysing data, provided advice on minimum standards for data and recommended guidelines for data collection. The USA believed it premature to adopt the RMP into the Schedule until the entire RMS can be adopted as a package. It is committed to science-based solutions to international environmental problems. There are still difficult issues to resolve which this Resolution does not address, including unauthorised whaling, illicit trade in whale products, under-reporting of catch data, the effects of environmental degradation and humane killing concerns. The Resolution does not give approval to any activity contrary to the moratorium or the sanctuaries established and the USA does not support a resumption of commercial whaling.

The Netherlands shared these views and accepted the Scientific Committee's advice on the RMP.

France associated itself in the appreciation of the work of the Scientific Committee in achieving the RMP and identified features in the text of the Resolution which led to its support, including the exclusion of any possibility of lifting the moratorium in the light of present knowledge. The UK generally associated itself with the remarks of the USA and France, but was not listed as a sponsor of the Resolution because there is no reference to humane killing which it regards as an issue of great importance and of relevance to some aspects of the RMS.

Ireland identified a series of concerns which it considered must be satisfied, including the question of Catch-cascading, small populations, the need for reliable data on catches, the g(0) issue and problems with the catch Limit Algorithm. Mexico considered the CLA unclear, and India shared the concerns of Ireland and Mexico.

Denmark saw no problem in taking a step forward by adopting the RMP, neither did St Vincent and The Grenadines, Chile regarded this as a matter of priority and New Zealand accepted the consensus of the complete package.

The Resolution (Appendix 5) was then adopted, Norway noting its existing objection to Schedule paragraph 10(e).

New Zealand introduced a Resolution (Appendix 6) on behalf of Australia, Netherlands, UK and the USA concerning the unreliability of past whaling data, which was also adopted by consensus.

A Resolution on international trade in whale meat and products sponsored by Argentina, Australia, Brazil, India, Monaco, New Zealand and the USA was then considered.

Japan reminded the meeting of its reservations in CITES and commented on operative paragraph 4. The USA noted the discussion in the Infractions sub-committee on whale meat from Taiwan, recalled the 1978 Resolutions on this subject and non-member whaling, and considered that the IWC must take an active role on the question. New
Zealand endorsed this approach and mentioned the possibility of genetic testing of samples. Norway stated its view that trade is not in the mandate of the IWC, a position shared by Sweden and Denmark, the latter believing CITES not IWC is the appropriate forum. Switzerland also had doubts on the legal competence.

Denmark had instructions to request a vote on the Resolution (Appendix 7), which was adopted by 14 votes in favour, 6 against with 7 abstentions.

**Supervision and control**

Discussion in the Plenary on the admission of observers to the Working Group involving Norway, Japan, USA, Netherlands, France, UK, Australia, Denmark and St Vincent and The Grenadines led to the understanding that the normal Commission rules would apply.

The matters agreed by the Working Group were all endorsed by the Commission.

A further extended discussion then took place between Denmark, Norway, Brazil, UK, France, New Zealand, Germany, Japan and Spain on the next meeting of the Working Group. This included consideration of the costs incurred for an intersessional meeting, the length of time needed for an adequate meeting and the importance of the subject. Eventually it was agreed to accept the offer of Norway to host an intersessional meeting in the second week of January 1995, followed by a one day meeting on the Monday of the week preceding the 47th Annual Meeting in Dublin. The Working Group report will go first to the Technical Committee for consideration.

### 12. WHALE SANCTUARY IN THE SOUTHERN OCEAN

#### 12.1 Report of Intersessional Working Group

The Report of the intersessional Working Group on a Sanctuary in the Southern Ocean held on Norfolk Island, South Pacific, in February 1994 was presented to the Technical Committee by the Chairman of the Working Group, Dr C-G. Ducret (Switzerland). The Working Group recommended by consensus to the Commission the 15 recommendations shown in Appendix 8:

(i) Recommendations 1, 10 and 13 relate to the Antarctic Treaty system and other intergovernmental arrangements;
(ii) Recommendations 3 and 7 were directed to the Scientific Committee;
(iii) Recommendations 5, 6 and 14 proposed specific actions by the IWC;
(iv) Recommendations 2, 8 and 12 related to legal questions;
(v) Recommendations 4, 9, 11 and 15 concerned the establishment of a sanctuary itself.

The Working Group proposed that the Commission should take note of its Report and further endorse the 15 recommendations, which was agreed by the Technical Committee and accepted by the Commission.

Japan asked the Chairman of the Scientific Committee if the Committee studied the specific questions raised at the Working Group. The Chairman of the Scientific Committee responded that there was no substantial discussion on the matter but there was little to gain in the context of the conservation performance of the RMP by modifying the procedure to take further account of environmental change. Also, the Scientific Committee believes that the RMP adequately considers the question of under-reporting of catches.

#### 12.2 Proposal by France, Australia, Brazil, Ireland, Monaco, Netherlands, New Zealand, Spain, UK and USA

The Chairman of the Technical Committee identified three choices arising out of Recommendation 9 for the geographical boundaries of a sanctuary in the Southern Ocean contained in documents submitted by France and nine co-sponsors, Japan and five co-sponsors, and Chile and three co-sponsors, and he invited comments from members on these proposals.

Following this exchange of views from all the members present, the Chairman concluded that this had been a valuable exercise which emphasised the range of opinions for the northern boundary set at 40ºS through a series of other options. It was clear that there was room for further discussions which might lead to a compromise which could achieve a consensus in the Plenary. Some delegations believed that no decision should be taken until the Scientific Committee had been asked to examine and report back on the scientific aspects of and give management advice on a Southern Ocean sanctuary, while others believed that there was no need to delay taking a decision since the time has now come for such action.

Japan, after hearing the Chairman's summary, called for a vote on the following proposal:

'That the Technical Committee recommends the Commission to instruct the Scientific Committee to give management advice on the specific questions in the Norfolk Island Working Group report prior to taking any full and final decisions on a Southern Ocean sanctuary.'

This was seconded by Norway although secondment was not required in the Technical Committee.

Prior to voting, Australia, seconded by France, proposed an amendment to replace the word 'management' by 'scientific' and to delete all the text from 'prior to ...'.

This amendment was adopted with 22 votes in favour, 6 against and with 4 abstentions.

Japan's original proposal was thus not put to the vote.

Following an adjournment, the amended substantive motion was put to the vote and adopted with 22 votes in favour, 1 against and 9 abstentions.

Thus, the Technical Committee recommended the Commission to instruct the Scientific Committee to give scientific advice on the specific questions in the Norfolk Island Working Group report, which the Chairman of the Technical Committee interpreted to be Recommendation 7(a)-(e).

The Technical Committee therefore forwarded these conclusions together with the one proposal and two proposed amendments in the documents submitted by France, Japan, Chile and their co-sponsors.

In the Plenary, Japan spoke of the need for such proposals to be based on scientific advice and its concern over the amount of fish consumed by whales that could provide human nourishment. Japanese research had contributed much to our knowledge and it took pride in the development of the RMP. It saw no reason to hurry to adopt such a proposal as no commercial whaling can ever be conducted in the area until completion of the RMS.

Spain believed that the severe depletion of whale stocks in the past has made it imperative to consciously protect them now. This is a minimum precautionary approach.
Responsible resource management through the RMP and RMS should not be rushed, and adoption of a Southern Ocean sanctuary is a clear example of responsibility.

St Vincent and The Grenadines emphasised the need for scientific advice to be presented before establishing a sanctuary, not to justify it afterwards. It believed the proposal would contravene Article V, and noted that the Chairman of the European Parliament’s Intergroup on Conservation and Development wrote that the IWC should base all management decisions on advice from its Scientific Committee and its basic task is to regulate whaling. It contrasted the need to justify aboriginal quotas yet the sanctuary is not put to any such test and the haste over the sanctuary while the RMS needs so much more work. The majority countries should not impose their attitude to whales on people from other cultures.

Venezuela, although unable to exercise its voting rights, spoke of its belief in the self-determination of nations. Cetaceans in its territorial waters are protected under national legislation, but it respected other countries with whaling as a cultural tradition. Most countries would consider a global whale sanctuary so long as those few remaining nations engaged in domestic whaling can secure a regulated catch and the question was can we share the planet’s natural sustainable resources in peace and goodwill?

Argentina recalled that it has supported the sanctuary initiative from the beginning. It favoured a compromise on the northern boundary to enlarge the basis of support, which has a sound scientific basis and is in line with the precautionary principle.

Australia commented that it has also supported the concept of a sanctuary since it first came before the Commission in 1992. There has been consideration and discussion, and there has been advice from the Scientific Committee and other bodies. It was pleased to see emerging a proposal which seems to have secured a wide measure of agreement.

12.3 Action arising

Mexico introduced a compromise proposal on behalf of itself, France and Chile, supported by Antigua and Barbuda, Argentina, Australia, Austria, Brazil, Finland, Germany, Ireland, Monaco, Netherlands, New Zealand, Russian Federation, South Africa, Spain, Sweden, UK and USA. This was based on political will and scientific foundations for the protection of the whales. France, in seconding this proposal, withdrew its own original proposal. It thanked Chile for its helpful amendment in earlier discussions and emphasised the strong scientific base of the latest formulation.

Dominica considered that the proposal was bypassing science and recalled the reasons for the resignation of the former Chairman of the Scientific Committee. It was not satisfied that there were enough data to justify the northern boundary and questioned the need of the Scientific Committee. It characterised the proposal as a triumph of chicanery over science and Dominica’s principles would not be compromised.

Japan stressed its strong commitment to the work on the RMP/RMS and introduced an amendment, seconded by Norway, which would have the effect of setting the northern boundary along the Antarctic Convergence except in the Indian Ocean where it would join that sanctuary at 55°S and exempt minke whales from the prohibition on commercial whaling when the RMS is adopted for that species.

Grenada stated its position as one in which principles and science take precedence over political expediency. It believed culling could occur in a sanctuary and noted the views of Margaret Thatcher, President Clinton and Vice President Gore that science must be the basis and guiding principle at all times. Elephants in Zimbabwe and crocodiles in Zambia are too numerous because CITES regulations have stopped them being taken. Similar things are happening with seals and we may finish up with a sea of whales and no fish, with a consequential impact not on the developed, industrialised world but on developing countries. It supported the Japanese amendment but, if that failed, would abstain on the main proposal.

Japan questioned if the Commission could make a decision on the sanctuary proposal or amendment when the Scientific Committee had not seen either, but the Chairman stated that the Commission has the power to make decisions on management or conservation.

France identified that the Japanese amendment meant that whales not presently hunted will not be hunted in the future and the whales now hunted will be hunted in the future. All the positions are well known and it was time to take decisions.

The People’s Republic of China spoke of its principles towards wildlife resources – protection, propagation and utilisation, and reserved its position on establishing the sanctuary until the Japanese amendment had been examined by the Scientific Committee.

Ireland pointed out that the original French proposal was considered by the Scientific Committee, a Working Group had discussed it and the present proposal is a subset of that.

The Japanese amendment was then put to the vote and defeated with 6 in favour, 23 against and 2 abstentions.

Before the vote on the substantive Mexico, France and Chile proposal, with support from 17 other governments, Norway stated that it would not take part. This proposal was to amend the Schedule by designating existing paragraph 7 as sub-paragraph 7(a), and adding the following sub-paragraph:

(b) In accordance with Article V(1)(c) of the Convention, commercial whaling, whether by pelagic operations or from land stations, is prohibited in a region designated as the Southern Ocean Sanctuary. This Sanctuary comprises the waters of the Southern Hemisphere southwards of the following line: starting from 40 degrees S, 50 degrees W; thence due east to 20 degrees E; thence due south to 55 degrees S; thence due east to 130 degrees E; thence due north to 40 degrees S; thence due east to 130 degrees W; thence due south to 60 degrees S; thence due east to 50 degrees W; thence due north to the point of beginning. This prohibition applies irrespective of the conservation status of baleen and toothed whale stocks in this Sanctuary, as may from time to time be determined by the Commission. However, this prohibition shall be reviewed ten years after its initial adoption and at succeeding ten year intervals, and could be revised at such times by the Commission. Nothing in this sub-paragraph is intended to prejudice the special legal and political status of Antarctica.

There were 23 votes in favour, 1 against and 6 abstentions, and so the amendment to the Schedule was approved by the necessary three-quarters majority.

Following the vote, Norway explained that it believed the action was not in accordance with the Convention, since there had been no scientific consultation. Japan repeated its view that these resources should not be denied for future human generations. Denmark saw no break in this action with its view of sustainable utilisation, while Chile expressed its satisfaction even though it would have
preferred the CCAMLR northern boundary. Mexico emphasised the large responsibility now taken on by the Commission.

13. ADOPTION OF REPORT OF THE TECHNICAL COMMITTEE

The Technical Committee had met under the Chairmanship of the Vice Chairman of the Commission, Dr P. Bridgewater (Australia). Its report on Items 10, 11 and 12 was adopted by the Technical Committee before being considered in the Plenary sessions on those matters and then formally adopted by the Commission.

14. SCIENTIFIC PERMITS

14.1 Report of the Scientific Committee

The Scientific Committee received an overview of the scientific programme carried out by Japan in the Southern Hemisphere Area IV in the 1993/94 season, which included a catch of 200 male and 130 female minke whales. A number of papers on specific aspects, including age distribution, segregation and relationship to oceanographic conditions, were discussed in the limited time available.

The results of the 1993 Norwegian programme were considered. Only 69 minke whales were taken, fewer than planned, because of poor weather and ice conditions, and permission was not received to operate in Russian Federation waters. Prey abundance, diet, genetics, reproduction and pollution studies were continuing.

Japan is continuing its Southern Hemisphere programme which the Scientific Committee has discussed extensively in the past. It noted that the minke whale population estimate in Area V is 295,000 and the planned sample size 300 ± 10%. Increased effort is being placed on environmental aspects of the programme in light of the Commission’s Resolution on environmental effects.

The Norwegian proposal for 1994 is the final year of its programme, with a planned take of 127 minke whales. Unless the operations are hampered by extreme weather, there are no immediate plans for a further catch of minke whales in Norwegian waters.

The Scientific Committee also reviewed a research programme from the Government of Japan to clarify the stock structure of minke whales in the northwestern North Pacific. Following the agreed review guidelines, the objectives of the research are to clarify the stock structure and mixing rates of minke whales around Japan based on problems encountered by the Scientific Committee in its discussion of implementation trials for North Pacific minke whales. The objectives directly address questions of interest to the Scientific Committee and the proposal gave a number of reasons why lethal sampling (100 whales in the first year feasibility study) was required. Much of the discussion centred on the replacement of the proposed research take by the collection of biopsy samples and the use of existing stored samples from earlier takes for genetic analysis. Japanese scientists judged from calculations on the impact of various levels of research catch that an annual take in the range of 100–200 whales would have no harmful effect on the populations, even in the worst case scenarios. The Scientific Committee noted the difficulties in adequately providing advice on this matter in the past and decided it should consider the general question of how to provide such advice at its next meeting. It agreed that the guideline for research cooperation had been met.

In the Plenary, the Netherlands concluded that none of the programmes meet the criteria established by the Commission and announced that it intended to propose Resolutions requesting Japan and Norway to review their programmes. New Zealand supported the Netherlands, urging Japan in particular to consider making use of DNA analyses of stored samples from the North Pacific and to develop biopsy techniques. The UK, USA, Spain, India, Germany, Austria, Brazil, France and Australia all supported the position of the Netherlands and New Zealand and expressed their doubts over the need for a lethal research programme.

Norway pointed out that there is little support in the report from the Scientific Committee to criticise the North Pacific proposal, a position strongly reinforced by Japan, while St Lucia, St Vincent and The Grenadines and Dominica referred to the favourable comments of the Scientific Committee.

14.2 Action arising

The Netherlands introduced three Resolutions dealing with special permit catches, proposed with Austria, Australia, France, Germany, Ireland, Monaco, New Zealand, UK and USA, and subsequently joined by Spain. Concerning the proposed take by Norway, it noted that no revisions had been made to the original programme, but welcomed the fact that Norway has decided not to issue any new permit in 1995. It believed that the objectives are unachievable in any realistic time frame in the Japanese Southern Hemisphere research proposal, but noted the attempts by Japan to address the concerns expressed by the Scientific Committee and acknowledged that the non-lethal methods for whale population assessment had been very valuable. The objectives of the Japanese North Pacific minke whale programme directly address questions of scientific interest, but it considered that these could be equally well, if not better, be met by non-lethal methods, utilising the more than one thousand stored samples and new biopsy samples. The Resolutions invited Norway to reconsider its programme for 1994 and Japan to restructure its two programmes so that the research interests are adequately addressed with non-lethal means.

Japan expressed its objection to this kind of Resolution, which does not reflect what was discussed in the Scientific Committee. There was no disagreement there on the research or the effect of the catches in the North Pacific, only three scientists raised the non-lethal means, while there was appreciation of the results from the Southern Hemisphere.

Norway put forward another Resolution on scientific permits by Japan for the take of minke whales in the North Pacific, which endorsed the review by the Scientific Committee.

New Zealand endorsed the comments of the Netherlands and supported those three Resolutions. It noted the critical minority statement on the North Pacific proposal and reiterated its view that the essential research needs identified in all three programmes can be conducted by non-lethal means.

After a discussion on the order in which these Resolutions should be taken, it was decided that although the three Resolutions had been presented first in the meeting, because the Norwegian Resolution had been submitted to the Secretariat before the others, it should have precedence.
The Netherlands proposed an amendment to the Norwegian Resolution, which with a further modification by Japan, was adopted by consensus (Appendix 9).

The Resolution (Appendix 10) introduced by the Netherlands on the Japanese North Pacific catches was also adopted, noting the strong objection recorded by Japan because the research proposal meets the objectives and guidelines established.

The next Resolution (Appendix 11) on the Japanese Southern Hemisphere catches was similarly adopted, again noting Japan's objection that it does not reflect the discussion of the Scientific Committee nor the large amount of biological knowledge accumulated.

The third Resolution on the Norwegian programme (Appendix 12) was, at the request of Norway seconded by Japan, put to the vote when it was adopted with 18 votes in favour, with 13 against and 6 abstentions.

15. SECOND INTERNATIONAL DECADE OF CETACEAN RESEARCH

15.1 Report of the Scientific Committee

The Scientific Committee reviewed the reports from four studies which had been supported in the last year: the IWC/IDCR Southern Hemisphere minke whale assessment cruise; the structure of fin whale populations in the Gulf of St Lawrence and West Greenland; Project YONAH and molecular genetic identification of sex and identity among humpback whales in the Southern Ocean.

Each of the proposals submitted for consideration this year was reviewed by a Working Group on the basis of its relevance to the objectives of the Scientific Committee and the work of the Commission, the scientific quality of the project, its chances of success, the competence of the proposers, the feasibility of the work schedule and the reasonableness of the budget. The Scientific Committee agreed that it should develop more specific guidelines concerning attendance of proposers, associates and cooperators during research proposal discussions and that it should review its policy on consideration of research proposals at next year's meeting. It appointed an intersessional Working Group to examine this matter further.

The Southern Hemisphere minke whale assessment cruise and three other proposals were forwarded by the Scientific Committee to the Finance and Administration Committee with recommendations for funding.

In the Plenary, Japan emphasised its commitment to research. The Antarctic stocks had been depleted by overhunting by many countries in the past, including Norway, UK, Netherlands, USA, USSR as well as Japan. These countries did not carry out research now and some criticised Japan for its efforts.

15.2 Action arising

The Commission endorsed the recommendations on research from the Scientific Committee and considered the funding aspects under the Report of the Finance and Administration Committee.

16. CONSERVATION OF WHALE STOCKS

16.1 Report of the Scientific Committee

A Steering Group was established by the Scientific Committee last year to identify a set of objectives for research on Southern Hemisphere blue whales and to identify individuals who could contribute to the development of a research proposal. An intersessional meeting of the Steering Group was held in Tokyo in October 1993. Three possible objectives were considered by the Scientific Committee: (a) to refine estimates of abundance in feeding areas; (b) to determine the distribution of breeding areas and whether animals that utilise a particular low latitude breeding area utilise particular feeding areas in the Southern Ocean; and (c) to evaluate the potential for competition for krill between blue whales, other baleen whales and other high-level predators.

A number of research projects were identified, some of which are already in hand. In view of the difficulties associated with estimating blue whale abundance, the Scientific Committee strongly recommended that the potential of acoustic methods for both determining areas of blue whale concentration and assessing their abundance be determined. It noted the value of the information obtained from the US Navy 'Whales 93' project and its future potential and strongly recommended that the USA ensures that this work is continued.

The Scientific Committee also considered the results of analyses of IDCR cruise data and agreed that as these cruises covered the major feeding grounds of blue whales, the estimate of 460 (95% CI 210–1,000) represents the best estimate of abundance available for Southern Hemisphere true blue whales for the 1985/86–1990/91 cruises.

Plans for a Japanese sightings cruise for blue and Bryde's whales around the Solomon Islands in September and October 1994 were presented, covering an area where blue whales have previously been seen. The Scientific Committee noted the relevance of this survey to its work, recommended that it be conducted and looked forward to receiving a report of the cruise.

The segregation of blue and pygmy blue whales in the Southern Hemisphere has been examined using available sightings data and catch records on the basis of separation at 55°S. The Scientific Committee concurred with the view that an identification key for separating the two sub-species at sea be developed if possible. Information on the final phase of pelagic exploitation of blue whales in the Southern Hemisphere and the actual catches of pygmy blue whales by Japan and the USSR were reviewed, including catches of over 9,000 pygmy blue whales not previously reported by the USSR during the seasons 1962/63–1971/72.

In the Plenary, the USA supported the study on competition for krill so long as it does not involve lethal takes. It also stated that it will make every effort to see that the work on the use of acoustics for determining areas of blue whale concentration and their abundance is continued. The UK confirmed that it is funding a two-year project to analyse Discovery data to investigate changes in feeding ecology and historical concentrations of blue and other large baleen whales in the Southern Ocean.

Australia and New Zealand, while supporting such work, questioned the practicality and financial implications of some of this research given the low number of sightings. Japan emphasised its initiative in promoting these studies to encourage the recovery and protection of the large baleen whales. It might be necessary to stop the passage of all vessels within the habitats and it thought it important that urgent international cooperation should be started and funded by the Commission.

16.2 Mechanism to finance research programme

The financial implications of any programme were such that the Scientific Committee agreed to bring this matter back to the Commission for further guidance and
consideration. If the Commission did approve the proposal in principle and were willing to make funds available, a detailed programme could be developed.

Japan proposed establishing a Working Group to include the Secretary, the Chairman of the Scientific Committee and a few of its relevant members to correspond initially and meet interessionally if necessary to start collecting and analysing data. It proposed a budget of up to £10,000 for this work. Australia considered this a useful and positive suggestion, and thought the Working Group might meet just before next year's Scientific Committee to save resources. Japan believed the Working Group could make the decision on if or when it should meet.

The Commission approved starting the work by correspondence coordinated by the Secretary and the Chairman of the Scientific Committee, and the Working Group will itself decide the necessity of meeting interessionally, or at the next Annual Meeting.

16.3 Action arising

Japan introduced a Resolution on promotion of research related to conservation of large baleen whales in the southern oceans. This noted the work of the intercessionof Steering Group and the Scientific Committee, the concerns on the status of the large baleen whales and the need for research, and allocated up to £10,000 for the development of research programmes to be presented at the 47th Annual Meeting for consideration of financial support.

New Zealand proposed a series of amendments to the text which were supported by the USA, UK and Brazil, and with these changes the Resolution (Appendix 13) was adopted, noting some continuing concerns from New Zealand.

17. RESEARCH ON THE ENVIRONMENT AND WHALE STOCKS

17.1 Report of the Scientific Committee

Last year the Commission passed a Resolution on the environment and whale stocks, and decided among other things that the Scientific Committee should give priority to research on this topic, that a special workshop should be convened before the 47th Annual Meeting, and that the Scientific Committee and Contracting Governments consider inviting participants to this year's Annual Meeting with expertise in these matters. The Chairman of the Scientific Committee drew attention to the fact that two invited participants were funded by the IWC specifically for this item and were joined by a number of specialists from member governments.

Responses to the request for information circulated by the Secretary indicated that a number of organisations have considerable expertise, data and research programmes related to monitoring the marine environment. These include IOC, ICUS/SCOR/SCAR, WMO, UNEP, FAO and CCAMLR. A major task will be to develop a framework that will enable the Scientific Committee to take advantage of this accumulated information and relate it to cetaceans – a project now also being investigated by the UK.

The Scientific Committee briefly considered a number of papers dealing with threats to cetaceans, climatic changes and ozone depletion, modelling and pollutants. It agreed that the focus of a workshop on the effects of environmental changes on cetaceans should be to identify research activities that might enable the eventual prediction of the effects of such factors, both direct and indirect, on cetaceans and incorporate such knowledge into conservation and management programmes.

Because of the number and range of factors that might be considered, it was neither feasible nor desirable to cover them all at a single workshop. The Scientific Committee proposed holding a workshop on issues related to chemical pollutants and cetaceans in the intersessional period, and established a Steering Committee. It believed a workshop on the potential ecological effects of climate change and ozone depletion on cetaceans should be delayed until autumn 1995. This would allow consultation with other international organisations; a Steering Group for this activity was also appointed.

17.2 Action arising

Grenada spoke of the need for whale/fisheries interaction studies, referring to the increased consumption of fish by marine mammals as the numbers of the latter increased. This has led to plans for controlling the fur seals off South Africa and grey seals by the UK. The growth of whale stocks could affect fish resources which are important for human nutrition. It suggested that the IWC Scientific Committee should cooperate with FAO and other agencies to mount a study to develop a framework to look into the effect of a sanctuary in the Southern Ocean.

Support for such an approach was expressed by St Lucia, St Vincent and The Grenadines and Spain. Norway recalled that this problem is addressed in its research programme while Australia questioned the recovery rates of depleted cetaceans.

The USA stated it was prepared to host both workshops and Norway offered to host the one on pollution. Japan spoke of the necessity to determine what practical aspects should be considered and the relationships with FAO and CCAMLR in the context of whales and fish stocks. Further exchanges led to agreement to endorse the approach proposed by Grenada and to accept the offers to hold the pollution workshop in Norway in the coming year and the environment workshop in the USA in autumn 1995. The Scientific Committee's outline of topics and experts to be invited were noted.

The USA subsequently introduced a Resolution submitted together with Austria, Ireland, Netherlands, New Zealand and the UK on research on the environment and whale stocks. This recalled the development of the Commission’s interest in this subject and encouraged further activity by the Scientific Committee and Contracting Governments. Australia expressed some concerns before the Resolution (Appendix 14) was adopted.

18. THE RESPONSIBILITY OF IWC FOR THE CONSERVATION AND SUSTAINABLE USE OF WHALE RESOURCES

Last year the Commission agreed to keep this item on its agenda to promote annual discussion.

The USA endorsed the concept of sustainable use of marine living resources as set forth in Agenda 21 of UNCED, but noted that this does not require consumptive use. Agenda 21 recognises the competence of an international organisation to prohibit the exploitation of marine mammals and the responsibility of the IWC for conservation and management of whale stocks and the regulation of whaling. The USA emphasised that whalewatching is a good example of sustainable use.
Australia took the same position, and suggested keeping this item on the agenda so the Commission can monitor international developments in this area.

Japan spoke of the increase in human population expected into the next century and the limited food resources available on land. It looked to the seas to prevent poverty and food shortages in developing countries, but protection of the whales denied such utilisation. It emphasised its view that the world trend of total protection of marine mammal species regardless of their population status is wrong and should be reviewed.

St Lucia referred to the preamble to the Convention talking about the sustainable exploitation of whales, taking into consideration the consumers of whale products and the whaling industry.

The UK is also committed to the principles of sustainable use as agreed in UNCED and supported the USA’s comments. It suggested deleting this item from the agenda in future, a position shared by the Netherlands, New Zealand (which noted it was the basis of all the Commission’s discussions), the USA and France. St Vincent and The Grenadines expressed surprise at such a suggestion for an item at the heart of the Convention, a view shared by Norway, Sweden, Japan and Denmark.

After further discussion in a meeting of Commissioners it was decided to retain the item on the agenda, for review at the next meeting.

19. WHALEWATCHING

19.1 Report of Working Group on Whalewatching

The report of the Working Group was presented by its Chairman, Mr F. von der Assen (Netherlands).

A report was prepared by the Secretary based on information submitted by 12 Contracting Governments in response to a questionnaire developed after the Resolution on whalewatching adopted by the Commission last year. In addition four other member governments presented their late returns to the Working Group.

The Working Group decided to revise the conclusions and recommendations of the Secretary’s report and present them as its conclusions and recommendations to the Commission.

Economic aspects

Whalewatching as a commercial enterprise is still in its infancy in many countries. But the rate of growth shown during the past few years suggests that it can become a significant economic activity, at least on a local basis, as it has in the USA.

It is clear that growth in the newly established whalewatching locations is extremely rapid in the first years of the enterprise — to such an extent that Mexico is now limiting further expansion of this activity in the Baja California lagoons to protect the whales and their environment. But it also seems that the growth in most of the USA has flattened out and the industry has effectively stabilised at the present level.

Regulation

The very fact of this rapid growth has led a number of governments to record their concerns over possible impacts on the behaviour, migrations and breeding biology of the various species involved. The number of whalewatching vessels and their deployment around the whales is seen as a potential cause of disturbance to normal activity by the animals, as well as possibly inflicting actual physical harm by collisions and cuts from propellers.

As a result of the perceived or actual disturbance or harm which might result from whalewatching activities, there is a general view reflected on the need for regulations to provide adequate safeguards for the whales. Not all countries have yet reached this stage of control because their whalewatching operations are so new. But some of the more experienced indicate that voluntary guidelines or codes of conduct may not always be strong enough controls.

The general view on the rules or guidelines needed include the number and behaviour of vessels and aircraft and other specific issues which coastal states may need to consider in regulating whalewatching.

One way of enforcing these regulations would be to licence approved operators and employ crews with an appropriate grounding in boat handling which will avoid any detrimental effects on the whales.

Scientific aspects

Scientific studies carried out in conjunction with whalewatching operations were reported to the Working Group.

Evaluation of the full potential of whalewatching activities as regular bases for scientific research does not yet appear to have been addressed in a comprehensive manner. Rather, the commercial operations are treated more as platform of opportunity; but a number of specific scientific programmes do provide spaces for whalewatching visitors who contribute finances and manpower to the activities.

A further important element is the educational role of properly run whalewatching cruises carrying trained personnel who can pass on information on whales and their environment to the passengers. A number of enterprises feature such teaching, not only for school parties but for all visitors.

Recommendations

Specific suggestions for IWC action are to convene a Working Group on whalewatching to:

(i) meet before the 47th Annual Meeting of the Commission to share experiences about the economic, social, scientific, educational and policy aspects related to whalewatching;
(ii) exchange information about existing regulations relating to whalewatching;
(iii) determine the use of whalewatching operations to gather data relevant to the IWC;
(iv) draw up a set of guidelines to assist coastal states in the management of whalewatching, based on the experience of member countries;

for the Scientific Committee, in order to provide advice on measures to be considered by those developing regulatory frameworks, to

(a) identify and assess the possible effects of whalewatching operations on cetaceans/whales;
(b) examine current status of methods of assessment of impacts, including assessment of behavioural change;
and
(c) provide advice on future whalewatching based on assessment of impacts;

and generally to redefine terms of reference as necessary for the Working Group.
19.2 Action arising
Japan raised the issue of animal rights and the invasion of privacy of the whales, to which the Chairman of the Working Group drew attention to the development of non-lethal uses of whales in the Commission. The report set out the general concern about the harm that might result from whalewatching activities to whale stocks. Thus there is the need for regulation by coastal states with the Commission providing guidelines for such regulation.

The Chairman of the Scientific Committee asked for clarification and the priorities of what was requested of his Committee, and Spain responded that the guidelines on the possible relative impact of different aspects of the effects of whalewatching were sought. Australia suggested that first there should be an identification of whalewatching activities which may have an impact on whales and other cetaceans, and then subsequently some assessment of the seriousness of those impacts from the perspectives of management and conservation. The UK agreed with those priorities which were approved by the Commission.

The Netherlands proposed that the Secretary should attend and report back on a meeting on whalewatching to be held in Italy in Spring 1995. Japan, besides its basic stance relating to the competence of the Commission on this subject, also had reservations about sending an observer to a meeting wholly organised by NGOs. The USA and Australia disagreed with such restraint on attendance at important meetings.

The UK later introduced a Resolution on whalewatching, proposed together with Australia, Austria, France, Germany, India, Monaco, Netherlands, New Zealand, South Africa, Spain, Sweden and the USA. This took account of the useful contributions and discussions thus far and requested further input and activity by the Scientific Committee and the Working Group.

Japan expressed its reservation before the Resolution (Appendix 15) was adopted.

22. ADOPTION OF THE REPORT OF THE SCIENTIFIC COMMITTEE

In adopting the report of the Scientific Committee the Commission took account of the following matters and endorsed the various recommendations as appropriate.

22.1 National progress reports on research
The Scientific Committee reaffirmed its view of the importance of progress reports and the Commission urged member nations to provide them following the approved guidelines. In future, progress reports should include information on the number of biopsy samples, by species and area, collected during the year.

22.2 Small cetaceans
This year the Scientific Committee considered especially the status and exploitation of small cetaceans in Latin America.

22.2.1 Vaquita
A preliminary estimate of the population, which is confined to the upper Gulf of California, is 315 (95% CI 118–847) confirming it is very rare. The Scientific Committee recommended that monitoring of fishing activity and incidental mortality be conducted in the entire range of the species and that immediate action be continued to eliminate incidental catches in the area. It also recommended that census surveys be conducted and welcomed the recent joint efforts by Mexican and US Government agencies in the study of vaquita.

22.2.2 Franciscana
The Scientific Committee concluded that with no estimate of abundance, incomplete information on stock identity within the range of the species and incomplete information on incidental takes, it was not in a position to assess the exploitation and status of the franciscana. The Committee recommended that critical research needs be addressed to clarify migration and stock identity and to provide reliable estimates of abundance. Demographic data should be collected from incidentally caught animals and individual recognition techniques utilised. This research should be coordinated in Brazil, Argentina and information and samples exchanged across national borders. It further recommended that the Commission requests that Brazil and Argentina establish routines for recording incidental and directed takes of small cetaceans and to submit all catch statistics to the Commission. It requested the Secretary to inform Uruguay of the findings of the Committee and invite it to submit data on takes and abundance of small cetaceans in its waters. Because of concerns for the possible levels of incidental takes of the franciscana range states are urged to implement steps to reduce such mortality.

22.2.3 Tucuxi
The Scientific Committee concluded that with no estimate of abundance, incomplete information on stock identity and incomplete information on incidental and directed takes it was not in a position to assess the exploitation and status of tucuxi. The Committee recommended that critical research on distribution, migration and stock identity should be conducted; abundance estimates obtained; demographic data collected from incidentally caught animals and research coordinated among countries within

20. THE RESIGNATION OF THE CHAIRMAN OF THE SCIENTIFIC COMMITTEE

St Lucia expressed its appreciation of the work of Dr Phil Hammond as Chairman of the Scientific Committee for two years before resigning shortly after the last Annual Meeting. The final stages of the RMP were completed under his leadership and it is with regret that the Commission received his resignation. St Lucia welcomed Dr Reilly as the new Chairman.

Australia thought all Commissioners could have taken the same views and Dominica indicated it wished to propose a Resolution in support of the Scientific Committee under Any Other Business, although in fact this did not occur.

21. COOPERATION WITH OTHER ORGANISATIONS
The Chairman of the Scientific Committee reported on the reports and information available and discussed from other organisations. These comprised NAMMCO, ICES, CMS/ASCOBANS, CCAMLR, IATTC, CITES, UNEP, FAO and IUCN. The initiative of IOMAC in a new Indian Ocean regional project for marine conservation was also noted.
the known and potential range (Brazil, Peru, French Guiana, Suriname, Guyana, Venezuela, Colombia, Costa Rica and Nicaragua).

The Committee expressed concern for the possible levels of incidental takes of the tucuxi and, as a precautionary action, the actual and possible range states are urged to implement steps to reduce incidental mortality. The Committee recommended that the Commission requests relevant member governments (Brazil, Costa Rica, Peru and Venezuela) to establish routines for recording incidental and any directed takes of tucuxi and to submit all catch statistics to the Commission. The Committee further requested that the Secretary informs the other range states of the findings of the Scientific Committee and invites them to submit data on takes and abundance of tucuxi in their waters.

22.2.4 Dolphins taken in the eastern Tropical Pacific purse seine tuna fishery

Although this subject was included in discussion under Latin America, the Scientific Committee noted that several countries from outside this region are active in the fishery.

Total dolphin mortality in the ETP tuna fishery was 3,609 animals in 1993. This represents a decrease of 97% from the 1986 level (133,000) and 77% from the 1992 level (15,500). Most of this improvement was due to changes in fishermen’s performance. Observer coverage was 100% in 1993. The Scientific Committee welcomed this continued rapid decline and reiterated its appreciation on the achievements and effective management action implemented by an international agreement negotiated by the IATTC and collaborating nations, and on the considerable effort of the fishermen conducting the release operation of entrapped dolphins. It encouraged that effort be continued to further reduce mortality levels, by continuing to improve the techniques to release dolphins.

22.2.5 Other stocks

Directed takes were reported from Chile, Peru, Colombia and Mexico and incidental takes were reported to occur widely in the Latin American region. The Scientific Committee therefore recommended that the Commission request that:

(1) IWC member countries in Latin America (Argentina, Brazil, Chile, Costa Rica, Ecuador, Mexico, Peru and Venezuela) establish routines for recording and reporting directed and incidental takes of small cetaceans, and submit all catch statistics to the Commission;

(2) non-member countries where directed exploitation of small cetaceans is documented (Colombia) are informed about the findings of the Scientific Committee, encouraged to establish routines for recording catch statistics and invited to submit all catch statistics to the Commission.

For species identified to be subject to significant incidental or directed takes, the Scientific Committee also recommended that abundance estimates be obtained following the Committee’s guidelines and that demographic data (such as age at sexual maturation, calving intervals and longevity) be collected from incidentally or intentionally caught animals.

Noting that there are national prohibitions of directed catches of cetaceans in Chile and Peru, and that these prohibitions impose constraints on the access to information on the continuation of catches, the Committee recommended that the ban on takes of cetaceans be enforced or the continued harvest be managed at sustainable levels, where these can be determined.

The Scientific Committee further recommended that, as a precautionary measure, steps be taken to reduce present mortality levels of dusky dolphins in Peru until sufficient information is available to estimate sustainable catch levels.

22.2.6 General recommendations

To better understand the stock structure of South American small cetacean species, the Scientific Committee recommended that various genetic studies or other types of stock identity techniques be pursued; and that methodology is explored and developed to construct satellite-linked transmitters suitable for application on franciscana, porpoises and other small dolphins.

Because incidental takes are a problem for most of Latin America, the Scientific Committee recommended that (1) efforts to minimise incidental mortality of cetaceans be started or continued through the development of more selective gears and through training programmes for fishermen; (2) when alternative gears or modes of fishing are considered, a full ecological assessment of their impacts is performed because of concerns that reduction in cetacean mortality may be achieved at the expense of other, perhaps higher ecological costs.

The Scientific Committee noted that there are extensive small cetacean bycatch problems occurring in many countries which have different fishery practices and fishery legislation. It recommended that observer schemes that incorporate a statistical sampling design be established. However, in some countries, certain fishing practices may render observer schemes impractical. In such circumstances, the Committee recommended that either monitoring programmes and/or modified observer schemes should be initiated; if this is not possible reporting schemes by fishermen should be formalised. However, the Scientific Committee cautioned that data collected by any means other than placement of observers on board fishing vessels are generally less reliable. Such schemes, adapted to local circumstances, should be implemented and managed by relevant authorities and full statistics submitted to the Commission.

22.2.7 Harbour porpoise in the North Atlantic and Baltic Sea

The findings of a Workshop to assess the status of harbour porpoises in the Northwest Atlantic and a proposal for international collaborative research to investigate population structure were reviewed. The Scientific Committee recommended that information be obtained on the level of bycatch along the Canadian east coast and the eastern mid-coast of the USA. It recommended that actions be taken to implement proposed plans to reduce the bycatch in the Gulf of Maine, and that plans be developed and implemented for the Bay of Fundy and other areas of high incidental mortality in the western North Atlantic.

The Scientific Committee recommended that observer programmes be set up to estimate bycatches by range state fisheries in the Northeast Atlantic, Baltic and North Seas and the results reported to the IWC, and that bycatches be reduced by whatever means possible. Data on life history parameters and the estimation of abundance should be collected to carry out an assessment of bycatch mortality and its effect on the population(s).
Recognising the aims of ASCOBANS concerning conservation and management of small cetaceans, IWC member countries that are also range states to ASCOBANS are encouraged to cooperate fully with ASCOBANS where appropriate.

22.2.8 Response to the 1993 Resolution on harbour porpoise
In response to the Commission’s Resolution last year, scientists from 12 countries provided the Scientific Committee with reports on progress in implementing at least some of the recommendations of the Resolution (Canada, Denmark, Germany, Greenland, Iceland, Ireland, Netherlands, Norway, Sweden, UK and USA). A summary of current research activities (61 programmes) from the above countries was compiled and discussed. During July 1994 a comprehensive abundance survey of the North Sea and Baltic will be conducted.

In the Plenary, both the UK and Germany submitted additional information on progress in implementing the recommendations in last year’s Resolution.

22.2.9 Striped dolphin fishery off Japan
Information on directed takes of striped dolphins was presented by Japan. The 1993 total of 544 was about half that in 1992 (1,045 dolphins). The Scientific Committee welcomed the information provided and appreciated the substantial reduction in kill levels achieved by domestic quota regulations in 1993. It recommended that information on stock identity, distribution, abundance and genetic studies be obtained as soon as possible to facilitate assessment of the striped dolphin.

22.3 Other
The Scientific Committee received a report on continuation of the use of 10-12km drift nets for swordfish in the Mediterranean Sea. The current fishery is mainly conducted by European Union nations (Italy and Spain) and Moroccan vessels and the activity is a contravention of the UN General Assembly Resolution 46/215 and for the EU countries (Spain and Italy) this activity violates the European Community Regulation 345/92 which prohibits drift nets in excess of 2.5km length in EU waters. The Mediterranean striped dolphin in particular could not sustain the reported levels of exploitation.

The Scientific Committee therefore recommended that Italy, Morocco and Spain be requested to establish a programme for recording incidental takes of cetaceans in the Mediterranean Sea and to report all catch statistics to the Commission.

In the Plenary, Spain pointed out that the recommendation could not extend to the Spanish case, considering that the very minor illegal drift netting carried out by a small number of Spanish vessels did not warrant the programme recommended. Furthermore, the data presented were superficial and were not properly reflected in the Scientific Committee’s Report which had concentrated more on the real problems raised by the other fleets mentioned.

Questions had been raised in the Scientific Committee over the way in which members who had not made their views known during the discussion were allowed to associate their names to views expressed by others at the Plenary session. It was requested that this critical procedural question be brought to the attention of the Commission.

A Spanish speaking scientist and the Japanese scientists noted that they would find their participation in discussions considerably easier if simultaneous translation facilities were available. A working paper was presented that the Scientific Committee agreed was more appropriate for discussion by the Technical Committee. The Secretary agreed to draw it to their attention.

23. FINANCIAL STATEMENTS AND BUDGET ESTIMATES

The Finance and Administration Committee met under the chairmanship of Dr. K. Chu (USA).

23.1 Review of Provisional Financial Statement 1993/94
(a) Income
The Provisional Financial Statement for the financial year 1993/94 prepared by the Secretariat assumed that all realisable contributions would be received, although one government had expressed an intention to withdraw from the organisation. Arrears payments had been received from the Russian Federation and Argentina.

A voluntary contribution had been offered from a Norwegian Institute (NINA) towards sponsored publications. Australia, the UK and USA had agreed to contribute funds to assist with the preparation and analysis of whale catch data from the former USSR.

Overall, income was more than £23,000 above the budget estimate. Additional observer fees could increase this further.

During the course of the Commission meeting the Commissioners agreed to accept a proposal for repayment of arrears of financial contributions due from the Government of Antigua and Barbuda. The schedule of repayments was accepted as the basis for full restoration of rights within the Commission, but it is implicit in this decision that any default in the payments will require a review of the situation by the Commission.

(b) Expenditure
Secretariat
Staff costs were slightly over budget because of a need to provide a temporary position during a period of maternity leave. There were market-driven increases considerably above the rate of inflation in both health and general insurances. Savings against other Secretariat budget items lead to overall savings of £9,000.

Annual Meeting
The cost to the Commission of the 1994 Annual Meeting would be the budgeted amount of £170,000. Any additional costs would be met by Mexico in keeping with IWC practice.

Research Fund
The prime source of income to the fund was the Commission’s allocation. Savings and higher bank interest resulted in a larger balance in the Research Fund which would be carried over to offset research costs in 1994/95.

New Zealand asked about the funding of invited participants and observed that most who received IWC support appeared to be associated with IDCR-related work. How were invitations determined and what was the basis upon which funding was made?

The Secretariat responded that at the Scientific Committee meeting each year, an attempt was made to identify the main agenda items for the meeting the following year. Sub-committees were identified and
convenors were appointed. During the year, the Scientific Committee Chairman, in consultation with the convenors and the Secretariat, prepared a list of invited participants. Although it was hoped that member governments would support relevant experts to Scientific Committee meetings, this was not always the case. Accordingly key individuals who should attend, if necessary with IWC support, were identified. An effort was made to get invited participants to find their own support. The Secretary reviewed the areas of expertise of the invitees in 1993/94, which demonstrated diversified areas of participation and noted that small cetaceans experts did not receive any IWC funds.

New Zealand, making it clear that it was not challenging the research programme, expressed concern about the lack of accountability in the current approach to the Research Fund. Brazil shared this concern.

Japan said it had no difficulty with the selection procedure for invited participants funded by the IWC, but recalled its concerns about the submission of several papers to the Scientific Committee which it considered not to be objective. It remained concerned that the current open-ended procedure allowed the participation of experts, especially on small cetaceans matters, whose views Japan believed were not objective.

Severance Pay
The Secretariat explained that the provision for severance pay is a contractual obligation and confirmed that there were sufficient funds to meet the maximum liability.

Enhancement of Reserves
The Secretariat advised that £46,000 would be added to the reserves in 1993/94, taking the projected balance to £463,000. In order to meet the agreed level of six months' operating costs, the reserves should total £512,000. While that level had not yet been reached, the current situation represented a continuation of the improvements in the reserves in recent years.

The Committee recommended and the Commission approved, subject to audit, the provisional Financial Statement 1993/94.

23.2 Consideration of Estimated Basic Budget 1994/95
The Secretariat explained that it had followed the customary approach of preparing an estimated basic budget taking account of anticipated expenditures. It was not possible to foresee the Commission's decisions and for that reason additional changes might need to be made during the Commission meeting.

(a) Expenditure
Secretariat
Secretariat salaries are based upon those of the International Maritime Organisation in London and increases in these and related costs, e.g. pensions, reflect scales issued by IMO in September 1993.

There was a considerable increase in proposed travel costs. This reflected the 1993 Commission decision that while IWC interests in many meetings could be addressed through representation of national delegates, some others might benefit from direct participation (e.g. UNEP Marine Mammal Action Plan Planning and Coordinating Committee; Portugal/IOC meeting with an agenda of oceanographic interest to the IWC, and a whalewatching meeting in Venice in March 1995). Nominal allocations were forecast, plus an additional amount in the event of any additional meeting requirements. The Commission would need to confirm whether it should be represented at such meetings, and if so, by whom. The Secretariat or the Chairman of the Scientific Committee were two possibilities.

Japan asked whether there was any precedent for travel funded through the IWC budget to meetings hosted by NGOs. The Secretariat responded there was not. However, there had been a number of meetings co-hosted by the IWC and other organisations, including NGOs. This led to extensive discussion about IWC participation in the whalewatching meeting in Italy.

The Secretariat commented that if information about the symposium suggested it would not be of value to the IWC's work, it would not attend the meeting and the funds would be held in reserve for next year's budget.

On the computing budget, the Secretariat hoped once more for a net gain by carrying out work in-house with consequent savings against purchased time on the Cambridge University mainframe computer. However, it cautioned that this would not continue indefinitely.

The UK commented that the computing budget seemed small and suggested there was value in developing a strategic plan for the Secretariat's computing needs, which could be used to justify future budgets. Australia agreed that a more strategic approach was important. The Secretariat responded that it would consult with the UK and others and develop an appropriate report for the 1995 meeting.

Research
The Scientific Committee Chairman was invited to present the Committee's 1994/95 Research Fund budget request. He outlined the proposed expenditures on the IDCR budget, database and analysis contract, and co-sponsorship of a genetics workshop. Eight specific research proposals had been presented to the Scientific Committee and were carefully reviewed. The first three on the list had been accorded 'high priority', the final project had been accorded 'medium priority' together with two other projects not recommended for funding this year.

New Zealand said it did not question the research programme as such. However, it was concerned about accountability of scientific research work. It was essential for the Commission to know what it expected from the use of its funds and what it would receive for this expenditure. The ultimate responsibility for determining accountability should rest with the Commission since it provided funding and was appropriate to consider the procedure that produced funding decisions. Brazil agreed with New Zealand. The Secretariat agreed it would be helpful to address accountability issues. A small working group might be established to devise a format for the presentation of future reports on expenditures under the Research Fund item. The Secretariat could also prepare a format for reporting on work under the IDCR. There was no resistance from the Scientific Committee to the provision of more detailed information.

The Finance and Administration Committee therefore recommended that the Secretariat should correspond with interested member governments about methods for improving accountability of the Research Fund.

In the Plenary, New Zealand proposed that the words 'for presentation together with any recommendations to the Finance and Administration Committee in 1995' should be added to this recommendation. This was agreed.

The Finance and Administration Committee agreed to recommend the 1994/95 research budget to the
Commission for its consideration, drawing attention to the proposed increase of 14.6% over the 1993/94 budget figure, mainly as a result of new activities recommended by the Scientific Committee.

Annual Meeting
The Secretariat referred to a suggestion last year that the Finance and Administration Committee might consider whether estimates of cost for the Annual Meeting exclude VAT. After some discussion, in which Germany expressed a preference for the past practice of budgeting on the basis of gross not net costs, it was agreed to maintain this longstanding approach. The Committee noted that whenever invitations were accepted for Annual Meetings to be held outside the UK, consequential reductions in the VAT recovery would occur.

Enhancement of Reserves
The Secretariat noted that if income and expenditure balanced exactly and given an assumption of UK inflation of something over 2%, £10,400 would be required simply to maintain the value of the fund. In order to make further progress towards the achievement of reserves sufficient to cover six months expenses, the Secretariat proposed that £14,000 be budgeted for enhancement of reserves.

Concluding comments on expenditure
New Zealand expressed general concern that the increase in the overall budget of 5.8% over the projected out-turn for the current year was significant at a time when other organisations were being kept to zero growth or indeed a reduction in funding. It hoped that expenditure could be constrained within more acceptable bounds in 1995.

Brazil suggested the basic budget be recommended to the Commission for consideration. However, it wished to call attention to the increase in the research budget, and in the Plenary elaborated on this point. It expressed its concern over the way unsolicited research proposals are accepted and looked for closer examination of such items.

It wished to leave this component open and review all research expenditure towards the end of the meeting, so that the present budget could be reviewed if other additions were too heavy.

(b) Income
Income was estimated on a conservative basis. There was no provision for late or voluntary payments. The Secretariat noted that contributions of £820,682 were required to balance the budget, but that this figure could increase if, for example, the Commission adopted the increased research expenditure proposed.

23.3 Consideration of advance budget estimate for 1995/96
The advance forecast budget was noted.

23.4 Observer Fees
The Finance and Administration Committee agreed that the Commission should maintain its current practice and accordingly that observer fees for 1995 for non-member governments and intergovernmental organisations be held constant at £800 while the fees for NGOs should be increased to £440 to take account of inflation.

23.5 Action Arising
It was agreed that the provisional Budget Estimate be recommended to the Commission for adoption. In the Plenary New Zealand built on its earlier comments and proposed that the Secretariat should be asked for a 1995/96 budget with zero growth in real terms, but without cutting any specific programmes. This position was endorsed by Australia, Denmark, Brazil, France and the UK. The 1994/95 budget was then approved (Appendix 16).

24. AMENDMENT OF THE RULES OF PROCEDURE AND DEBATE

24.1 Amendment of the Rules of Procedure
24.1.1 Documentation
Discussion within the Scientific Committee last year revealed that the Rules of Procedure of the Scientific Committee, particularly Rule E.7 concerning the publication and availability of scientific papers and reports, are not entirely satisfactory because they do not make clear the procedure to be followed in every case. The Secretary had therefore prepared a document which described the present practice of the Secretariat concerning the Commission’s documents and reports. It includes specific proposals to amend the relevant parts of the Scientific Committee’s Rules of Procedure and to introduce a new rule into the Commission’s Rules of Procedure to clarify the availability of all Commission documentation.

Japan agreed with all the recommended changes, with the exception of point 3 of proposed new paragraph Q where it was obliged to reserve its position. It recognised the Secretariat was seeking to address Japan’s concerns raised in 1993 with the proposal to adopt paragraph Q (i.e. it was up to each member to decide whether to make his or her document confidential or not). However, it maintained its views expressed last year that what should be corrected is not the current Rule E.7, but rather the current practice.

It was agreed to recommend these proposals to the Commission, noting Japan’s reservation about point 3 of paragraph Q. The amended Rules of Procedure as approved by the Commission are shown in Appendices 17 and 18.

24.1.2 Composition of Committees
At the 45th Annual Meeting the Commission endorsed the request of the Finance and Administration Committee that ‘the Secretariat develop for consideration next year a proposal for amendment of Rules of Procedure M.1 and M.2 concerning minimum composition of the Committee reflecting the divergent views on these issues’.

After consideration of the background and existing arrangements the Committee agreed to recommend amendment of the Rules of Procedure M.1 and M.2 developed by the Secretary. The amended Rules of Procedure as approved by the Commission are shown in Appendix 18.

24.1.3 Voting
The USA presented a proposal intended to clarify the distinction between the procedures for handling proposals which seek to amend the Schedule and proposals which would not require any Schedule amendment. Several delegations expressed support. There was also some discussion about how best to formulate language on a related provision concerning voting in committees. Wording suggested by Spain and other delegations resulted in the formulation for amendment of Rule of Procedure E. Voting as the recommendation to the Commission. This was adopted by the Commission and is also shown in Appendix 18.
24.2 Amendment of the Financial Regulations
The Secretariat drew attention to the fact that an inconsistency has become apparent in the Financial Regulations with respect to the due date for payment of contributions by Contracting Governments. A proposed clarification and amendment were put forward to deal with the situation of a Contracting Government which elected to postpone payment of any increased portion of its contribution to 31 August. The intention is to recognise 31 August as the 'due date' in this situation.

New Zealand expressed concern that the meaning of the amendment was not entirely clear and the Committee subsequently agreed to recommend a slightly modified text.

Additionally the Committee noted that in Financial Regulation E.2 the words 'be deemed to' are redundant. As an editorial improvement with no consequences for the meaning it is recommended that they be deleted.

The amended Financial Regulations as adopted by the Commission are shown in Appendix 19.

24.3 Amendment to the Rules of Debate
Last year, because of the problems which had been encountered with the Rules of Debate and procedural matters, the Commission asked the Secretary to make a compilation of interpretation for use in the Plenary.

Submission of Motions
At present Rule B.1 of the Rules of Debate indicates that '... no proposal shall be discussed at any Plenary session unless copies of it have been circulated to all delegations no later than the day preceding the Plenary session.' Recent practice has been for the Chairman to designate the time for such submissions.

Denmark described this as an important item. Noting the need for consultation, translation, time differences between countries and other factors, Denmark stressed the need for a considered approach. Several delegations agreed, expressing a preference for a range of different formulations. There was a general consensus that some time limit for the presentation of Resolutions was desirable, but that an element of flexibility was also important.

It was agreed to recommend that Rule of Debate B.1 be amended to read '... no later than 6pm, or earlier if so determined by the Chairman in consultation with the Commissioners, on the day preceding. ...'. In making this recommendation the Committee understood that Article III.2 of the Convention gives the Commission the power to determine its own rules of procedure. The Commission could decide to suspend this rule if appropriate.

In the Plenary, Australia proposed an amendment to give maximum flexibility to Commissioners, a position shared by Ireland. Denmark pointed out that the wording proposed by the Finance and Administration Committee had been agreed after lengthy discussions. Australia then suggested inserting the word 'normally' at the start of the proposed language and this was agreed. The revised text is shown in Appendix 20.

The Secretary pointed out that the time indicated was when documents were circulated to delegates, not the time they were received in the Secretariat. Spain and Denmark supported this view but France, USA and UK preferred the time to reflect when the document was handed in.

Australia suggested the Secretary should advise the appropriate time of submission at the start of each meeting to abide by this rule on a trial basis, and this was agreed by the Commission.

24.3.2 Interpretation of the Rules of Debate
The Secretary referred to the document he had prepared and a letter from the former Russian Commissioner noting that there has been a certain degree of confusion about the meaning and interpretation of the Commission's Rules of Debate and Procedure. It was agreed that the contents of the document as amended by the Committee should be incorporated in the Chairman's Report of the meeting as a guide for the future as follows:

To adjourn means to suspend for a certain length of time. To adjourn the session means, for example, to break the morning session to reconvene in the afternoon or possibly the next day. To adjourn the debate would normally mean deferring further debate on the particular subject under consideration until the next session of the meeting—e.g. example, a morning meeting could suspend discussion on the particular subject until the afternoon or the next day.

To close the debate means that it will not be reopened in the current meeting. This closure may be followed by a vote or another form of decision.

25. DATE AND PLACE OF ANNUAL MEETING
25.1 47th Annual Meeting, 1995
At the time of the meeting of the Finance and Administration Committee meeting no formal offer to host the 1995 meeting had been received. However, at the opening Plenary session of the Commission meeting the Government of Ireland announced that it is honoured to invite the member countries of the IWC and all interested organisations to Ireland for the 47th Annual Meeting, to be held in Dublin Castle in May 1995.

25.2 48th Annual Meeting, 1996
The Secretariat advised that at the time of the Committee meeting there had been no formal offer to host the 1996 Annual Meeting. As a precautionary measure, a United Kingdom venue had been tentatively booked for June 1996. At the opening Plenary Monaco indicated that it is currently studying very seriously the possibility of inviting the 48th Annual Meeting in 1996.

26. ADOPTION OF REPORT OF FINANCE AND ADMINISTRATION COMMITTEE
In adopting the report of the Finance and Administration Committee and endorsing all its recommendations, the Commission took note of the following additional matters.

26.1 Non-Governmental Organisation Observers
The Secretariat explained that with over 130 NGOs accredited to the organisation, some administrative difficulties were being experienced. Pressure was particularly intense immediately before the Annual Meeting. In order to be able to deal with the necessary administration in an orderly and timely fashion the Secretariat had prepared some suggested guidelines for consideration by the Commission this year. It recognised
that these were too late to be formally adopted. However, it hoped that, if appropriate, they could be endorsed for adoption in 1995 and that the Commission could direct the Secretariat to apply them in the preparations for the 1995 meeting.

26.1.1 Applications for Accreditation of new NGOs
The Secretariat suggested that Rule of Procedure C.1.b be amended so that a new NGO seeking accreditation to the IWC should submit its application 60 days prior to the start of the meeting (instead of 30 as at present). After clarification that the change was intended to apply only to new applications, the Committee recommended this amendment for formal adoption next year. It also agreed to recommend that the Commission should direct the Secretary to apply this procedure for the 1995 meeting.

26.1.2 Payment of NGO Fees
The Secretariat expressed concern about the failure of some NGO organisations to comply with its existing guidelines for payment of fees and suggested the setting of a condition that fees shall be payable no later than 30 days before the start of an Annual Meeting. The USA questioned whether the Secretariat did in fact experience sufficient inconvenience to warrant this change and requested that its reservation be noted. Brazil suggested that the Chairman of the Commission request greater cooperation in this regard from NGOs at the Commission meeting. If they did not improve their performance, further consideration should be given to the application of a surcharge on observers who failed to pay their registration fees on time. This was agreed.

Australia asked whether there was a due date for observer fees. The Secretariat said there was not. The Committee agreed that it would be appropriate to review the situation in the light of the response by NGOs to the request for cooperation and if the Secretariat continued to experience difficulties to consider the matter again next year.

26.1.3 NGO Interpreters
On the question of interpreters for NGOs, the Secretariat referred to potential problems as a result of limited space and continued growth in interest about IWC meetings. The Secretariat clarified that it was seeking guidance on how to address requests, rather than presenting a suggestion for adoption. Japan expressed concern with any suggestion for the imposition of limits on the entry of interpreters. The USA and Brazil agreed. The Finance and Administration Committee recommended that observers be allowed to have an interpreter accompany them, if necessary, but that if the potential difficulties were realised the matter should be raised again at that time.

26.2 Procedure for Calculating Financial Contributions – Allocation of Shares for whale-watching
Norway introduced its views, noting that this was a follow-up to its contribution to the whalewatching debate. Norway was aware that five countries paid fees based on their whaling activities, but that according to the 1993 IWC resolution on whale-watching over US$300 million was earned through whalewatching ventures. Norway considered this to be important as this level of income was of a magnitude greater than that from whaling itself. One positive element was the strong commercial aspect. Norway believed the Commission should consider whether it was appropriate for those with whalewatching activities to make an additional contribution to the Commission budget. It asked that this concern be noted in the report to the Commission so it might be given full consideration at a later stage.

The USA commented that this idea was intriguing only in that it provided evidence of Norway's view that whalewatching was an activity within the competence of the IWC, a view it fully shared. However, the current financial arrangements were carefully negotiated. If other factors were to be taken into account, these might include objections to the Schedule, small cetaceans catch, the take of whales for research purposes, etc. These were all very controversial. Accordingly the USA preferred the current arrangement and saw no reason to address this suggestion.

Australia agreed in principle with the USA, but disagreed about the reasons. Mexico, New Zealand and the UK also endorsed the USA's view. The UK added that it was premature to address this issue now as the IWC's role in respect of whalewatching was still developing and had yet to be agreed.

Japan said it would study Norway's proposal with interest and in the Plenary added that since whalewatching is clearly a commercial activity it should contribute fees to the Commission.

Norway emphasised that it wished only to raise rather than resolve the matter this year, and comments by Antigua and Barbuda, Argentina and Spain respectively on competence, fees and the need for further discussion were noted by the Commission.

26.3 Commission Resolutions
Australia asked whether it might be possible in future to number resolutions adopted by the Commission for ease of reference. The Chairman directed the Secretariat to consider the request, and the Secretary subsequently proposed that this could be readily achieved by using a reference of the form 'IWC Resolution 1994–1.'

27. REGISTER OF WHALING VESSELS
The Secretary noted that since 1980 the Register of Whaling Vessels has been drawn up and distributed annually. Last year amendments to the 8th edition were prepared and circulated. No new information has been received this year and, since the work is carried out on behalf of the Secretariat by a contractor who was prepared to carry on for one more year, should this be done?

Norway and Japan repeated their policy of not giving such data because of attacks on their vessels and Denmark confirmed that it will provide a revised list of Greenlandic vessels next year.

Australia proposed that this item should remain on the agenda because it has an intersection with the development of aspects of the Revised Management Scheme, but there was no need to do a lot more work. The UK concurred and this was agreed by the Commission.

28. WHALING ACTIVITIES BY NON-MEMBER COUNTRIES
Last year the Commission adopted a Resolution to obtain information on whaling by non-member countries and their reasons for remaining outside the IWC. A document
prepared by the Secretary on the few replies received was considered by the Commission.

Japan pointed out the effect of non-member whaling on stocks and the IWC's emphasis on protection rather than rational utilisation of whale resources.

Switzerland, Germany and France thought the exercise should be repeated, the latter noting the need to deal directly with authorities such as those in the Philippines. The UK, USA and New Zealand considered that Contracting Governments should help on a regional basis, while Argentina pointed to other, non-governmental avenues.

On the suggestion of the USA and UK, it was agreed to retain this item on the agenda for the next Annual Meeting.

29. 45TH ANNUAL REPORT
The draft 45th Annual Report of the Commission was approved, subject to amendments and updating.

30. ELECTION OF CHAIRMAN
On the proposal of the Netherlands, seconded by Argentina, Dr P. Bridgewater (Australia) was elected as Chairman of the Commission for the next three years.

31. ELECTION OF VICE-CHAIRMAN
Dr L. Botha (South Africa) was proposed by St Vincent and The Grenadines, seconded by Spain and elected as Vice-Chairman of the Commission.

32. ANY OTHER BUSINESS
Mexico intimated that it intends to propose the inclusion of an item ‘Operation of the 1946 Convention’ in the agenda for the 47th Annual Meeting. This would allow the IWC to gather and analyse relevant information related to the operation of the Convention, to assess the effects of the entry into force of UNCLOS on the Convention, and evaluate its conformity with the principles for conservation and sustainable utilisation of living marine resources adopted at UNCED and other fora.

At the conclusion of the meeting Dr P. Bridgewater thanked Dr Luis Fleischer for his Chairmanship over the past three difficult years, and his promotion of the maximum level of consensus in this body with often diametrically opposing views.

33. SCHEDULE AMENDMENTS
The amendments to the Schedule to the 1946 International Convention for the Regulation of Whaling adopted at the 46th Annual Meeting are shown in Appendix 21.

Appendix 1. IWC Resolution 1994—1
RESOLUTION ON THE USE OF THE ELECTRIC LANCE AS A SECONDARY METHOD OF KILLING WHALES

The International Whaling Commission:
AWARE that Article V.1(f) of the International Convention for the Regulation of Whaling provides that the Commission may amend the Schedule to prohibit or specify the types of gear and apparatus to be used in whaling operations;
RECALLING that the 1980 Workshop on Humane Killing Techniques for Whales (IWC/33/15) recommended that 'controlled studies be undertaken to determine the effect of electrocution' in order that electrical methods might be evaluated as a humane killing technique for whales;
RECALLING the discussion which took place during the 1992 Workshop on Whale Killing Methods convened by the Commission and the resulting Resolution on Humane Killing, adopted by consensus, approving an 11 point action plan as the basis for advice to members of the IWC; and that point 4 of the action plan is to ‘review effectiveness of secondary methods with a view to reducing time to death’;
NOTING the difficulties that have been identified in IWC discussions over a number of years over the effective application of the electric lance as a secondary method of killing whales; including the need for accurate placement of electrodes and a frequent need for multiple applications;
CONCERNED that the conclusions of preliminary research made available to the 46th IWC Annual Meeting indicated the probable ineffectiveness of the electric lance as a secondary killing method in modern whaling activities; and that the electric lance was accordingly not a humane method of secondary killing;
NOTING that no further data have yet been made available to assess times to death achieved by the use of the electric lance;
WELCOMING the discussion at IWC 46 on the electric lance and, in particular, the willingness expressed by participants to provide and exchange relevant information over the period prior to the 1995 Workshop on Humane Killing;
Now, THEREFORE;
CALLS upon member governments that use the electric lance, or have conducted studies on its efficacy as a secondary killing method, to exchange relevant information over the period prior to the Workshop on Humane Killing so that a thorough review of this method can be conducted at that time and decisions taken will be based on the best available information;
URGES member governments to submit all available information on the use of the electric lance as a secondary killing method to the Workshop on Humane Killing due to take place prior to the 47th Annual Meeting;

RECOMMENDS that acknowledged experts in matters relevant to discussion about the electric lance be invited to participate in the Workshop on Humane Killing and determines to find means of facilitating their involvement;

AGREES to consider, at its 47th Annual Meeting, in the light of the currently available information on the technique and its application, also the advice of the forthcoming Workshop on Humane Killing, recommending an alternative to the electric lance as a method of secondary killing;

CALLS upon member governments, in the meantime, to develop more satisfactory methods of killing whales which will lead to reduced times to death.

Appendix 2. IWC Resolution 1994—2

RESOLUTION ON SMALL CETACEANS

The International Whaling Commission:

AWARE of continued concern about adverse impacts on stocks of small cetaceans and the need for cooperation to conserve and restore threatened and depleted stocks;

RECALLING Resolutions IWC/42/26, IWC/43/29 and IWC/44/25 which recommend providing information to and continuing the work of the Scientific Committee with respect to inadequately documented or severely threatened stocks;

WELCOMING the helpful information and contributions provided by certain Governments on some species of small cetaceans;

CONSCIOUS of the sovereign rights of coastal states, as set out in the United Nations Convention on the Law of the Sea, and without prejudice to the different views of Contracting Governments on the IWC’s competence in relation to small cetaceans;

RECALLING that the 44th Annual Meeting set up a Working Group to Consider a Mechanism to Address Small Cetaceans in the Commission with a view to considering a consensual procedure for action on small cetaceans while respecting the differing views of Contracting Governments;

FURTHER RECALLING that Resolution IWC/45/29 referred to a mechanism for addressing small cetaceans in the IWC and identified topics on which to seek understanding for proceeding in these matters;

RECOGNISING that close contact and full participation from States in whose waters the relevant small cetaceans are found is a key element for the successful outcome of any efforts related to small cetaceans;

Now, THEREFORE, the Commission:

COMMENDS the Scientific Committee for its work to date on identifying the problems facing small cetacean species and advising on ways in which those threats can be eliminated or minimised;

ALSO COMMENDS the Working Group to Consider a Mechanism to Address Small Cetaceans in the Commission for its confidence-building effort towards setting up a consensual procedure under which to operate in regard to small cetaceans;

FURTHER COMMENDS those Contracting Governments which have taken actions to conserve small cetaceans;

INVITES all Contracting Governments to cooperate fully in the provision to the Scientific Committee of available information on direct takes, incidental takes, population estimates and threats to small cetaceans from degradation of the marine environment;

RECOMMENDS that efforts be made to continue to consider the problems facing small cetacean stocks, including reviewing developments on topics that have been addressed in the past, by

(a) engaging, with the assistance of the Secretary to the IWC, the coastal and range States concerned from the beginning in the current process of selecting stocks of small cetaceans for review;

(b) examining jointly with representatives from the coastal and range States concerned, sound and reliable scientific data obtained in full cooperation with those States;

(c) assessing the condition of stocks jointly with representatives from the coastal and range States concerned;

(d) identifying any kind of assistance required by the coastal and range States concerned;

REQUESTS the Working Group to Consider a Mechanism to Address Small Cetaceans in the Commission to continue its efforts to address issues in a consensual manner, identifying problems in close liaison with the Scientific Committee’s sub-committee on small cetaceans and to report to the Commission progress made at the 47th Annual Meeting;

REQUESTS the Scientific Committee to review its guidelines for the identification of stocks of small cetaceans for review at its future meetings, taking full account of the views of Contracting Governments expressed at the 46th Annual Meeting, and to present these, with any relevant explanatory information, to the Working Group to Consider a Mechanism to Address Small Cetaceans for consideration;

DECIDES to establish an IWC voluntary fund to allow for the participation from developing countries in future small cetaceans work and requests the Secretary to make arrangements for the creation of such a fund whereby contributions in cash and in kind can be registered and utilised by the Commission;
CALLS upon Contracting Governments and non-Contracting Governments, intergovernmental organisations and other entities as appropriate, in particular those most interested in scientific research on small cetaceans, to contribute to the IWC voluntary fund for small cetaceans; and AGREES that there is much benefit in maintaining a cooperative dialogue with other intergovernmental organisations with responsibility for or expertise in relation to small cetaceans, in particular UNEP and the bodies created under the Bonn Convention.

Appendix 3. IWC Resolution 1994—3

RESOLUTION ON BIOSPHERE RESERVE OF THE UPPER GULF OF CALIFORNIA AND THE COLORADO RIVER DELTA

AWARE that the vaquita, which is endemic to the Upper Gulf of California, is endangered and that the Scientific Committee reviewed the first quantitative estimate for this species and confirmed previous conclusions that it is very rare; RECOGNISING therefore, the need to ensure that the vaquita population is able to increase as rapidly as possible from its current low levels; WELCOMING the decision of the Mexican Government to establish the Technical Committee for the Protection of the Vaquita and the Totoaba, which has worked to further the conservation of the ecosystem within which the vaquita resides and has developed a plan for its recovery; AWARE of the vaquita’s small population size and current evidence that indicates that incidental catches could cause its extinction; RECOGNIZING that the Mexican Government should continue to monitor the fishing activity and incidental mortality of vaquita throughout the entire range of the species; AWARE OF the decision by the Mexican Government to restrict fishing operations in the core area of the ‘Biosphere Reserve’ and the immediate need to eliminate incidental catches of vaquita throughout the entire range of the species; and CONSCIOUS of the sovereign rights of Mexico within its coastal waters and of the socio-economic challenges facing local communities affected by the ban on drift-netting in those waters;

Now, THEREFORE, the Commission:

(1) CONGRATULATES AND COMMENDS the Mexican Government for the establishment of the ‘Biosphere Reserve’ in the Upper Gulf of California, established on June 10, 1993, by President Carlos Salinas de Gortari;
(2) FURTHER COMMENDS Mexico for applying an ecosystem approach to conservation in declaring that the ‘Biosphere Reserve’ includes the area’s fragile habitat as well as marine and terrestrial species;
(3) COMPLIMENTS Mexico for the successful efforts of the Technical Committee for the Protection of the Vaquita and the Totoaba, and for the information submitted on the National Research and Conservation activities during IWC 46;
(4) INVITES the Mexican Government to develop expeditiously an overall management plan for the ‘Biosphere Reserve’; and
(5) FURTHER INVITES IWC member nations to offer to the Mexican Government such technical, scientific and financial assistance on mutually agreed terms to implement the management plan.

Appendix 4. IWC Resolution 1994—4

RESOLUTION ON A REVIEW OF ABORIGINAL SUBSISTENCE MANAGEMENT PROCEDURES

WHEREAS at its 43rd, 44th and 45th Annual Meetings the Commission discussed a standing request from the Scientific Committee for guidance on a review of the current management procedures for aboriginal subsistence whaling;
WHEREAS the Commission has not yet responded to the Scientific Committee's request;
WHEREAS the Scientific Committee has substantially completed its scientific work on a Revised Management Procedure for commercial whaling;
WHEREAS the approach taken in the Revised Management Procedure may be applicable to the development of a new management procedure for aboriginal subsistence whaling;
WHEREAS paragraph 13 of the Schedule currently contains a footnote that seeks the advice of the Scientific Committee on minimum stock levels below which whales should not be taken, even to meet aboriginal subsistence need;
WHEREAS paragraph 13 of the Schedule lists three principles by which the Commission is to balance aboriginal subsistence need and protection of whale stocks;
WHEREAS the Commission accepted at its 34th Annual Meeting three broad management objectives for aboriginal subsistence whaling recommended by the 1982 ad hoc Technical Committee Working Group on Management Principles and Guidelines for Subsistence Catches of Whales by Indigenous (Aboriginal) Peoples;
The Commission RESOLVES that:

(1) The Scientific Committee should investigate potential management regimes for aboriginal subsistence whaling, including regimes based on the approach
taken in the Revised Management Procedure and utilising simulation trials where appropriate.

(2) The review conducted by the Scientific Committee should be based on the principles listed in sub-
paragraph 13(a) of the Schedule and shall also consider the footnote to that sub-paragraph, taking account of
any recent developments in conservation theory.

(3) The objectives of any potential regime shall continue
to be those accepted by the Commission at the 34th
Annual Meeting, which are to:
(a) ensure that the risks of extinction to individual
stocks are not seriously increased by subsistence
whaling;
(b) enable aboriginal people to harvest whales in
perpetuity at levels appropriate to their cultural
and nutritional requirements, subject to the other
objectives; and
(c) maintain the status of stocks at or above the
level giving the highest net recruitment and to
ensure that stocks below that level are moved
towards it, so far as the environment permits.

(4) Highest priority shall be accorded to the objective
of ensuring that the risk of extinction to individual
stocks are not seriously increased by subsistence
whaling.

Appendix 5. IWC Resolution 1994—5
RESOLUTION ON THE REVISED MANAGEMENT SCHEME

WHEREAS the International Convention for the
Regulation of Whaling recognises the interests of the
nations of the world in safeguarding for future generations
the great natural resources of the whale stocks;

WHEREAS the provisions of Schedule paragraphs
10(a) to 10(c) proved to be deficient in several important
respects as a framework for the management of whale
stocks;

WHEREAS the Commission as a consequence of these
deficiencies adopted paragraph 10(e) of the Schedule
establishing a moratorium on commercial whaling and
committed itself to the undertaking of a comprehensive
assessment of the effects of its decision;

WHEREAS the Commission, having considered the
advice of the Scientific Committee at its 44th Annual
Meeting adopted a Resolution (Rep. int. Whal. Commn 43:
40) which: (i) accepted Annex H, Draft Specification for
the Calculation of Catch Limits in a Revised Management
Procedure for Baleen Whales (Rep. int. Whal. Commn 43:
146–52); (ii) reaffirmed its agreement regarding the
conditions for any future implementation of the Revised
Management Scheme; and (iii) noted the additional steps
required to complete the Revised Management Scheme;

WHEREAS the Scientific Committee has reviewed and
subsequently revised the Draft Specification for the
Calculation of Catch Limits in a Revised Management
Procedure, resulting in substantial improvements in
clarity, and the finalised version is available as Annex H
(Rep. int. Whal. Commn 44:145–52);

WHEREAS the Scientific Committee has provided its
advice on minimum standards for data (Rep. int. Whal.
Commn 44:44–7) and guidelines for conducting surveys
and analysing the data (Annex J, Rep. int. Whal. Commn
44:168–74), as well as providing full documentation of the
program implementing the Catch Limit Algorithm
underlying the Revised Management Procedure (Rep. int.
Whal. Commn 44:44 and Annexes H and I, Rep. int. Whal.
Commn 44:145–67);

WHEREAS the Scientific Committee has now provided
its advice regarding the data which are required for
monitoring whale stocks subject to management within the
framework of the Revised Management Scheme (Annex
O, IWC/46/4);

WHEREAS the Scientific Committee and the
Commission have considered the findings and
recommendations of the Report of the NMFS Review of
the IWC Revised Management Procedure for Commercial
Whaling (IWC/46/24);

WHEREAS the Commission has been informed of the
significant under-reporting of whale catches by the Union
of Soviet Socialist Republics, including substantial
numbers of blue, humpback and right whales;

WHEREAS the Commission at its 45th Annual
Meeting adopted a Resolution on research on the
environment and whale stocks which calls for the
convening of a special Scientific Committee workshop to
consider the effects of environmental changes on
cetaceans in order to provide the best scientific advice for
the Commission to determine appropriate response
strategies to these new challenges;

Now, THEREFORE, the Commission:

(1) EXPRESSES its appreciation for the work of the
Scientific Committee in completing the Revised
Management Procedure, its specification and
documentation, and consideration of associated
scientific issues;

(2) WELCOMES the full documentation of the
program which implements the Catch Limit Algorithm
underlying the Revised Management Procedure;

(3) ACCEPTS that the specification of the Revised
Whal. Commn 44:145–52) including its attached
annotations as amended by Annex N (IWC/46/4) and
completes the main scientific component in the
development of a Revised Management Scheme for
commercial baleen whaling;

(4) NOTES that this specification should not be
modified, reconfigured or adjusted unless expressly
instructed by the Commission;

(5) ENDORSES the ‘Guidelines for Conducting Surveys
and Analysing Data within the Revised Management
Scheme’ given in Annex J (Rep. int. Whal. Commn
44:168–74) subject to any revision arising from the
completion of outstanding work specified in Annex P
and Annex H of IWC/46/4;

(6) FURTHER ENDORSES the ‘Guidelines for data
collection and analysis under the Revised
Management Scheme other than those required as
direct input to the *Catch Limit Algorithm* given in Annex O (IWC/46/4);

(7) NOTES the Scientific Committee's agreement that all points raised by Committee meeting documents which dealt with concerns arising from the NMFS review of the Revised Management Procedure had been adequately addressed;

(8) ASKS that the Secretary, with the assistance of the Scientific Committee, thoroughly investigate past catch data and that the Scientific Committee evaluate implications of these findings during the implementation simulation trials for each relevant species/area;

(9) NOTES that the additional steps required to complete the Revised Management Scheme include agreement on:

(i) an effective inspection and observation scheme which fully addresses *inter alia* the issues of under-reporting and mis-reporting of catches;

(ii) further elaboration of the 'Guidelines for conducting vessel surveys and analysing data within the Revised Management Scheme' given in Annex J (Rep. int. Whal. Commn 44:168–74), as endorsed by the Commission, to ensure adequate levels of international collaboration in the survey design, conduct and analysis;

(iii) arrangements to ensure that the total catches over time are within the limits set under the Revised Management Scheme;

(iv) incorporation into the Schedule of the specification of the Revised Management Procedure and the other elements of the Revised Management Scheme;

(10) While NOTING the advice of the Scientific Committee that there would be little advantage in modifying the *Catch Limit Algorithm* further to account for environmental change, CONSIDERS that results emanating from the Scientific Committee's planned workshops on chemical pollution and climate change may nevertheless have an impact on other elements of the RMS and the Comprehensive Assessment;

(11) AGREES that the Revised Management Scheme shall be structured so that:

(i) commercial whaling shall only be permitted for populations in areas and seasons for which catch limits are in force;

(ii) these catch limits shall have been calculated by the Scientific Committee in accordance with the Revised Management Procedure and forwarded to, and approved by the Commission in conformity with all provisions of the Revised Management Scheme; and

(iii) commercial catch limits for all other populations in all areas and seasons shall be zero;

(12) REAFFIRMS that until all aspects of the Revised Management Scheme are incorporated into the Schedule the Revised Management Procedure should not be implemented; and

(13) CONFIRMS that nothing in this Resolution shall be deemed to authorise or give any form of approval to any activity that is contrary to the moratorium on commercial whaling (contained in paragraph 10(e) of the Schedule) or any sanctuary established in accordance with the International Convention for the Regulation of Whaling.

---

Appendix 6. IWC Resolution 1994—6

RESOLUTION ON THE UNRELIABILITY OF PAST WHALING DATA

AWARE that concerns have been raised for many years about under reporting of commercial whale catches;

NOTING the importance of having complete historical catch data available for the proper implementation of the RMP;

NOTING that earlier this year a Russian Federation official published a report which stated that past whaling statistics submitted by the former Union of Soviet Socialist Republics were unreliable in many aspects; and

NOTING that the Russian Federation has made available to the Scientific Committee in 1994 previously unreported data on past Soviet whaling operations in the Southern Hemisphere;

Now, THEREFORE, the Commission:

(1) CONGRATulates and COMMENDS the Government of the Russian Federation for its efforts to locate original catch records from past Soviet whaling activities and to provide these records to the IWC;

(2) URGES the Government of the Russian Federation to continue its efforts to secure and provide to the IWC any additional original catch and positional data from past Soviet catches as may be available and authorises the Secretariat to provide necessary assistance from voluntary funds for this project;

(3) INVITES any other IWC Contracting Governments to examine data on their past whaling operations for inaccuracies or falsification and to provide any revised data to the Commission.

---

Appendix 7. IWC Resolution 1994—7

RESOLUTION ON INTERNATIONAL TRADE IN WHALE MEAT AND PRODUCTS

WHEREAS it is the purpose of the 1946 International Convention for the Regulation of Whaling (ICRW) to provide for the effective conservation and management of whale stocks through a coherent system of international regulation;

WHEREAS the International Whaling Commission is
the universally recognised competent international organisation responsible for the management of whales and whaling;

WHEREAS the Commission’s Resolution at its 31st Annual Meeting (Rep. int. Whal. Commn 30: 38) and prior Resolutions, declared that member States should not import whale products from non-member States;

WHEREAS at a Special Meeting in Tokyo in 1978, the Commission recognised that, to reinforce adherence to IWC regulations, it is desirable to use each international opportunity to ban trade in those species and stocks of whales that receive total protection from commercial whaling;

WHEREAS at the Special Meeting, the Commission requested the Second Meeting of the Conference of the Parties to the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) to take all possible measures to support the IWC ban on commercial whaling for certain species and stocks of whales, as provided in the Schedule to the ICRW;

WHEREAS at the Special Meeting, the Commission resolved that each Contracting Government take all appropriate measures to prevent the import of any whale or whale product taken or processed under the jurisdiction of any non-IWC member countries;

WHEREAS in 1979, CITES recognised that the meat and other products of protected stocks of whales are subject to international trade that cannot be controlled effectively by the IWC alone;

WHEREAS in 1979, the Second Meeting of the Conference of the Parties recommended that CITES Parties agree not to issue for primarily commercial purposes any import or export permit, or certificate for introduction from the sea, for any specimen of a species or stock protected from commercial whaling by the ICRW;

WHEREAS at its Annual Meeting in 1982, the Commission set catch limits for the killing for commercial purposes of whales from all stocks for the 1985 coastal and the 1985–86 pelagic seasons at zero, which catch limits remain in effect under paragraph 10(e) of the ICRW Schedule;

WHEREAS under CITES there is a prohibition on commercial trade, including introduction from the sea, in all stocks of whales for which the IWC has set zero catch limits;

WHEREAS at its Annual Meeting in 1986, the Commission resolved that the products of research whaling should be used ‘primarily for local consumption’;

WHEREAS the Commission is concerned by reports of the discovery of whale products appearing for sale in, or en route to, importing countries, from no plausible legitimate source;

WHEREAS the Commission in 1993 sought information on possible illegal whaling activities by non-member governments, and is concerned to prevent such activities and the trade in whale products derived from such activities;

Now, THEREFORE, the International Whaling Commission:

(1) CALLS UPON all IWC members to enforce strictly their existing international obligations under the ICRW, including fully complying with the moratorium on commercial whaling declared in paragraph 10(e) of the Schedule and under CITES, relating to the control of international trade in whale products.

(2) REAFFIRMS the need for Contracting Governments fully to observe earlier IWC resolutions addressing trade questions, particularly resolutions prohibiting the import of any whale or whale product taken or processed under the jurisdiction of any non-IWC member countries;

(3) OBSERVES that any commercial international trade in whale products obtained from research whaling or fisheries bycatch makes illegal commerce more difficult to detect and undermines the effectiveness of the IWC’s conservation program;

(4) CONSIDERS, THEREFORE, that meat and products from research whaling should be utilised entirely for domestic consumption; and

(5) INVITES each Contracting Government to report to the Infractions Sub-committee at every Annual Meeting:

(a) information on whale meat and products available on its domestic market and the specific source of those items (i.e., commercial whaling, research whaling, fisheries bycatch);

(b) any shipments of whale meat and products intercepted in international commerce, especially those involving their nationals or interests, and what measures the Government has taken in response; and

(c) any other developments relevant to trade in whale meat or products (e.g., new laws or regulations).

Appendix 8

RECOMMENDATIONS TO THE COMMISSION BY THE NORFOLK ISLAND INTERSESSIONAL MEETING OF THE WORKING GROUP ON A SANCTUARY IN THE SOUTHERN OCEAN

The Working Group recommended to the Commission that:

(1) It reinforces the cooperation and coordination with the Antarctic Treaty System, in particular, the Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR), the United Nations Environment Programme (UNEP) and other relevant international organisations.

(2) Bearing in mind their special responsibility, as recognised by the United Nations Convention on the Law of the Sea (UNCLOS) provisions, the States that may have maritime areas under their jurisdiction within the boundaries which may be decided for a sanctuary, take for these areas the appropriate measures in conformity with the provisions relating to a sanctuary.
(3) The IWC Scientific Committee (SC) continues to provide the Commission with precisely requested scientific advice on issues related to a sanctuary in the Southern Ocean.

(4) It notes that existing international instruments do not form any irreconcilable legal impediment to the designation of a whale sanctuary in the Southern Ocean.

(5) The establishment of a sanctuary in the Southern Ocean requires commonly-agreed objectives. Such a sanctuary, if established, could provide an opportunity to members of the IWC to promote further research activities in the Southern Ocean and, with the advice of the Scientific Committee, stimulate co-ordination thereon with other relevant international organisations on the following issues:
   (a) linkages between a sanctuary and the need for the scientific research in it, in particular the type of research needed, who will undertake it and the level of expenses to be met;
   (b) to monitor and compare the management of whale stocks to which an RMS may be applied with a situation where no whale catch would occur.

(6) Recognising the need for broader understanding of environmental changes in the Southern Ocean which may have emerged since the implementation of the moratorium and which have yet to be assessed by the Commission, the Commission re-visits the Resolution of the 44th Annual Meeting, passed by consensus, on the need for further research on environmental threats affecting whale stocks in the Antarctic marine ecosystem (Rep. Int. Whal. Commn 43: 39–40).

Member states should commence exchange of research, on-going or completed, on environmental changes in the Southern Ocean and the Commission should seek financial support from those contracting governments able to contribute funds for the coordination of such research. UNEP should be encouraged to continue exploring with the IWC appropriate funding and research coordination mechanisms. Furthermore, the Commission should apply the precautionary principle in discussions regarding a Southern Ocean Sanctuary and act in a risk-averse manner in future decisions concerning the management of whales therein.

(7) In the light of a number of specific ecological issues requiring clarification, the SC continues to study and gives guidance to the Commission concerning, inter alia, the following:
   (a) areas of specific whale activity, e.g. feeding and breeding grounds and the length of stay in any area;
   (b) north-south migrations between feeding and breeding areas;
   (c) east-west migrations for information on the possibility of significant movements between major ocean basins and populations;
   (d) species interaction including inter-species competition;
   (e) global environmental and abiotic factors affecting whales in the Southern Ocean.

(8) If it were to adopt a sanctuary which includes waters under coastal states jurisdiction, it ensures that the sovereign rights and all other rights of the coastal states as recognised in UNCLOS will be respected in such a sanctuary.

(9) It further examines options for the geographical boundaries of a sanctuary in the Southern Ocean.

(10) Bearing in mind the special legal and political status of Antarctica, it closely cooperates with the Antarctic Treaty System as regards a sanctuary in the Southern Ocean.

(11) It reaches common understandings, inter alia, on the following issues:
   (a) the necessity and level of any additional resources for meeting the costs of management, monitoring and surveillance requirements in a sanctuary;
   (b) financial options for providing any such resources.

(12) It considers the possibility of convening a legal panel on matters related to a sanctuary.

(13) It re-examines the status of its participation in the Marine Mammal Action Plan developed jointly by UNEP and FAO.

(14) It welcomes the willingness of the Russian Federation in response to a request by the Working Group to submit to the Secretariat of the IWC updated statistical data on the USSR’s whale catches.

(15) It notes that there are no irreconcilable objections to establishing a sanctuary in conformity with Article V of the 1946 Convention among the members of the Working Group and that a sanctuary can be created by the Commission if its members so decide.

Appendix 9. IWC Resolution 1994—8

RESOLUTION ON SCIENTIFIC PERMITS

RECALLING that the Scientific Committee is charged with the task of reviewing the performance of scientific research programmes;

NOTING that the research programme to clarify the stock structure of minke whales in the northwestern Pacific (SC/46/NP1) has been reviewed by the Scientific Committee;

NOTING FURTHER that the full Scientific Committee agreed that all relevant guidelines concerning the proposal, its objectives and research cooperation have been met and that some questions were raised whether the methodology of the programmes was in accordance with the relevant guidelines (IWC/46/4);

NOW, THEREFORE, the Commission:

ENDORSES the review of the Scientific Committee of the research programme to clarify the stock structure of minke whales in the northwestern Pacific.

Brandon
RESOLUTION ON SPECIAL PERMIT CATCHES BY JAPAN IN THE NORTH PACIFIC

WHEREAS the Commission has encouraged Contracting Governments to base their research programmes to the maximum extent possible on non-lethal methods (Rep. int. Whal. Commn 40:70);

WHEREAS the Commission recognises the past efforts by Japan in research on whales in the North Pacific, which do not involve the taking of whales;

WHEREAS the Commission has considered the Report of the Scientific Committee (IWC/46/4) concerning the proposed catch of minke whales described in SC/46/NP1;

WHEREAS the Commission acknowledges that the Scientific Committee has agreed that the objectives of the research proposal directly address questions of scientific interest; and at the same time the Commission notes that these questions could also be addressed by non-lethal methods using biopsy sampling and DNA-analyses;

WHEREAS the Commission takes cognisance of Article VIII of the International Convention for the Regulation of Whaling, under which the granting by any Contracting Government to its nationals of a Special Permit authorising the killing, taking or treatment of whales for purposes of scientific research remains the responsibility of each Contracting Government, exercising its sovereign rights in respect of maritime areas under its jurisdiction and freedom of the high seas;

Now, THEREFORE, the Commission:

CONSIDERS taking into account the comments in the Report of the Scientific Committee (IWC/46/4), that the proposed kill of minke whales in the North Pacific described in SC/46/NP1 does not fully satisfy the criteria specified in both the 1986 Resolution on Special Permits for Scientific Research and the 1987 Resolution on Scientific Research Programmes;

RECOMMENDS the Government of Japan to restructure its research programme concerning minke whales in the North Pacific in such a manner that the research interests are adequately addressed with non-lethal methods;

INVITES the Government of Japan to reconsider the proposed research take of minke whales in the North Pacific under special permit in 1994 in the light of the above.

RESOLUTION ON SPECIAL PERMIT CATCHES BY JAPAN IN THE SOUTHERN HEMISPHERE

WHEREAS the Commission has considered the Report of the Scientific Committee (IWC/46/4) concerning the results of the Japanese catches of minke whales in the Southern Hemisphere described in SC/46/SH11, 12, 13, 14, 15, 20 and O24, the proposed catch in 1994/95 described in SC/42/SH16, and the responses of the Government of Japan to earlier criticisms of the research programme arising in the Scientific Committee's reports (IWC/39/4; Report of Special Meeting Cambridge 1987, IWC/40/4 and IWC/41/4, IWC/42/4, IWC/43/4 and IWC/44/4);

WHEREAS the Commission has encouraged Contracting Governments to base their research programmes to the maximum extent possible on non-lethal methods (Rep. int. Whal. Commn 40:70) and the Government of Japan has made important contributions to the development of non-lethal whale population assessments methods, especially under the IWC/IDCR programme of Southern Hemisphere Minke Whale Assessment Cruises;

WHEREAS the Government of Japan, through its various modifications to the original research programme, including those outlined in SC/46/SH16 has attempted to address the concerns expressed by the Scientific Committee in its earlier reports;

WHEREAS Japan has not provided any information which adequately addresses the concerns expressed in the Scientific Committee on the ability to estimate the age specific mortality of Southern Hemisphere minke whales;

WHEREAS the Commission takes cognisance of Article VIII of the International Convention for the Regulation of Whaling, under which the granting by any Contracting Government to its nationals of a Special Permit authorising the killing, taking or treatment of whales for purposes of scientific research remains the responsibility of each Contracting Government, exercising its sovereign rights in respect of maritime areas under its jurisdiction and freedom of the high seas;

Now, THEREFORE, the Commission:

CONSIDERS taking into account the comments of the Scientific Committee, that the proposed kill of minke whales in the Southern Hemisphere described in SC/46/SH16 does not fully satisfy the criteria specified in both the 1986 Resolution on Special Permits for Scientific Research and the 1987 Resolution on Scientific Research Programmes in that the proposed research is not structured so as to contribute information presently required for the management of whaling in these areas for this species, though it addresses certain research interests;

RECALLS that each of its previous resolutions on the catches under Special Permit under this research programme, which have expressed similar conclusions, has not produced the required restructuring of the scientific research programme;

INVITES the Government of Japan to reconsider the proposed research take of minke whales under special permit in 1994/95 in the light of the above;

RECOMMENDS the Government of Japan to restructure its research programme concerning minke whales in the Southern Hemisphere in such a manner that the research interests can be adequately addressed with non-lethal methods.
RESOLUTION ON SPECIAL PERMIT CATCHES BY NORWAY

WHEREAS the Commission adopted a Resolution on a Norwegian proposal for special permits in 1993, inviting the Government of Norway to reconsider its proposed take of minke whales in 1993 and 1994 under special permit (Rep. int. Whal. Comm. 44, Appendix 8);

WHEREAS the Commission has considered the Report of the Scientific Committee IWC/46/4 concerning the results of the Norwegian catches of minke whales in the North Atlantic described in SC/46/NA2 and 3, and the proposed catch in 1994 described in SC/46/NA3;

WHEREAS the Commission recognises the past efforts by Norway in research on whales and investigation of their habitat which do not involve the taking of whales;

WHEREAS the Commission takes cognisance of Article VIII of the International Convention for the Regulation of Whaling, under which the granting by any Contracting Government to its nationals of a Special Permit authorising the killing, taking or treatment of whales for purposes of scientific research remains the responsibility of each Contracting Government, exercising its sovereign rights in respect of maritime areas under its jurisdiction and freedom of the high seas;

Now, THEREFORE, the Commission:

CONSIDERS taking into account the comments of the Scientific Committee (IWC/45/4 and IWC/46/4); that the proposed kill of minke whales in the North Atlantic described in SC/46/NA3 and SC/46/NA5 does not fully satisfy the criteria specified in both the 1986 Resolution on Special Permits for Scientific Research and the 1987 Resolution on Scientific Research Programmes, in that the proposed research is not structured so as to contribute information presently required for the management of whaling in these areas for this species;

REITERATES its invitation to the Government of Norway to reconsider the proposed research take of minke whales under special permit in 1994 in the light of the above;

WELCOMES the decision of the Government of Norway not to issue special permits in 1995 and expresses its strong hope that it will be possible for Norway to continue its research programme through non-lethal methods.

RESOLUTION ON PROMOTION OF RESEARCH RELATED TO CONSERVATION OF LARGE BALEEN WHALES IN THE SOUTHERN OCEANS

WHEREAS the Commission passed a Resolution on Research Related to Conservation of Large Baleen Whales in the Southern Oceans at the 45th Annual Meeting requesting the Scientific Committee to provide an outline of objectives, methodologies, chances of success and short and long term financial implications;

NOTING that an intersessional meeting of the Steering Group on such research based on the above mentioned Resolution was held in Tokyo last October, and reported to the Scientific Committee so as to facilitate its work, including suggestions for possible objectives and a possible sequence of work;

NOTING public concern regarding the status of the populations of large baleen whales, especially after the under-reporting of whale catches by former Soviet whaling fleets in the Southern Hemisphere; and

RECOGNISING the increasing concerns of the need for research on the effects of environmental changes on whale resources by Resolution passed at the 45th Annual Meeting of the Commission:

NOTING that Japan plans a sighting survey cruise for blue and Bryde’s whales in the waters of the Solomon Islands in September and October 1994;

Now, THEREFORE, the Commission:

APPROVES the objectives and sequence of work suggested by the Steering Group in 1994 and discussed by the Scientific Committee at the 46th Annual Meeting in so far as they do not require lethal methods;

REQUESTS the Chairman of the Scientific Committee in collaboration with the Secretary of the Commission to establish an intersessional correspondence group to clarify and initiate the preparatory work on the research items identified in Annex L of IWC/46/4;

REQUESTING that group to meet as a Steering Committee prior to next year’s meeting of the Scientific Committee as may be deemed necessary to consolidate their work;

FURTHER REQUESTS that the group consider among other items:

(a) the practical and financial implication of using passive, towed acoustic arrays to expand the search path width for sighting surveys of blue, pygmy blue and other whales;

(b) ways in which work can commence on developing shipboard identification methods to separate true from pygmy blue whales;

(c) the practical and financial implications of using satellite tracking to locate feeding and breeding grounds for blue whales and compile a summary of relevant applications and development work.

REQUESTS the Scientific Committee to prepare a discussion paper of these topics for presentation to the Commission at its 47th Annual Meeting with the objective of gaining Commission approval and financial support for research programme implementation in 1995/96;

AGREES that the Secretariat shall allocate no more than £10,000 in the 1994/95 budget for the work of the intersessional working group; and

ENCOURAGES all Contracting Governments to structure their own national research projects related to this subject so as to contribute to any approved research programme.
RESOLUTION ON RESEARCH ON THE ENVIRONMENT AND WHALE STOCKS

RECALLING that at its 44th Annual Meeting, the Commission adopted a Resolution on the need for research on the environment and whale stocks which established a regular agenda item in the Scientific Committee to address the impact of environmental changes upon whale stocks;

RECALLING that at its 45th Annual Meeting, the Commission adopted a Resolution recommending the Scientific Committee give priority to research on the effects of environmental changes on cetaceans in order to provide the best scientific advice to the Commission to determine appropriate response strategies to these new challenges;

FURTHER RECALLING that at its 45th Annual Meeting, the Commission reiterated its concern for the impact of pollutants in the marine environment by adopting a Resolution on the Preservation of the Marine Environment;

WELCOMING the information and data received from Contracting Governments, relevant international organisations, scientists and other experts, on changes in the marine environment and their effects on whale populations, that was presented to the Scientific Committee in 1994;

NOTING FURTHER that the Scientific Committee focused on several factors on environmental changes to be considered in the context of cetaceans including (1) global warming; (2) ozone depletion; (3) pollution; (4) direct (international and incidental mortality) and indirect (ecological ramifications) effects of fisheries; and (5) noise; and

NOTING TOO that the Scientific Committee agreed all these factors warrant consideration and that there should be two workshops, one on pollution, to be convened before the 47th Annual Meeting and a second on the effects of global warming and ozone depletion before the 48th Annual Meeting, with further consideration of other factors occurring at least initially in the context of Annual Meetings;

NOTING ALSO that the Scientific Committee at the 46th Annual Meeting concluded that it should focus its attention on addressing the questions of environmental influences in their own right and not merely in the context of catch limits;

The Commission DECIDES:

(1) to endorse the plans of the Scientific Committee to pursue study on environmental changes and their impacts on cetaceans;

(2) to encourage Contracting Governments to continue to cooperate in providing available information on environmental changes as identified above and their known or potential ecological effects on cetaceans to the workshops;

(3) to reaffirm that Contracting Governments should encourage participation of individuals with relevant expertise on the factors identified above, in the Special Workshop and at the Scientific Committee; and

(4) to accept the recommendation in the Scientific Committee report that the focus of the workshop on the effects of environmental changes on cetaceans should be to identify research activities that might enable the eventual prediction of the effects of factors both direct and indirect on cetaceans and incorporate such knowledge into conservation and management programmes for cetaceans.

Appendix 15. IWC Resolution 1994—14

RESOLUTION ON WHALEWATCHING

The International Whaling Commission:

RECALLING its Resolution adopted by consensus at the 45th Annual Meeting inviting Contracting Governments to report on the extent and value of whalewatching activities; requesting the Secretariat to prepare a report; and establishing a Working Group to make recommendations to its 46th Annual Meeting;

GRATEFUL for the returns made by contracting parties and the work of the Secretariat in compiling a report from them;

DESIRING to encourage the further development of whalewatching as a sustainable use of cetacean resources;

ACKNOWLEDGING, however, that the regulation of whalewatching activities is a matter for the responsible coastal state, rather than for the Commission;

RECOGNISING, nevertheless, that the Commission can provide advice to member and non-member governments on the regulation of whalewatching and on the collection of useful data from whalewatching operations;

NOTING the useful and productive discussions which took place at the Working Group prior to the 46th Annual Meeting, and the recommendations made by that Group to the Commission:

Now, THEREFORE, the Commission:

(1) REQUESTS all contracting parties who have not yet submitted the information requested by the Commission on whalewatching operations in their territories to report this information to the Commission;

(2) REQUESTS the Scientific Committee to provide the advice sought by the Working Group

(3) REQUESTS Contracting Governments to submit additional relevant information to the Scientific Committee to assist in their deliberations, and where necessary to send appropriate experts to the Committee in this regard;

(4) REQUESTS the Working Group to take account of the Scientific Committee’s advice to prepare a framework for future guidelines, which could be considered by coastal states developing regulatory
frameworks for whalewatching, and to make an interim report to the 47th Annual Meeting with a view to finalising recommendations for such guidelines for adoption at a subsequent meeting.

(5) ALSO REQUESTS the Working Group to keep under review developments relating to all aspects of whalewatching, under the Commission's responsibilities.

Appendix 17

Amendments to the RULES OF PROCEDURE OF THE SCIENTIFIC COMMITTEE

Delete A.7

D. Meetings
1. Meetings of the Scientific Committee as used in the paragraphs above these rules include all meetings of subgroups of the Committee, e.g. sub-committees, workshops, etc. [old A.7 amended]
[Renumber existing D.1 – D.3]

E. Scientific Papers and Documents
Delete E.6 and renumber following paragraph.

7. Publication of Scientific Papers and Reports Primary scientific papers and reports shall be included in the Commission’s archives in the form in which they were considered by the Committee or its sub-committees.
Documents submitted to or developed at Reports of the meetings of the Scientific Committee shall be available outside the Commission after distribution to the Commission. on demand immediately after the meetings unless authors indicate otherwise. Except that They are strictly confidential prior to that time. In particular, the
Report of the Annual Meeting of the Scientific Committee shall be available at the time of the opening plenary of the Commission meeting.

Scientific papers and reports (revised as necessary) may be selected for publication and will be selectively included in the Committee Report published by the Commission. The Secretariat, with the concurrence of the Scientific Committee, shall issue guidelines for the technical revision of the papers or reports. Papers shall be subject to peer review before publication.

Appendix 18

Amendments to the RULES OF PROCEDURE [OF THE COMMISSION]

(old language struck-out, new language in italic)

E. Voting

[Note that existing paragraph E.3 is now sub-divided as follows]

3. (a) Where a vote is taken on any matter before the Commission, a simple majority of those casting an affirmative or negative vote shall be decisive, except that a three-fourths majority of those casting an affirmative or negative vote shall be required for action in pursuance of Article V of the Convention.

(b) Action in pursuance of Article V shall contain the text of the regulations proposed to amend the Schedule. A proposal that does not contain such regulatory text does not constitute an amendment to the Schedule and therefore requires only a simple majority vote. A proposal that does not contain such regulatory text to revise the Schedule but would commit the Commission to amend the Schedule in the future can neither be put to a vote nor adopted.

(c) At meetings of committees appointed by the Commission, a simple majority of those casting an affirmative or negative vote shall also be decisive. The Committee shall report to the Commission all cases in which the decision has been arrived at as a result of the vote.

(d) Votes shall be taken by show of hands, or by roll call, as in the opinion of the Chairman, appears to be most suitable.

M. Committees

1. The Commission shall establish a Scientific Committee, a Technical Committee and a Finance and Administration Committee. At each meeting of the Commission, the Chairman shall poll the Commissioners shall notify their desire to be represented to determine if they desire representation on the Scientific, and Technical Committees and Finance and Administration Committees 28 days prior to the meetings, and the Commissioners shall designate the approximate size of their delegations their members. The Finance and Administration Committee shall consist of five Commissioners appointed by the Chairman.

2. The Chairman may constitute such ad hoc Committees as may be necessary from time to time, with similar arrangements for notification of the numbers of participants as in paragraph 1 above where appropriate. Each Committee shall elect its Chairman. The Secretary shall furnish appropriate secretarial services to each Committee.

Add Rule to follow present Rule P as a new Q - Commission documents

1. Reports of all Committees, Sub-committees and Working Groups are strictly confidential until the opening plenary session of the Commission meeting to which they are submitted.

2. Reports of intersessional meetings are similarly confidential until they have been distributed by posted to Commissioners and Contracting Governments.

3. Any document submitted to the Commission for distribution to Commissioners, Contracting Governments or members of the Scientific Committee is considered to be in the public domain unless it is designated by the author or government submitting it to be restricted. Such restrictions are automatically lifted when the report of the meeting to which it is submitted becomes publicly available under 1. above.

4. All meeting documents shall be included in the Commission's archives in the form in which they were considered at the meeting.

[Renumber Rule Q as R]

Appendix 19

AMENDMENTS TO THE FINANCIAL REGULATIONS

(Old language struck-out, new language in italics)

E. Contributions

2. Payment shall be in pounds sterling, drafts being made payable to the International Whaling Commission and shall be deemed to be payable within 90 days of the said request from the Secretary or by the following 28 February, the 'due date' whichever is the later. It shall
be open to any Contracting Government to postpone the payment of any increased portion which shall be payable in full by the following 31 August, which then becomes the ‘due date’.

F. Arrears of Contributions
1. If a Contracting Government’s annual payments have not been received by the Commission by the due date referred to under Regulation E.2 compound interest shall be added to the outstanding annual payment at a rate of 10% per annum with effect from the following March day following the due date and thereafter on the anniversary of that day. The interest, calculated to the nearest pound, shall be payable in respect of complete years and continue to be payable in respect of any outstanding balance until such time as the amount in arrears, including interest, is settled in full.

Appendix 20

Amendment to the RULES OF DEBATE
(new language in italics)

Amend Rule of Debate B.1 to read:

1. Proposals and amendments shall normally be introduced in writing in the working language of the meeting and shall be submitted to the Secretariat which shall circulate copies to all delegations in the session. As a general rule, no proposal shall be discussed at any plenary session unless copies of it have been circulated to all delegations normally no later than 6pm, or earlier if so determined by the Chairman in consultation with the Commissioners, on the day preceding the plenary session. The presiding officer may, however, permit the discussion and consideration of amendments, or motions, as to procedure, even though such amendments, or motions have not been circulated previously.

Appendix 21

AMENDMENTS TO THE SCHEDULE

At its 46th Annual Meeting held in Puerto Vallarta, Mexico, 23–27 May 1994, the International Whaling Commission adopted the following amendments to the Schedule (changes in bold type):

1. Designate existing paragraph 7 as sub-paragraph 7(a), and add the following sub-paragraph:
   (b) In accordance with Article V(1)(c) of the Convention, commercial whaling, whether by pelagic operations or from land stations, is prohibited in a region designated as the Southern Ocean Sanctuary. This Sanctuary comprises the waters of the Southern Hemisphere southwards of the following line: starting from 40 degrees S, 50 degrees W; thence due east to 20 degrees E; thence south to 55 degrees S; thence due east to 130 degrees E; thence due north to 40 degrees S; thence due east to 130 degrees W; thence due south to 60 degrees S; thence due east to 50 degrees W; thence due north to the point of beginning. This prohibition applies irrespective of the conservation status of balaen and toothed whale stocks in this Sanctuary, as may from time to time be determined by the Commission. However, this prohibition shall be reviewed ten years after its initial adoption and at succeeding ten year intervals, and could be revised at such times by the Commission. Nothing in this sub-paragraph is intended to prejudice the special legal and political status of Antarctica.

2. Amend sub-paragraph 13(b)(1)(i) to read:
   (i) For the years 1995, 1996, 1997 and 1998, the number of bowhead whales landed shall not exceed 204, and the number of bowhead whales struck shall not exceed 68 in 1995, 67 in 1996, 66 in 1997 and 65 in 1998, except that any unused portion of the strike quota for each year shall be carried forward from that year and added to the strike quota of any subsequent years, provided that no more than 10 strikes shall be added to the strike quota for any one year.

3. Amend paragraph 13(b)(2)(i) to read:
   (i) The number of gray whales taken in accordance with this sub-paragraph in each of the years 1995, 1996 and 1997 shall not exceed the limit shown in Table 1.

4. Amend Table 1 for the North Pacific Eastern Stock of gray whales so that the catch limit is 140 with the same footnote.

5. Amend Table 1 so that for West Greenland fin whales: the number in Table 1 is changed to 19, with a footnote 2) reading:

2Available to be taken by aborigines pursuant to paragraph 13(b)3. Catch limit for each of the years 1995, 1996 and 1997.

6. Amend Table 1 so that the North Atlantic central stock of minke whales has a footnote 2) which reads as above.

7. Amend paragraph 13(b)(3)(ii) to read:
   (ii) For each of the years 1995, 1996 and 1997, the number of minke whales struck from the West Greenland stock shall not exceed 165, and the total number of whales struck shall not exceed 465 in these three years.

8. Revise paragraphs 11 and 12, and Tables 1, 2 and 3: by substitution of the dates 1994/95 pelagic season, 1995 coastal season, 1995 season, or 1995 as appropriate.
Report of the Scientific Committee
Report of the Scientific Committee

The Committee met at the Marriott Casa Magna Hotel, Puerto Vallarta, Mexico, from 2-14 May 1994 under the Chairmanship of Dr S. Reilly. The Chairman of the Commission welcomed the participants to Mexico on behalf of the host government. A list of participants is given in Annex A.

1. ACTING CHAIRMAN'S WELCOME AND OPENING REMARKS

Reilly welcomed the participants to the meeting.

2. ELECTION OF CHAIRMAN FOR THE 46TH MEETING

In view of the resignation of Hammond during the year, Reilly, the vice-Chairman had acted as Chairman. The Committee agreed that Reilly should chair the present meeting. A Chairman and vice-Chairman for the coming year was elected at the end of the meeting in the usual way (Item 20).

3. ADOPTION OF AGENDA

The adopted Agenda is given as Annex B. A statement on the Agenda is given in Annex R.

4. ARRANGEMENTS FOR MEETING

4.1 Appointment of Rapporteurs

Donovan was appointed Rapporteur, with various members of the Committee assisting as appropriate. Chairmen of sub-committees appointed rapporteurs for their meetings.

4.2 Meeting procedures and time schedules

The Committee agreed to a work schedule similar to that in previous years. This took into account comments, suggestions and procedures agreed to at earlier meetings (IWC, 1982; 1988).

4.3 Establishment of sub-committees

Four sub-committees were established (management procedures; Southern Hemisphere baleen whales; stocks subject to aboriginal subsistence whaling; and small cetaceans) and their reports are given as Annexes D-G, respectively. A number of working groups were established to examine specific subjects, including: abundance estimation; the IWC/IDCR Southern Hemisphere minke whale assessment cruise; and research proposals. Their reports are given as Annexes or incorporated under the relevant agenda items.

4.4 Computing arrangements

Allison outlined the computing facilities available to the meeting. There were 11 personal computers, including a 586, some of which were available for use by Committee members. In addition, the usual link to the University of Cambridge computing system was established.

5. REVIEW OF AVAILABLE DATA, DOCUMENTS AND REPORTS

5.1 Documents submitted

The list of documents submitted is given as Annex C.

5.2 National progress reports on research

The revised guidelines for national progress reports are given in IWC (1989b). The progress reports received this year are listed in Annex C. The Committee reaffirmed its view of the importance of progress reports and again recommends that the Commission urges member nations to provide them following the approved guidelines. The Committee agreed that in future, progress reports should include information on the number of biopsy samples, by species and area, collected during the year.

5.3 Data collection, storage and manipulation

5.3.1 Catches and other statistical material

During the previous year the Secretariat received the following: (i) individual data from the 1993 research catch and commercial catch in the North Atlantic by Norway; (ii) individual data from the 1993/94 Japanese research catch in the Antarctic; (iii) data from the 1993/94 IWC/IDCR sightings cruise and (iv) an updated version of the Japanese Scouting Vessel (JSV) data.

5.3.2 Progress on data coding projects

Allison reported that good progress continued to be made on data coding projects. The IWC catch data base has been transferred from the University of Cambridge computer system to PC. This change has entailed a considerable amount of work but has the advantages of making the data more easily accessible and being cheaper to maintain.

Details of Southern Hemisphere catch data now contained in the IWC data base were circulated. During the past year, coding activity concentrated on encoding data from catches taken off Australia and Africa in the 1920s and 1930s, including data held by the Natural History Museum, London. All data from the Discovery marking scheme in the Southern Hemisphere have been encoded but data prior to 1936 have yet to be validated. In addition, validation of the data from the 1992/93 IWC/IDCR sightings cruise is almost complete and data from the 1993/94 cruise have been encoded.
5.3.3 Progress on program verification and other projects
Allison reported that the population dynamics module (BALEEN II) has been validated. Full documentation for the Bayesian synthesis program (BAYSYN2 and BERGS) has been received by the Secretariat and validation of the programs is in progress. Further details are given in Annex F.

Allison also reported that most of the management Implementation Simulation Trials for North Pacific minke whales as specified in IWC (1994e) have been run. These are discussed further under Item 9.2.1. Progress made on the sightings database contract is reported and discussed in Item 4.2 of Annex D.

5.4 Whale marking
The following national progress reports contained information on natural markings: Australia; Brazil; Denmark; Germany; Ireland; Japan; New Zealand; UK and USA.

6. CO-OPERATION WITH OTHER ORGANISATIONS

6.1 NAMMCO
The reports of the IWC observers at the third and fourth meetings of the NAMMCO Council are given in IWC/46/10 A1 and A2. The Committee noted that NAMMCO had agreed to convene an international conference on the impact of marine pollution on marine mammals in 1994 (and see Item 7). Last year (IWC, 1994d), this Committee had agreed that scientific co-operation with the NAMMCO Scientific Committee should be encouraged, where appropriate (and see Item 10.2.1). It was agreed that Larsen should act as IWC observer at the next meeting of the NAMMCO Scientific Committee.

6.2 ICES
The report of the IWC observer at the 81st Statutory Meeting of ICES (23 September – 1 October 1993) is given in IWC/46/10B. The Marine Mammals Committee (MMC) began discussions on how marine mammal working and study groups can best be structured within the reorganisation being undertaken within ICES. An ad hoc Group was established to develop a policy on the handling of marine mammal issues and report to the 82nd Statutory Meeting. The MMC reviewed reports by the Study Group on Seals and Small Cetaceans in European Seas, the Study Group on Long-Finned Pilot Whales and the Workshop on Distribution and Sources of Pathogens in Marine Mammals. Information was presented on preparations for the joint NAFO/ICES Symposium on the role of Marine Mammals in the Ecosystem, to be held in September 1995 (and see Item 7).

The Committee thanked Bjørge for attending the meeting on its behalf. He agreed to act as the IWC observer at next year’s ICES meeting.

6.3 CMS/ASCORBANS
The observer’s report on the preliminary meeting of range states of ASCORBANS (Agreement on the Conservation of Small Cetaceans of the Baltic and North Seas), an agreement under the auspices of the Convention on the Conservation of Migratory Species of Wild Animals (CMS), is given as IWC/46/10C.

Progress on the agreement was summarised by Lockery and is given in IWC/46/OS ASCORBANS. Of particular interest to the Scientific Committee is the international survey for assessing small cetacean abundance in the North Sea and adjacent waters (SCANS) to be conducted in June and July this year and which involves several range states of ASCORBANS. The major target species of this survey is the harbour porpoise. The Committee has in the past called for further information on the status of the harbour porpoise in this area (e.g. IWC, 1992d) and the Committee welcomed the survey and looked forward to receiving the results.

As last year, the Committee welcomes the exchange of data and information with ASCORBANS through the Interim Secretariat. Further discussion of ASCORBANS is given under Item 15.2.2 and in Annex G. Hammond agreed to act as IWC observer at the forthcoming ASCORBANS meeting.

6.4 CCAMLR
The observer’s report of the 12th Annual Meeting of the Scientific Committee of CCAMLR is given as IWC/46/10D. Last year, the IWC had requested information from CCAMLR relevant to its discussions of the effects of environmental changes on whale stocks. The CCAMLR Scientific Committee noted that a framework for the collection of data directly applicable to the IWC’s interest has not yet been established. However, a listing of CCAMLR data holdings which might be of relevance has been forwarded to the IWC Secretariat. This is discussed further under Item 7. The Committee thanked Koch for acting as its observer to the CCAMLR Scientific Committee and agreed that he should again represent the IWC Scientific Committee at the next CCAMLR meeting.

In this regard, it was also noted that there may be circumstances in the future where it would be desirable for the Chairman of the IWC Scientific Committee to attend certain CCAMLR Scientific Committee meetings or working groups.

6.5 IATTC
Hall reported on recent developments in the tuna dolphin programme of the IATTC and on the International Dolphin Conservation Program that began in 1992 that includes all fishing vessels operating in the eastern Pacific. A system of declining annual cetacean quotas is in place for 1993–99. A review panel has access to the observer data to verify compliance with the regulations; observer coverage is 100%. Incidental dolphin mortality in the eastern Pacific declined to 3,609. This represents a 97% reduction over 1986 levels. Most (70%) of the reduction has come from improvements in fishing practice.

Matters relating to IATTC are discussed further under Item 15.1.4 and in Annex G. Tillman agreed to act as IWC observer at the next meeting of IATTC.

6.6 CITES
CITES had asked the IWC for comments on proposed revisions to its criteria for placing species on its Appendices. However, it was noted that new revisions are being developed and the Committee agreed to wait until these are received before discussing this matter further. On the final day of the meeting, CITES informed the IWC that the new revisions would be forwarded ‘soon’. The Committee agreed that it was unable to determine a Committee view before the forthcoming CITES meeting in November. It draws this to the attention of the Commission.
It was agreed that the Secretariat should identify an IWC observer for the forthcoming CITES meeting should cetacean issues be placed on the agenda.

6.7 UNEP

Borobia reported that UNEP had attended the IWC Open-ended Intersessional Working Group Meeting on a Sanctuary in the Southern Ocean. It had presented a working paper that noted that the Global Action Plan for Marine Mammals (MMP) provided a suitable mechanism for UNEP’s involvement in helping the IWC address the issue of a research programme and of environmental changes and their potential impact on whale populations. With a view to maximising cooperation with the IWC, UNEP reiterated its willingness to foster initiatives which may include: (i) exchange of information; (ii) identification of relevant existing programmes and strengthening links with the IWC; (iii) facilitation and coordination of research plans; and (iv) seeking catalytic funds. UNEP encourages cooperation with the Scientific Committee particularly through the MMP which it believes would be timely in light of the process to update the Action Plan. A first draft is expected at the forthcoming meeting of the Planning and Coordinating Committee. It is hoped that as the revision process develops it will include input from the Scientific Committee.

Recent activities supported by the MMP have continued to focus on Latin America and Africa, and particularly the implementation of the Action Plan for the Conservation of Marine Mammals in the South-East Pacific and its planned extension to the Pacific coast of Central America. A number of projects on the status and distribution of cetaceans and fisheries interactions on the East and West African coasts have been initiated. These should also provide some sightings information on humpback whales off Mauritius and La Réunion.

A volume on Marine Mammals of the World has just been published with FAO under FAO’s Fact Sheet Series (Jefferson et al., 1993). Other work in progress includes modelling exercises by the Scientific and Advisory Committee on testing the protocol developed for the evaluation of cull proposals and a comprehensive review of existing marine mammal legal regimes. UNEP is co-sponsoring a symposium on marine mammals of the Black Sea in Istanbul from 23–27 June 1994.

Last year the Committee had recommended that it participate to the extent possible in the revision process of the cetacean component of the MMP. The meeting anticipated for 1993 would now be held in June 1994.

6.8 FAO

Komatsu reported that the Government of Japan will host an international conference on Sustainable Fisheries for Food Security which will be held in Autumn 1994. FAO will cooperate by providing technical assistance for this conference, which will address sustainable use of all elements of marine ecosystems including socio-economic aspects.

6.9 IUCN

The second five-year action plan for the conservation of whales, dolphins and porpoises (1994–98) is currently being printed (Reeves and Leatherwood, 1994). It lists 50 research and conservation projects which have been determined by the Cetacean Specialist Group to be of highest priority. Many of these relate directly to areas of concern identified by the sub-committee on small cetaceans in recent years.

ICUN is currently revising its criteria for listing of species in various categories of threat (endangered, vulnerable, etc.) and would welcome comments regarding the applicability of the criteria to cetaceans.

6.10 Other

Holt reported that a meeting on the scientific aspects of managing whaling was to be held in Venice in March 1995, supported by a number of NGOs and IGOs. Invitations have not yet been issued, but he believed one would be issued to the IWC. It was agreed that should an invitation be received, the Secretariat would identify an appropriate participant.

7. EFFECTS OF ENVIRONMENTAL CHANGE ON CETACEANS

Last year the Commission passed a resolution on research on the environment and whale stocks (IWC, 1994b). It decided:

1. that the Scientific Committee should give priority to research on the effects of environmental changes on cetaceans in order to provide the best scientific advice for the Commission to determine appropriate response strategies to these new challenges;
2. that to this end a special workshop be convened under the auspices of the Commission before the 47th Annual Meeting;
3. to accept the recommendation in the Scientific Committee’s report to its 45th Annual Meeting that the Secretariat contact other relevant international organisations to obtain information for presentation to the Scientific Committee and the special workshop;
4. that Contracting Governments provide available relevant information to the Scientific Committee and contribute to the workshop;
5. that the Scientific Committee and Contracting Governments consider inviting participants to the 46th Meeting of the IWC with expertise in addressing the impact of such environmental changes and the impact of such changes on cetaceans.

The Chairman introduced this item, explaining that the primary task of the Committee was to determine the topics to be covered at the intersessional Workshop. He welcomed the participants with special expertise who were attending the meeting; they included invited participants and those sponsored by member Governments. The Committee first received short presentations of the relevant papers, recognising that it was not intended that they be fully discussed, rather that they would provide background to the determination of Workshop topics.

7.1 Response from international organisations and Governments

The Secretary reported that in response to items (3) and (4) of the Commission’s Resolution, responses had been received from a number of organisations and from the Government of the UK (SC/46/O 4).

The International Oceanographic Commission (IOC) has, since the 1960s, promoted the co-ordination of scientific research in the Southern Ocean. This includes studies of the role of the ocean in global climate change and variability, and the investigation of marine pollution. There is extensive interaction with other organisations including ICOOS/SCOR/SCAR, WMO, UNEP and FAO, through the Global Ocean Observing System (I-GOOS).

The Committee was informed that the 2nd International Oceanographic Congress would be held in Lisbon in November and that a major item on the Agenda included
change in marine environments and effects on living resources. It agreed that the IWC Secretariat should approach the IOC Secretariat with a view to IWC participation.

The International Council for the Exploration of the Sea (ICES) reported that it does not at present undertake much activity concerning environmental factors affecting marine mammals (although see Item 6.2).

The Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR) referred to its Ecosystem Monitoring Programme.

The UK has funded a three year project at its Sea Mammal Research Unit to develop a framework for investigating the effects of environmental change on whale populations. Progress thus far is reported in SC/46/O 28.

The World Meteorological Organisation (WMO), in addition to its activities related to IOC, has major long term world weather watch programmes, world climate observations, marine meteorology and associated oceanographic data collections.

SC/46/O 17 provided information on the status of environmental change studies relevant to the marine environment that are supported by the United Nations Environment Programme (UNEP). At the global level, UNEP, IOC and WMO have developed a programme for a ‘long-term global monitoring system of coastal and near-shore phenomena related to climate change’. This ambitious programme is at an early stage. A regional approach is also being encouraged through the Regional Seas Programmes and ‘Task Teams’ have been established for 11 regions that have both long- and short-term objectives. UNEP is also involved with a number of global monitoring programmes including the Global Climate Observing System (GCOS), the Global Sea Level Observing System (GLOSS) and, in particular, I-GOOS and the work of the Intergovernmental Panel on Climate Change (IPCC).

The Committee welcomed the information provided by these responses to the Commission’s request. It recognised that a number of organisations have considerable expertise, data and research programmes related to monitoring the marine environment. A major task in the Committee’s work will be to develop a framework that will enable it to take advantage of this accumulated information and relate it to cetaceans.

7.2 Papers presented in response to the Resolution

The Committee then considered a number of papers presented to the meeting. Author’s summaries of the papers are included below. Discussion under each paper is brief as it is intended that these papers be discussed more fully at the intersessional Workshop, where appropriate.

SC/46/O 15 presents an holistic approach for a comprehensive assessment of threats to cetaceans. It is based on the assumption that all known threats to cetaceans must be considered collectively because of the synergistic interactions between threats. This ‘absolute threat’ to cetaceans is summarised in a series of illustrations, in which the general categories of threats are included: pollution (organochlorines, heavy metals, petroleum hydrocarbons and nuclear wastes); habitat degradation (over-fishing, eutrophication, anthropogenic noise); environmental change (ozone depletion, global warming); deliberate killing (commercial whaling, subsistence hunting and bycatches from fisheries); and expected and unknown threats – category of threat is also given. The paper demonstrates the complexity of threats to cetaceans and considers the relationship between environmental threats and threats due to direct killing. The author emphasised the importance of considering all threats in the management of cetaceans.

In discussion, some suggested improvements and omissions were drawn to the attention of the author. Other members believed that the complexities reported suggested that an ecosystem based approach was most appropriate.

Climatic changes and ozone depletion

The next group of papers considered climatic changes and ozone depletion.

SC/46/O 7 discusses briefly the potential effects of climatic change on Antarctic marine ecosystems. Examples are given on complex relationships among ice, plankton and cetaceans. The author further emphasised the need to incorporate discussions on current theoretical ecology (global change, ecosystems, long-term ecology) as a framework for a workshop on cetaceans and global change.

In discussion of this paper it was agreed that it was important that some participants at a workshop should be theoretical ecologists and that an attempt should be made to put whale related questions into the context of current theory on biodiversity and ecosystem processes.

SC/46/O 3 summarises the literature on the temporal and spatial response of oceans to climatic change. Two processes were reviewed: CO₂-induced global warming and chlorine-catalysed destruction of stratospheric ozone. Results of general circulation models investigating the effects of doubling and quadrupling atmospheric CO₂ were presented (see Manabe et al., 1991; Manabe and Stouffer, 1994). The models predicted sluggish responses for the Southern Ocean and northern North Atlantic Ocean due to the thermal inertia associated with deep vertical mixing and water mass formation. The greatest warming was predicted for the North Pacific Ocean. Ecological implications concerning ozone depletion over Antarctica were also presented. Ecological consequences will probably depend on the magnitude of any alterations among trophic relationships due to enhanced levels of UV-B radiation.

In discussion, some participants referred to papers that provided lower estimates of the effects of the ozone hole on primary production that had not been included in the review. It was agreed that it was not appropriate to consider this debate further given that the primary purpose of this meeting was to identify Workshop topics.

SC/46/O 18 provides a conceptual model of Antarctic krill using an ecosystem approach. It is intended to serve as a framework to organise future modelling efforts. At present, a single simulation model that would encompass all physical, chemical and biological processes that affect the distribution and abundance of krill would be too complex to effectively initiate; however, the authors propose the development of a set of coupled sub-models, which examine specific processes. The submodels incorporate processes ranging from microscale to mesoscale and from the cellular to the population level.

There was some discussion of the value of this type of modelling exercise. Some members believed that this was a valuable approach and consistent with that taken by other bodies such as GLOBEC. Others noted that while a modelling framework was useful, the limitations of such an approach should be recognised. In particular, it was important that models established for one purpose, e.g. to
identify potential key factors in a system, should not be used for other purposes e.g. prediction. As was the case in the RMP development process, the question of adequately taking uncertainty into account was also stressed. It was agreed that this subject warranted serious consideration at the Workshop.

SC/46/O 28 describes the rationale for and some preliminary results of a study to develop a framework for investigating the effects of environmental change on whale populations. The work will concentrate on developing methods to relate information on whale populations to environmental information in order to take advantage of data which are expected to become available in the future. Two approaches are proposed. A broad scale approach is to investigate whether cetacean distribution and abundance can be described in terms of biological and physical oceanographic and environmental data. A preliminary analysis on predicting Southern Hemisphere abundance from purely physical data is presented to illustrate the approach. A fine scale approach is to investigate whether the foraging and breeding behaviour of individual animals can be adequately described by models utilising oceanographic and environmental data. This work will initially use existing data on southern elephant seals obtained by telemetry and will require similar data on cetaceans to progress further.

In discussion, several members commented that the twofold approach adopted in this paper was valuable. Comments were made that attempts to determine factors important to cetacean distribution, abundance and movements should focus on environmental variables which show changes from year to year.

Butterworth referred to an earlier paper (Butterworth and De Oliveira, 1994) which considered the question of whether the effects of systematic environmental change on Antarctic whale species could be determined empirically by monitoring abundance trends. Even assuming a ‘best case’ scenario for several factors, the results show that these effects cannot be so determined within a 50-year time horizon, and further, that in many situations other whale dynamics parameters are better estimated by ignoring the possibility of such changes rather than by attempting to co-estimate them. Simply expressed, this is an example of the statistical truism that estimation considerations render a simple though incorrect model capable of better predictive power than one which is correct but complex (with many estimable parameters). These results emphasise the importance of prior feasibility studies concerning the possibility of empirical validation of hypotheses on the effect of environmental change on whale populations as an essential initial component of an investigative initiative in this regard.

Annex K3 considers possible practical methods of detecting the effects of environmental changes on whales. The authors believed that such effects would first become apparent as changes in the health, nutritional status, growth, reproduction and mortality rates of whales and that trends in abundance would probably only be detectable too late. Given this they considered that monitoring populations required lethal sampling, either as part of a directed programme or in conjunction with commercial whaling under the RMS.

This view was shared to some extent by the authors of SC/46/SM15. They noted that beaked whales (mostly southern bottlenose whales, Hyperoodon planifrons) have been shown by IWC/IDCR and JARPA (Japanese Antarctic Research Programme) cruises to be both abundant and widely distributed in the Antarctic. They believed that they can be considered key odontocete indicator species of long-term changes in the environment because they occupy a high trophic level and are long-lived predators feeding on squid which are, in turn, good indicators of short-term changes in the environment because they are short-lived predators occupying a high trophic level. They suggested that a research take of Antarctic beaked whales would both improve knowledge of their biology and provide a means of monitoring environmental change.

Discussion of these ideas focussed on two areas: (1) whether the information specified could only be obtained by lethal means; and (2) whether, even if the concept of indicator species was useful, that beaked whales could be considered acceptable. A number of reasons why other species would be more appropriate were suggested. The Committee agreed that the value or otherwise of using cetaceans as indicator species could be a topic for discussion at the intersessional Workshop.

Pollutants

The Committee then discussed a number of papers on pollutants and cetaceans.

SC/46/O 8 considers whether there are reasons to be concerned about the level of contaminants in cetaceans. The answer to this lies mainly in an assessment of the risk of exposure to contaminants and the responses of the animal in the process between uptake and elimination. The paper initially reviews types of compounds identified, geographical differences in environmental pollution and the kinetics of contaminants in relation to age, sex and diet. It then discusses species vulnerability, future trends in the types and levels of pollutants and the necessity of a multiple response approach to an assessment of the risks to cetaceans posed by contaminants. In summary, although there are some studies where high levels of contaminants can be linked to certain disorders in cetaceans, it is not possible to make generalisations as there are studies on other cetaceans where no effects have been demonstrated. The author emphasised that pollutants and their effects should be considered in an ecosystem context. He concluded that the existing experimental and epidemiological data and the persistence of pollutants, was sufficient to warrant concern over the effect of pollutants on cetaceans. He urged that a stringent monitoring scheme should be established.

SC/46/O 14 reviews the interactions between cetaceans and various types of marine pollution: bioaccumulating substances (i.e. organochlorines and heavy metals); oil; polynuclear aromatic hydrocarbons; persistent synthetic marine debris; and sewage effluent. These interactions have been little studied but relevant information continues to accrue. Moreover, the available information can be augmented, with appropriate caution, by information from other species (including our own). Expert opinion has been incorporated into the evaluation and a broad picture of significant threats from pollution to marine cetaceans is developed. The precise nature of these threats cannot always be defined but the magnitude of at least some (e.g. those caused by certain organic chlorinated compounds and marine debris) is increasing. Although the threats are impossible to quantify, there are already strong indications of significant impacts.

SC/46/O 12 presents results from analyses of polychlorinated dibenzo-p-dioxins (PCDDs), polychlorinated dibenzofurans (PCDFs) and specific polychlorinated
biphenyl (PCB) congeners in the blubber of Hector’s dolphin and other open ocean species of cetaceans stranded on the coast of New Zealand. Concentrations of PCB congeners were highest in the nearshore odontocete (Hector’s dolphin), intermediate in open ocean odontocetes (beaked whales and open ocean dolphins) and lowest in open ocean baleen whales (minke, blue, pygmy right whale). The concentration of planar chlorinated hydrocarbons (PCHs) in cetaceans was related to both food habit and proximity to the coast. The sources of chlorinated PCB congeners reported for open ocean cetaceans are believed to be derived from the atmosphere.

SC/46/O 16 discusses the requirements and difficulties of carrying out an accountable and representative comprehensive assessment of pollution in cetaceans. Three key areas are addressed: quantification of pollutants both in the marine environment and in cetaceans; evaluation of the effects of pollutants on cetaceans; and the identification of an ‘absolute’ pollutant threat to cetaceans, defined as the summation of all individual pollutant effects and their synergistic interactions. The paper shows that the limitations in the research methodology and the absence of adequate baseline data to address the first two key areas have severely restricted our ability to identify the absolute pollutant threat to cetaceans. In the presence of this accumulated uncertainty, the author suggested that the IWC should carry out a comprehensive assessment of pollution in cetaceans before making any decisions about the future of commercial whaling. He believed this should include the compilation of the most reliable and up-to-date information on pollutants in cetaceans and that this must be co-ordinated with an increased international research effort directed towards the improvement of both our present and future understanding of pollution.

In discussion of this paper, reference was made to the simulation studies given in SC/46/Mg12 and considered in Annex D and later in this section, where environmental threats are discussed in the context of the RMP.

SC/46/O 20 presents a literature review of heavy metal contamination in cetaceans. Whilst the baseline data on heavy metals in cetaceans have increased considerably in the last decade, there is a considerable degree of uncertainty with regard to their physiological and pathological effects. This is attributed to three sources of heterogeneity (animal, habitat and pollutant) that affect rates of heavy metal uptake and biomagnification. Animal heterogeneity includes: age; sex; dietary preference and seasonal variations; geographical location; relative position in and length of food chain; and health of the animal. Habitat heterogeneity includes: salinity; pH; oxygen content; and temperature of the water. Pollutant heterogeneity includes: chemical specification; metal availability; inter-metal competition for available body sites; and inter-metal synergistic effects. A number of examples illustrating this variability are described. Comparisons are also made between baleen and toothed whales.

O’Shea and Brownell (1994) reviewed organochlorine and metal contaminants in baleen whales. They found that there were variations in contaminant levels with a number of factors including age, sex, region of exposure and feeding habits. Concentration levels were low and even maximum concentrations were generally lower than in other marine mammal species, both on global and local scales. They conclude that although more information on contaminants in baleen whales would be of value, research priorities for baleen whales should focus on reducing human-caused mortality and increasing habitat carrying capacity.

Discussion of this paper broadened into considering the potential effect on humans of eating mysticete and odontocete meat, but it was agreed that this was outside the remit of the Committee.

It was generally agreed that questions related to pollution were important, particularly in relation to odontocetes, and that pollution could be considered to be both a global as well as a local problem. It was further agreed that consideration of establishing systematic and routine sampling programmes to monitor pollution would be an important topic for future consideration.

Environmental factors and the RMP

SC/46/Mg12 examined by simulation the interactions between the performance of the Catch Limit Algorithm of the RMP and changes in whale populations caused by adverse environmental influences. The simulations included reductions in carrying capacity, recruitment or survival ranging from none at all to complete (100%) reduction, with rates of onset ranging from immediate and sudden to quite slow (50 years), and with a duration ranging from a few years to forever. The results showed that the relative depletion of the population caused by the catches is not greatly different in the presence or absence of environmental effects, even if these are very severe. Likewise, the relative reduction caused by the environmental effects is similar in the presence and absence of catches. There thus appears to be relatively little to gain by adjusting the management of the exploitation of whales to take explicit account of environmental influences.

The Committee concurred with the author’s conclusion that it should focus its attention on addressing questions of environmental influences in their own right and not merely in the context of catch limits.

7.3 Workshop topics

The Committee agreed that the focus of a workshop on the effects of environmental change on cetaceans should be to identify research activities that might enable the eventual prediction of the effects of such factors (both direct and indirect) on cetaceans and incorporate such knowledge into conservation and management programmes. It would not be appropriate for a workshop merely to review the literature on environmental change.

Discussion focussed on a number of factors that might be considered in the context of cetaceans: (1) global warming; (2) ozone depletion; (3) pollution; (4) direct (intentional and incidental mortality) and indirect (ecological ramifications) effects of fisheries; (5) noise; and (6) other human activities (e.g. tourism, coastal developments). Implicit in this is the question of the synergistic and cumulative effects of all of these factors.

It was agreed that it was neither feasible nor desirable to cover all of these topics at a single workshop, although all warranted consideration. There was considerable discussion as to the order in which such topics should be addressed. The Committee agreed, in the light of the Commission’s resolution, to initially discuss items (1)-(3). Given the different nature of the subject matter it was agreed to form two working groups, one to develop plans for further consideration of global warming and ozone depletion, and the other to do the same for pollution.

The Committee noted that it already discussed aspects of items (4)-(6) at its meetings and agreed that they warranted
further consideration. This might be achieved in the context of annual meetings, at least initially.

The Committee agreed that it was feasible to hold a Workshop on issues related to chemical pollutants and cetaceans in the intersessional period. A draft Agenda and list of suggested participants is given as Annex K1. A major aim of the Workshop will be to determine if the relationship between pollution loads and effects on cetaceans can be clarified. The Committee agreed to appoint a steering group comprising Bjorge, Walloe, Reijnders, Aguilar and Demaster. It was noted that, subject to timing considerations, the USA would be willing to host this workshop. The steering group will take into account related activities by other international organisations (see item 6).

The Committee believed that a workshop to discuss whether the potential ecological effects of climate change and ozone depletion are of concern to the management of cetaceans relative to other issues should be delayed until autumn 1995. This is to allow consultation with other international organisations and to await the report being prepared by the Intergovernmental Panel on Climate Change that is expected in mid-1995. An outline of issues to be considered is given in Annex K2. The Committee agreed to appoint a steering group comprising Reilly, Ichii, Swartz, Hammond, Skjoldal and de la Mare.

The Commission's attention is drawn to the fact that environmental threats affect all species of cetaceans, not only those subject to direct capture. In fact, the most vulnerable species to such threats might well be those species that are already reduced in numbers, i.e. those for which the RMP would set zero catch limits even if it were applied. Thus the IWC may also have to contemplate response strategies outside its direct management of whaling operations if it wishes any identified threats to be alleviated. This may include local measures in terms of habitat protection to much wider considerations concerning pollutants and greenhouse gas emissions.

8. COMPREHENSIVE ASSESSMENT – SOUTHERN HEMISPHERE BALEEN WHALES

8.1 Research programme for large baleen whales – blue whales

8.1.1 Intersessional Steering Group

An intersessional meeting of the Steering Group on research related to the conservation of large baleen whales in the Southern Ocean was held in Tokyo immediately after the IDCR Southern Hemisphere Minke Whale Assessment Cruise Planning Meeting. The report was distributed to all Steering Group members, including those unable to attend, before submission to the Committee. Bannister introduced its report which is given as Annex L.

The Committee agreed that this report should be passed on to the Commission. An executive summary of the report is given below.

The Steering Group was established by the Scientific Committee (IWC, 1994d, pp. 52–3) to identify a set of objectives for research on Southern Hemisphere blue whales and to identify individuals who could contribute to the development of a research proposal at the 1995 meeting. The Committee had suggested that at the 1994 meeting, a Working Group could then be convened to develop a revised research programme proposal, including: an outline of objectives; methodology; the chances of success; short- and long-term financial implications.

Should the Commission approve the revised proposal in principle and be willing to make funds available, a detailed programme should be developed at a subsequent meeting. Three possible objectives suggested by the Committee in 1993 (IWC, 1993b, p.52) were considered:

(a) To refine estimates of abundance in feeding areas

A number of ways in which to attempt to improve estimates from already available data were suggested. In addition collection of new data was discussed. The primary reason for refining estimates of abundance in feeding areas is to improve the ability to detect trends. Two promising topics for future work include improvement in differentiating between ‘true’ blue and pygmy blue whales and selection of a sub-area of the Southern Ocean for close scrutiny.

(b) To determine the distribution of breeding areas and whether animals that utilise a particular low latitude breeding area utilise particular feeding areas in the Southern Ocean

Emphasis was placed on the need to discover the location and extent of the breeding grounds; determine the structure of the stocks; and relate the breeding and feeding grounds.

A number of techniques were considered that might be used in such studies, including: satellite tracking of movements; biopsy sampling for linkages; acoustics for locating the breeding grounds and distinguishing the true and pygmy forms; photo-identification.

It was recognised that achieving this objective, particularly in determining stock structure, would assist in achieving objective (a).

(c) To evaluate the potential for competition for krill between blue whales, other baleen whales and other high-level predators

Four possible approaches to resolving the issue were discussed: (i) comparison of predator consumption with krill production; (ii) investigation of possible response of some species to a ‘krill’ surplus; (iii) direct observation of ‘competition’ between individual animals (including comparison of diet data: present/historic); (iv) development of multispecies models (possibly as an extension of (i)).

Possible budget and financial implications

A number of research projects were identified. Some of these are already in hand (development of satellite tags, ‘in transit’ surveys of breeding grounds, biopsy work). These are important and should be continued. The analysis of historical data (Discovery marks, catches, environmental and other Discovery data, sightings rates) should also be undertaken in order to improve the efficiency of future surveying, both on feeding grounds to assess abundance and to locate breeding grounds and their linkages to feeding areas. Satellite tag deployment, further biopsy and photo-identification work could then take place. Whilst analysis of historical data is undertaken, however, any surveys to locate breeding grounds and supply new data should be regarded positively. Opportunities to conduct such work in transit should certainly be taken. A table summarising a possible sequence of work is given in Annex L.

1 Editor's note. Subsequently, it was agreed that this Workshop will take place from 27-29 March 1995 in Bergen, Norway.
During discussion by the Committee, the question of acoustic searching and surveying for blue whales was raised. Clark commented that the results of the US Navy ‘Whales 93’ programme (see Annex M1) supported the view that surveys of blue whales (and fin and minke whales) might be successfully conducted using a combination of passive acoustic array systems and traditional sightings surveys.

In view of the difficulties associated with estimating blue whale abundance discussed in Annex L, the Committee strongly recommends that the potential of acoustic methods (including towed arrays) for both determining areas of blue whale concentrations and assessing their abundance be determined. The Committee also noted the value of the information obtained from the Whales ‘93 project (Annex M1) and its future potential and strongly recommends that the USA ensures that this work is continued.

The Committee also considered the results of the analyses of IDCR cruise data given in SC/46/SH24 and discussed in Annex E and Items 8.2 and 8.4. It agreed that as the cruises covered the major feeding grounds of blue whales, that the estimate represented the best estimate of abundance following available for Southern Hemisphere true blue whales: 460 (95% CI 210–1,000) for the 1985/86–1990/91 cruises.

8.1.2 Japanese sighting survey in the austral winter, 1994
Annex M2 presents plans for a Japanese sightings cruise for blue and Bryde’s whales around the Solomon Islands in September and October 1994. The research area covers an area where blue whales have previously been seen (Ohsumi and Shigemune, 1993). In addition to the sightings component of the survey, it is intended to collect oceanographic data, photo-identification data and biopsy samples. The Committee noted the relevance of this survey to its work (see Annex L) and recommends that the work be conducted. It looks forward to receiving a report of the cruise.

8.1.3 Segregation of blue and pygmy blue whales
SC/46/SH10 addresses one of the questions raised in Annex L. The segregation of blue and pygmy blue whales in the Southern Hemisphere was examined using the available sightings data (JSV, IWC/IDCR, Japanese sighting surveys) and catch records, on the basis of separation at 55°S. Blue whales were often seen in the Indian Ocean and occur in a wide latitudinal area, even in mid-summer, when they might be expected to be feeding in the Antarctic. The animals in lower latitudes in summer are almost certainly pygmy blue whales and are found in more northerly waters (north of the Antarctic convergence) than true blue whales. The analysis suggested the presence of pygmy blue whales in the western South Pacific and eastern South Atlantic. The authors recommended that an identification key for separating the two subspecies at sea be developed if possible. The Committee concurred with this view.

SC/46/SH6 reviewed the final phase of pelagic exploitation of blue whales in the Southern Hemisphere and the actual catches of pygmy blue whales by Japan and the USSR. Zemsky and Sazhinov (1982) reported catches of over 11,000 pygmy blue whales but the paper was published in Russian and had been previously overlooked by all non-Russian speaking investigators. The authors of SC/46/SH6 were able to allocate these catches by country: 2,574 were previously reported taken by the Japanese during seasons 1959/60–1963/64; 9,179 were taken by the Soviets but not previously reported during the seasons 1962/63–1971/72. The number of pygmy blue whales killed by Soviet operations after this subspecies was protected in 1965/66 was 4,068.

8.2 Priority species – humpback whales
8.2.1 Stock identity

SC/46/SH23 reported that a total of 56 unique sequences (i.e. nucleotypes) has been identified among samples from 81 individual humpback whales from four stock components. Most nucleotypes were unique to only one stock component. Of the six nucleotypes shared by more than one region, only one nucleotype was found in all four stock components, three were found in Western Australia and Eastern Australia or Tonga, one was found in Eastern Australia and New Zealand and one was found in Western Australia and the Antarctic Peninsula. The sex of 88 whales was identified by molecular genetic techniques; a strong male bias was found in the samples from Western Australia and the Gorgona Islands, while a female bias was found in Tonga.

A preliminary cladistic analysis of gene flow suggests significant genetic divisions among the four Southern Ocean stocks, although a pattern of historic interchange is evident. Of particular interest is the presence of a previously described North Pacific clade of nucleotypes in the Gorgona Islands. This provides evidence of historic gene flow from the North Pacific to the Southern Hemisphere, probably about 3,000–10,000 years ago (Baker et al., 1993). The fact that this clade appears only in the Gorgona Island region (the Group VI-I stock) suggests that migration between Southern Hemisphere stocks may be limited over periods of thousands of years.

The Committee noted that more samples were required from other areas of the range of Southern Hemisphere humpback whales, particularly from feeding grounds, before a comprehensive understanding of stock structure could be obtained. The availability of tissue samples from southern humpback whales is discussed in Annex E, Appendix 4.

8.2.2 Migration
SC/46/SH22 provided evidence for possible sex-segregated migration in southern humpback whales. Biopsy sampling of the northern and southern migration off eastern Australia from May to October 1992 (n=180) produced a sex ratio of 2.39 males to 1 female, with no obvious indications of bias. The proportion of males was similar to that recorded in eastern Australian humpback whaling (2.1:1) and an excess of males in catches was also recorded for low latitude areas such as Western Australia, New Zealand, Congo, Madagascar, South Africa and the Grenadines. Catches from high latitudes of the Southern Hemisphere however indicated an excess of females. The authors concluded that approximately 50% of females in Area V might not migrate to the breeding grounds each year, possibly remaining in feeding areas throughout winter.

The results of an IWC contract study to investigate the parameters of the southern migration of humpback whales on the west coast of South Africa were given in SC/46/SH4. Theodolite tracking revealed that both net and average bearings for the direction of movement of humpback whale groups were distributed virtually uniformly to all four

compass quadrants. A migratory index (average speed/net speed) showed that even those groups with low migratory indices (and thus travelling more or less in a straight line) were equally distributed to all four compass quadrants. Individual identification photographs revealed that some whales were resighted on several occasions over a period of up to 20 days. Apparent feeding behaviour was observed and it appeared that the southern migration had been suspended during the survey period, possibly in response to local abundance of food.

A report on the occurrence and photo-identification of humpback whales in Brazil is given as Annex E, Appendix 6.

8.2.3 Estimates of abundance
SC/46/SH24 presented sighting estimates for a number of species including humpback whales based on IDCIR and Japanese Scouting Vessel (JSV) data. In its discussions, the sub-committee on Southern Hemisphere baleen whales considered the results of the analyses *in toto* because their interpretation required an understanding of how the data for other species were collected (Annex E, Item 7.2). The details of the analyses are given in Annex E.

The Committee agreed that the best estimate for the number of humpback whales south of 60°S that could be obtained from these data were those presented in SC/46/SH24 using two sets of circumpolar IDCIR cruise data: 4,500 (CV 0.23) for the 1978/79–1983/84 surveys and 5,600 (CV 0.28) for the 1985/86–1990/91 surveys. It noted that these estimates pertain to only a part of the range of humpback whales at the time of the surveys. The sightings were too sparse to allow estimation with reasonable precision by area or by other longitudinal subdivisions within the IDCIR survey stratum.

SC/46/SH24 used data from non-random Japanese Scouting Vessel (JSV) cruises to estimate the area south of 30°S but a number of problems were identified with this approach as discussed in Annex E (Item 7.2). Further discussion of the results in SC/46/SH24 is given under Item 8.4 below.

In light of the disagreement over the validity of the extrapolated figures based on the JSV surveys, the Committee agreed to tabulate other independent estimates of current stock size for Southern Hemisphere humpback whales (Table 1).

8.2.4 Assessments
In SC/46/SH5(Rev.), assessments of humpback whale stocks in Groups IV and V were attempted in response to the revelation of previously undeclared Soviet catches in the Antarctic (see Item 8.3). Recent data had indicated fairly rapid increases in abundance on both eastern and western coasts of Australia. If catching of humpback whales had stopped at legal protection in 1963, one might have expected the increase to be manifested sooner but estimates made in 1962 or 1963 were not substantially less than equivalent estimates made in the late 1970s/early 1980s. SC/46/SH5(Rev.) estimated that fixed annual undeclared catches from 1963 to 1971 of 49 (Group IV) and 46 (Group V) were sufficient to reconcile the 1962/63 data points with the subsequent trajectories, but these catch estimates had low precision. These simulations were conducted using estimates of current abundance which were crudely adjusted to allow for the partial absence of females (SC/46/SH22): if these population estimates were adjusted to higher levels still, then the estimates of undeclared catch were even higher. A number of problems with the assumptions made in this analysis were identified (Annex E, Item 7.3).

The Committee agreed that it was not in a position to attempt to carry out assessments for Southern Hemisphere humpback whales at this meeting. The Committee's view on how its assessment work might proceed is given under Item 8.2.5.3.

8.2.5 Future work
The Committee first reviewed progress on the topics that had been proposed last year under this Item (IWC, 1994d, p.52).

8.2.5.1 Short term
(1) Completion of coding of catch and marking data. Allison reported that (apart from the revised Soviet data), coding of available catch data was well advanced (Annex E, Appendix 2). The Committee recommends that the marking data for humpback whales under the 'Discovery' scheme (especially from Australia and New Zealand) be validated, as a priority. Zemsky and his colleagues undertook to attempt to locate the original Soviet Southern Hemisphere marking data and transmit it to the IWC Secretariat.

(2) Inventory of biopsy samples from Southern Hemisphere humpback whales. Bannister reported...
that this task had been undertaken (see Annex E, Appendix 4). The Committee recommends that member governments be requested to include the numbers of tissue samples collected for genetic analysis (from all species) in their annual progress reports (and see Item 5.2).

(3) **Photo-identification studies.** The Committee noted that development of a central catalogue may not be essential and would in any case not be possible unless resources were made available to maintain and operate such a facility. A viable alternative at present appeared to be to ensure that there was good cooperation between active groups, with provision made for long-term archiving of the material. A partial catalogue has been produced for primarily east coast Australian material. International cooperation in photo-identification work on southern humpback whales is described in SC/46/SH21. Other material, primarily from Area IV (Australian west coast) and from the Antarctic had been included on the humpback database maintained by the US NMFS Seattle laboratory, but support for updating it has now been discontinued although it remains properly archived. The Committee recommends that those responsible (including those at NMFS) be asked to ensure that the existing electronic and reference photographic material is properly archived and maintained as a potentially important resource in the longer term and to provide information on their archives to the Committee.

The Committee noted that although some assessments of abundance based on photo-identification were available, it had not reviewed the more general question of the reliability of such assessments for humpback whales. It also noted the potential contribution of natural marking studies in assessments of movement between areas and exchange between populations, site fidelity, and seasonal and other movement. The Committee recommends that time be allocated at its 1995 meeting for a review of the utility of photo-identification studies for Southern Hemisphere humpback whale assessments. Material should be made available at that meeting that would allow it to:

1. assess sources of error and bias in estimates of Southern Hemisphere humpback whale abundance based on fluke and other photography;
2. review the utility of the technique for other studies (such as local and seasonal movement, relationships between breeding and feeding areas, site fidelity and short-term behavioural studies) relating to assessment and management;
3. identify sources, quantity and nature of existing holdings of Southern Hemisphere humpback photo-identification material and arrangements for access and co-operative studies.

Baker volunteered to undertake item (3).

**8.2.5.2 Long-term**

Historical catch data such as that presented by Townsend (1935) may provide useful information on the distribution of whales in warmer waters during the postulated breeding season. Cawthorn undertook to provide the positions of the humpback whale catches in a subset of the Townsend data that he had obtained, and to present it to next year’s meeting. The Committee recommends that such an analysis be undertaken.

SC/46/SH9 presented a proposal to examine the ‘Discovery’ and other historical data held by several UK institutes. Relatively little of the data is relevant to southern humpback whales, however. Although not listed in SC/46/SH9, some of these same institutes held collections of biological material from whales that might be of interest. An inventory of such material is included in the UK’s Data Inventory submission that is lodged with the IWC Secretariat as part of the Comprehensive Assessment.

**8.2.5.3 Assessments**

The Committee considered how future assessments of humpback whales might proceed. It was agreed that the critical pieces of information needed were (i) estimates of current abundance, (ii) current increase rates and (iii) accurate historical catch series.

(i) Estimates of current abundance are available from the IDCR cruise series, but the extrapolation of these to the whole summer range of the species needs some reanalysis. And, in any event, the estimates themselves are of low precision (see Item 8.2.3). The Committee recommends that estimation of current abundance from shore-based surveys and photo-identification studies in lower latitudes be reconsidered in light of the suggestion of notable partial absence of females discussed above.

(ii) Estimates of increase rates are also available from shore-based surveys, but it is unclear whether the rates observed were affected by transient effects such as a changing proportion of the population migrating or migrating closer to the coast. A modelling exercise is required to see if the rates of increase observed are biologically feasible, but it is unclear whether there is sufficient information on demographic parameters of southern humpback whales for this purpose (although some is available for northern humpbacks). It was agreed that the degree to which increase rates might be influenced by transient age structure effects could be readily examined using existing assessment models.

(iii) Once the final Soviet catch data set is available, a more accurate catch series can be constructed. However, without adequate information on stock identity and mixing it will be difficult to allocate pelagic catches in some areas to specific breeding stocks (if an assessment was done on a breeding stock basis), and conversely, to allocate some catches in lower latitudes to feeding aggregations, if the latter were to be the basic assessment units.

**8.3 Catch history revisions**

Earlier this year, Yablokov (1994) had reported that official Soviet whaling statistics previously submitted were unreliable in many aspects. During the meeting, the Russian Federation scientist reported that an examination of original catch records from past Soviet whaling operations in the Southern Hemisphere from 1949/50 was revealing considerable falsifications of the records that had been submitted by the Soviet authorities to the Bureau of International Whaling Statistics (BIWS) and which are held in the IWC Secretariat database. A summary of the information obtained thus far is given in Annex E. The Committee expressed its appreciation for the efforts of Zemskoy and his colleagues in locating and securing these extremely important records that go back for many decades.
Zemsky reported that he and his colleagues are continuing their work to find additional catch and positional data for past Soviet catches.

The Committee encouraged the Russian scientists to provide the Commission with a report that provides the general background to the Soviet whaling operations and the revised catch statistics. Zemsky stated that something of this nature will be provided in future.

8.3.1 Implications for Committee's work
The Committee reviewed the implications of these new data for its work. It noted that further information on the catches is still being sought; in particular, the lack of positional data makes it difficult to be species/area specific with respect to implications. It also noted that falsification of records was not confined to under-reporting; in some years the catches of certain species were under-reported, whilst others were under-reported - this was presumably related in some way to total production data.

Current abundance
The Scientific Committee now only uses estimates of current abundance based on direct methods such as sighting surveys or on other methods that do not depend on catch data, such as photo-identification. Revisions to past catch data thus have no effect on the estimates of current abundance accepted by the Committee.

Depletion level
Models such as HITTER/FITTER (and indeed the Catch Limit Algorithm, CLA) estimate depletion levels from estimates of current abundance and historic catch series. In general, if catches are under-reported, the level of depletion (expressed as a percentage of current to initial population size) will be underestimated to some degree, depending on the level of the catch relative to the current stock estimate and their distribution over time (i.e. the true initial population size will be higher than the estimated initial population size; under-reporting in more recent years will have a larger effect than the same level of under-reporting in earlier years). The reverse is true for over-reporting.

Population recovery
If a population has been reduced to low levels, continued catching after protection may be sufficient to prevent or slow recovery of the population. Such unreported catches may in some cases be sufficient to explain an apparent failure of a stock/species to recover under protection, without recourse to other explanations. For populations for which increases have been observed, then if these increase rates are back extrapolated over the period protection was assumed (rather than the true period), the lowest absolute population size that the population is estimated to have reached will be lower than the true value.

The RMP
The CLA of the RMP uses estimates of recent abundance (from surveys) together with a time series of recorded or estimated historic catches, to determine appropriate catch limits. It has previously been tested for robustness to underestimation of total historic catches by up to 50%. Results of further simulation tests involving underestimation of historic catches by up to 99% are given in Appendix 4 of Annex D. The simulation tests have assumed that future catches will be accurately known. The performance of the CLA can be affected when the true historic catches are substantially different from the values used (for example if the recorded or estimated catch is small compared with the current population size but the true catch was a large proportion of the population). The issue is discussed further under Item 9.1.

In such cases the performance of the CLA will be degraded but it will nevertheless perform adequately. The effect of under-reporting may result in higher initial catch limits than if the true catches were used, in some circumstances. If it is suspected that substantial under-reporting of the total historic catch might have occurred for any species/region then further trials may be specified at the implementation stage.

At present, implementation of the RMP is only being considered for minke whales. Available information for minke whales suggests that the level of misreporting is small, certainly less than 50%.

8.4 Other stocks of Southern Hemisphere baleen whales
8.4.1 Minke whales
Kasamatsu et al. (in prep.) reviewed information on possible breeding areas and southbound migration routes of southern minke whales, by considering Japanese sighting vessel data. Sightings north of 30°S were considered to be indicative of the likely location of breeding grounds. Four areas of high density were identified in this stratum, one in the western Indian Ocean (30°-40°E), one in the eastern Indian Ocean (80°-120°E), one between 170° and 130°W in the southwest Pacific and one between 120°W and 100°W in the southeast Pacific. The animals appeared more dispersed on these grounds than humpback or right whales. Sightings in more southerly latitudes in later months suggested that whales from these breeding grounds moved almost directly south but on reaching waters south of 50°S dispersed in an east-west direction.

The Committee noted that this analysis did not include the South Atlantic because of a lack of sighting effort in that region, but they believed that at least one other breeding population (off northern Brazil) could be identified in that ocean.

SC/46/SH19 reported the first confirmed records of minke whales off the coast of Peru and noted that minke whales do not appear to be common in the area. A review of the past and present occurrence of southern minke whales (including the dwarf form) off Pacific Colombia, Ecuador, Peru and Chile (SC/46/SH19) revealed only 15 specimen and sighting records. The minke whales in Area I of the Antarctic cannot therefore migrate due north to breeding grounds off the Pacific coast of South America, but must move either to the west or east or both.

The Committee noted that the rarity of minke whale records from the Pacific coast of South America (SC/46/SH19) was consistent with the low sighting rates for that area presented by Kasamatsu et al. (in prep.) and felt that it was possible that minke whales in Area I were linked to the "breeding ground" between 120° and 100°W. The Committee recommends that NOAA records of minke whales from the eastern tropical Pacific be summarised and presented to the Scientific Committee. Discussion on the taxonomic status of both forms of minke whale in the Southern Hemisphere relative to each other and to those in the Northern Hemisphere, revealed the need for a comprehensive review of their systematic status. Attention was drawn to recent papers on the genetic relationship
between minke whales in at least two of these areas (Arnason et al., 1993; Pastene et al., 1994; SC/46/SH14).

SC/46/SH13 examined the genetic structure of minke whales in Antarctic Areas IV and V. The 1,257 samples had been arbitrarily divided into four longitudinal sectors (Area 1VE and W, Area VE and W), and two time periods, early (December-January) and late (January-March). Mitochondrial DNA haplotype frequencies were used to determine relationships between these groups. After pooling samples from different seasons, a marked spatial and temporal heterogeneity was found. A group of whales sampled in Area 1IV in the early part of the season was significantly different in haplotype composition from all but one of the other spatial and temporal groups analysed. Furthermore, a group of whales sampled in Area VE late in the season was significantly different from all but one other grouping. It is possible that these belonged to different breeding stocks. Of 123 haplotypes identified, 8 were dominant, but were present in all six groups, so that no stock markers could be identified.

In discussion, Pastene reported that his group was considering the use of other genetic techniques, including examination of nuclear DNA. Baker commented that the data presented in SC/46/SH13 were amenable to more powerful statistical analyses to examine relationships (e.g. by clustering and analysis of molecular variance by permutation procedures) and Pastene stated that these were being planned. The Committee recommends that further analysis on a temporal basis should be undertaken to examine the distinctions between the apparently different groupings early in Area IVW and late in VE. It understood that some material was already available from Area IVW for this analysis.

8.4.2 Estimates of abundance for species other than minke and humpback whales
As noted under Item 8.2.1, SC/46/SH24 presented an analysis of estimates of abundance for seven cetacean species (including three odontocetes) sighted on the first 13 IDCRI cruises (1978/79–1990/91). The Committee agreed that the estimates of abundance for the area covered by the IDCRI surveys (south of 60°S) which are shown in Table 2 are as good as any that are likely to be obtainable from these data, given the small sample sizes involved.

It agreed that, apart from the estimates for blue whales (see Item 8.1), the estimates represented only partial stock estimates and a number of species specific problems are identified in Annex E.

There was considerable discussion in the sub-committee on Southern Hemisphere baleen whales on whether JSV data could be used in conjunction with the IDCRI cruise data to obtain estimates for the area south of 30°S, as had been done in SC/46/SH24. The Committee agreed that the sensitivity of the population estimates south of 30°S, provided by extrapolation based on JSV data to longitudinal disaggregation, should be examined. Results should be calculated with this extrapolation carried out at a half-Area and Area level, in addition to the circumpolar aggregation basis of SC/46/SH24. These results should include an indication of the differences resulting from interpolating densities for regions with minimal JSV effort, and considering the population abundances in such regions to be zero.

The Committee noted that the current cruise planning for IDCRI vessels made it unlikely that any useful information on current abundance of sei whales would be forthcoming in the near future. It stressed that it would be difficult to undertake a comprehensive assessment of this species in the Southern Hemisphere without more reliable estimates of current stock size.

9. COMPREHENSIVE ASSESSMENT – REVISED MANAGEMENT SCHEME
In this report, terms defined under the RMP in IWC (1994f) and Annex N are given in italics.

9.1 Further developments of the RMS
The Committee noted that the Commission paper IWC/46/24, the report of an independent panel appointed by the government of the USA to review the RMP, was relevant to its work. Issues arising out of that report are considered under relevant agenda items, where appropriate.

9.1.1 Matters directly related to the calculation of catch limits

DOCUMENTATION OF PROGRAMS
Last year, the Committee noted that in addition to the documentation that was available on RMP-related computer programs in fulfilment of the Commission's requirements, it would be of value to the Committee's

* During the Committee meeting, an error in the manner in which data from the 1990/91 cruise had been incorporated into the analysis was noted, but Butterworth noted that correcting for this will result in only slight modifications to the results in this Table.

work to formulate more detailed documentation (IWC, 1994d, p.44). Suggestions on improving the documentation that were received in the intersessional period were incorporated into the published documentation of the program implementing the Catch Limit Algorithm (IWC, 1994g).

**Process Error**

Last year the Committee had identified some further work on the question of process error that could usefully be undertaken, whilst noting that use of the CLA need not be postponed while this was carried out (IWC, 1994d, p.45). A working group to examine matters relating to process error was established. The group specified some calculations, the results of which are given in Annex D, Appendix 2. The Committee did not have time to review these results but agreed that an intersessional working group comprising Allison, Borchers, Butterworth, Cooke, Hammond (Convener), Palka, Punt, Schweder and Smith, should guide the Secretariat in finalising these calculations during the coming year.

**Progress on Standard Analysis Programs for Estimating Absolute Abundance**

Last year, it was agreed to fund a contract to develop a database for sighting survey data and software to enable the calculation of abundance estimates required by the CLA (IWC, 1994f, h).

The contract specifies that the database will contain the disaggregated Japanese Scouting Vessel (JSV) data, the IDCR Antarctic survey data and NASS survey data. The Committee agreed that the mid-latitude Japanese Survey data and other data identified in IWC (1993d) should also be included in the database. The inclusion of these data is not covered under the current contract. The Committee recommends that the contract be extended to accommodate this (see Item 18).

**Further Trials of the CLA**

The Committee considered SC/46/Mg7, which investigated the performance of the CLA when the underlying dynamics of the true population being modelled were substantially different from that assumed by the CLA. The trials investigated the behaviour of the CLA to ranges of the population dynamics model parameters, including allowing for deponensation and stochastic variability, the CV of abundance estimates available to the CLA and high levels of under-reporting of historical catches. A summary of the results is given in Annex D, Item 4.4.1.

Considering the results of the trials, the Committee agreed that the CLA was robust in all the additional trials on differing population dynamics including deponensation and stochastic variation in recruitment, even in those cases tested in SC/46/Mg7 which lay outside the plausible range for whale populations. It was pointed out that the management procedure developers had considered both deponensation and stochastic recruitment at an early stage of the development process, but had concluded that these would produce less severe problems than some of the other robustness tests actually carried out. The aim in developing the management procedure had been to prevent exploitation at low population levels where deponensation may be a cause for concern. Because this had been achieved, there was felt to be no specific need to carry out robustness tests which could only demonstrate no appreciable effect. Similarly with respect to stochastic recruitment, the robustness tests had included systematic variations in recruitment which switched from 1% to 4% at regular intervals. This is more difficult for a management procedure to deal with than simple stochastic variability from year to year. Nonetheless, the Committee was pleased to see that the robustness of the CLA was confirmed in these extra trials.

The Committee heard that concerns expressed by the USA internal review panel (IWC/46/224) on the question of multispecies effects, included the possibility that population dynamics exhibiting multiple stable states may exist. The Committee recalled that a very wide range of multispecies effects are equivalent to variations over time in carrying capacity and recruitment in the exploited population and that the CLA had proved to be robust to these problems. The Committee considered that the major effects of models exhibiting multiple stable states would be similar to those used in the robustness trials where varying carrying capacity and recruitment were used. This is because switching to an alternative stable state would occur over a time scale similar to that in which carrying capacity and recruitment were varied in the existing trials.

SC/46/Mg12 was presented in response to concerns expressed about the performance of the CLA in the presence of environmental degradations. A range of severity of the impact of an external influence on recruitment, survival or carrying capacity was tested, ranging from no impact to complete loss (100% reduction). A range of speeds and timings of onsets from immediate and sudden to long-term and gradual were tested, and a range of persistence of impacts from a few years to forever. The results showed that the differences in CLA performance (in terms of depletion of the population relative to the unexploited stock) between scenarios with and without the external impacts were small to moderate (ranging from a 4% increase to a 21% decrease in depletion relative to that which would occur in the absence of catches). The timing and speed of onset and the persistence of the external influence had little effect.

Effects of external influence on CLA performance were slightly worse when surveys were conducted only every 10 years instead of every five years. A more detailed summary of SC/46/Mg12 is given in Annex D, Appendix 3.

The Committee agreed that these results strengthened the results of earlier trials conducted by the Committee in showing that the CLA is robust to a wide range of uncertainty and believed that there would be little advantage in modifying the CLA further to incorporate adjustments to account for environmental change. Some suggestions were made for possible modifications to the trials conducted in SC/46/Mg12 but the Committee believed that it was not necessary to recommend further trials. Any potentially damaging effects of environmental change should be addressed outside the context of the CLA itself.

In the context of whether additional trials were desirable, the Committee stressed that the CLA had been tested extensively by simulation, far more than any other procedure proposed or used for the management of a marine resource.

**Block Quotas**

In 1992, the Committee had noted that the possibility of block quotas had been raised and that it was ready to consider this issue should the Commission so require (IWC, 1992b, p.60). SC/46/Mg4 suggested how this issue might be investigated using simulation trials, both at the generic single-stock level and for Implementation.
PRESENTATION OF TRIAL RESULTS

During the development of the RMP, trial results were presented in a standard manner, showing the results for each candidate procedure on the same graph. While this was appropriate for comparing procedures, SC/46/Mg6 suggested an alternative presentation of trial results for the CLA as adopted, that would more easily allow identification of potential factors of importance when developing or considering the results of Implementation Simulation Trials. The Committee recommends that the Secretariat provides a graphical presentation of results of all trials thus far carried out for the CLA in a format along the lines proposed in SC/46/Mg6. It noted that this could be published as part of the planned Special Issue on the Development of the RMP discussed under Item 19.

In the same context, SC/46/Mg6 also raised the question of the performance of the CLA at values of trial parameters other than those tested. The Committee agreed that there was merit in making further calculations to document the behaviour of the CLA in cases where there is positive bias in abundance estimates and where historical catches (i.e. catches taken prior to the implementation of the RMP) have been underestimated. Annex D, Appendix 4 contains the results of these calculations.

UNDER-REPORTING OF HISTORICAL CATCHES

The Committee agreed to use the results of the calculations which had been carried out for presentational purposes in Annex D, Appendix 4, as further information to address the question of under-reporting of historical catches asked at the meeting of the intersessional open-ended working group of the Commission to discuss the proposed Southern Ocean whale sanctuary (Item 14.2). The effects of under-reporting of historical catches depends on the size of both the reported and the unreported catch, in relation to population size, and not merely on the fraction of the catch that is reported.

In scenarios where the total historical catch is small compared to the current population size (development cases), the fraction of the historical catch that is reported would be of little or no importance and these trials were not run. The variants of the remaining base case trials (R1, R4, S1) were set up in two ways. In the first set, the total catch was held constant while the fraction of the catch that was reported was varied. In the second set, the reported catch was held constant, while the amount of additional, unreported catch was varied. The latter results are pertinent to cases where a record of historical catches is available, but it is suspected that there may have been additional, unreported catches of unknown extent.

Tables 3 and 4 give the relevant results of these calculations.

In the first set of trials the fraction of the total catch that was recorded was varied from 1% to 100%. Under-reporting degrades performance in an approximately linear fashion. With 1% reporting, lower 5%-iles of final population sizes are 57-90% of their values for the base case (100% reporting). Intermediate levels of reporting lead to intermediate results.

The results are qualitatively different when the reported catches are held fixed and the unreported catches are varied. Relative to current population size, final population sizes are higher when there have been unreported catches than they would be in the base case. This is because the existence of unreported catches implies a higher pre-exploitation population size and hence more scope for recovery. For example, with unreported catches of five times the reported catch, the lower 5%-iles of the ratio of final to current (start of management) population sizes in the R1, R4 and S1 cases are 2.8, 14.7 and 1.5 respectively. The corresponding ratios for the base case (no unreported catches) are 1.8, 3.0 and 1.0.

Expressed as a fraction of the pre-exploitation population size, the lower 5%-iles of the final population size with unreported catches of five times the reported catch are 32%, 99% and 46%, respectively of their base-case values for the R1, R4 and S1 cases. As a fraction of pre-exploitation size, the population sizes at the start of management in the three cases are 22%, 20% and 32% of their base-case values.

The Committee noted that in these trials, under-reporting of historical catches is assumed to have occurred in each and every year of exploitation prior to implementation of the RMP.

DOCUMENTATING PERFORMANCE IN COMBINATION TRIALS

A comprehensive set of trials had been analysed at the Oslo workshop on management procedures to investigate whether any of the effects of combining errors were non-additive. The Committee concluded that ‘interactions between the factors generally do not have a strong impact’ (IWC, 1992e, p.273) and later concluded that those factors which did interact ‘had been taken into account’ (IWC, 1991b, p.91). Although the CLA itself had not been finalised at that time, the Committee believed that results from these trials of the CLA would give the same conclusions because the procedures tested were similar. Nevertheless, the Committee agreed that it was useful to make further calculations and document the results to help in formulating future Implementation Simulation Trials and interpreting the results. The Committee agreed that the intersessional working group identified above should guide the Secretariat in this task. The results of this work could also be published as part of the planned Special Issue on the Development of the RMP discussed under Item 19.

SC/46/Mg6 also raised the point that what constituted ‘adequate performance’ in robustness trials has not been explicitly defined, e.g. at the Tokyo workshop (IWC, 1992a). Whilst not questioning the judgements made by the Committee, SC/46/Mg6 believed that it was essential for the basis of these decisions to be clearly identified so that the results of the robustness trials could provide a point of reference against which Implementation Simulation Trial results could be gauged at least under similar circumstances. This reinforced the need for a readily comprehensible document detailing the performance of the CLA wherein the specific results which had been judged acceptable or not would be readily apparent.

The Committee agreed that this was an important issue, but one which has been difficult to resolve on entirely
Table 4

Results for trials when the reported historical catch and the absolute population size at the start of management were held fixed, and the true catch varied from 1 to 6 times the reported value.

9.1.2 Matters not directly related to the calculation of catch limits

'MONITORING' AND DATA REQUIREMENTS

SC/46/Mg9 outlined a view of the role of science in resource management and recalled those principles identified and agreed by the Special Scientific Committee Working Group on Management Procedures (IWC, 1981):

Principle 1: Stocks should be defined on the basis of scientific evidence regarding biological differentiation;
Principle 2: Management measures should take into account the status of individual stocks and be applied to stocks individually;
Principle 4: All management measures should be accompanied by adequate collection of data so that the consequences of particular action can be monitored;
Principle 5: Account should be taken of the need to obtain information to improve the scientific basis of management action;
Principle 7: ... the uncertainties in ... information should be taken into account so that the risks of adverse effects on the achievement of the objectives are not significantly increased;
Principle 8: Management measures should take into account the effect on whale stocks of environmental change due to either natural causes or to human activities.

The Committee agreed to structure its discussion of the issues raised in SC/46/Mg9 within the framework represented by these six principles. The Committee agreed that these were all principles which had been taken into account in developing the RMP, although there remained some differences of opinion whether sufficient account had been taken of some of them.

Principle 7, taking account of uncertainty, has been given great weight in the RMP, both in its development and in the procedure for Implementation Simulation Trials and review. The trials have covered uncertainty in population dynamics, trends in the environment, uncertain stock identity, etc. The CLA itself takes into account the statistical uncertainty in the estimates of absolute abundance used in calculating catch limits. The results of the many trials show that the RMP is robust to the plausible range of uncertainties, and the limits to the range of bias in fundamental data has been examined. The Committee is satisfied that the RMP is in sufficient accord with this principle.

With regard to Principle 1 (biologically differentiated stocks), the Committee agreed that the RMP is based on this principle, and is satisfied that it is adequately met by the RMP. However, in the particular cases examined to date, trials have shown that a degree of uncertainty about biologically differentiated stocks does not mean that the RMP cannot be applied. The RMP has been developed giving great weight to Principle 7 (uncertainty), and ways have been found to take uncertainty in stock identity into account, at least in a number of cases. This has been achieved by examining the plausible range of hypotheses on the number of stocks, their distribution and mixing rates, based on reviews carried out under the Comprehensive Assessment of the information currently available on stock identity. These hypotheses are used to formulate Implementation Simulation Trials, the major function of which is to determine how to apply the RMP’s multi-stock rules in specific cases. If uncertainty over stock identity is critical in deciding whether or not to apply the RMP in a particular case, Implementation of the RMP should not proceed until new information is obtained, and satisfactory performance is attained in revised Implementation Simulation Trials, with the cycle being repeated if necessary. An additional paragraph to be included in the RMP annotations (IWC, 1994d) is given in Annex A. A description of Implementation Simulation Trials which would give further explanation to those not familiar with details of the RMP is given in Annex D, Appendix 5. The Committee agreed that it would be valuable to review this description further and that this could be accounted for within the framework of the proposed Special Issue on the Development of the RMP (Item 19).

Principle 2, the application of management to individual stocks, is closely related to Principle 1 and is adequately met by the RMP. The multi-stock rules are designed to allow for the possibility that biologically differentiated stocks may not always be geographically distinct. For example, stocks with separate breeding grounds may share a common feeding ground, at least in part of their range. In such cases, the application of the Small Area definition allows as far as possible for the application of management to individual stocks, despite geographical overlap in part of their range.

Different interpretations of Principle 4 were part of the reason which led to differing views within the Committee at last year’s meeting (IWC, 1994d, p.45). The difference of opinion was over whether the minimum data specified.
within the RMP itself were adequate to monitor the consequences of the application of the particular management action. The Committee agreed that the minimum data specified under the RMP along with other data, such as those specified in IWC (1994d, pp.46–7), in conjunction with the enabling clause defined there could be used by the Committee in a manner sufficient to meet this principle.

A working group was established by the sub-committee on management procedures to develop a set of guidelines for the collection and analysis of data including those previously specified in IWC (1994d, pp.46–7) in anticipation that they could form an element of the RMS and would be kept under review by the Committee. These guidelines were not completed in time for consideration by the sub-committee, and were reviewed by the full Committee.

There was some discussion of the draft guidelines concerning whether or not it was appropriate to allow for periodic reviews of the overall condition of the harvested stocks of a given species in a Region, in addition to and to be conducted less frequently than Implementation Reviews. The Committee agreed that this was appropriate. Additional points raised addressed matters discussed last year (IWC, 1994d, pp.45–7). These included the times when data should be reported to the Secretariat, the requirements for collection and analysis of material for ageing, and the necessity for the Committee to refine operational data requirements. This latter issue should be addressed at next year’s meeting and should include consideration of new methods for the collection and recording of operational data. The timing of the Committee’s regular reassessment of data requirements was most appropriately linked to the schedule for Implementation Reviews.

The Committee agreed that the ‘Guidelines for Data Collection and Analysis under the Revised Management Scheme other than those required as Direct Input for the Catch Limit Algorithm’ given in Annex O should form part of the RMS, and that annotation 12 (IWC, 1994) should be amended to refer to these Guidelines (see Annex N).

The Committee agreed that the difference of views recorded last year (IWC, 1994k) was fully resolved by the inclusion as part of the RMS of the Guidelines given in Annex O.

On Principle 5, the Committee agreed that account is taken of the need to obtain information to improve the scientific basis of management action through the process of Implementation Reviews, which review all the scientific information relevant to the Implementation of the RMP. However, attention was drawn in SC/46/Mg9 and SC/46/Mg5 to the possibility of improving other aspects of the scientific basis for management (including, for example, the structure of the RMP itself and the underlying population models used in its development and testing) through the use of other types of data described under Principle 3 above.

Particular attention was drawn to the importance of obtaining and including in these Implementation Reviews the information required to confirm or modify the application of the multi-stock rules (SC/46/Mg8). The Committee agreed that this was an important consideration, but it concluded that, because methodology in this particular field was in a state of rapid evolution, it would be impossible to be prescriptive about the types of data and analyses required for refining multi-stock applications at this stage. The Committee also noted that methods such as satellite tracking and genetic studies may be required, and that either alone may not be sufficient for refining the application of the multi-stock rules.

Further specification of additional information beyond that contained in the RMP for meeting Principle 5 are included in the guidelines in Annex O. The Committee agreed that the RMP and the additional guidelines given in Annex O were in accord with this principle.

Principle 8, taking into account environmental effects, has been considered in the RMP development through trials which showed that the RMP was robust to trends in the environment which affected whale populations, even when these were not identified. Additional trials reported in SC/46/Mg12 and summarised in Annex D, Appendix 3 have further illustrated robust properties of the RMP to environmental trends. The Committee concluded that overall, the combined effect of catch within the catch limits set by the CLA and external environmental influences on the population are only slightly to moderately different than those caused by the external influences alone, even when the external environmental effects are severe. However, it was noted that data on the physical environment and its change might be useful in interpreting variability in abundance estimates. The specification of such data for the application of RMP is also discussed in the guidelines in Annex O.

**INTERPRETATION OF IMPLEMENTATION TRIAL RESULTS**

The preliminary Implementation Simulation Trials for North Pacific minke whales (see Annex D, Item 9.2.1) show that selecting an application of the multi-stock rules for this species and Region depends greatly on hypotheses about sub-stock structure. SC/46/Mg4 posed the questions: what basis is required to propose the existence of sub-stocks, and what information is sufficient to refute such hypotheses?

Some members considered that a sub-stock structure should not be assumed to exist unless there was positive evidence in favour of such a hypothesis. Other members, based on some observed aspects of whale behaviour, considered that a sub-stock structure should normally be considered as a plausible hypothesis, which required evidence against it for such a structure to be excluded from Implementation Simulation Trials. The Committee agreed that results from genetic and radio-tracking studies would be useful for testing hypotheses about stock structure and mixing. The question of how to define plausible hypotheses and the question of what data would be required to distinguish between alternative hypotheses concerning stocks and sub-stocks were referred to Item 16.

**9.1.3 Conclusions and recommendations**

The Committee agreed that all the points raised by papers presented to the meeting which dealt with concerns expressed in the report of the independent panel appointed by the government of the USA to review the RMP (IWC/46/24) had been adequately addressed.

The Committee reiterated its recommendations of last year that the Commission adopt the specification of the RMP (IWC, 1994f) and endorse the annotations therein (including the minor amendments to annotations given in Annex N), and adopt the Guidelines for Conducting Surveys and Analysing Data within the Revised Management Scheme (IWC, 1994h). In addition, the Committee recommends that the Guidelines for Data Collection and Analysis under the Revised Management
9.2 Preparations for implementation of the RMS

9.2.1 North Pacific minke whales

At last year's meeting, the Committee had discussed for the first time the formulation of Implementation Simulation Trials for North Pacific minke whales. The Committee agreed to the specification for an initial set of trials (IWC, 1994d) to be run intersexually and guided by a steering group (IWC, 1994d, p.50). SC/46/Mg14 presented results from the trials run intersexually by the Secretariat. A summary of these results is given in Annex D. Although there was insufficient time to explore the results in detail or to discuss their implications for the formulation of further trials, it was clear that the results indicated poor performance for some of the hypotheses for stock and sub-stock structure (see also SC/46/Mg11).

SC/46/NP2 presented an analysis based on Hardy-Weinberg equilibrium predictions to estimate the relative proportions of minke whales from different stocks in certain sub-areas of the western North Pacific. For sub-areas 7 and 11 (IWC, 1994e, p.127) the results could be used in further Implementation Simulation Trials. SC/46/NP3 questioned a number of matters adopted last year for the initial Implementation Simulation Trials, concluding that the sub-stock structure assumed is not plausible, that the mixing of whales from the J and O stocks should be re-examined (SC/46/NP2 may help to resolve this) and that there was no evidence for the existence of a W stock separate from the O stock. Further work planned was described in SC/46/NP1 (and discussed under Item 12.2.1).

The Committee agreed that it would be premature to formulate additional Implementation Simulation Trials at this time because that process would be overtaken by the results of new studies which are planned for the coming year (see also discussion under Item 12.2.1).

A further general matter which needs to be resolved is how to interpret the results of trials where sub-stocks are modelled as stocks, as has been done in the initial Implementation Simulation Trials for North Pacific minke whales (IWC, 1994e).

SC/46/O 22 described a proposal for Japanese sightings surveys in summer 1994 and January-March 1995 in the North Pacific. The Committee welcomed this proposal as an important contribution to its work on minke whales and other species and strongly recommends that these surveys be conducted.

9.2.2 Southern Hemispheric minke whales

NORTHERLY EXTENT OF SMALL AREA BOUNDARIES

Last year the Committee had received a proposal to move the northern boundaries of the Small Areas for Southern Hemisphere minke whales up to 55°S, which had been made to avoid complications which have arisen in IDCR cruise planning when ice is expected to be encountered north of the current 60°S boundary. The Committee recalled its recommendation last year that variations in the northernly extent of these boundaries should be considered taking into account geographical and other factors (IWC, 1994d, p.49). The Committee agreed that any changes to Small Area boundaries should be based on a clear scientific analysis of the available information. It further agreed that the question of moving the northern boundaries of the Small Areas for Southern Hemisphere minke whales could be reconsidered when such an analysis was available.

SECTORS OF 15° RATHER THAN 10° FOR SMALL AREAS?

Last year the Committee had received a proposal that Small Areas for Southern Hemisphere minke whales might more appropriately be 15° rather than 10° sectors (IWC, 1994d, p.49). The Committee had noted the provision made under the RMP for Implementation Reviews and that these would only be carried out before the scheduled time (after 5 years) if substantial new information was available. It had agreed to put this matter on the agenda this year to determine whether such an Implementation Review was warranted (IWC, 1994d, p.50).

Discussion concentrated on the general issue of how the Committee will decide whether an Implementation Review was warranted before the scheduled time. The process of Implementation Review is defined under the RMP to allow reconsideration of Small Areas, normally five years after a previous Implementation or Review but exceptionally before this time (IWC, 1994f). They will include examination of new data, re-examination of old data and the results of Implementation Simulation Trials addressing alternative plausible hypotheses. Implementation Reviews are expected to take more than one year if further Implementation Simulation Trials need to be specified and run.

The Committee will need to decide whether or not to initiate an Implementation Review before the five year period has elapsed, taking into account the new information available and the work load of the Committee. One of the reasons for the five year period between Implementation Reviews was that the Committee was not required to revisit each Implementation at frequent intervals. When the Committee has made the decision to initiate an Implementation Review, it would need to identify the range of plausible hypotheses so that the specifications for any additional Implementation Simulation Trials could be developed.

The Committee agreed that the question of changing the size of Small Areas for Southern Hemisphere minke whales should be addressed within the framework described in IWC (1994f) and elaborated upon above.

There was some discussion of the circumstances leading to the Committee's decision to select 10° sectors as Small Areas. Some members believed that these circumstances had unfairly restricted the opportunity to include the 15° Small Area definition in Implementation Simulation Trials. Other members believed that the selection of 10° Small Areas was in accord with the RMP specifications given in IWC (1994f).

Komatsu referred to the Special Meeting of the Committee in 1992 where the choice of specifying 10° sectors (and attendant combined 30° sectors for Catch-cascading) had largely been based on the format in which the sightings data were available (IWC, 1993e). The Committee had also noted at that time that "it had insufficient time to attempt to specify trials that addressed the question of the appropriate size of the 'Small Areas'." At the subsequent meeting (IWC, 1993b), although the Committee had agreed that 10° sectors represented the 'best present option' (it had not attempted trials with 15° sectors) it had further stated that 'this might require revision as more information is obtained'. Accordingly, he believed that it was implicit in the Reports of the
Committee that this matter should be considered more fully as soon as it became practical.

Noting its continuing heavy workload, the Committee agreed that, notwithstanding the exact circumstances leading to the Committee’s decision last year to select Small Areas as 10° sectors, an Implementation Review for Southern Hemisphere minke whales should be scheduled according to IWC (1994).

9.2.3 North Atlantic minke whales
There was no business to discuss under this item.

9.3 Methodology

9.3.1 Estimation of $g(0)$
SC/46/NA8 contains a re-analysis of some of the data from independent observer experiments used in Schweder et al. (1993) for estimating $g(0)$ in the 1988/89 Northeastern Atlantic minke whale sighting survey. The paper presented (1) additional developments in the basic theory for estimating $g(0)$ developed by Schweder and Host (1992) and in Schweder et al. (1991; 1992; 1993); (2) simulation results on the performances of the estimator; and (3) a detailed discussion of the input data with respect to the classification of surfacing into trials or non-trials and the problems of identifying duplicate surfacing and whales. SC/46/NA8 was seen to represent a significant contribution to the development and application of the method used for estimating $g(0)$ in Schweder et al. (1993).

For the data set that was used in SC/46/NA8 (i.e., the 1989 survey plus the 1990 experimental data), $g(0)$ was estimated to be 0.587 with a CV of 0.063 compared to 0.36 (CV 0.079) in Schweder et al. (1993) which used the 1989 survey data and the combined 1989 and 1990 experimental data sets. The Committee reviewed in detail the source of the difference in the estimates of $g(0)$ and identified five potential factors in the two analyses which contribute to the difference in the estimates. These are:

1. the data set used in the analyses (i.e. Schweder et al. used the combined data set from the 1989 and 1990 independent observer experiments while SC/43/NA8 only used the data from 1990);
2. the method used for classifying surfacing into successes, failures and non-trials;
3. the model used for estimating the two dimensional detection function;
4. the fitting method and criteria used when initial sightings data were included in the estimation (SC/43/NA8 used the traditional likelihood approach fitted to the two dimensional frequency distribution while Schweder et al. used a simulated likelihood method fitted to three marginal statistics); and
5. inclusion of measurement errors in angles and distances into the $g(0)$ estimation procedure (the Schweder et al. method included measurement error and SC/46/NA8 did not).

A complete evaluation of how each of these differences contributed to the overall difference in $g(0)$ was not possible because a set of comparable estimates of $g(0)$ in which only one or a sub-set of each the differences was varied was not available.

The inclusion or non-inclusion of the 1989 experimental data could be a substantial cause of the difference in the estimates of $g(0)$. The only estimates that were available for direct comparison of $g(0)$ from the 1989 and 1990 data were estimates in Schweder et al. (1991; 1992) based only on the Bernoulli trial data. In this case, $g(0)$ for the 1989 data set was 0.427 and 0.547 for the 1990 set. It was agreed that it was preferable to use as complete a data set as possible. If further analyses along the lines of SC/46/NA8 were to be conducted, then the 1989 data should also be taken into account in the analyses in order to be able to compare the results with the estimate of $g(0)$ from Schweder et al. (1992). However, it was noted that with the 1989 data there may be a higher proportion of cases in which definite judgements as to duplicate status cannot be made because the protocol of the 1989 experiment was quite different from that of the 1990 experiment.

In order to estimate $g(0)$ from the independent observer data, it is necessary to classify each surfacing identified by platform 1 into one of the following four categories (although cases C and D do not need to be explicitly distinguished from one another):

(A) surfacing not seen by platform 2 and whale also not seen previously by platform 2 (Bernoulli trial with a ‘failure’ outcome);
(B) surfacing seen by platform 2 and whale not previously seen by platform 2 (Bernoulli trial with a ‘success’ outcome);
(C) surfacing not seen by platform 2, but whale previously seen by platform 2 (no Bernoulli trial);
(D) surfacing seen by platform 2, but whale also previously seen by platform 2 (no Bernoulli trial).

The method used and the resulting differences in the classification of the surfacings into successes, failures and non-trials is one factor which contributed to the difference in the g(0) estimates. SC/46/NA8 and Schweder et al. used different approaches for performing this classification. Table 5 provides a summary of the number of success and failures that were identified by the two classification methods for the 1990 independent observer data.

There was extensive discussion of the source of the difference in Table 5. One of the major factors appears to be in how the two methods classified potential duplicate whales from non-simultaneous surfacings in which estimated positions suggested that the surfacings were in close proximity to each other. Another important source of the difference in the classification was the treatment of surfacings where the radial sighting distance and/or angles were missing. Two other sources for the differences in classification were also identified: (1) how surfacings with possible inaccurate times were evaluated; and (2) sequences of surfacings in which one team identified a pod of two whales and the other team identified surfacing of single whales which could be interpreted as the same whales.
There was discussion, but no agreement, concerning the merits of the different classification approaches. The importance of explicitly identifying the criteria used to classify surfacings was noted and the Committee recommends that a full description of the criteria should be included in any future analyses. It was noted that uncertainties will exist with any classification system and that some errors in classification (i.e. false duplicates and missed duplicates) will occur, especially in high density areas. Accurately collected data on times and position of each observed surfacing will minimise the extent of the uncertainty. The Committee recommends that any future estimates of $g(0)$ need to include quantitative analyses of the error in duplicate classification and their effects on the estimates of $g(0)$. It was also recognised that this may not be a simple task and that methods and procedures need to be developed for performing such analyses.

Comparisons of estimates of $g(0)$ for the two different classification methods could only be made for the 1990 data base and only on the Bernoulli trial data. In this case, the effect of the different methods for classification appears relatively small. The classification method used in SC/46/NA8 resulted in $g(0)$ estimates of 0.634 and 0.590 for two different models, while the classification method in Schweder et al., yielded estimates of 0.65 and 0.547 for the same two models. However, this comparison cannot be generalised with respect to the overall effect that the two different classification methods might have on the estimates of $g(0)$, if the 1989 data were included in the analyses or if the initial sighting survey data were also included in the analyses.

Superficially, the comparisons indicated in the previous paragraph might seem to suggest that the overall difference in the $g(0)$ estimates reported by Schweder et al. (1993) and SC/46/NA8 reflects essentially different choices of data rather than the consequences of alternative methodologies. However, it was noted that the inclusion of the survey data along with the Bernoulli trials data did not have a substantial effect on the estimates of $g(0)$ in SC/46/NA8. This is in contrast to the results in Schweder et al. (1993) in which the inclusion of the combined data had a large effect on the estimate of $g(0)$. The reason for this difference in sensitivity was not clear and further analyses are required.

It was agreed that additional information was needed to evaluate the merits of the different models for the two dimensional detection function. However, the resulting estimates of $g(0)$ for the different models were similar. Overall, it was thought that the difference in model selection was not a major cause of the difference in the $g(0)$ estimates.

It was noted that the development of an automated system for identifying duplicate sightings of independent observers would be useful. Further, the analytical use of measurement error in estimated surfacing times, distances and angles in classifying sightings as duplicates in SC/46/NA8 was considered an important and useful step in developing an automated process. However, there was disagreement as to whether field trials to estimate measurement error in sighting distances and angles was representative of actual sightings conditions in a survey mode. In general, errors in angle and distance estimates in field trials would tend to be less than measurement errors that occur during sighting surveys.

The discussion of SC/46/NA8 highlighted the importance of accurate and careful data collection procedures and methods for duplicate identification when independent observer experiments are to be used for estimating $g(0)$. The Committee agreed that it was important that a set of guidelines be developed for future surveys and analyses and agreed to consider the draft guidelines given in Annex H, Appendix 3, at next year’s meeting.

The underlying causes of the differences in the estimates of $g(0)$ in SC/46/NA8 and Schweder et al. (1993) raise a number of important issues. The Committee agreed that these matters should be fully addressed at next year’s Scientific Committee meeting. In order to ensure that sufficient progress was made on this matter during the year, an intersessional working group was formed. The extensive list of tasks that will be undertaken by this group are given in Annex P. Polacheck was appointed convened of this group. Members of the Working Group who will be attending the sighting survey planning meeting in Tromsø in November 1994 agreed to review progress to date and plan any additional work.

**NEW APPROACHES**

SC/46/O 23 presents a theoretical development of estimators for $g(0)$ and effective strip width. While the derivation is different, the estimates in SC/46/O 23 are similar to those used previously (e.g. Butterworth and Borchers, 1988) and the proposed estimator of $g(0)$ would be positively biased due to unresolved problems of heterogeneity.

9.3.2 Avoidance/attraction

SC/45/NA8 (presented last year) suggested that vessel attraction behaviour could be biasing shipboard line transect estimates for North Atlantic minke whales. It was noted that there were no quantitative analyses in this paper, or generally available, for assessing whether attractive or avoidance behaviour does occur in this population. In addition, occasional observed examples of approach behaviour cannot be used to conclude on average whether attraction, avoidance or no reaction is occurring. It was also pointed out that behaviour observed in relationship to stationary or slow moving vessels cannot be extrapolated to the expected behaviour in relationship to survey vessels travelling at 10–12 knots.

There was discussion regarding whether information on avoidance/attraction of Southern Hemisphere minke whales to survey vessels could be applied to the North Atlantic. There was general agreement that the comparative approach was unlikely to produce reliable results because of differences in behaviour and evidence that they may be two different species. Rather, some direct approaches were identified: (1) radio-tracking studies of individual animals; (2) independent platforms of observation for observing the response of individual animals approached by survey vessels; (3) analyses of information on swimming directions at the time of initial sighting; and (4) analyses of implied swimming tracks derived from linked observed surfacing sequences (e.g. using the data from the $g(0)$ independent observer experiments). Problems were identified with all of these approaches and there was no agreement on what would be the best approach for investigating this problem or what priority should be placed on determining if noteworthy reactive behaviour occurs in North Atlantic minke whales with respect to approaching survey vessels. Improved methods for estimating whether attraction or avoidance behaviour are occurring would be desirable.
10. COMPREHENSIVE ASSESSMENT – FUTURE WORK

10.1 North Pacific Bryde’s whales
The Committee considered the report of the steering group to advise on the Comprehensive Assessment of North Pacific Bryde’s Whales (Annex Q). The Committee endorsed the report. It recommends that the sightings cruises outlined in SC/46/O 22 be undertaken and notes the importance to their success of the granting of research or entry permits into the EEZs of relevant countries. The Committee agreed that it should begin the Comprehensive Assessment process for North Pacific Bryde’s whales at its next meeting.

10.2 Other
Several abundance estimates were identified in working papers but time did not permit review of these estimates. It was noted that if the Scientific Committee was to use these estimates in its future work they would need to be reviewed (i.e. eastern North Atlantic fin whales – SC/46/AS15; eastern tropical Pacific humpback whales – SC/46/NP4; North Pacific minke whales – SC/46/NP6).

10.2.1 Survey plans for the North Atlantic
A cooperative project between the Institute of Marine Research and the Norwegian Computing Center (Research Council of Norway) has been initiated to conduct a survey for North Atlantic minke whales starting in July 1995. The intention is to survey the same area as covered by Norwegian vessels in 1989 (see SC/46/NA4) and also the western part of the Norwegian Sea including the Jan Mayen area. No decision has yet been taken with regard to methodology and coverage, other than that the survey will be a vessel survey and two independent teams of observers will be on each vessel. The first stage of the preparations for this research are scheduled to be completed by the end of 1994. Results from the survey will be available in the spring of 1996.

The Committee supported the general survey as proposed and the plan to incorporate independent observers on each survey platform in order to estimate goes as part of normal survey operations. Smith noted that a cetacean survey in the western North Atlantic east to Sable Island, Canada has been scheduled for the summer of 1995. The Committee encourages the principal investigators directing these surveys to communicate with one another to ensure, to the extent possible, that the data are compatible and that survey effort is distributed in time and space in an efficient manner.

The Committee also noted the survey plans for coordinated North Atlantic cetacean sightings surveys outlined in SC/46/NA10. The Committee welcomed the surveys and the invitation to Committee members to contribute to the planning process. The Committee noted the potential value of these data to its work and requests that the Secretariat enquire about their availability.

10.2.2 Survey plans for North Pacific minke whales
Sighting surveys in the North Pacific have been scheduled by the National Research Institute of Far Seas Fisheries (NRIFSF) of Japan for the summer of 1994. Line transect methods will be employed. The proposed area of study includes the Sea of Japan, the east China Sea, the Yellow Sea, and other areas in the western Pacific including the EEZ of some countries (see SC/46/O 22). The primary target species include minke whales, Bryde’s whales, Dall’s porpoises, short-finned pilot whales and Mesoplodon spp.

In addition, a winter sighting survey is scheduled by NRIFSF in the North Pacific in the South China Sea and the western tropical North Pacific between January and March 1995. The objective of this cruise is to collect information on the wintering distribution of Bryde’s, minke and humpback whales.

The Committee endorsed the general need for the summer surveys targeting minke whales in developing RMP implementation trials for the North Pacific minke whales (IWC, 1994e).

10.2.3 Genetics workshop
SC/46/O 13 describes a conference on marine mammal genetics including a workshop on the analysis of genetic data to address problems of stock identity as related to management. It is planned to take place from 23–28 September 1994 in La Jolla, California. Noting the direct relevance of this conference to its work, the Committee recommends that the IWC co-sponsors this conference. Financial implications are discussed under Item 18.

The Committee also noted the establishment of a Collaborative Centre for Genetic Analyses of Cetaceans and other Marine Mammals at the University of Cambridge. The Committee welcomed this initiative.

11. ABORIGINAL SUBSISTENCE WHALING

11.1 Aboriginal subsistence whaling scheme
Last year, the Committee reiterated its request of earlier years that the Commission consider the question of objectives and provide the Committee with advice that could be used in the development of a new aboriginal subsistence whaling scheme (IWC, 1994d, p.59). In the absence of this advice (IWC, 1994j, p.17), the Committee was not in a position to discuss this item.

11.2 Bering-Chukchi-Beaufort seas stock of bowhead whales
11.2.1 Stock identification, migration and distribution
There has been no new information provided on this subject since the stock was last assessed in 1991 (IWC, 1992c). While there is considerable information showing segregation by age and sex, there appears to be only a single stock whose movements through the Bering, Beaufort and Chukchi Seas are governed by food aggregations and ice conditions (Annex F, Appendix 2). Recent satellite tagging has given information on distribution in the autumn, with one animal, in particular, moving from the Canadian Beaufort Sea to the Siberian coast within 34 days (Annex F, Appendix 3).

11.2.2 Catch history
COMMERCIAL CATCHES
Table 6, updated from IWC (1992c, p.140), represents the most up to date information on the commercial, i.e. pelagic, catch. ‘Recorded’ catches and zeros in the table can refer equally to no information and no catch. While it was taken over the whole range of the stock, there are uncertainties in the catch history. Concern was expressed about the degree of variation in the historic kill estimates. In the study that provided the basic source, Bockstoce and Botkin (1983) used a 19% sample of western Arctic voyage logsbooks, 1848–1914, to obtain the number of bowheads caught plus those recorded as struck and lost dying, expanded to the total kill by the ratio of total voyages to logsbooks sampled.

Notes:
1. The Bayes Empirical Bayes method is not designed to give estimates that are consistent from year to year, but rather to give estimates for each year that are conservative. The extent of the conservatism varies from year to year and depends on the spatial distribution of whales. Thus these estimates are not comparable from year to year and cannot be used to infer population changes (see SC/46/AS13).
2. Preliminary estimate because analysis incomplete.
3. Preliminary estimate based on partial data.
4. Preliminary estimate because based on partial data and incomplete analysis.

The Committee recommends that the variability associated with the historic pelagic kill estimates be investigated and taken account of in the modelling process.

ABORIGINAL SUSTAINABILITY CATCHES
The Committee reviewed the 1993 catch (SC/46/AS17) and a revision of data from 1973 to 1993 (SC/46/AS10). They are included in Table 6.

11.2.3 Abundance and trend estimates
REVIEW OF CENSUS PROCEDURES
SC/46/AS17 reviewed the 1993 ice-based visual census off Point Barrow, Alaska, in which more whales (3,383) and calves (66) were seen than in any previous year. The raw count was 62% higher than the previous highest, in 1988. Much of the increase was due to the high proportion of animals within 4km of the census perch. The migration was also highly directed and uninterrupted, with 91% of animals heading north, compared with a maximum of 85% previously.

As far as possible, census techniques were compatible with those used previously. No significant effect could be attributed to the more southerly perch location in 1993, but introduction of plotting sheets may have given more conservative results than before.

Acoustic studies have complemented the visual counts since 1984. The 1993 study was the most successful so far in number of hours of data collected (>1,000), amount of season covered (94%) and relative quality of recording conditions (SC/46/AS19). A preliminary analysis of 469 hours of data showed that most vocalising animals were closer to the ice edge (75% within 3km, 96% within 6km) than in previous years.

Since 1978, aerial surveys have been conducted in spring to study bowhead distribution or to obtain length measurements and individual identifications (SC/46/AS4). The most recent, in 1992, was in conditions of higher ice cover (64% with 90–100% cover) than before. More juveniles than adults were seen in ice cover of 60% or more. Most bowhead sightings were within 8km of the shelffast ice edge, but there were sightings out to 32km.

REVIEW OF ESTIMATION PROCEDURES
The Bayes Empirical Bayes methodology has been used essentially unchanged over the past six or seven years, but SC/46/AS13 reviewed aspects revised since the analysis of 1988 census data. When the population was last assessed, in 1991 (IWC, 1992c), it was agreed the approach was the most appropriate for estimating current population size.

SC/46/AS13 summarised the methodology, as follows:
(i) the season is divided into time periods that are homogeneous with respect to the type of monitoring (visual only, acoustic only, or both) and the conditions (e.g. visibility) under which monitoring took place, and into three geographical zones (nearshore, offshore and acoustic) as shown in Fig. 1 of Raftery and Zeh (1993);
(ii) locations are linked together to form tracks using a tracking algorithm;
(iii) for each period and zone, the probability distribution of the number of whales is calculated, given the census data, or posterior distribution – this is based on a biological and geometric stochastic model of the census process and whale behaviour;
(iv) the results for different periods and zones are combined to obtain an overall posterior distribution for the entire season;
(v) uncertainty about tracking algorithm and model parameters is incorporated by rerunning steps (ii)-(iv) for a collection of plausible parameter values, and combining the results.

An alternative estimation method, not dependent in any way on the tracking algorithm, (SC/46/AS12, 13), uses the estimate $N_P$, where $N$ is the estimated number passing within visual range of the perch (4km) and $P$, the estimated proportion of the population, obtained from acoustic locations, passing within that range.

CURRENT POPULATION SIZE
Using the Bayes Empirical Bayes methodology, a preliminary estimate of 6,600 (95% CI 5,700–7,600) was obtained for the 1993 population size (SC/46/AS13). It was preliminary because not all the acoustic data had been able to be analysed in time for the meeting. The alternative ($N_P$) method gave 7,992 (95% CI 6,900–9,200, computed as recommended by Buckland (1992)).

The Committee recognised that the lower abundance estimate for 1993 is essentially conservative, particularly by comparison with that obtained for 1988 (7,500, 95% CI 6,400–9,200; IWC, 1992c, p.144). The 1988 census was the most complete to be undertaken before the most recent assessment, in 1991. The 1992 census, which the Committee had recommended be undertaken, gave poor results because of environmental conditions, with only 291 whales seen. The 1993 estimate does not imply a reduction in population size over the period, but reflects the concentration of whales nearer the ice edge that year. Abundance estimates thus far obtained for this stock are given in Table 6.

The Committee agreed that the 1988 Bayes Empirical Bayes estimate (7,500 with 95% probability interval 6,400–
9,200) was the best estimate to use for assessment purposes. The best available estimate of current population size is the 1993 \( N_{\text{A}}/P_{\text{A}} \) estimate of approximately 8,000 (95% CI 6,900–9,200).

RECENT TRENDS IN ABUNDANCE
SC/46/AS12 estimated a trend in annual numbers passing within viewing range of the perches, of 4.9% (95% CI 1.4–8.5%) for the 1978–93 period. It used an unweighted regression of \( N_{\text{A}} \) from ten censuses over the period. The unweighted regression reduced the influence of the high 1993 estimate, which was high largely because of the large number of animals (91%) passing within viewing range; in previous years, up to half the whales passed beyond viewing range.

A weighted regression using the population estimate \( N_{\text{A}}/P_{\text{A}} \) for those years when acoustic data were available (1985, 1986, 1988 and 1993 only) gave an increase rate for 1985–1993 of 2.5% (95% CI –3.5–9.0%). It took account of whales passing beyond the visual range. Its confidence interval was wide because the regression was based on only four points. More precise estimates of recent trends of abundance are given under Item 11.2.6.

HISTORICAL POPULATION SIZE
No new information was available on minimum historical population size, apart from an estimate given in SC/46/AS14, derived as a result of the Bayesian assessment and considered further under Item 11.2.6.

11.2.4 Biological parameters and life history
The new information available at the meeting is summarised below.

SIZE CLASS FREQUENCY
In SC/46/AS3, an update of length structure information obtained from aerial photogrammetry of bowhead whales off Barrow in 1985, 1986 and 1989–1992, gave the proportions of adults, juveniles and calves as 41.1, 53.7 and 5.2% respectively. Technical, biological and sampling biases were found to be relatively small.

POPULATION GROWTH FROM LENGTH CLASS FREQUENCY
A study undertaken to assess change in population size from length frequency data (SC/46/AS9), showed that to have a reasonable chance of detecting a change in the length frequency distribution, sample sizes of between 500 and 1,000 animals would be required. Although larger than could be obtained from photogrammetry in any one year, survey results from several years could be pooled. In discussion it was pointed out that length structure can be quite sensitive to the growth curve and age-dependent natural mortality (e.g. de la Mare, 1985).

PREGNANCY RATE
An uncorrected rate of 22% was obtained from examination of 72 mature females from 1973 to 1993. Some allowance for bias, e.g. correcting for missed small foetuses by sampling only during the autumn, and using a length at sexual maturity of 13.5m rather than 13.0m, to allow for stretching of carcasses hauled on to the ice, gave a rate of 34%, indicating a 3 year calving interval. Allowing for the lack of lactating females caught would give a calving interval closer to 4 years (SC/46/AS17).

During the previous assessment (IWC, 1992c, p.145), calving intervals of 4–7 years had been reported, with the possibility of 3–4 years under optimal conditions.

LONGEVITY
The recovery of two stone harpoon points of a pattern generally out of use since the turn of the century and certainly since 1920, from a large whale in 1993, together with three others recorded since 1980, suggests that bowhead whales may be very long-lived, perhaps up to 100 years (SC/46/AS17). The Committee’s attention was drawn to an earlier study (Nerini, 1983) based on changes in eye lens structure, suggesting a similar result (see also Item 11.2.6).

MORTALITY
A small proportion of animals examined in the catch since 1976 showed evidence of killer whale attack and ship strikes (4–8 and 1%, respectively) (George et al., 1994). The frequency of killer whale scars was significantly lower in small (<13m) whales, and lower than in the Davis Strait stock where killer whales may have been partly responsible for that stock’s failure to recover (Mitchell and Reeves, 1982). Ship strike incidence was lower, for example, than for North Atlantic right whales, where it is a notable source of mortality (Kraus, 1990).

GROWTH AND AGE
Comparisons with southern right whales were made in SC/46/S6/18, where stable isotope ratios in the baleen of eight animals showed much greater oscillations (amplitude up to 7ppt) than in bowheads (4ppt). From their greater asymmetry in right whales, it seemed that right whales spent considerably more time feeding in areas of carbon depletion than enrichment. If the oscillations occur annually, right whale baleen must be growing faster (28–30cm per year) than in bowheads (16–25cm per year). The utility of right whale baleen for age determination is more limited than in bowhead whales, because in right whales it grows only to 2–2.5m, compared with 4m in bowheads, and shows only 7 growth layers at the most compared with 20 in bowheads. Nevertheless, a similar hiatus in post-weaning body growth seems to occur in both species, although it must be much shorter in right whales, given the difference in age at maturity (6–10 cf 15+ years), consistent with the smaller baleen apparatus and faster baleen growth in right whales.

11.2.5 Indirect effects of human activities
SC/46/AS6 tabulated detailed information on the timing of the Alaskan bowhead hunt from 1973 to 1993, in order to help minimise impacts from oil exploration and drilling off the North Slope on the whales and on their availability to the hunters. The Committee agreed that such information is useful to managers. It recognised that the introduction of noise into the environment, rather than the presence of rigs, for example, was the probable cause of any insidious effects on whales.

DeMaster provided information on seismic activities directly in the path of the fall migration off Camden Bay, Alaska. The final results of studies monitoring the effects on marine mammals, including bowhead whales, will be available later this year. It is unlikely that any geophysical activities will occur off the North Slope in 1994 when bowheads are migrating through the Beaufort Sea.
11.2.6 Assessment
Bayesian Synthesis

Last year the Committee agreed (IWC, 1994d, pp.55–60) to recommend the Bayesian synthesis approach for use in this year’s assessment. SC46/AS14 had been prepared in response to that decision. The method relies on a Bayesian combination of the available evidence about the inputs and outputs of a population dynamics model, and weights model simulations on the basis of how compatible they are with the combined evidence. Unlike methods used in previous assessments, the Bayesian synthesis method takes full account of the evidence and uncertainty about bowhead life history, abundance and age distribution.

Concerns over the sensitivity of the procedure were contained in SC46/AS2 (plus addendum), leading to a response in SC46/AS5. A working group examined the issues and the most appropriate assessment approach (Annex F, Appendix 4). Its conclusions were accepted, i.e. that should the Committee agree on premodel distributions for model inputs and outputs similar to those used in SC46/AS14, the consequent assessment would be accepted as a basis for advice at this meeting.

The Committee agreed that although the programme had not been completely validated as required under its procedures for assessments (see Annex F, Item 5), it could be used at this meeting.

The pre-model distributions used in SC46/AS14 were compared with the parameter values accepted at the last assessment meeting (IWC, 1992c). An agreed set of conclusions was determined as summarised in Table 8.

Most discussion centred on juvenile survival rate (Sj), mature survival rate (S), initial stock size (K), the maximum sustainable yield rate (MSYR) for the mature stock, the current rate of increase and the maximum historic ratio of calves/mature females.

In the absence of direct evidence of survival rates, there was some discussion of a likely relationship between adult survival and the age at sexual maturity. The higher the latter, the higher the survival rate.

Given the recent evidence from isotope studies of sexual maturity at age 17+, and from photogrammetry of animals becoming adult in their teens or early twenties (Koski et al., 1992), the Committee agreed to accept a range for age at attainment of sexual maturity of from 14 to 26 (Table 6). This is considerably later than has been found for other baleen whales and is suggestive of a high adult survival rate.

There was general agreement that the low incidence of killer whale scarring and evidence for ship collision, together with the low incidence of disease found in examined specimens indicates that the adult bowhead survival rate is very high. Further support for that conclusion is provided by the anecdotal information on longevity from recovered harpoon heads (see Item 6.4), aspartic acid racemisation studies (Nerini, 1983) and inferences from Southern Hemisphere right whales. Ages of 120+ years had been postulated on the basis of Nerini’s work. After considerable discussion, the Committee agreed to adopt the distribution for the adult survival rate given in Table 8. In the absence of any information on juvenile survival rates, apart from the general view that it would be lower than adult survival rate, the Committee agreed to use the broad distribution shown in Table 8 (Butterworth, expressed reservations; see Annex F, Appendix 12).

In respect of MSYR for mature adults, the Committee agreed, after considerable discussion, to use a uniform distribution, with values 1–7%. Following concerns expressed over the validity of that approach, and its consistency with previous discussions on MSYR_{mature} by the Committee, a sensitivity trial was undertaken. It used the distribution for MSYR_{mature} given in SC46/AS14, with greater weight given to values between 1 and 4% and values between 0 and 1% given non-zero, although low, probability. The results of the trial are shown in Annex F, Appendix 5. They were accepted as confirming that the influence on RY of the MSYR premodel distribution chosen was not great.

In respect of the increase rate, concerns were expressed over which results, or combinations of them, were most appropriate. Three estimates were available in SC46/AS12. Two of these, using the visual census results from 1978 to 1993, were particularly affected by the high 1993 value, although account had been taken of that as far as possible. The third estimated rate, since it was based on actual population estimates instead of estimated numbers of whales that passed within viewing range, was not affected by year-to-year variability in the proportion of whales that passed within viewing range but it had high variance, with only four data points. A revised approach was presented (Annex F, Appendix 6) incorporating the available information for the years 1978–1993. The resultant estimate of an increase rate of 3.1% (95% CI 1.4–4.7) was adopted for use in the assessment (but see further consideration of this conclusion under Management Advice, below).

There was also much discussion of the maximum historic ratio of calves to mature females. An upper bound of 0.5, corresponding to a calving interval of 2 years, was adopted. A lower bound of 0.25, corresponding to a calving interval of 4 years, was also adopted. This was supported by the analyses of pregnancy rates described under Item 11.3.4. Two calving intervals of 4 years have been observed in photographically identified bowheads and mean calving intervals in the range of 3.3 to 4.5 years have been estimated, based on rates of occurrence of calves in photographs (Miller et al., 1992).

The pre-model distributions as agreed (see Table 8) were then used in a revised Bayesian assessment with the results shown in Annex F, Appendix 7. The median and 95% postmodel probability intervals obtained in that assessment were as follows:

| Initial stock size | 12,599 (10,945; 17,431) |
| MSYR_{mature}     | 4.44% (1.93%, 6.65%)   |
| Rate of increase   | 2.31% (0.92%, 3.44%)   |
| RY                 | 199 (97, 300) with 5th percentile 104. |

The estimated depletion level is 0.36 with 95% CI (0.27, 0.44), and the probability that the stock is above MSYL is estimated to be 0.002. These estimates are calculated relative to the mature part of the stock.

The results indicate a more robust and fertile stock than shown in SC46/AS14, because of the less conservative nature of the modifications to the pre-model distributions agreed by the Committee. By comparison with SC46/AS14, there is an increase in the 5th percentile value of RY from 68 to 104.

It was noted that as a function of density, RY is generally considered to be unimodal with its peak at MSYL. That is, RY will increase as abundance increases from very low levels to the MSYL, and will decrease to 0 as abundance continues to increase from MSYL to K. Thus, if this population continues to recover, it was recognised that reporting MSY values would be more informative for the
purposes of management than continuing to report RY values, for scenarios where the population is assessed to be above MSYL. A proposal was therefore made for later consideration that the RY statistic be replaced by one equal to RY for population size below MSYL, but equal to MSY above MSYL.

OTHER APPROACHES
A simple estimate of RY was obtained from the estimate of current stock size and increase rate. The Committee noted that the approach does not take account of all the available information or the associated uncertainty as effectively as the Bayesian synthesis, but agreed that the results (see Annex F, Appendix 8) are, as expected, consistent with the view that the Bayesian approach represents a more complete method of estimating RY for this population.

The Working Group examining assessment methodology (Annex F, Appendix 4) had considered an alternative use of the Bayesian synthesis framework which would avoid direct assumptions about initial stock size. Punt reported that the results obtained using this alternative method were different from those given above. The Committee agreed that this approach could be examined interseasonally.

MANAGEMENT ADVICE
The Committee had agreed above on a median value of 199 for RY (95% probability interval 97, 300, and the 5th percentile, 104).

In reviewing that value under this Item, further concerns were raised over the methodology used in Annex F, Appendix 6, to obtain a revised estimate of increase rate. The concerns were centred around the use of a weighted regression and the adjustment made to deal with the lack of acoustic data before 1985.

The Committee agreed that the unweighted analysis in SC/46/AS12, which was based on visual census estimates $N_A$, uncorrected for whales that passed beyond viewing range, was appropriate to allow for the errors contributed by the varying proportion $P_A$ of whales within viewing range.

A weighted analysis as in Annex F, Appendix 6 was appropriate when $P_A$ was accounted for, since there was greater uncertainty associated with the $P_A$ values used when acoustic data were not available.

The Committee agreed that the most appropriate way to estimate the rate of increase for bowhead whales would be to estimate the proportion of the population within viewing range for all years for which census data are available. For the years before acoustic data were available, this would involve using information on wind and ice conditions and aerial survey data on offshore distributions of the whales. The Committee recommends that this analysis be carried out interseasonally.

It had not been possible to complete such an analysis at or before this meeting. Therefore, the Committee accepted an estimated rate of increase of 3.1% (95% CI: 1.4% – 4.7%). This estimate was calculated by applying the average $P_A$ from the years with acoustic data to the estimates for which acoustic data were not available (Annex F, Appendix 6). An alternative way of dealing with the fact that no estimates of $P_A$ are available prior to 1985 would have been to use the estimate of rate of increase for the period 1985–1993 given under Item 6.3.3. This would ignore 60% of the visual census data. The approach of Annex F, Appendix 6 allowed a more precise estimate by using all of the visual census data together with the acoustic data on offshore distribution.

The accepted estimated rate of increase provided a pre-model distribution for the agreed Bayesian synthesis assessment. The post-model distribution of the 1978–1993 annual rate of increase, from that assessment, had a median of 2.3% and a 95% probability interval (0.9%, 3.4%). The assessment also provided an estimate of
depletion level for the mature part of the stock of 0.36 with 95% probability interval 0.27, 0.44.

Baker expressed reservations over the choice of increase rate, see Annex F, Appendix 12. Butterworth and Punt queried the specification for premodel distributions for initial population size and survival rates for reasons reflected in Annex F, Appendices 4 (section 2.3, para. 2) and 12, respectively.

The Committee agreed that to provide advice on the effect of the aboriginal catches, population trajectories for the period 1994–1998 would be calculated for assumed annual catches of 0, 47 and 75 animals, based on the present catch quota and half of the difference between the latter and the 5th percentile of the Bayesian synthesis post-model distribution for RY, for the period 1995–1998; for 1994 a catch of 52 was assumed given the maximum number of strikes allowed under the current quota. The methodology is described in Annex F, Appendix 9. The results are shown in Table 8.

In view of its concern over the then apparently very low stock size, the Committee in 1981 had recommended the take of smaller animals and avoidance of older animals and reproductive females. The Committee agreed that in view of current improved estimates of abundance, and its view that the population is increasing towards MSYL, there is no scientific reason to reiterate that recommendation. It recognised that this does not preclude other humanitarian or operating efficiency reasons for making such a recommendation. Given the high modal estimate for adult survival rate obtained from the Bayesian synthesis assessment (0.983), the benefit from such a measure is small.

There was some discussion of the feasibility of increasing the information available on certain parameter values, e.g. adult survival rate, through recommending the catch of certain classes of animals, such as mature adults. Given the current inability to age older animals, and the likelihood that for practical reasons, including the effects of weather, the whalers would be unlikely to select the size of their catch, it was agreed not to pursue the matter further.

The Committee welcomed the information provided in SC/46/AS10, indicating a continuing increase in hunting efficiency. It also noted that a higher percentage of those whales struck and lost were considered to have died, perhaps reflecting the continuing emphasis on hunting efficiency and weapon improvement. The average hunting efficiency (numbers landed/numbers struck) in 1992 and 1993 was 78% compared with the mean for the years 1973–91 of 51%. The Committee agreed that every encouragement should be given for that increase in efficiency to be continued.

The Committee’s attention was drawn to the results in SC/46/Mg10, where the RMP catch limit algorithm had been applied to the historic catches and the most recent estimate of abundance. The paper showed that the application of the CLA in the RMP to the bowhead whale stock yields a zero catch limit in 1991 and the tuning level yielding the catch limit of 47 whales was 41% of the initial stock size in the D1 trial (compared to 72% in the CLA).

The Committee noted that there has as yet been no development of a procedure comparable to the RMP designed to meet the objectives of the Commission in relation to aboriginal subsistence whaling (see item 11.1). Current management advice has therefore to be formulated under the existing Aboriginal Management Scheme.

A question was raised concerning the level of possible genetic interchange between the Bering-Chukchi-Beaufort Seas stock and other, more depleted, stocks. The level that the stock would eventually reach without a catch would be higher than if even a sustainable catch was allowed. This might affect the possibility of movement of even a few individuals between it and those other stocks. The Committee agreed that it should reiterate its recommendation (IWC, 1992c) that stock identity of bowheads should be examined, in particular using molecular genetic techniques. It was informed that the results of work on sequence information from the mitochondrial DNA of a small number of whales obtained during the 1992 catch would be available next year.

Conclusions

Under the Aboriginal Whaling Scheme, the Committee is required to provide advice on the size of the stock in relation both to the MSY level and ‘a minimum level below which whales shall not be taken’.

The Bering-Chukchi-Beaufort Seas stock of bowhead whales is clearly well above the latter minimum level, given that it has been increasing under a regime of catches of some 15–50 animals since 1978. Although it was unable to provide an estimate for the MSY level in terms of mature females, the Committee agreed that on the assumption that the level lies between 0.4 and 0.8, there is a very high probability that the number of mature females as a proportion of the pre-exploitation number is currently below that level. As long as annual removals are below 104, the stock will, with 95% probability, continue to move towards the MSY level, at a rate depending on the annual level of catch. Table 9 provides information on the rate of that increase under a range of different catch levels.

11.2.7 Recommendations
In addition to those already agreed, the Committee recommends that investigation of ageing techniques be undertaken, including re-examination of the aspartic acid racemisation technique.

11.3 Eastern stock of North Pacific gray whales
11.3.1 Distribution
There was no information available at this meeting to alter the conclusion at the 1990 assessment meeting that the eastern and western North Pacific populations of gray whales probably represent separate stocks (IWC, 1993c).

11.3.2 Catch history
Zemsky reported that there had been no Russian catch from this stock in 1992 or 1993.

11.3.3 Abundance and trend estimates from shore-based censuses
Shore count estimates were available from the southern migration past Carmel, California, in 1992/93 and 1993/94. Survey methods were the same as in previous seasons and the analysis method was consistent with that used earlier (Buckland et al., 1993b). Although the 1992/93 estimate (17,674 animals; 95% CI 15,800–19,800) was significantly lower than that for 1993/94 (23,109, 95% CI 20,800–27,500), the latter was not significantly different from the 1987/88 census estimate (20,869, CV 4.37%). The Committee accepted that sampling variability was either underestimated or was not the only source of variation in the estimates.

A study of animals migrating at night (SC46/AS1), gave no reason to reject the null hypothesis that passage rates did not differ during the day or night.

Aerial surveys in the census area during the 1993/94 southern migration, compared with earlier results, showed most whales were migrating within 3 n.miles of the shore, with yearly variations of 1 and 5% of animals beyond that distance (SC46/AS8).

Results of seven annual census surveys undertaken since 1981, from a location 70 miles south of the Carmel site, showed a remarkably constant pattern of annual migration, with northbound and southbound migrations overlapping within a one week period in February and a mean one day overlap of 10–11 February (SC46/AS11).

SC46/AS18 used the 1992/93 and 1993/94 abundance estimates reported in SC46/AS7 together with those obtained between 1967 and 1988 to update the earlier estimate of trends in abundance discussed in IWC (1993c). The same assumptions were made as in the earlier study, i.e. that there was no trend in the proportion of pods missed, that passage rate is not different at night or affected by poor visibility or weather, that adjustments for missed pods and biased estimates of pod size are correct for all years, and that the Hermite polynomial model used is appropriate for fitting migration dates and fits the tails of the distribution adequately.

The revised estimate of annual population increase was 2.65% (SE 0.36%). It is lower than the earlier estimate (Buckland and Breiwick, 1995) largely because of the low 1992/93 population estimate. The analysis indicated that the population is still below carrying capacity.

A simple rate of increase, calculated during the meeting, using a logarithmic regression of the estimated population size against time, and giving equal weight to each population estimate, for reasons given in Annex F, gave a rate of increase of 2.57% (SE = 0.4%).

SC46/AS16 used a Bayesian method to estimate population parameters for this stock, including a rate of increase. In contrast to the results given in SC46/AS18, it indicated that the rate of increase had substantially decreased in recent years and that the population had passed the inflection point in the growth curve. Concerns were expressed over the uniform input priors used in the analysis, and the lack of discussion in the paper of the basis for their use. In some cases at least, the priors used were informative. The results may also have been unduly influenced by the low 1992/93 population estimate. The effect of weather and process errors may not have been fully accounted for. The conclusion that the population was highly likely to be above the MSY level was regarded as questionable by the Committee. The CVs for the surveys appear to indicate an unrealistically high degree of precision. The analysis in SC46/AS18 was preferred, indicating that it is not yet possible to determine with any great certainty whether or not the population is above MSYL.

The increase rate obtained in SC46/AS16 was very similar to that already obtained in SC46/AS18. It was not possible to redo the Bayesian analysis at the meeting and the results of the logarithmic regression were accepted, i.e. an increase rate of 2.57% (SE 0.4%).

11.3.4 Biological parameters and life history
Information is available from material collected since 1980 from the Soviet aboriginal catch, when a large decrease in pregnancy rate had been observed, but no data on individual animals are available from prior to that date and therefore no revised estimate of pregnancy rate prior to that date could be provided to the meeting. Since there were no catches in 1992 and 1993, no new estimate could be provided.

A count of calves in the northbound migration is being undertaken during the 1993/94 migration. The results will be available at next year’s meeting.

At least one record of annual breeding is available (Jones, 1990).

There was discussion of the merit of obtaining an estimate of calf production from studies of photo-identified calves in the breeding lagoons. While it recognises that the method will only yield results in the long term, the Committee recommends that such studies should proceed.

11.3.5 Indirect effects of human activities
O’Shea and Brownell (1994) indicated that pollution levels in whales examined from this stock are extremely low.

A review of tourism and other developments in gray whale critical habitats was developed at the meeting (Annex F, Appendix 10).

To plan development compatible with the conservation of the animals and their critical habitats, the effects of past and current potential impacts of development require study. For gray whale breeding lagoons in Baja California, the major aim should be to protect and maintain the integrity of the lagoon habitats. That could be achieved by:

(i) evaluating and considering the effects of lost habitats elsewhere;

(ii) careful comprehensive planning of any development to accommodate the needs of developers and wildlife, e.g. gray whales;

(iii) implementing an ongoing research and monitoring programme to allow detection and analysis of any changes in use of the lagoon by gray whales that could
be associated with development, including existing levels of tourism.

The Committee agreed that in this way the benefits both of economic development and maintenance of a unique wildlife resource could be achieved, and recommends that such action be continued. It took special note of Mexico's recognition of the importance of the gray whales' breeding lagoons and of Mexico's actions to conserve these critical habitats by designating some of them as 'Wildlife Refuges' within a biosphere reserve.

11.3.6 Assessment
APPLICATIONS OF BOWHEAD BAYESIAN SYNTHESIS METHOD
An attempt to apply the Bayesian synthesis methodology used for bowhead whales to the eastern Pacific gray whale stock had been made in SC/46/AS18. The majority of the population trajectories obtained, however, gave a decreasing population during the period 1967–80. Very little weight was therefore given to those trajectories. It seems that either the population dynamics model used does not adequately capture the population's recent and past dynamics, or some of the data inputs are incorrectly specified, e.g. the historic catches and the sex ratio.

The Committee agreed that this method could not be applied, as it depends on the availability of catch information from the onset of exploitation of the stock. There are considerable problems in this regard, as was recognised during the previous assessment of this stock (IWC, 1993c).

OTHER METHODS
The Committee agreed that for reasons already recognised (see Item 11.3.3) it was unable to use results of the Bayesian synthesis approach contained in SC/46/AS16. In addition to reservations already discussed, the analysis relied on assumptions for the population age structure in 1966. The Committee recommends that sensitivity to this assumption should be explored.

The Committee recognised that this decision did not negate the general validity of a Bayesian approach for this stock and that the approach possesses more power than the methods used in SC/46/AS18.

The Committee noted that the analysis in SC/46/AS18 indicated that it is not as yet possible to determine with certainty whether or not the population was above MSYL.

MANAGEMENT ADVICE
There was no new information available at this meeting to cause the Committee to alter the conclusion reached when the stock was last assessed (IWC, 1993c, p.251), i.e. that:

1) this stock is not a Protection Stock;*
2) given lack of information on MSYL, no conclusion can be reached on whether it is a Sustained or Initial Management Stock;*
3) given the recent history of increase under a regime of constant catches, the stock does not fall within the alternative definition of a Sustained Management Stock;*
4) although the Committee was unable to determine the minimum level below which catches should not be taken, as required under the Aboriginal Whaling Scheme (IWC, 1993a, Para. 13), it agreed that the stock was well above such a level.

* See IWC, 1993a, Para. 10.

The Committee was nevertheless able to calculate RY as detailed in Appendix 11. This gave an estimate of 611, which is well above the mean catch of 159 whales over the period 1968–1993. The 95% CI for this estimate is (484, 733) or (452, 786) and the lower 5th percentile 505 or 475, depending on the CV assumed for the 1988 abundance estimate. If the catch was greater than reported, then the estimate of RY given above would be negatively biased.

11.3.7 Recommendations
In addition to the recommendations already included in the text, the Committee recommends that the possible reasons for the discrepancy between the sampling estimates of CV from the surveys and the CV of the survey estimates about the overall population trend should be explored.

11.4 West Greenland fin whales
The Committee reviewed SC/46/NA7 which reported progress on genetic analyses based on mitochondrial DNA extracted from samples from 97 fin whales in the Gulf of St Lawrence and 25 from West Greenland. The homogeneity tests revealed no significant level of heterogeneity between the Gulf of St Lawrence and West Greenland samples. Although the results lend no support to the current division of eastern Canadian fin whales (including the Gulf of St Lawrence) and West Greenland fin whales, this may be caused by a lack of resolution in the method applied.

SC/46/AS15 presented the results of an aerial survey for minke and fin whales conducted off West Greenland in 1993. The design of the survey was similar to earlier years with the exception that certain blocks (2–5) were further divided into an offshore and a coastal block. As previously (Hiby et al., 1989) data were analysed with the case-counting procedure as summarised by Buckland et al. (1993a) using the program DISTANCE (Laake et al., 1993). The lack of survey coverage in the central offshore blocks due to poor weather, which in previous surveys have shown a considerable number of fin whales, resulted in a total of only six primary cues from fin whales being recorded. This led in turn to an estimate of abundance for blocks 4–5 of 327 (95% CI: 167–551) using the half-normal model. Because of an error in the weighting procedure used for the pooled estimate, a revised estimate was calculated as 178 (95% CI: 51–626). The author suggested that consideration is required as to the most appropriate mean and variance cue rate values to use when estimating abundance.

The Committee agreed that because of the lack of survey coverage in the central offshore blocks, this estimate should not be considered as applying to the whole of West Greenland. These blocks had contained relatively large numbers of fin whales in earlier surveys.

The most recent estimate of the number of fin whales off West Greenland agreed by the Committee was 1,096 animals (95% CI: 520–2,106) (IWC, 1993b, p.75) based on surveys conducted in 1987 and 1988. The Committee last considered this stock in 1992. At that time, as in previous years, it had been unable to provide management advice, given the lack of information, particularly on stock identity, but also stating its belief that it was unlikely that West Greenland fin whales constituted a separate stock. However, if it is a separate stock, the small estimate of stock size and its approximate lower bound are a cause for concern. The Committee agreed that it was unable to provide any new advice at this meeting.

Information on stock identity is crucial to any understanding of the status of fin whales in this region. The
Committee therefore recommends that existing plans for stock identification studies, especially employing analyses of nuclear markers, should be implemented as a matter of urgency.

The Committee noted the high variance associated with the estimates of abundance and recommends that surveys be continued and expanded.

11.5 West Greenland minke whales
SC/96/AS15 presented information on the distribution and abundance of minke whales off West Greenland in 1993. The distribution of the sightings confirmed the results of earlier surveys that minke whales are predominantly found inshore and in the southernmost blocks. Using the half-normal model, an abundance estimate of 8,371 (95% CI: 2,414–16,929) was obtained. Although the estimate is potentially biased by the low survey coverage in the central offshore blocks, this is not believed to be a major problem. The author suggested that consideration is required as to the most appropriate mean and variance cue rate values to use when estimating abundance.

In discussion, it was suggested that further studies should examine the fit of a variety of models to the radial distance distribution more closely, to attempt to determine whether or not the shape-flexibility of the half-normal model used at present might be introducing bias into the resultant estimates of abundance.

The Committee concurred with the view put forward when this stock was last considered (IWC, 1992b, p.70), that the West Greenland minke whales do not seem to comprise a separate stock, but are part of a larger stock. Given the lack of knowledge, the Committee agreed to reiterate the advice given then, i.e. that although there is no information upon which to determine the status of the stock in relation to MSYL, it believes such a stock is above the minimum level below which aboriginal subsistence catches should not be taken. It could offer no advice on the size of catches which would allow the stock to move towards MSYL.

The Committee recommends the continuation of stock identification studies, including analyses of nuclear markers. It further recommends that the aerial surveys be continued and expanded in order to reduce the large variance associated with the present estimates of abundance.

11.6 East Greenland minke whales
The most recent estimate of stock size for the Central (Atlantic) stock is 28,000 (approximate 95% CI 21,600–31,400), obtained in 1990 (IWC, 1993b, p.74). The Committee has not previously given specific advice on this stock in relation to the aboriginal hunts conducted off East Greenland. The Commission has in the past noted the information on abundance provided by the Committee on this stock and established a catch limit of 12 animals (IWC, 1993b).

11.7 Humpback whales off St Vincent and The Grenadines
The Committee was informed by Hester that in the 1994 season, that ended in March, the whales had operated but had not struck any whales. He also reported that the two whales taken in 1993 (IWC, 1994d) were a cow and calf, the latter of unknown sex.

As in previous years, the Committee agreed that a catch of three whales would be unlikely to harm this stock. It again recommends that if whales are taken every effort should be made to collect as much information as possible, in particular photographs of the ventral surface of the flukes and tissue samples for genetic studies. It noted that such information had again not been received from the catch.

12. SCIENTIFIC PERMITS
12.1 Review of results from existing scientific permits
12.1.1 Japan
SC/96/SH15 reported an overview of the scientific programme (JARPA) carried out in Area IV in the 1993/94 season. Research was divided into two components, one covering the entire research area and the other covering the ‘Special Monitoring Zone’, where seasonal changes in distribution were to be examined. Survey methods had been modified to try to improve the representativeness of the sampled animals. One vessel was devoted exclusively to sightings in order to improve the estimates of abundance. A total of 688 primary sightings of minke whales (1,619 animals) and 267 secondary sightings (1,200 animals) was recorded during 17,932.6 n.miles of searching. A total of 330 (200 males and 130 females) ordinary form minke whales were taken.

A number of papers (SC/96/SH13 and 21, SC/96/SM15 and SC/96/O 23) are discussed elsewhere in the Committee’s deliberations. Other studies arising out of the programme are summarised briefly below.

SC/96/SH12 used abundance estimates from the 1991/92 and 1992/93 JARPA cruises to adjust previously estimated age distributions. In the latter cruise, sighting methodology was modified in order to facilitate comparisons with the 1985/86 IDCR cruise that had used closing mode.

SC/96/SH20 estimated the age distributions of minke whales in Areas IV and V using data collected in 1991/92 and 1992/93. The Area IV samples showed a typical age distribution pattern, although the distribution of females in Area V did not fit the pattern completely. Yearly fluctuations were observed between the two surveys for immature individuals in both Areas.

SC/96/SH11 presented an analysis of the segregation of minke whales in Areas IV and V by adopting a simple logistic regression model. The results showed that the proportion of males increased with the progress of the season and with school size, and that mature females were concentrated in Prydz Bay and the Ross Sea later in the survey season.

SC/96/SH17 presented a preliminary analysis of the relationship between the distribution pattern of minke whales and oceanographic conditions derived from XBT observations.

SC/96/O 24 summarised cetacean research conducted and supported by the Institute of Cetacean Research (ICR), particularly with respect to JARPA. Various studies were listed, including pollution studies.

SC/96/SH14 described a phylogenetic analysis of minke whales from different oceanic regions. Samples included minke whales from the North Pacific and Southern Hemisphere (including dwarf and ordinary forms). In the analysis, published sequence data of the North Atlantic minke whale were also used. The method used was amplification by PCR of the non-coding control region followed by direct sequencing of 343 base-pairs. A phylogenetic tree constructed from a total of 117 sequences showed that dwarf and ordinary forms of the Southern Hemisphere, North Pacific and North Atlantic minke whales are separated from each other, suggesting
independent genetic populations. The authors believed that dwarf minke whales are more closely related to Northern Hemisphere minke whales than to the ordinary form of the Southern Hemisphere, and are more closely related to North Atlantic minke whales than to North Pacific minke whales. The dwarf form minke whale is clearly remote from the ordinary form despite the overlap in their distribution and apparent ecological niche.

Comments and discussion
Although only limited time was available to discuss the results in any detail, several members commented on certain aspects of the work. Walloe and Hestor welcomed the information provided by JARPA and its contribution to our understanding of the role of minke whales in the Antarctic ecosystem. Hestor further noted the contribution to questions of stock structure and identity that he believed would be valuable at the Implementation Review stage of the RMP and monitoring under the RMS. Reilly noted the oceanographic work with interest and offered to provide advice on a statistical approach to the question. Comments that were also relevant to the 1994/95 programme are discussed under Item 12.2.1.

12.1.2 Norway
Walloe briefly summarised the results of the programme presented in SC/46/NA2 and SC/46/NA3. He also referred to information included in SC/46/ProgRep Norway and IWC/46/HK1. Field work was carried out in spring (5 animals taken), summer (35 animals) and autumn (29 animals). Stringent procedures were in place to ensure random sampling of animals. Poor weather and ice conditions meant that fewer animals were taken than had been originally planned. In addition, unlike in 1992, permission was not received to operate in Russian Federation waters.

Estimates of potential prey abundance were made concurrent with minke whale sampling. Preliminary analyses suggest that fish play an important role in the diet. Gadoid fish predominated in spring. Krill predominated in summer and autumn in the northernmost areas, reflecting the severe decrease in capelin and increase in krill observed in the area. Herring was the major prey species in coastal areas. Sampling was carried out for a number of other studies in the Norwegian programme, including those concerning genetics, reproduction and pollution.

Walloe noted that analyses of the data in the context of MULTSPEC that he had expected to be presented this year (IWC, 1994d, p.61) had not yet been completed. He indicated that they would probably be presented at a Symposium in Tromsø at the end of November this year. Results would also be submitted to next year’s meeting.

Comments and discussion
Ichii commended the programme and in particular its emphasis on elucidating the dynamic predator-prey relationship. Stokes commented that some interesting qualitative information was emerging. He expressed his disappointment, however, that although the objectives of the programme (see SC/44/NA18) relate to improving multispecies management of the Barents (and possibly Norwegian) Sea, the programme seemed to be contributing little to the MULTSPEC project. He noted, in particular, the absence of papers referring to whales arising from the MULTSPEC project since it was presented to the Committee in 1992. Walloe responded that this work was ongoing and that, in addition to the quantitative aspects that would come out of the MULTSPEC programme, Schweder was carrying out other quantitative analyses which will be presented to the Committee in due course.

Smith was concerned at the implication of the change in sampling areas brought about by being unable to enter the Kola region, particularly in the context of MULTSPEC. Walloe responded that he had discussed this with MULTSPEC scientists and that as samples were being obtained from a very similar area on the Norwegian coast near to Russia, this should not be problematic. However, he reported that permission was being sought to operate in Kola this summer. Smith also noted with concern the expansion of the goals of and study area for the research suggested by the designation of three whales to be taken in the North Sea in commercial whaling operations. Walloe drew attention to SC/46/NA3 where the main purpose of this catch will be to increase the number of samples for genetic analyses.

Lankester queried the availability of data on the question of ship-seeking behaviour and noted that Walloe had informed the Committee that data were being collected last year. Waller responded that some data on swimming speeds had been considered by the Working Group on abundance estimation (Annex H). Data on direction of swimming had also been collected and work is continuing this year. A report will be presented at next year’s meeting. He believed that additional data would be collected in conjunction with the 1995 sighting survey.

12.2 Review of new or revised Scientific Permit proposals
12.2.1 Japan
The Committee noted that the proposal (SC/46/SJH16) was a continuation of the programme it has discussed extensively in the past (e.g. IWC, 1989a; 1990; 1991a; 1992b; 1993b; 1994d, pp.60–1). It draws the Commission’s attention to those discussions which are not repeated here. It further notes that the population estimate in Area V is 295,000 (95% CI: 225,000–386,000). The planned sample size is 300±10%. In addition to the usual research items, a new experiment has been added. In order to try to assess whether sampling activity may affect abundance estimation, an observational study of the behaviour of minke whales other than those targeted for capture will be carried out in high density areas. Increased effort is being placed on environmental aspects of the programme in light of the Commission’s Resolution on Environmental effects (IWC, 1994b and see Item 7).

Comments and discussion
Notwithstanding the problems discussed in previous meetings about using the data from this programme to estimate age-specific mortality rates, Polacheck expressed his concern that despite efforts to obtain a representative sample of the age distribution and to reduce the CVs of the sightings survey abundance estimates, the sampled age distributions do not appear to be representative of the population’s age structure and the recent abundance estimates have high CVs. He also expressed concern about the implication of these results for the ability of the programme to achieve its stated objectives. Fujiwara responded that he believed that the problems stem largely from stock identity questions and seasonal variations in the migration patterns for different age groups. Work underway should lead to a reduction in the apparent bias by identifying to which stock each animal belongs and by
elucidating migration patterns. Nishiwaki commented that the relatively high CVs of the sightings survey estimates could be because of differences in the methodology used in the analysis of the data, compared to IWC cruises. Efforts are being made to improve the methodology and increased effort will be put into the sightings survey.

Polacheck and Smith expressed concern that no attempts had been made to present preliminary estimates of even average mortality rates from the data collected thus far. They believed that this may prove useful in identifying whether the programme might meet its objectives and/or ways in which the research programme could be improved, for example in determining relative amounts of effort to be devoted to the sighting and sampling elements of the research. They also noted with concern that the principal objective indicated in the proposal (to estimate age-specific mortality rates) was different than in the previous year's proposal (to estimate average mortality rates). They judged the likelihood of the research programme meeting this year's objective to be less than the likelihood of meeting the previous objective. They also referred to comments about the importance of abundance estimates with respect to the research on Southern Hemisphere minke whales under special permit and suggested that consideration should be given to the relative levels of effort that should be put into sightings versus sampling.

Ohsumi commented that biological knowledge of the stock and its seasonal migrations is accumulating as the surveys progress. Ways of elucidating stock structure are being developed as knowledge increases. He stressed that such contributions to our knowledge of Southern Hemisphere minke whales should be encouraged rather than criticised. This is a long-term iterative programme, once the age-composition is established, then natural mortality rates can be studied. The final objective is to obtain an age-specific mortality rate and whilst working towards that objective, a value for the average mortality rate can be obtained. This is perfectly consistent with the previous pattern of research, and no change in that is proposed for the future.

In addition, Tanaka et al. (1990) have devised a method of combining the age data with those from sighting surveys in order to obtain the most precise results while limiting the number of samples required.

It was noted that there is no clear single statement in the published record of the intended duration of the Japanese Southern Hemisphere minke whale programme. However, it is the Secretary's recollection that the main programme proposed after the initial 2 years of feasibility studies was for a period of 14 years.

De la Mare noted that earlier work presented to the Committee (de la Mare, 1989; 1990) had shown that precision in the surveys is critical to the ability to estimate mortality rates. The levels being obtained in the JARPA surveys, the additional problem of process error and the bias in the age structure of the catch led him to believe that the objectives of the programme in terms of mortality rates were not achievable in a realistic time frame. Butterworth referred to his and his co-authors' more optimistic appraisals of the utility of the age-structure data obtained from this programme (Butterworth and Punt, 1990; Bergh et al., 1991), and believed that although the likely under-representation in the samples of the young animals in the population would indeed increase estimation variance, it would require further analysis to determine the extent to which this would affect ability to achieve adequate estimation of demographic parameters.

Hester referred to his view expressed under Item 12.1.1 that these surveys provided valuable data with respect to both the RMP and RMS.

Ohsumi expressed his appreciation to those members of the Committee who had provided useful and constructive comments. Where appropriate they will be taken into account in the final version of the research plan.

12.2.2 Norway
The Norwegian proposal for 1994 is given in SC/46/NA.3. This is the final year of the programme. Sampling will be carried out under the same design as previous years. The total number of whales to be taken is 127 excluding the Kola region. Unless the operations are hampered by extreme weather conditions, there are no immediate plans for a future catch of minke whales in Norwegian waters.

Comments and discussion
The Committee referred to its comments made in previous years (1993b; 1994d) and under Item 12.1.2.

12.2.3 Japan – North Pacific
The Committee reviewed SC/46/NP1 from the Government of Japan concerning a research programme to clarify the stock structure of minke whales in the northwestern North Pacific. The proposal was circulated to the Committee on 16 March 1994. The Committee agreed to review the proposal in accordance with its previous guidelines.

(A) The Proposal
The relevant guideline is as follows:

'A statement as to whether the permit proposal adequately specifies the four sets of information required under paragraph 30 of the Schedule.'
1. 'Objectives of the research;' (Sched. Para. 30)
2. 'Number, sex, size and stock of the animals to be taken;' (Sched. Para. 30)

The objectives of the research are to clarify the stock structure and mixing rates of minke whales around Japan based on problems encountered by the Scientific Committee in its discussion of implementation trials for North Pacific minke whales (Item 9.2.1); in particular to clarify whether the 'W' stock exists and if so the mixing rate between the 'W' and 'O' stocks and to clarify the validity of the 'O' sub-stock scenario. The first year of the research is a feasibility study. It is intended to take 100 animals in sub-area 9 (IWC, 1994e), in an area which extends from 157°-170°E, south of the 200 mile EEZ of the Russian Federation and the USA, and north of 35°N. Random sampling will be carried out.

Comments
The Committee agreed that the relevant guidelines have been met.

(B) Objectives
The relevant guidelines are as follows:

1. 'Comments on the objectives of the research to be carried out under the proposed scientific permit, including in particular how they might relate to research needs identified by the Scientific Committee';
   (Rep. int. Whal. Commn 36:133)
2. 'The proposed research is intended, and structured accordingly to contribute information essential for rational management of the stock';
3. 'The research addresses a question or questions that should be answered in order to conduct the comprehensive assessment or to meet other critically important research need';
   (Rep. int. Whal. Commn 38:27-8)
4. ‘The number, age and sex of whales to be taken are necessary to complete the research and will facilitate the conduct of the comprehensive assessment.’ (Rep. int. Whal. Commn 37:25)

The Committee agreed that the objectives directly addressed questions of interest to the Scientific Committee and that the proposal fulfilled these guidelines.

Hester commented that this proposal addressed the matter of stock identity and structure which is of utmost importance to respecifying the Implementation Simulation Trials for North Pacific minke whales, as discussed under Item 9.2.1 and Annex D.

(C) Methodology

The relevant guidelines are as follows:

1. ‘Comments on the methodology of the proposed research and an evaluation of the likelihood that the methodology will lead to achievement of the scientific objectives. These comments may also include evaluation of the methodology in terms of current scientific knowledge.’ (Rep. int. Whal. Commn 36:133)

2. ‘The objectives of the research are not practically and scientifically feasible through non-lethal research techniques.’ (Rep. int. Whal. Commn 37:25)

3. ‘The research addresses a question or questions that cannot be answered by analysis of existing data and/or use of non-lethal research techniques.’ (Rep. int. Whal. Commn 38:27-28)

4. ‘Whales will be killed in a manner consistent with the provisions of Section III of the schedule, due regard being had to whether there are compelling scientific reasons to the contrary.’ (Rep. int. Whal. Commn 37:25)

[TThe Commission agreed that it has been intended by this for the Committee to report if cold grenade harpoons were used in special permit catches. (Rep. int. Whal. Commn 38:13)]

5. ‘The research is likely to yield results leading to reliable answers to the questions being addressed.’ (Rep. int. Whal. Commn 38:27-28)

The proposal (pp. 9–10) gave a number of reasons as to why lethal sampling was required: (1) biopsy sampling may not yield sufficient sample material per whale for some of the types of analyses proposed; (2) it is not practical to collect the required number of samples from a large vessel in the open ocean using biopsy sampling; (3) results additional to those from DNA analyses are required to meet the objectives including those from analyses of isozymes, conception date data, morphometrics, pollution and parasite burdens, all of which are useful in providing information on stock structure, as has been shown in past studies. All whales would be killed using explosive grenade harpoons.

Comments and discussion

Much of the discussion of genetic analyses centred on two issues:

(i) replacement of the proposed research take by collection of biopsy samples; and

(ii) use of existing stored samples from earlier takes for genetic analyses.

In relation to biopsy samples, Slooten, Baker and Lankester commented that with currently available genetic techniques, the programme’s objectives could be met by non-lethal sampling. They also referred to use of the PCR approach which can utilise stored samples as well as ‘fresh’ tissue from biopsy samples (see Annex D, Appendix 6). It is possible to analyse the data in a way similar to allozyme data (e.g. deviations from Hardy-Weinberg and Wright’s FST) and the resolution is higher. Slooten noted that over 1,000 samples already existed that could be analysed in this way, and that doing so would help in the design of future studies. Zeh noted that apart from sex, biopsy samples provided no information on the age, length and reproductive status of the animal concerned. Butterworth drew attention to results in Table 3 of SC/46/NP2 which indicate that the Adh-14 allele frequency proportion for the O stock (found in subareas 7 and 11) is already determined with high precision from existing data.

In response, Hatanaka referred to SC/46/NP1 and explained that none of the existing samples were from subarea 9 and that possible sampling in future years in other areas would depend on the results of analysing existing material and any development in biopsy techniques. Isozyme analyses had already been carried out for many of these whales (e.g. Wada and Numachi, 1991). Miyashita reported briefly on the poor results of attempts to use biopsy guns from a large catcher boat in open ocean. Slightly better results had been obtained using a small type whaling vessel in coastal waters but this vessel cannot operate in the open ocean. Pastene commented that while he agreed that the PCR approach was valuable, experience from several studies showed that data from several techniques were required to attempt to elucidate stock structure and mixing rates.

Hatanaka commented that attempts to use the PCR approach on preserved samples was providing mixed results. It had failed with samples from Korea but appeared successful with some from coastal Japan and analyses of these are underway.

Swartz, Slooten and Lankester questioned the proposed sample size and the likely power of the approach to meet the objectives of the programme. Butterworth introduced SC/46/NP2 which addresses this question in terms of the use of allele frequency data to provide estimates of the extent of mixing, based on Hardy-Weinberg equilibrium. Calculations were made of the power of the method to determine the ‘O’ : ‘W’ stock ratio in a subarea as a function of sample size and other parameters. Unfortunately in the absence of data from sub-area 9, it is not possible to refine sample size requirements until the results of the feasibility study are available to provide estimates of those other parameters.

Baker commented on the relationship between genetic resolution and sample size, noting the relatively low resolution of allozyme methods. Wallace noted that allozyme data had been used successfully in addressing some stock identity questions in North Atlantic minke whales.

Smith noted the intention to analyse existing data and encouraged further attempts to develop an effective biopsy sampling technique. He suggested that the question of optimal sampling rates might be addressed using satellite telemetry. He noted that this was a feasibility study and if the research described was carried out, he expected a more refined and elaborate proposal would be received for review by the Committee next year.

Hatanaka responded that the biopsy technique would be tested further, and that satellite telemetry techniques were being developed. He further commented that results of the feasibility study and a full scale proposal will be submitted to the Committee next year.

Polacheck and Smith referred to comments about the importance of abundance estimates in the context of the RMP and suggested that consideration should be given to the relative levels of effort that should be put into sightings versus sampling. Butterworth referred to SC/46/Mg11, the results of which showed that information on ‘O’: ‘W’ stock structure and mixing is essential for refining the range of
hypothese to be considered in the Implementation Simulation Trials for North Pacific minke whales.

In response Hatanaka stated that the importance of the sightings data was already recognised and referred to the information presented in SC/46/NP5, NP6 and SC/46/0 22.

(D) Effect of catches on the 'stock'
The relevant guidelines are:

1. 'A review of the most recent information on the stock or stocks concerned, including information on any exploitation, stock analysis and recommendations by the Scientific Committee to date (including, where appropriate, alternative analyses and conclusions and points of controversy).'
   (Rep. int. Whal. Commn 36:133)

2. 'An evaluation of the specification in the permit proposal of 'possible effect on conservation of the stock'. As appropriate, the Scientific Committee may carry out its own analysis of the possible effects.'
   (Rep. int. Whal. Commn 36:133)

3. 'The research can be conducted without adversely affecting the overall status and trends of the stock in question or the success of the comprehensive assessment of such stocks.'
   (Rep. int. Whal. Commn 38:27-28)

SC/46/NP1. Appendix 1. reported calculations carried out to advise on the impact of various levels of research take of minke whales from sub-area 9 of the North Pacific. Two 'worst-case' scenarios (in the context of risk) had been examined, based upon slight variants of the trials developed in 1993 by the Committee for an initial evaluation of the application of the RMP to North Pacific minke whales. Both trials assumed MSYR_{mature} = 1% for all stocks. In the first, the 'O' stock was assumed to extend to the eastern boundary of sub-area 9 with no mixing from the 'W' stock in that region; this means that the stock from which the proposed research catch would be taken would be the same as that which had earlier been impacted by historical catches close to the coast of Japan. In the second, sub-area 9 was assumed to contain an isolated stock at (nearly) its pre-exploitation level, because hardly any previous catch had been taken from that sub-area. This second scenario was seen by the authors as implausible. Results were reported for percentiles of depletion for annual takes of 0, 50, 100, 150 and 200 from sub-area 9 for a period of five years. Although the proposal pertained to a take from the sub-area for a single year, calculations had been conducted for a period of five years because the proposal allowed for the possibility that similar levels of take might be maintained for that period.

Japanese scientists (SC/46/NP1) judged on the basis of these results that an annual take in the range 100 to 200 whales had no harmful effect on the populations, even in these 'worst case' scenarios. Wallace supported this view.

Stokes commented that, in addition to the points made by Butterworth, attention should be drawn to the following aspects. The results presented in the Tables in SC/46/NP1. Appendix 1 needed to be interpreted differently to Implementation Simulation Trial results which showed the implications of RMP application over a 100 year period (with feedback control) rather than a five year fixed catch. The trial assuming a discrete isolated stock in sub-area 9, which Butterworth regarded as implausible, showed a marked decrease in both the median and lowest 5%-ile final stock size over a five year period. In terms of guideline D3 this could be interpreted as an 'adverse trend'. The trial assuming that the 'O' stock extends over a wide area north and east of Japan, which Butterworth regarded as more plausible, showed apparently small differences in median and lowest 5%-ile trial population sizes at catches of 100 or 200 per year for five years, compared to zero catches. However, even in this trial, the median final population size results (after five years) could be interpreted to indicate that if such catches were taken for an extended period, the median final population sizes achieved would be below the adopted target level of 0.72 for the RMP. He did not express an opinion as to the implications for North Pacific minke whale stocks.

Butterworth believed that the scenario of an isolated stock in sub-area 9 was implausible because it assumed the number of minke whales in the whole North Pacific east of sub-area 9 that were part of the stock in that sub-area to be zero. The actual number was likely to be well above zero, given the area involved. Taking account of these additional whales would result in extents of depletion much less than the extremes reported in Appendix 1 of SC/46/NP1.

DeMaster raised the point that an approach more similar to the aboriginal subsistence whaling scheme would be more appropriate for evaluating the effect of catches related to research whaling on the stock than the approach used in SC/46/NP1.

Lankester, Holt, de la Mare, Pascal and Donoghue commented that, as on previous occasions, the Committee has to give advice on a permit which is planned to be issued for a limited period, i.e. one year only. They considered that, while the effect of a catch of 100 whales for one year is unlikely to have an adverse effect on the status of the stock or stocks, this research is presented as a feasibility study. The level of any future research catches still needs to be determined and might be considerably higher. Therefore it is not possible to judge the effect of longer term catches.

The Committee noted the difficulties in adequately providing advice on this matter in the past. Usually it has some knowledge of catch history (in this case a negligible historical catch, IWC, 1994c) and an estimate of abundance (in this case 8,264 (CV 0.396)). Its advice has normally taken the form that the take of x whales (in this case 100 whales) for a short (in this case 1 year) period would have little effect on the status of the stock. It then goes on to state that 'however it believed that the effect of a small take for a short period would always be negligible'.

The Committee decided that it should consider the general question of how to provide such advice at its next meeting.

(E) Research co-operation
The relevant guideline is:

1. 'Comment on the adequacy and implications of specified arrangements for participation by scientists of other nations'.
   (Rep. int. Whal. Commn 36:133)

The Committee agreed that this guideline had been met.

Additional comments
At the conclusion of the discussion, Berzin proposed that the work on abundance of minke whales in the southwest part of the Pacific Ocean be specified. He also requested a detailed write-up on the strategy of the whaling operations: how the factory ships and whaling ships will operate in the area; and how the take will be conducted (whether by random or non-random selection). Finally, he proposed that it was necessary to undertake a full biological analysis of taken whales. From such an analysis, information on size, sex, age and life history parameters will be obtained which is just as important as population segregation. He also considered that it is necessary to conduct morphometric studies to help address the questions of
population structure of minke whales in the northwestern part of the Pacific Ocean. Japanese scientists agreed to include Berzin’s proposals in their programme. Berzin expressed his desire that the Japanese proposal will be accepted by the Committee.

Hatanaka expressed appreciation to those members of the Committee who had provided positive and constructive comments; these comments would be taken account of in the final version of the research plan.

13. SECOND INTERNATIONAL DECADE OF CETACEAN RESEARCH

13.1 Review of results from 1993/94

(a) IWC/IDCR Southern Hemisphere minke whale assessment cruise

The report of the cruise is given as SC/46/S3 and discussed in Annex I.

(b) Structure of fin whale populations of Gulf of St Lawrence and West Greenland

The report of this study is given as SC/46/NA7 and discussed in Annex F.

(c) Project YONAH (Years of the North Atlantic Humpback)

The report of this study is given as SC/46/NA5.

(d) Molecular genetic identification of sex and identity among humpback whales of the Southern Oceans

The report of this study is given as SC/46/S23 and is discussed in Annex F.

13.2 Review proposals for 1994/95

13.2.1 Southern Hemisphere minke whale assessment cruise 1994/95

The Committee received the report of the Working Group established to consider the 1994/95 survey (Annex I). It endorses the recommendations of that report. In particular, the Committee agreed that Area III east of 40°E and part of Area IVW be surveyed with details being deferred to the planning meeting.

The Working Group asked the Committee to consider the amount of effort that should be devoted to experimental work during the cruise.

The Committee agreed that:

(i) although there was scientific value in obtaining biopsy samples and photo-identification material, the primary function of the cruise was to obtain sightings estimates of Southern Hemisphere minke whales in the survey area – this should not be jeopardised by experimental work;

(ii) as noted in its Guidelines last year (IWC, 1994h), estimated distance and angle experiments are essential;

(iii) it is not possible to identify a minimum number of biopsy samples required – this depends on the issues they are intended to address and the area being surveyed – and it was noted that for both biopsy sampling and photo-identification work, accumulation of even small amounts of additional data over a period is valuable.

The Committee agreed that these considerations should be taken into account by the planning meeting, in addition to those identified in Annex I. It was probably more appropriate to give cruise leaders a guideline as to an approximate total time that might be allocated to biopsy and/or photo-identification work rather than try to specify a number of samples/photographs. This should be similar to that expended in previous cruises.

Also under this Item, the Committee discussed and endorsed a recommendation from Annex I, that the 1993/94 IDCR cruise data be analysed as part of an extension to the contract study already being undertaken (see Item 18).

In this regard, Polacheck and Smith commented on the differences between estimates obtained from IDCR and JARP A cruises. Butterworth responded that care needed to be taken in making such comparisons because of differences in survey methodology and areal coverage. The Committee agreed that it was not practical to investigate this at the present meeting and noted that its present work structure did not easily accommodate such a discussion. It recommends that this matter be included on next year’s Agenda and notes that considerations under Item 9.1.1 on the IWC database are relevant as to how much progress may be made.

13.2.2 Other

A Working Group to review research proposals was established and its report is given in Annex J.

The Working Group reviewed each proposal on the basis of its relevance to the objectives of the Scientific Committee and the work of the Commission, the scientific quality of the project, its chances of success, the competence of the proposers, the feasibility of the work schedule and the reasonableness of the budget.

The Committee agreed with the view of the Working Group that it should develop more specific guidelines concerning attendance of proposers, associates and cooperators during Research Proposal discussions.

During discussion of the report, a problem arose as to the handling of one of the proposals. This was referred to the Convenors who concurred with the conclusion of the Working Group as expressed in Annex I.

The Committee agreed that three proposals be accorded high priority:

(b) Genetic analysis sub-project – Years of the North Atlantic humpback whale – SC/46/RP3. Amount requested £10,000.

(c) Survey of humpback whale breeding grounds in Southern Madagascar and their relationship to other breeding grounds in the southwest Indian Ocean – SC/46/RP6. Amount requested £7,520.

Providing the recommendations about priorities in Annex R are met, the Committee also recommends funding of SC/46/RP2 (Photo-ID and behaviour study of humpback whales in New Caledonia, South Pacific). Amount requested US$10,500.

The Committee endorsed proposal SC/46/RP5 (Geographic structure of nuclear and mitochondrial DNA variation among humpback whales: refining the stock concept) but noted that sample sizes were small in terms of addressing some of the objectives, particularly for the eastern Australia/New Zealand/Tonga region. It recommends that this proposal be resubmitted next year provided the problem of sample size is addressed.

The Committee also endorsed SC/46/RP4 (Histo-pathology of kidney and liver tissues of the pilot whales off
the Faroe Islands, related with high levels of cadmium and mercury) and agreed it should be further reviewed at the forthcoming pollution workshop (see Item 7) for consideration for funding. Consideration of SC/46/RP7 (Improving information resources in the IWC/IDCR program: A proposal) was deferred to the IDCR cruise planning meeting.

In view of the problems that occurred this year, the Committee agreed that it should review its policy on consideration of research proposals at next year's meeting. It appointed an intersessional working group to examine this matter further (Reilly, Donovan, Swartz, Kato, Anderson).

13.3 Further analysis of IDCR photo-identification and biopsy specimens
The Secretary reported that all available photo-identification material from IDCR cruises is now held at the Secretariat. Discussion of IDCR biopsy samples is given in Annex I.

14. WHALE SANCTUARIES

14.1 Indian Ocean Sanctuary
The Indian Ocean Marine Affairs Cooperation (IOMAC) is initiating a new Indian Ocean regional project for marine conservation (IWC/46/26). The project will provide a framework for future whale- and dolphin-related activities. The objectives for the project include studies on the effects of pollutants and environmental changes on marine mammals; monitoring the recovery of depleted whale stocks; identifying expanding gillnet fisheries which take marine mammals; the development of long-term research programmes to estimate population size, abundance and distribution of Indian Ocean mammals, and to collect sighting data. IOMAC feels that it should take a leadership role in organising and intensifying effective and long-term research, deriving from IOMAC's declaration in 1990 of the Indian Ocean as a sanctuary for whales for all time.

The Committee recalled its earlier work on planning for research in the Indian Ocean Sanctuary as summarised in Leatherwood and Donovan (1991). It recognises the value in establishing co-operation with the IOMAC Scientific Committee and draws this to the attention of the Commission.

The Committee also received two papers related to the Indian Ocean Sanctuary, one concerning marine debris (SC/46/O 26) and the other concerning observations of cetaceans made during a cruise undertaken in May-July 1993 (SC/46/O 27). The Committee welcomed this information.

In response to a suggestion that the Committee should develop guidelines for cetacean studies from platforms of opportunity, there was a brief discussion of the value of such data. It was recognised that it was not possible to address the issue in the time available at this meeting. The Committee agreed that this item should be discussed at next year's meeting. It requested that the USA provide relevant information on and results arising from its long-running platforms of opportunity programme.

14.2 Southern Ocean
An intersessional open-ended working group of the Commission met on Norfolk Island in February 1994 to discuss the French proposal for a Southern Ocean whale sanctuary (IWC/46/19). During that meeting Reilly (attending as acting Chairman of the Scientific Committee) was asked to provide information on a number of topics, including the extent to which environmental threats and under-reporting of catches had been taken into account in trials of the RMP. He had provided brief verbal summaries to the meeting but agreed to provide a more detailed account to the next meeting of the Commission.

At the beginning of this meeting, Reilly had announced that he only intended to address the issue of providing the more detailed information to the Commission under this Agenda Item. Although there were a number of other scientific related matters in the report of the Norfolk Island Meeting, he believed it was inappropriate to address these before the report had been presented to the Commission. He also agreed, however, that if time was available he may allow a brief discussion of other matters. The Committee had concurred with this plan.

In addition to the earlier work on environmental factors and the RMP, the Committee had discussed the matter extensively at this meeting, both in the context of Items 7 and 9.1.1. The Commission is referred to those discussions. In summary, the Committee concluded that there was little to gain in the context of the conservation performance of the RMP by modifying the procedure to take further account of environmental change.

Similarly, this year the Committee had carried out further work on the effects of under-reporting of catches. This is discussed under Item 9.1.1 and in Annex D. In summary, the Committee believes that the RMP adequately considers the question of under-reporting of catches.

At the end of the discussion of this Item, Komatsu expressed his regret that the Committee had not seen fit to address a number of outstanding items with respect to providing the Commission with the full range of scientific advice that it needed to fully consider the question of a Southern Ocean sanctuary; this included development of trials as discussed in IWC (1994d, p.58); consideration of the northern boundary; ecological interactions among whale species; and the planning of research and the resultant financial implications.

15. SMALL CETACEANS

15.1 Review of the status and exploitation of small cetaceans in Latin America
15.1.1 Vaquita Phocoena sinus
DISTRIBUTIONS AND ABUNDANCE
Thirty-five sightings (59 individuals) of vaquitas were obtained during six cruises carried out in the Gulf of California, Mexico, between July 1992 and November 1993 (SC/46/SM7). Total trackline searching effort was 10,230 n.miles, of which 2,369 n.miles were on a cruise by the Southwest Fisheries Science Center (SWFCS) of the US National Marine Fisheries Service (August-November 1993) and 7,861 n.miles on five cruises (July 1992-October 1993) by the Programa Nacional de Investigación y Conservación de Mamíferos Marinos de México (PNICMM) of the Mexican Secretariat of Fisheries (SEPESCA). All but one sighting occurred in a small area in the northwestern side of the Gulf of California. The other sighting was ca 50 n.miles to the east of the others. These and previous data provide additional evidence to support the conclusion that the vaquita is restricted to the upper Gulf of California (Brownell, 1986; Vidal et al., In press). This is the most limited distribution of any marine
etaceous. About 40% of the sightings made by Silber (1990) and of those obtained during the SWFSC and PNICMM surveys were made outside the boundaries of the recent declared Biosphere Reserve of the Upper Gulf of California and the Colorado River Delta.

There have been no recent surveys conducted in the shallow waters (<20m) of the northernmost Gulf of California.

A line-transect survey was carried out in the upper Gulf of California during August 1993 (SC/46/SM23). Based on 22 sightings, the authors estimated the population within the area surveyed to be 316 (95% CI 118-847). It was noted that this is a preliminary estimate that may be improved by further analysis. Because some vaquita habitat lies outside the area surveyed (particularly in shallow waters <20m), the total population estimate might be higher. Nevertheless, this first quantitative estimate of vaquita population size confirms previous conclusions that it is very rare. The PNICMM is planning to continue its surveys efforts.

LIFE HISTORY AND HABITAT

A sample of 56 vaquitas (30 females, 26 males) collected over several years, most of them killed in fishing nets, provided an opportunity to evaluate the life history of this species (SC/46/SM19). The results are summarised in Annex G and suggest that the life history of the vaquita appears to be similar to that of the harbour porpoise (P. phocoena) in a highly exploited population from the Bay of Fundy, Canada, with the important exception that calving does not appear to be annual and thus that the potential rate of increase may be lower.

Concerns were expressed on the negative effects that the reduction of the Colorado River flow could have caused on the habitat of the vaquita. No data were provided to address this problem.

INCIDENTAL MORTALITY

Gillnets are the most widely used fishing gear within the habitat range of the vaquita and large mesh gillnets have been the most important documented cause in vaquita incidental mortality. A minimum of 35 vaquitas were killed in 1985 and 1990 in these fisheries. Until recently, large mesh nets were mainly used to catch totoaba, Totoba macdonaldi, an endangered sciadid fish. Although this fishery was banned in 1975, at least until February 1992 some fishermen in the upper Gulf continued to fish totoaba. In February 1992, the Mexican government banned the use of mesh sizes larger than 25cm, and on 10 June 1993 declared the Biosphere Reserve of the Upper Gulf of California, mainly to protect the vaquita, the totoaba and their habitat. A management plan is currently being developed for the Biosphere Reserve.

SC/46/SM8 presented a preliminary analysis of the incidental mortality of the vaquita in gillnets with mesh sizes of less than 25cm. Fishing activities were monitored in only one (El Golfo de Santa Clara) of the four fishing ports with activities in the range of the vaquita, between January 1993 and March 1994. A total of 14 vaquita deaths were reported in gillnets of mesh sizes between 7 and 15 cm and one probably in a commercial shrimp trawl. It was stressed that this should be considered a minimum since only one fishing town was monitored. SC/46/SM8 concluded that because mortality of the vaquita occurred in gillnet fisheries previously not monitored, the past total mortality may have been higher than previously believed. Vaquitas are being caught in virtually all gillnet fisheries. Several members of the Committee noted that data presented on incidental mortality is still preliminary and that further analyses are required. It is also important to obtain mortality data for the other ports.

It was noted that SEPESCA has monitored the incidental mortality of vaquitas in gillnets during 1993 in two ports (El Golfo de Santa Clara and San Felipe), and that new information will be available also from the Mexican shrimp trawl observer programme. An analysis of vaquita deaths in totoaba experimental fishing conducted in previous years has been completed (Mexican Committee for Vaquita and Totoaba, Comite Técnico para la Conservacion de la Vaquita y la Totoaba (CTPVY)), but the results were not available for the Committee.

The Committee noted: (1) the similarities of population parameters with harbour porpoise in Gulf of Maine – Bay of Fundy; (2) the indication of a calving interval of more than one year SC/46/SM19 and; (3) that information (SC/46/SM8) of incidental takes was provided for only one of four fishing ports. It agreed that the vaquita can probably not sustain the present levels of incidental mortality in fishing gear.

RECOMMENDATIONS

The Committee recommends that monitoring of fishing activity and incidental mortality of vaquita be conducted in the entire range of the species in the northern Gulf of California in order to obtain an estimate of total annual incidental mortality. The Committee recommends that census surveys, including shallow waters of the uppermost Gulf of California, be conducted to refine current estimates of abundance and improve understanding of the spatial and temporal distribution patterns of this species. In this regard, the Committee welcomed recent joint efforts by Mexican and US government agencies in the study of the vaquita, and encouraged further cooperative efforts.

The Committee recognises the importance of recent efforts by the Mexican government to protect the vaquita, and in particular commends it for the declaration of the Biosphere Reserve in the upper Gulf of California. The reserve includes the ban of fishing activities in the core zone and is an important step in the conservation of the vaquita.

Considering the low estimate of abundance, the limited distribution of the population, the low potential rate of increase, and levels of continuing incidental catches, the Committee expresses extreme concern over the status of this species. Although it recognises the utility of further research, in view of the precarious state of the vaquita the Committee recommends that immediate action be continued to eliminate incidental catches in the area. The available information indicates that present levels of incidental catches could cause the extinction of the vaquita.

5.1.2 Franciscana Pontoporia blainvillei

STOCK IDENTITY AND DISTRIBUTION

The distribution of the franciscana extends from Ituñas in Espíritu Santo state (18°25'S), Brazil to Rio Negro Province (41°09'S), in Argentina; it is confined to coastal and inshore waters. Morphometric data allow two geographic forms to be identified, a smaller form, between 22°S-27°S and a larger form, between 32°-38°S (SC/46/SM12). These two forms should be considered separately for management and conservation purposes. No abundance estimates are available.
GROWTH, REPRODUCTION AND FEEDING

Biological data collected from incidental catches in Rio Grande do Sul are reported in SC/46/SM12. This included information on stomach contents, age at sexual maturity (2–4 years) and reproduction. Age data for animals collected in Rio Grande do Sul from 1976 to 1986 revealed a high vulnerability of the species to gillnets in the first 3 years of life: 50% of the dolphins caught were less than 4 years old, i.e. before or at the age of sexual maturation (SC/46/SM12).

INCIDENTAL CATCHES

A number of papers considered the occurrence and levels of incidental catches in fishing operations in Brazil (SC/46/SM12, SC/46/SM10) and Argentina (SC/46/SM25). These are discussed in Annex G. In response to a suggestion that fishing effort in Argentina should be shifted from gillnets to longlines, the Committee emphasised that the ecological impact of this needs further investigation before any advice on gear change can be given.

An increase in fishing effort has occurred since 1982 in Rio Grande but there is no information about possible shifts in fishing grounds (SC/46/SM12). Between 1982–1986, the relative frequency in the catch of franciscana older than 3 years increased, compared with the 1976–1980 period. If it is assumed that fishing grounds have remained the same between 1976–1986, the age composition shift may indicate that the franciscana population structure is being affected by coastal gillnet fisheries.

Although over a thousand franciscana were reported caught since 1976 along the three southern Brazilian states, it is not possible to evaluate the impact of these catches on the population in the absence of abundance estimates (SC/46/SM12).

RECOMMENDATIONS

The Committee concluded that with no estimate of abundance, incomplete information on stock identity and incomplete information on incidental takes, it was not in a position to assess the status of the franciscana. The Committee recommends that the critical research needs identified below be addressed.

(1) Research should be undertaken to clarify migration and stock identity of franciscana from areas within its known range where there is little or no information. Morphometric studies and genetic analysis using molecular techniques such as e.g. DNA fingerprinting, protein electrophoresis and microsatellite polymorphisms, should be conducted on data and samples from incidentally caught animals. Telemetry methods should be applied to study migrations of free-range animals and for collecting data on surfacing intervals and time spent at the surface.

(2) Reliable abundance estimates should be obtained for the total population and for those stocks which should be regarded as separate units for management purposes, taking into account the guidelines for conducting surveys and analysing data provided by the Scientific Committee (IWC, 1994h).

(3) Demographic data, such as age at sexual maturity, calving intervals and longevity, should be collected from incidentally caught animals, especially from areas where these data are not yet available.

(4) Information on abundance, demography and vital rates should be obtained by using modified techniques based on individual recognition for localised groups of franciscana that show possible site fidelity in shallow inshore waters.

(5) The research items identified above should be coordinated for Brazil, Uruguay and Argentina the exchange of samples and information across national borders should be facilitated.

The Committee noted that although incidental takes were documented for Brazil (SC/46/SM10; SC/46/SM25) and Argentina (SC/46/SM25), they were incomplete. Incomplete information on catches was also provided in SC/46/ProgRep Brazil; no progress report was received from Argentina. The Committee recommends that the Commission requests that Brazil and Argentina establish procedures for recording incidental and directed takes of small cetaceans and that catch statistics are submitted in the national progress report in accordance with the guidelines (IWC, 1989b). The Committee requests the Secretary to inform Uruguay of the findings of the Committee and to invite them to submit data on takes and abundance of small cetaceans in their waters. The Committee expressed concern at the possible levels of incidental takes of the franciscana suggested by the available data. As a precautionary measure, range states are encouraged to implement steps to reduce incidental mortality.

15.1.3 Tucuxi Sotalia fluvialis

STOCK IDENTITY, DISTRIBUTION AND ABUNDANCE

Two forms of the tucuxi, a coastal marine form and a smaller freshwater form, have been identified on the basis of variation in skull dimensions and body size. Further studies are needed to determine relationships among populations in marine and freshwater environments, particularly using genetic techniques.

The marine form appears to have a continuous distribution, from the Florianopolis region, Brazil (27°35'S, 48°34'W) north to Panama (09°22'N, 79°54'W); recently it has been found in waters off Nicaragua. The freshwater form of this species inhabits the Amazon and Orinoco drainages. It is commonly seen in the Amazon and has been found as far inland as Southern Peru.

No abundance estimates are available for either form.

INCIDENTAL CATCHES

The marine tucuxi is commonly caught in artisanal gillnet fisheries along the Brazilian coast and possibly in the remainder of its range (SC/46/SM10) but the sparse information available does not allow an estimate of total mortality to be made. Preliminary data suggest that the tucuxi may be among the most commonly caught small cetacean species along the Caribbean coast. The level of incidental mortality of the freshwater form appears to be low in the Amazon basin.

Recommendations

The Committee concluded that with no estimate of abundance, incomplete information on stock identity and incomplete information on incidental and directed takes, it was not in a position to assess the status of tucuxi. The Committee recommends that the following critical research needs are addressed.

(1) Research on distribution, migration and stock identity is required. Telemetry techniques should be applied to
track movements of free ranging animals while morphometric and genetic techniques are needed to study stock identity.

(2) Abundance estimates should be obtained following the Committee’s guidelines (IWC, 1994h); modified techniques maybe required for inshore and riverine waters.

(3) Demographic data and information on age at sexual maturation, calving intervals and longevity should be collected from incidentally caught animals.

(4) Research should be coordinated among countries within the known and potential range of the tusculi (Brazil, Peru, French Guiana, Surinam, Guyana, Venezuela, Colombia, Panama, Costa Rica and Nicaragua).

The Committee expressed concern at the possible levels of incidental takes of the tusculi suggested by the available data and, as a precautionary measure the states listed above are urged to implement steps to reduce incidental mortality. The Committee recommends that the Commission requests relevant member governments (Brazil, Costa Rica, Peru and Venezuela) to establish procedures for recording incidental and any directed takes of tusculis and that catch statistics are submitted in national progress reports in accordance with the guidelines (IWC, 1989b). The Committee further requests that the Secretary informs the relevant non-member states of the findings of the Committee and invites them to submit data on takes and abundance of tusculi in their waters.

15.1.4 Dolphins taken in the ETP purse seine tuna fishery
Although this subject was included in discussion under Latin America, the Committee noted that several countries from outside this region are active in the fishery (SC/46/SM4).

SC/46/SM4 and SC/46/SM21 relate to the levels of incidental catches of dolphins in the ETP tuna fishery and their possible impact on dolphin populations. SC/46/SM21 presented time series of relative abundance estimates of seven dolphin populations that have been subject to varying levels of mortality in this fishery. Most populations showed a decline during the late 1970s, with numbers levelling off at, or just after, the end of the decade and remaining fairly constant since then. In contrast, the abundance index of the northern stock of common dolphins showed a strong decline in the study area from 1980 to 1986. It remained relatively stable from 1987–1990 but from 1991–1993 dropped considerably even though mortality by the tuna fishery was very low in this period. Independent information indicates that the abundance of animals of this type has simultaneously increased by a factor of 5 in waters off California, perhaps as a result of oceanographic changes. The Committee noted that this was an example of how abundance estimates from only part of a population’s range might give misleading results if considered in isolation. A further anomaly highlighted by this paper was a series of significant positive correlations between dolphin abundance and both the number and proportion of net sets on dolphins, indicating that the index may be biased. The most likely explanation is that it is a result of recent operational changes in the fishery. Further work will attempt to address this.

SC/46/SM4 reported that total dolphin mortality in the ETP tuna fishery was 3,609 animals in 1993. This represents a decrease of 97% from the 1986 level (133,000) and 77% from the 1992 level (15,500). Most of this improvement was due to changes in fishermens’ performance. Observer coverage was 100% in 1993. SC/46/SM4 also presented information on the level of relative mortality (incidental deaths/estimated population size) for each of the populations affected by this fishery. Hall reported that mortality rates for all species were considerably below conservative estimates of sustainable losses for these populations. The highest figure was of 0.16% (for the northeastern spotted dolphin). Hall drew the Committee’s attention to the fact that net sets on free-swimming tunas schools and especially on floating objects (logs), while reducing dolphin mortality, dramatically increased (a) the level of incidental mortality of other organisms (such as sea-turtles, mahi-mahi, billfish rays and sharks); (b) the tonnage of discarded tuna; and (c) the catches of small and sexually immature tunas.

The Committee welcomed the continued rapid decline in the size of dolphin bycatch in the ETP tuna fishery. It reiterates its appreciation of the effective management action implemented by an international agreement negotiated by the IATTC and collaborating nations, and of the considerable effort by the fisheremen in conducting release operations for entrapped dolphins. The Committee encourages continued effort to further reduce mortality levels, particularly by refining techniques to release dolphins.

15.1.5 Information on other stocks
Directed takes were reported from Chile (SC/46/SM11), Peru (SC/46/SM16), Colombia (SC/46/O 30) and Mexico (SC/46/SM24) and incidental takes were reported to occur widely in the Latin American region (SC/46/O 6; SC/46/SM12; SC/46/SM10).

Directed takes
The Committee noted that takes of small cetaceans for use as crab bait were reported from Chile (SC/46/SM11). Despite legislative protection since 1977, Peale’s, Chilean and Commerson’s dolphins continue to be taken. However, according to SC/46/SM11, a decline in catches has occurred since 1990 and in 1992 the use of dolphins was assumed not to exceed 10% (45 tonnes) of the demand for crab bait (an equivalent of 600 dolphins). The authors explained this as due to: (1) a decrease in fishing effort that lessened the demand for bait; (2) the fact that the waste from slaughterhouses and industrial fisheries covered an increasing part of the amount of bait needed; and (3) that the availability of dolphins had declined.

The Committee noted that bait reduced availability of dolphins might have been due to possible stock depletion arising from previous takes.

Continued directed fisheries were also reported from Peru where a ban on cetacean exploitation and utilisation was passed in 1990 (SC/46/SM16). Estimates of mixed directed and incidental catches were reported for four fishing ports monitored (Pucusana 1.65±1.53 in 1990; Cerro Azul 2.118±389 in 1992 and 1.956±133 in 1993; Ancón 2.296±329 in 1991 and 1.838±274 in 1992; Chimbote 1.825±220 in 1993) and an extrapolation was made to other areas indicating a rough estimate of about 17,600 small cetaceans per year taken in Peru (SC/46/SM16). The Committee noted that several assumptions (which were not explored) need to be met before this extrapolation can be considered reliable, but that the information from the four monitored harbours indicated high levels of total takes in Peru. The proportions of directed and incidental takes in these catches were not
reported and the Committee was informed that the mixed incidental and illegal catches made collection of catch and effort data difficult.

Four species (dusky dolphin, long-beaked common dolphin, Burmeister's porpoise and bottlenose dolphin) were most frequently caught in Peru, while catches of six other small cetacean species were also reported (SC/46/SM16). A shift in species composition was reported in SC/46/SM26. Two samples from 1985–89 (n = 5,322) and 1991–93 (n = 2,021) respectively, were compared. The proportion of dusky dolphins declined from 78% to 52.9% while the proportion of long-beaked common dolphins increased from 7% to 31.8%. The author suggested that this could be explained by high takes of dusky dolphins and a replacement in the niche by long-beaked common dolphins. The Committee stressed the fact that such changes could also be caused by long-term ecological changes and that the observed change in relative abundance in the two species could not on its own be assumed to show that there had been a population decline in dusky dolphins. However, the Committee agreed that catch levels of dusky dolphins as indicated in SC/46/SM16 and SC/46/SM26 may not be sustainable.

Directed takes were also reported from two communities in Colombia where dolphins (tentatively described as spotted dolphins and bottlenose dolphins) were harpooned for use as shark bait (SC/46/O 30).

Estimates of incidental takes of small cetaceans in artisanal fisheries were reported from two monitored ports in Ecuador (SC/46/O 6). From December 1992 until December 1993 a sample fleet of six vessels from the two ports made 2,764 fishing trips and bycaught 217 small cetaceans. Average daily capture rate and total estimated yearly take were respectively 0.038±0.014(SE) dolphins/boat/day and 315±60 dolphins per year at Puerto Lopes and 0.104±0.025(SE) and 1.466±182 dolphins per year at Santa Rosa. Four species were recorded from this fishery: short-beaked common dolphins (86%), short-finned pilot whales (9%), spotted dolphins (2%) and one dwarf sperm whale.

Monitoring of bycatches and strandings was reported from Brazil (SC/46/SM12; SC/46/SM10) and Colombia (SC/46/O 30). In addition to franciscana and tucuxi catches, nine small cetacean species involved in fishery entanglements were identified in Brazil (SC/46/SM12; SC/46/SM10), but for most areas both species composition and information on total incidental take levels were not available. SC/46/SM24 suggests that direct takes may occur in Mexico, but neither localities nor the magnitude of the takes or the methods of data collection were specified. The Committee noted that much more monitoring effort is needed to further document and evaluate these takes.

The Committee recognises the work of UNEP with respect to small cetaceans, with the implementation of the Action Plan for the Conservation of Marine Mammals in the South-East Pacific. In particular it commends the governments of Colombia, Chile, Ecuador, Panama and Peru for their effort in addressing fisheries related mortality of small cetaceans through the adoption of this plan.

**RECOMMENDATIONS**

Noting that: (1) species composition in directed and incidental takes was not known for many areas; (2) that estimates of total incidental and directed takes from monitored ports were available for only four ports in Peru and two ports in Ecuador; and (3) that catch statistics were not provided SC/46/ProgRep Mexico, statistics in SC/46/ProgRep Brazil were incomplete and no progress reports were received from Argentina, Chile, Costa Rica, Ecuador, Peru and Venezuela, the Committee recommends that the Commission requests that:

1. IWC member countries in Latin America (Argentina, Brazil, Chile, Costa Rica, Ecuador, Mexico, Peru and Venezuela) establish procedures for recording and reporting directed and incidental takes of small cetaceans, and to submit all catch statistics to the Commission;

2. non-member countries for which directed exploitation of small cetaceans is documented (e.g. Colombia), are informed about the findings of the Committee, encouraged to establish procedures for recording catch statistics and invited to submit all catch statistics to the Commission.

For species identified to be subjected to significant incidental or directed takes, the Committee recommends that:

1. abundance estimates be obtained following the Committee's guidelines (IWC, 1994b); and

2. demographic data such as age at sexual maturation, calving intervals and longevity, be collected from incidentally or intentionally caught animals.

Noting that there are national prohibitions of directed catches of cetaceans in Chile and Peru, and that these prohibitions impose constraints on the access to information on the continuation of catches, the Committee recommends that the ban on takes of cetaceans be enforced or that the continued harvest be managed at sustainable levels, where these can be determined.

The Committee further recommends that as a precautionary measure, steps be taken to reduce present mortality levels of dusky dolphins in Peru until sufficient information is available to estimate sustainable catch levels.

**15.1.6 General recommendations**

**STOCK IDENTIFICATION**

A number of small cetacean species (bottlenose dolphin, dusky dolphin, Peale's dolphin, Burmeister's porpoise) are directly harvested or incidentally caught on both the Pacific and Atlantic coasts of South America, but nothing is known about stock structure of these species in these waters. In addition, the stock structure of the franciscana and the tucuxi is poorly known. To better understand the stock structure of these and other South American species, the Committee recommends that various genetic studies and other types of stock identity techniques be pursued.

**TELEMETRY**

Little information is available on the distribution, migration or stock identity for several of the small cetacean species directly harvested or incidentally caught in Latin America. The Committee has made recommendations for the use of telemetry to address these research needs. At present, this technology is not readily available for satellite-linked radio transmitters suitable for use on the smallest cetacean species.

The Committee therefore recommends that the methodology is explored and developed to allow the construction of satellite-linked transmitters suitable for application on species such as the franciscana, porpoises and other small dolphins.
FISHING PERFORMANCE AND FISHING GEAR

The present review has identified incidental takes of small cetaceans as a problem for most of Latin America; these incidental catches are a global problem for many net fisheries (IWC, 1994a). The Committee recalled that the substantial reduction of dolphin mortality in the ETP purse seine fisheries for tuna was achieved by adjustment of fishery performance and gear modifications. The Committee therefore recommends that: (1) efforts to minimise incidental mortality of cetaceans be started or continued through the development of more selective gear and through training programmes for fishermen; (2) when alternative gears or modes of fishing are considered, a full ecological assessment of their impact is performed because of concerns that reduction in cetacean mortality may be achieved at the expense of other, perhaps higher ecological costs.

IMPLEMENTING ROUTINES FOR RECORDING BYCATCH DATA

The Committee noted that there are extensive small cetacean bycatch problems occurring in many countries which have different fishery practices and fishery legislation. The Committee recommends that observer schemes that incorporate a statistical sampling design be established. However, in some countries, certain fishing practices may render observer schemes impractical. In such circumstances, the Committee recommends that either monitoring programmes and/or modified observer schemes should be initiated; if this is not possible reporting schemes by fishermen should be formalised. However, the Committee cautioned that data collected by any means other than placement of observers onboard fishing vessels are generally less reliable. Such schemes, adapted to local circumstances, should be implemented and managed by relevant authorities and full statistics submitted to the Commission.

15.2 Harbour porpoise in the North Atlantic and Baltic Sea

15.2.1 Northwestern Atlantic

The findings of a workshop to assess the status of harbour porpoises in the Northwest Atlantic and a proposal for an international collaborative research to investigate population structure were summarised in SC/46/SM18.

During the workshop, it was reported that abundance estimates for harbour porpoises in the Gulf of Maine/Bay of Fundy region during 1991 and 1992 were 37,500 (95% CI 26,700 to 86,400) and 67,500 (95% CI 32,900 to 104,600). A weighted average estimate was 47,200 (95% CI 39,500 to 70,600), where each annual estimate was weighted by the inverse of its variance. The reason for the nearly two-fold, but statistically non-significant inter-annual difference was unknown, but may reflect either a real change in abundance due to a distribution change or methodological errors. No abundance estimates for the Gulf of St. Lawrence and Newfoundland were presented.

Bycatch estimates for the US Gulf of Maine and Gulf of St. Lawrence gillnet fisheries were reported to the workshop. In the US Gulf of Maine, the bycatch was estimated to be 2,400 (95% CI 1,600 to 3,500), 1,700 (95% CI 1,100 to 2,500) and 900 (95% CI 700 to 1,200) for 1990, 1991 and 1992. The 1993 estimate was not complete. For the Gulf of St. Lawrence in 1989 and 1990, from a mailed questionnaire to fishermen it was estimated that about 1,900 harbour porpoises are killed, but the reliability of estimate is questionable given the low return rate of the mail survey. No bycatch estimates were presented for the US mid-Atlantic coast, the Bay of Fundy or Newfoundland.

The Committee was informed of a proposal to reduce US bycatch by closing three large areas of the Gulf of Maine for one month in each area. SC/46/SM18 also described a research proposal for collaboration on North Atlantic harbour porpoise population structure. This is summarised in Annex G, Appendix 3.

RECOMMENDATIONS

The Committee recommends that information be obtained on the levels of bycatches of harbour porpoises along the Canadian east coast and the eastern mid-coast of the USA.

In light of the high estimates of incidental mortality in the Gulf of Maine – Bay of Fundy, the Committee welcomed the plans to reduce the by-catch in the Gulf of Maine by temporal closure of fishing areas. The Committee recommends that actions be taken to implement the proposed plans for the Gulf of Maine and that plans be developed and implemented in the Bay of Fundy and other areas of high incidental mortality of harbour porpoises in the western North Atlantic.

The Committee noted the proposal for an international programme to study the population structure of the North Atlantic harbour porpoise and recommends that this be conducted and extended so that other questions might be addressed, such as methods to modify fishing gear and practices in order to reduce the bycatch.

15.2.2 Northeast Atlantic and Baltic Sea

SC/46/SM13 summarised findings of autopsies of 295 (142 males and 121 females) stranded and bycaught harbour porpoises between 1985 and 1994 from England and Wales, and from Scotland before 1992. Approximately a quarter of the stranded animals were assessed to be bycatches from autopsy examination (SC/46/ProgRep UK).

SC/46/SM14 presented results from a preliminary mtDNA analysis of the genetic patterns of 50 out of 124 stranded and bycaught animals from various parts of the UK. The analyses revealed no between population differences between the Shetlands and Eastern England and eastern England and western England, although differences between western England and Shetland populations were significant. Overall, 95% of the diversity in the 50 sequences was found within populations and 5% between populations. Taken as a whole the results do not show significant divisions in population structure (p = 0.09).

It was noted that Denmark has an observer programme for several North Sea fisheries. During 51 observed trips, 117 harbour porpoises were caught. Using these data, a preliminary annual estimate of 4,000+ harbour porpoises killed in Danish turbot and cod set net fisheries was obtained (SC/46/ProgRep Denmark).

RECOMMENDATIONS

The Committee recommends that observer programmes be set up to estimate bycatches by range state fisheries in the northeast Atlantic, Baltic and North Seas. The results should be reported to the IWC and include information on levels of observer effort, spatial and temporal coverage and methods used to estimate at least rough total bycatch levels. To enable it to carry out an assessment of bycatch mortality and its effect on the population(s), the Committee recommends the collection of data on life
history parameters and the estimation of population(s) abundance. In this regard the Committee noted the international survey being undertaken in July this year (see Item 6.3).

The Committee discussed several possible methods for reducing the bycatch of North Atlantic harbour porpoises, including modifications of fishing gear and fishing practice, as well as time/area closures. The best method or combination of methods were not determined. Given the apparent high levels of take in recent years (more than 7,000 reported from three areas (Annex G)), and the lack of information on population structure, abundance and growth rate, the Committee recommends that bycatch be reduced by whatever means possible.

Recognising the aims of ASCOBANS concerning conservation and management of small cetaceans, IWC member countries that are also Range States to ASCOBANS, are encouraged to cooperate fully with ASCOBANS where appropriate.

15.2.3 Response to the 1993 Resolution on harbour porpoise
In response to the Commission’s Resolution last year (IWC, 1994a), scientists from 12 countries provided the Committee with reports on progress in implementing at least some of the recommendations of the resolution (Canada, Denmark, Germany, Greenland, Iceland, Ireland, Netherlands, Norway, Sweden, UK and USA). A summary of current research activities (61 programmes) from the above countries, was compiled in SC/46/SM17 and discussed in Annex G. As noted under Item 6.3, during July 1994, a comprehensive abundance survey of the North Sea and Baltic will be conducted. Total bycatch estimates have been made only for the US Gulf of Maine and Danish fisheries. In most countries, samples from bycaught and stranded animals are or were being collected to investigate life history and feeding characteristics and to determine pollutant levels. However, sample sizes are currently still very low. Other aspects of biology that are being investigated (by Germany, Ireland, Netherlands, Norway and the UK) include parasitology, pathology, virology and histopathology. Canada, Denmark, Germany, UK and USA are currently investigating methods to reduce bycatches, such as acoustic alarms on nets, time/area closures and alternative net characteristics.

The Committee noted that specific responses to the IWC Resolution are given in IWC/46/33.

15.3 Striped dolphin fishery off Japan
Information of directed takes of striped dolphins was presented in SC/46/ProgRep Japan. A total of 94 striped dolphins was taken by the hand-harpoon fishery in the Chiba and Wakayama prefectures while 450 striped dolphins were taken by drive fisheries in the Wakayama prefecture. The 1993 total of 544 was about half that in 1992 (1,045 dolphins). Nomura informed the Committee that this reduction was caused by strict quota regulations. The Committee welcomed the information provided in SC/46/ProgRep Japan and appreciated the substantial reduction in kill levels achieved by domestic quota regulations in 1993. No new documentation on biological studies or abundance estimates were presented to the Committee this year. The Committee was informed that in order to obtain more information on stock identity, distribution and abundance, a sighting survey in an extended area, focused on striped dolphins and biological studies of caught animals will be continued; genetic samples will be exchanged between Japanese and US scientists.

The Committee recommends that this information be obtained as soon as possible in order to facilitate an assessment of the striped dolphin as defined at last year’s meeting (IWC, 1994d, p.65).

15.4 Ways by which the sub-committee on small cetaceans identifies stocks for review
Last year the Commission adopted a Resolution on Addressing Small Cetaceans in the IWC (1994e), that identified four topics for future discussion. One of these concerned the way in which the Scientific Committee identified stocks for review by its sub-committee on small cetaceans.

The sub-committee on small cetaceans suggests priority topics for its meeting from which stocks for review can be identified. Since 1982 it has proposed priority topics for its next meeting and in recent years it has identified priority topics for more than one year ahead to facilitate more time for relevant research and documentation to be completed ahead of meetings. A detailed description of how the sub-committee selects priority topics is given in Annex G, item 9.3. This description provides a summary of the guidelines provided by the Commission, and examples of priority topics selected according to these guidelines.

15.5 Other
SC/46/O 21 reported on the continuation of the use of 10-12km driftnets for swordfish in the Mediterranean Sea. According to SC/46/O 21, the current fishery is mainly conducted by European Union nations (Italy and Spain) and Moroccan vessels. The activity is a contravention of the UN General Assembly Resolution 46/215. For the EU countries (Spain and Italy) this activity violates the European Community Regulation 345/92 which prohibits driftnets in excess of 2.5km in length in EU waters.

In recent years, the Italian fishery may have taken as many as 8,000 cetaceans per year in the Mediterranean Sea (SC/46/O 21). The Mediterranean driftnet fishery takes the striped dolphin Stenella coeruleoalba among other species. The Committee (IWC, 1992b, p.53) has previously concluded that the Mediterranean striped dolphin could not sustain the reported levels of exploitation. The Committee further noted that the striped dolphin suffered significant mortality during an epizootic in 1990 and 1991 and that the long term impact of the epizootic on the population is not clear.

The Committee recommends that Italy, Morocco and Spain be requested to establish a programme for recording incidental takes of cetaceans in the Mediterranean Sea and to report all catch statistics to the Commission.

The Committee expressed its concern over the status of striped dolphin population(s) in the Mediterranean Sea and recommends that the Commission requests the relevant countries to bring their driftnet fisheries into accord with existing international regulations.

The Committee recommends that the Secretary be requested to convey this information to the relevant national and international authorities.

15.6 Nomenclature
In accordance with Heyning and Perrin (1994) the Committee recommends that its list of accepted cetacean species be amended to recognise the division of the common dolphin into the short-beaked common dolphin, Delphinus delphis and the long-beaked common dolphin, Delphinus capensis.
16. WORKPLAN FOR 1994/95 AND INITIAL AGENDA FOR 1995 MEETING

The Committee identified six specific topics that should be considered for discussion at the 47th Annual Meeting:

(1) the refinement of operational data requirements under the RMS (see Annex O);
(2) the value of data from platforms of opportunity (see Item 14.2);
(3) the question of determining plausible hypotheses for Implementation Simulation Trials, including sub-stock structure;
(4) g(0) estimation (see Item 9.3);
(5) the differences in abundance estimates resulting from IDCR and JARPA sighting surveys (see Item 13.2.1);
(6) the provision of advice on the effect of stock(s) of scientific permit catches on stock(s) (see Item 12.2.2).

Three ad hoc groups were established to work during the intersessional period on:

(1) g(0) estimation (see Item 9.3.1) [Convener – Polacheck];
(2) procedures for review of research proposals (see Item 13.3.2) [Convener – Reilly]; and
(3) completion of process error calculations and combination trials under the RMP [Convener – Hammond].

An initial agenda and a revised workplan will be drafted by the Chairman in consultation with convenors and the Secretariat following the meeting of the Commission and circulated to Committee members.

17. DATA PROCESSING AND COMPUTING NEEDS FOR 1995

A number of recommendations included in the report address data needs and requirements for the coming year. These are in addition to continuing validation and coding projects and will be added to the work schedule of the IWC computing facility.

18. FUNDING REQUIREMENTS FOR 1994/95

Items requiring funding for the coming year were identified as:

<table>
<thead>
<tr>
<th>Invitation to Committee</th>
<th>£23,000</th>
</tr>
</thead>
<tbody>
<tr>
<td>17th IDCR Southern Hemisphere cruise</td>
<td>£55,150</td>
</tr>
<tr>
<td>Sightings survey data analysis (Year 2)</td>
<td>£50,000</td>
</tr>
<tr>
<td>1993/94 data analysis</td>
<td>£11,000</td>
</tr>
<tr>
<td>Incorporation of JSV data</td>
<td>£7,500</td>
</tr>
<tr>
<td>Data copying and coding</td>
<td>£1,500</td>
</tr>
<tr>
<td>Genetics workshop (partial support)</td>
<td>£5,000</td>
</tr>
<tr>
<td>Research proposals</td>
<td>£43,120</td>
</tr>
<tr>
<td>North Atlantic fin whale genetics</td>
<td>£15,000</td>
</tr>
<tr>
<td>YONAH genetics analysis</td>
<td>£10,000</td>
</tr>
<tr>
<td>Humpback whales off Madagascar</td>
<td>£7,500</td>
</tr>
<tr>
<td>Humpback whales off New Caledonia</td>
<td>£10,300</td>
</tr>
<tr>
<td>GRAND TOTAL</td>
<td>£174,170</td>
</tr>
</tbody>
</table>

In addition, the Commission had decided that a special workshop on the effects of environmental changes on cetaceans should be held before the 47th Annual Meeting. The Committee has proposed two workshops to address the issues fully (Item 7), the first, within the prescribed timeframe will require funding in the coming financial year.

19. PUBLICATIONS

Donovan reported on progress on forthcoming special issues and in particular referred to the issue on the Revised Management Procedure which will be edited by Kirkwood and which is also discussed under Item 9. The Committee agreed that the Editorial Board should comprise Donovan, Reilly, Hammond, Bannister, Brownell and Bjørge. It was noted that in the light of the revelations about Soviet catch statistics (Item 8), the plans for preparing a draft 'Omnibus' volume of whaling statistics had been postponed.

20. ELECTION OF OFFICERS

The Committee unanimously elected Reilly as Chairman and Bannister as vice-Chairman.

21. ANY OTHER BUSINESS

Komatsu noted that in discussion of the adoption of the report under Item 12.2.3, questions had been raised over the way in which members who had not made their views known during the discussion were allowed to associate their names to views expressed by others at the plenary discussion. He requested that this critical procedural question be brought to the attention of the Commission.

Corcuna and the Japanese scientists noted that they would find their participation in discussions considerably easier if simultaneous translation facilities were available.

A working paper was presented that the Committee agreed was more appropriate for discussion by the Technical Committee. The Secretary agreed to draw it to their attention.

22. ADOPTION OF REPORT

The Report was adopted at 19:09 on 14 May 1994. Items 16–22 were finalised by the Editorial Board. The Chairman thanked the IWC Secretariat and the Mexican support staff for their hard work in ensuring that the meeting ran smoothly, at least in a Bayesian context!

Agenda

1. Acting Chairman’s welcome and opening remarks
2. Election of Chairman for 46th meeting
3. Adoption of Agenda
4. Arrangements for meeting
   4.1 Appointment of Rapporteurs
   4.2 Meeting procedures and time schedule
   4.3 Establishment of sub-committees
   4.4 Computing arrangements
5. Review of available data, documents and reports
   5.1 Documents submitted
   5.2 National progress reports on research
   5.3 Data collection, storage and manipulation
      5.3.1 Catches and other statistical material
      5.3.2 Progress on data coding projects
      5.3.3 Progress on program verification and other projects
   5.4 Whale marking
6. Cooperation with other organisations
   6.1 NAMMCO
   6.2 ICES
   6.3 CMS/ASCOBANS
   6.4 CCAMLR
   6.5 IATTC
   6.6 CITES
   6.7 UNEP
   6.8 FAO
   6.9 IUCN
   6.10 Other
7. Effects of environmental change on cetaceans
   7.1 Response from international organisations and Governments
   7.2 Papers presented in response to the Resolution
   7.3 Workshop topics
8. Comprehensive Assessment – Southern Hemisphere baleen whales
   8.1 Research programme for large baleen whales – blue whales
      8.1.1 Intersessional Steering Group
      8.1.2 Japanese sighting survey in the austral winter, 1994
      8.1.3 Segregation of blue and pygmy blue whales
   8.2 Priority species – humpback whales
      8.2.1 Stock identity
      8.2.2 Migration
      8.2.3 Estimates of abundance
      8.2.4 Assessments
      8.2.5 Future work
         8.2.5.1 Short-term
         8.2.5.2 Long-term
         8.2.5.3 Assessments
   8.3 Catch history revisions
      8.3.1 Implications for Committee’s Work
   8.4 Other stocks of Southern Hemisphere baleen whales
      8.4.1 Minke whales
      8.4.2 Estimates of abundance for species other than minke and humpback whales
9. Comprehensive Assessment – Revised Management Scheme
   9.1 Further developments of the RMS
      9.1.1 Matters directly related to the calculation of catch limits
      9.1.2 Matters not directly related to the calculation of catch limits
      9.1.3 Conclusions and recommendations
   9.2 Preparations for implementation of the RMS
      9.2.1 North Pacific minke whales
      9.2.2 Southern Hemisphere minke whales
      9.2.3 North Atlantic minke whales
   9.3 Methodology
      9.3.1 Estimation of $g(0)$
      9.3.2 Avoidance/attraction
10. Comprehensive Assessment – Future work
    10.1 North Pacific Bryde’s whales
    10.2 Other
       10.2.1 Survey plans for the North Atlantic
       10.2.2 Survey plans for North Pacific minke whales
       10.2.3 Genetics workshop
11. Aboriginal subsistence whaling
    11.1 Aboriginal subsistence whaling scheme
    11.2 Bering-Chukchi-Beaufort Seas stock of bowhead whales
       11.2.1 Stock identification, migration and distribution
       11.2.2 Catch history
       11.2.3 Abundance and trend estimates
       11.2.4 Biological parameters and life history
       11.2.5 Indirect effects of human activities
       11.2.6 Assessment
       11.2.7 Recommendations
    11.3 Eastern stock of North Pacific gray whales
       11.3.1 Distribution
       11.3.2 Catch history
       11.3.3 Abundance and trend estimates from shore-based censuses
       11.3.4 Biological parameters and life history
       11.3.5 Indirect effects of human activities
       11.3.6 Assessment
       11.3.7 Recommendations
    11.4 West Greenland fin whales
    11.5 West Greenland minke whales
11.6 East Greenland minke whales
11.7 Humpback whales off St Vincent and The Grenadines

12. Scientific Permits
12.1 Review of results from existing Scientific Permits
12.1.1 Japan
12.1.2 Norway
12.2 Review of new or revised Scientific Permit proposals
12.2.1 Japan
12.2.2 Norway
12.2.3 Japan – North Pacific

13. Second International Decade of Cetacean Research
13.1 Review of results from 1993/94
13.2 Review proposals for 1994/95
13.2.1 Southern Hemisphere minke whale assessment cruise 1994/95
13.2.2 Other
13.3 Further analyses of IDCR photo-ID and biopsy specimens

Annex D
Report of the Sub-Committee on Management Procedures

1. ELECTION OF CHAIRMAN
Hammond was elected Chairman.

2. APPOINTMENT OF RAPPORTEURS
De la Mare and Donovan acted as rapporteurs.

3. ADOPTION OF AGENDA
The Agenda adopted is given in Appendix 1.
In this report, terms defined under the RMP in IWC (1994c) and Annex N are given in italics.

It was noted that the Commission paper IWC/46/24, the report of an independent panel appointed by the government of the USA to review the RMP, was relevant to the work of the sub-committee. Issues arising out of that report are considered under relevant agenda items, where appropriate.

4. MATTERS DIRECTLY RELATED TO THE CALCULATION OF CATCH LIMITS
4.1 Documentation of programs
Last year, the Committee noted that in addition to the documentation that was available on RMP-related computer programs in fulfillment of the Commission’s requirements, it would be of value to the Committee’s work to formulate more detailed documentation (IWC, 1994a, p.44). Suggestions received in the inter-sessional period were incorporated into the published documentation of the program implementing the Catch Limit Algorithm (IWC, 1994d).

It was noted that the documentation considered both the full program to implement the CLA and the computationally less time-consuming version used for the purposes of the Implementation Simulation Trials. SC/46/Mg4 drew attention to the performance of the numerical procedure for integration over the prior for the productivity parameter $\mu$ in the approximate form of the CLA used for trial purposes, when periods exceeding 100 years or particularly precise estimates of abundance were considered. The author of SC46/Mg4 recommended that the 5-step numerical procedure used be replaced for the time being by a 50-step procedure for such purposes. This matter is addressed in Appendix 2a.

4.2 Process error
Last year the Committee had identified some further work on the question of process error that could usefully be undertaken, whilst noting that use of the CLA need not be postponed while this was carried out (IWC, 1994a, p.43).

A working group to examine matters relating to process error was established. The group specified some calculations, the results of which are given in Appendix 2b. The sub-committee had insufficient time to discuss these results.

4.3 Progress on standard analysis programs for estimating absolute abundance
Last year, it was agreed to fund a contract to develop a database for sighting survey data and software to enable the calculation of abundance estimates required by the CLA (IWC, 1994c: c).

SC46/Mg13 described the structure and initial content of the sightings database for line transect abundance estimation by Small Area which is being developed under contract at the University of St. Andrews. The database will contain the disaggregated Japanese Scouting Vessel (JSV) data, the IDRAC Antarctic survey data, and NASS survey data. With the exception of one NASS aerial survey data set, all these data are from shipboard surveys. The sub-committee agreed that the mid-latitude Japanese survey data and other data identified in IWC (1993d, p.112) should also be included in the database. The inclusion of these data is not covered under the current contract. The sub-committee recommends that the contract be extended to accommodate including these data and noted that this had financial implications. The JSV data need to be handled differently from the other data sets because they do not contain the information required for estimation of effective strip width. Storage and extraction of the non-JSV data in a uniform way requires extensive modification of the data, particularly for the effort data, which will be disaggregated into segments of uniform effort type. However, the data structure will be modified only in ways that both streamline extraction and allow the original data set to be recreated if necessary.
The system will be implemented using Paradox database software operating in a Windows environment with menu-driven data extraction. The extraction procedures will support extraction of data specifically for abundance estimation as well as other data (data for plots of the location of survey effort within Small Areas, for example).
The analysis procedures being developed will allow density and abundance estimation by Small Area using the DISTANCE software package (Buckland et al., 1993; Laake et al., 1995) as far as possible. Estimation methods not supported by DISTANCE (such as estimation of g(0) and of smoothing parameters) will be implemented by modifying existing IWC estimation software.

A number of suggestions regarding the project were made and these will be taken into account by the contractors.

4.4 Further trials of the CLA

4.4.1 Performance for populations with alternative population dynamics

SC/46/Mg7 investigated the performance of the CLA when the underlying dynamics of the true population being modelled were substantially different from that assumed by the CLA. The trials investigated the behaviour of the CLA to ranges of the population dynamics model parameters, including allowing for depensation and stochastic variability, the CV of abundance estimates available to the CLA and high levels of under-reporting of historical catches.

The trials investigated extreme conditions not previously considered by the Committee. The results confirmed that the behaviour of the CLA does not depend critically on the choice of population dynamics model parameters and stochastic variability used for the simulated whale population. The authors suggested that for very high levels of precision in the abundance estimates that the performance of the CLA can become undesirable under two circumstances. The first is where there has been only 1% of the historical catch reported, in which case little or no recovery of a depleted population occurs. The second occurs where there is a high level of stochastic variation in recruitment, which can lead to variability in catch limits.

When only 1% of historical catches were assumed reported, the CLA performed quite well, allowing some recovery when abundance estimates have high coefficients of variation and behaving as expected when abundance estimates are very precise by stabilising the stock at about the expected fraction of the population size at the beginning of the application of the procedure.

Butterworth expressed appreciation for the work but requested that, in the future, results be presented in the standard format familiar to the Committee.

Considering the results of the trials, the sub-committee agreed that the CLA was robust in all the additional trials on differing population dynamics including depensation and stochastic variation in recruitment, even in those cases tested in SC/46/Mg7 which lay outside the plausible range for whale populations. It was pointed out that the management procedure developers had considered both depensation and stochastic recruitment at an early stage of the development process, but had concluded that these would produce less severe problems than some of the other robustness tests actually carried out. The aim in developing the management procedure had been to prevent exploitation at low population levels where depensation may be a cause for concern. Because this had been achieved, there was felt to be no specific need to carry out robustness tests which could only demonstrate no appreciable effect. Similarly, with respect to stochastic recruitment, the robustness tests had included systematic variations in recruitment which switched from 1% to 4% at regular intervals. This is more difficult for a management procedure to deal with than simple stochastic variability from year to year. Nonetheless, the sub-committee was pleased to see that the robustness of the CLA was confirmed in these extra trials.

SC/46/Mg2 brought to the attention of the Committee a family of population models that could be used to investigate the performance of the CLA to trials involving net recruitment subject to depensation.

4.4.2 Other

On the question of multi-species effects, SC/46/Mg3 raised the question of whether the concerns expressed by the USA internal review panel (IWC/46/24) were because it was unaware of the results of trials already conducted by the Committee (IWC, 1992c, pp.115–16) or because it believed these trials were inadequate. The sub-committee recalled that a very wide range of multi-species effects are equivalent to variations over time in carrying capacity and recruitment in the exploited population and that the CLA had proved to be robust to these problems. Taylor reported that the review panel was aware of these trials and that concerns expressed included the possibility that population dynamics exhibiting multiple stable states may exist. The sub-committee considered that the major effects of such models would be similar to those used in the robustness trials where varying carrying capacity and recruitment were used. This is because switching to an alternative stable state would occur over a time scale similar to that in which carrying capacity and recruitment were varied in the existing trials.

SC/46/Mg12 was presented in response to concerns expressed about the performance of the CLA in the presence of environmental degradations. A range of severity of the impact of an external influence on recruitment, survival or carrying capacity was tested, ranging from no impact to complete loss (100% reduction).

A range of speeds and timings of onsets from immediate and sudden to long-term and gradual were tested, and a range of persistence of impacts from a few years to forever.

The results showed that the differences in CLA performance (in terms of depletion of the population relative to the unexploited stock) between scenarios with and without the external impacts were small to moderate (ranging from a 4% increase to a 21% decrease in depletion relative to that which would occur in the absence of catches). The timing and speed of onset and the persistence of the external influence had little effect. Effects of external influence on CLA performance were slightly worse when surveys were conducted only every 10 years instead of every 5 years.

A summary of SC/46/Mg12 is appended to this report (Appendix 3).

The sub-committee agreed that these results strengthened the results of earlier trials conducted by the Committee in showing that the CLA is robust to a wide range of uncertainty and believed that there would be little advantage in modifying the CLA further to incorporate adjustments to account for environmental change. Some suggestions were made for possible modifications to the trials conducted in SC/46/Mg12 but the sub-committee believed that it was not necessary to recommend further trials. Any potentially damaging effects of environmental change should be addressed outside the context of the CLA itself.

Some questions were raised with respect to the behaviour of the CLA in response to the tests conducted in SC/46/Mg12, in particular concerning the linearity of response to external influences and the additivity of effects.
Some members believed that some re-running of the robustness trials on the CLA would be useful to confirm additive behaviour in this context. The sub-committee agreed that it is important to document and display the basic properties of the CLA in a clear manner and that those factors investigated in SC/46/Mg12 should be addressed in a way similar to that described in Appendix 4 (see Item 4.5.4).

In the context of whether additional trials were desirable, the sub-committee stressed that the CLA had been tested extensively by simulation, far more than any other procedure proposed or used for the management of a marine resource.

4.5 Other

4.5.1 Block quotas
In 1992, the Committee had noted that the possibility of block quotas had been raised and that it was ready to consider this issue should the Commission so require (IWC, 1993c, p.60). SC/46/Mg4 suggested how this issue might be investigated using simulation trials, both at the generic single-stock level and in Implementation Simulation Trials.

4.5.2 Continuing catch statistic
One of the Commission’s three objectives for the RMP (IWC, 1990, p.18) requires ‘making possible the highest possible continuing yield’. The Scientific Committee has used the ‘continuing catch’ (C) statistic (IWC, 1992b) to measure performance in this regard in simulation trials for the RMP and in Implementation Simulation Trials. However, analyses (Butterworth and Punt, 1994; SC/46/Mg4) have shown that this statistic has not stabilised even after the conventional 100-year management period used for trials, rendering its use for comparative purposes problematic in some circumstances. SC/46/Mg4 proposed that it be replaced by the total catch taken over years 151–300 of a management period.

The sub-committee noted that this matter had no immediate implications for application of the RMP and that Butterworth intended to continue to investigate this further.

4.5.3 MSYL/MSYR
Butterworth and Best (1990) had earlier put forward an approach for estimating lower bounds for MSYR which indicated values rather higher than the MSYRmat = 1% used for risk assessment in RMP trials. The premise underlying their approach had been questioned at the previous meeting of the Committee (IWC, 1994g). SC/46/Mg4 suggested that the basis for such questioning also implies that MSYL < 0.5K, in contrast to the ‘base case’ value of 0.6K used in RMP simulation trials. This led the authors of SC/46/Mg4 to the conclusion that the present approach of using a combination of MSYL > 0.5K and MSYRmat = 1% was implausible as a ‘worst case’ scenario for risk assessment and that interpreting the results of such trials in relation to a ‘protection level’ of 0.54K (which is related to the assumption of 0.6K for MSYL) accordingly provided an inflated impression of the risk associated with the RMP.

Butterworth also reiterated concerns expressed previously (Butterworth and Best, 1994) that the constraints imposed by the Commission specifying a protection level at 0.54K (IWC, 1993a) led to inconsistencies in terms of meeting the earlier specified objectives of the Commission (IWC, 1988; 1990).

Specifically, he believed that that paper demonstrated that without that constraint it would be possible to tune the RMP to achieve higher continuing yields without incurring any serious risk of extinction.

The sub-committee noted that the RMP as specified in IWC (1994e) incorporated the decisions taken by the Commission with respect to tuning and protection levels.

4.5.4 Presentation of trial results
During the development of the RMP, trial results were presented in a standard manner, showing the results for each candidate procedure on the same graph. While this was appropriate for comparing procedures, SC/46/Mg6 suggested an alternative presentation of trial results for the CLA as adopted, that would more easily allow identification of potential factors of importance when considering the results of Implementation Simulation Trials. The sub-committee recommends that the Secretariat provides a graphical presentation of results of all trials thus far carried out for the CLA in a format along the lines proposed in SC/46/Mg6. It noted that this could be published as part of the planned Special Issue on the development of the RMP (see plenary Item 19).

In the same context, SC/46/Mg6 also raised the question of the performance of the CLA at values of trial parameters other than those tested, in particular under-reporting of historical catches. The sub-committee agreed that there was merit in making further calculations for ‘base cases’ to document the behaviour of the CLA over a range of values for under-reporting of historical catches and for bias in absolute abundance estimates, in particular. The sub-committee recommends that these calculations be carried out by the Secretariat according to the specification given in Appendix 4. Some results are included in that Appendix but the sub-committee did not have time to review them.

A comprehensive set of trials had been conducted at the Oslo workshop on management procedures to investigate whether any of the effects of combining errors were non-additive (IWC, 1992d). Although the CLA itself had not been finalised at that time, the sub-committee believed that results from these trials of the CLA would give the same conclusions because the procedures tested were similar. Nevertheless, the sub-committee agreed that it was useful to make further calculations and document the results to help in formulating future Implementation Simulation Trials and interpreting the results. The sub-committee agreed that this task could be best achieved by establishing a working group at this meeting to report to the Committee and for an intersessional steering group to guide the Secretariat.

SC/46/Mg6 also raised the point that what constituted ‘adequate performance’ in robustness trials has not been explicitly defined, e.g. at the Tokyo workshop (IWC, 1992a). Whilst not questioning the judgements made by the Committee, SC/46/Mg6 believed that it was essential for the basis of these decisions to be clearly identified so that the results of the robustness trials could provide a point of reference against which Implementation Simulation Trial results could be gauged at least under similar circumstances. This reinforced the need for a readily comprehensible document detailing the performance of the CLA wherein the specific results which had been judged acceptable or not would be readily apparent.

The sub-committee agreed that this was an important issue, but one which has been difficult to resolve on entirely objective grounds. The Tokyo workshop had discussed a
number of decision-theoretic approaches to developing performance criteria, but none of the approaches considered were deemed satisfactory.

The sub-committee agreed that factors examined in robustness trials will need to be examined, either singly or in combination, in *Implementation Simulation Trials* when appropriate. However, under these circumstances the criteria for interpreting the results would not necessarily be the same as those used in the robustness trials; more stringent criteria may be applicable in judging the performance of the RMP in *Implementation Simulation Trials*. The Scientific Committee will need to continue to document fully the results of *Implementation Simulation Trials* and carefully record the basis on which it makes decisions on its advice to the Commission on each *Implementation*.

5. MATTERS NOT DIRECTLY RELATED TO THE CALCULATION OF CATCH LIMITS

5.1 ‘Monitoring’ and data requirements

Paper SC/46/Mg9 outlined a view of the role of science in resource management and recalled those principles identified and agreed by the Special Scientific Committee Working Group on Management Procedures (IWC, 1981); it noted that six were relevant to its discussions here.

- Principle 1: Stocks should be defined on the basis of scientific evidence regarding biological differentiation.
- Principle 2: Management measures should take into account the status of individual stocks and be applied to stocks individually.
- Principle 4: All management measures should be accompanied by adequate collection of data so that the consequences of particular action can be monitored.
- Principle 5: Account should be taken of the need to obtain information to improve the scientific basis of management action.
- Principle 7: ... the uncertainties in ... information should be taken into account so that the risks of adverse effects on the achievement of the objectives are not significantly increased.
- Principle 8: Management measures should take into account the effect on whale stocks of environmental change due to either natural causes or to human activities.

The sub-committee agreed to structure its discussion of the issues raised in SC/46/Mg9 within the framework represented by these six principles. The sub-committee agreed that these were all principles which had been taken into account in developing the RMP, although there remained some differences of opinion whether sufficient account had been taken of some of them.

Principle 7, taking account of uncertainty, has been given great weight in the RMP, both in its development and in the procedure for *Implementation Simulation Trials* and review. The trials have covered uncertainty in population dynamics, trends in the environment, uncertain stock identity, etc. The *CLA* itself takes into account the statistical uncertainty in the estimates of absolute abundance used in calculating catch limits. The results of the many trials show that the RMP is robust to the plausible range of uncertainties, and the limits to the range of bias in fundamental data has been examined. The sub-committee is satisfied that the RMP is in sufficient accord with this principle.

With regard to Principle 1 (biologically differentiated stocks), the sub-committee agreed that the RMP is based on this principle and is satisfied that it is adequately met by the RMP. However, in the particular cases examined to date, trials have shown that a degree of uncertainty about biologically differentiated stocks does not mean that the RMP cannot be applied. The RMP has been developed giving great weight to Principle 7 (uncertainty), and ways have been found to take uncertainty in stock identity into account, at least in a number of cases. This has been achieved by examining the plausible range of hypotheses on the number of stocks, their distribution and mixing rates, based on reviews carried out under the Comprehensive Assessment of the information currently available on stock identity. These hypotheses are used to formulate *Implementation Simulation Trials*, the major function of which is to determine how to apply the RMP’s multi-stock rules in specific cases. If uncertainty over stock identity is critical in deciding whether or not to implement the RMP in a particular case, *Implementation* of the RMP should not proceed until new information is obtained and satisfactory performance is attained in revised *Implementation Simulation Trials*, with the cycle being repeated if necessary.

Principle 2, the application of management to individual stocks, is closely related to Principle 1 and is adequately met by the RMP. The multi-stock rules are designed to allow for the possibility that biologically differentiated stocks may not always be geographically distinct. For example, stocks with separate breeding grounds may share a common feeding ground, at least in part of their range. In such cases, the application of the Small Area definition allows as far as possible for the application of management to individual stocks, despite geographical overlap in part of their range.

Different interpretations of Principle 4 was part of the reason which led to differing views within the Committee at last year’s meeting. The difference of opinion was over whether the minimum data specified within the RMP itself were adequate to monitor the consequences of the application of the particular management actions. The sub-committee agreed that the minimum data specified under the RMP along with other data, such as those specified in IWC (1994a, pp.46–7), in conjunction with the enabling clause defined there, could be used by the Committee in a manner sufficient to meet this principle.

A working group was established to develop a set of guidelines for the collection and analysis of data including those previously specified in IWC (1994a, pp.46–7). It was anticipated that these guidelines could form an element of the RMS and would be kept under review by the Committee. These guidelines were not completed in time for consideration by the sub-committee and were referred to the full Committee.

On Principle 5, the sub-committee agreed that account is taken of the need to obtain information to improve the scientific basis of management action through the process of *Implementation Reviews*, which review all the scientific information relevant to the *Implementation* of the RMP. However, attention was drawn in SC/46/Mg9 and SC/46/Mg5 to the possibility of improving other aspects of the scientific basis for management (including, for example, the structure of the RMP itself and the underlying population models used in its development and testing) through the use of other types of data described under Principle 4 above.

Particular attention was drawn to the importance of obtaining and including in these *Implementation Reviews* the information required to confirm or modify the application of the multi-stock rules (SC/46/Mg8). The sub-committee agreed that this was an important consideration, but it concluded that, because methodology in this particular field was in a state of rapid evolution, it
would be impossible to be prescriptive about the types of data and analyses required for refining multi-stock applications at this stage. The sub-committee also noted that methods such as satellite tracking and genetic studies may be required, and that either alone may not be sufficient for refining the application of the multi-stock rules. Further specification of additional information beyond that contained in the RMP for meeting this principle are to be included in the guidelines referred to above.

Principle 8, taking into account environmental effects, has been considered in the RMP development through trials which showed that the RMP was robust to trends in the environment which affected whale populations, even when these were not identified. Additional trials reported in SC/46/Mg12 have further illustrated robust properties of the RMP to environmental trends. The sub-committee concluded that overall, the combined effect of catches within the catch limits set by the CLA and external environmental influences on the population are only slightly to moderately different than those caused by the external influences alone, even when the external environmental effects are severe. However, it was noted that data on the physical environment and its change might be useful in interpreting variability in abundance estimates. The specification of such data for the application of RMP is also discussed in the guidelines referred to above.

The working group drafting the guidelines was also given the task of drafting a description of Implementation Simulation Trials which would give further explanation to those not familiar with details of the RMP. This is given in Appendix 5. The sub-committee did not have time to review Appendix 5 which was referred to the full Committee.

5.2 Appropriate times for submission of data to Secretariat
This item was carried over from last year (IWC, 1994a, pp. 46–7) and was considered under Item 5.1.

5.3 Interpretation of Implementation Simulation Trial results
The first issue raised under this agenda item arose primarily as a result of the preliminary Implementation Simulation Trials for North Pacific minke whales (see Item 6.1.1). The trials results show that selecting an application of the multi-stock rules for this species and Region depends greatly on hypotheses about sub-stock structure. SC/46/Mg4 posed the questions: what basis is required to propose the existence of sub-stocks and what information is sufficient to refute such hypotheses?

Some members considered that a sub-stock structure should not be assumed to exist unless there was positive evidence in favour of such a hypothesis. Other members, based on some observed aspects of whale behaviour, considered that a sub-stock structure should normally be considered as a plausible hypothesis, which required evidence against it for such a structure to be excluded from Implementation Simulation Trials. The sub-committee agreed that results from genetic and radio-tracking studies would be useful for testing hypotheses about stock structure and mixing. The question of what data would be required to distinguish between alternative hypotheses concerning stocks and sub-stocks was referred to the full Committee.

The second issue discussed was the question of the interpretation of risk when examining depletion statistics from a series of Implementation Simulation Trials.

SC/46/Mg4 proposed that a composite fifth percentile of the lowest and final stock sizes be used, calculated from all the Implementation Simulation Trials using 1% MSY_per rate, with each scenario being given equal weight noting also the Committee's previous practice of preferential selection of more difficult trials in a risk context. This was proposed as a less extreme alternative than considering only the worst case performance.

The sub-committee noted that the proposal in SC/46/Mg4 constituted replacing a 'worst case' risk assessment with some form of absolute risk assessment. Some members considered that it would not be appropriate to integrate over the results of a range of trials because this could mask poor performance for plausible hypotheses. The sub-committee did not have time to consider this further.

Adopting a proposal along the lines of that in SC/46/Mg4 would have important implications which would need to be carefully considered.

6. PREPARATIONS FOR IMPLEMENTATION

6.1 Southern Hemisphere minke whales

6.1.1 Northerly extent of Small Area boundaries
Last year the Committee received a proposal to move the northern boundaries of the Small Areas for Southern Hemisphere minke whales up to 55°S. The proposal had been made to avoid complications which have arisen in IDC cruise planning when ice is expected to be encountered north of the current 60°S boundary. The Committee had recommended that variations in the northerly extent of these boundaries should be considered this year taking into account geographical and other factors (IWC, 1994a, p.49). The sub-committee recalled that the agreed northern boundaries (specified in IWC, 1994f) were chosen primarily for practical reasons related to the coverage of the IDCR surveys. It was reported that there were no problems distinguishing the dwarf form of minke whale from the 'true' minke whale in closing mode during surveys, nor in catching operations. Some members believed that the proposal from last year should be adopted.

In discussion, the sub-committee recalled that there were a number of factors which needed to be addressed in reconsidering the extent of the northern boundaries. These included the position of the Antarctic Convergence and annual and seasonal variation in the position of the ice edge. It was suggested that an analysis of these and other data may indicate alternative solutions. The sub-committee agreed that any changes to Small Area boundaries should be based on a clear scientific analysis of the available information. Any proposals for such changes should be supported by such an analysis. It was agreed that the question of moving the northern boundaries of the Small Areas for Southern Hemisphere minke whales could be reconsidered when such an analysis was available.

6.1.2 Sectors of 15° rather than 10° for Small Areas?
Last year the Committee had received a proposal that Small Areas for Southern Hemisphere minke whales might more appropriately be 15° rather than 10° sectors (IWC, 1994a, p.49). The Committee had noted the provision made under the RMP for Implementation Reviews and that these would only be carried out before the scheduled time (after five years) if substantial new information was
available. It had agreed to put this matter on the agenda this year to determine whether such an Implementation Review was warranted (IWC, 1994a, p.49).

This year, SC/46/Mg4 proposed extending the existing Implementation Simulation Trials to address the question of increasing the size of the Small Areas. Kato drew the sub-committee’s attention to the results in Kato et al. (1993) which supported the designation of Small Areas larger than 10°. The sub-committee recalled that the decision to choose sectors of 10° for Small Areas had been based on consideration of the available information in the context of the definition for Small Areas in the RMP.

Discussion concentrated on the general issue of how the Committee will decide whether an Implementation Review was warranted before the scheduled time. The process of Implementation Reviews is defined under the RMP to allow reconsideration of Small Areas, normally five years after a previous Implementation or Implementation Review but exceptionally before this time (IWC, 1994c). They will include examination of new data, re-examination of old data and the results of Implementation Simulation Trials addressing alternative plausible hypotheses. Implementation Reviews are expected to take more than one year if further Implementation Simulation Trials need to be specified and run.

The Committee will need to decide whether or not to initiate an Implementation Review before the five-year period has elapsed taking into account the new information available and the workload of the Committee. One of the reasons for the five-year period between Implementation Reviews was so that the Committee was not required to revisit each Implementation at frequent intervals. When the Committee has made the decision to initiate an Implementation Review, it would need to identify the range of plausible hypotheses so that the specifications for any additional Implementation Simulation Trials could be developed.

The sub-committee agreed that the question of changing the size of Small Areas for Southern Hemisphere minke whales should be addressed within the framework described in IWC (IWC, 1994c) and elaborated upon above.

6.1.3 Other
SC/46/Mg4 raised the matter of how catches in Residual Areas are taken account of under the RMP. This issue arose last year in the context of Implementation Simulation Trials for Southern Hemisphere minke whales concerning Brazilian catches taken outside the defined Small Areas (IWC, 1994a, p.81–82). The paper suggested that this example might lead the Committee to reconsider specifications for taking account of catches outside Small Areas.

In discussion, de la Mare recalled that the RMP has a method to take catches from outside Small Areas into account through Catch-capping applied to an appropriate Medium or Large Area. Butterworth believed that the form of solution suggested in SC/46/Mg4 was superior and was, in principle, generally applicable.

The sub-committee recalled its previous discussions on the matter of amendments to the RMP (IWC, 1994a, p.47) and reiterated that such amendments should be considered very carefully. A mechanism for this has been recommended (IWC, 1994a, p.47).

6.2 North Atlantic minke whales
There was no business to discuss under this item.

6.3 North Pacific minke whales
6.3.1 Results of interseasonal trials
At last year’s meeting, the Committee had discussed for the first time the formulation of Implementation Simulation Trials for North Pacific minke whales. The Committee agreed to the specification for an initial set of trials (IWC, 1994b) to be run interseasonally and guided by a steering group (IWC, 1994a, p.50).

SC/46/Mg14 presented results from the trials run interseasonally by the Secretariat. There had been insufficient time to conduct all the trials. A number of modifications to the initial values chosen for the operating model parameters had had to be made to enable the simulations to conform to the range of plausible hypotheses about stock structure and mixing. Standard summary statistics for each putative stock (‘J’, ‘O’ and ‘W’) in each trial were presented. Detailed results for each assumed sub-stock were also presented for each trial. Some new statistics were presented to help understand the behaviour of the simulated populations at different levels of initial stock depletion, which ranged widely in each trial. Specifically, for each range of initial stock depletion (<0.40, 0.40–0.45, 0.45–0.50 .... >0.60) the number of the 100 simulations which fell into that category, the proportion of those simulations where the population fell below the initial level and the maximum decline experienced by the population in terms of absolute depletion were presented. In addition, a series of graphs were presented showing plots of various percentiles of depletion for the sub-stocks simulated over the 100 year period under regimes of (i) catches set by the CLA and (ii) no catches.

The sub-committee recalled that the results were from trials designed to be the first phase of Implementation. The most difficult trials were those in which MSYR = 1%. There was insufficient time to explore the results in detail or to discuss their implications for the formulation of further trials. However, it was clear that results for the trials conducted so far indicated poor performance for some of the hypotheses for stock and sub-stock structure (see also SC/46/Mg11).

6.3.2 Further consideration of NP minke trials
SC/46/NP2 presented an analysis based on Hardy-Weinberg equilibrium predictions for genotype frequencies to estimate the relative proportions of minke whales from different stocks in certain Sub-Areas of the western North Pacific. For Sub-Areas 7 and 11 (IWC, 1994b, p.287) the results could be useful in further Implementation Simulation Trials. Results were also presented on the power of the method to determine the ratio of ‘O’ stock:‘W’ stock whales in a Sub-Area, as a function of sample size. It was suggested that DNA analyses of existing material may be helpful. Kato informed the sub-committee that preliminary results from such analyses had been affected by the poor preservation of samples. Baker agreed to draft a short report on DNA extraction from samples which were old or in poor condition (included as Appendix 6) to address this matter and to address issues raised in Annex F.

SC/46/NP3 questioned a number of matters adopted last year for the initial Implementation Simulation Trials, in particular the basis for assuming that the ‘J’ and ‘O’ stocks comprised a number of sub-stocks. It re-examined the use made of the data at last year’s meeting and also presented information not considered explicitly at that time.
SC/46/NP3 concluded that the sub-stock structure is not plausible, that the mixing of whales from the ‘J’ and ‘O’ stocks should be re-examined (SC/46/NP2 may help to resolve this) and that there was no evidence for the existence of a ‘W’ stock separate from the ‘O’ stock. More information should be collected to resolve these issues. Further work planned was described in SC/46/NP1.

Concerning the question of sub-stock structure, there was some discussion about using the location of historical whaling grounds to support the existence of sub-stocks. Some members believed that this was not justified because the separation of whaling grounds was caused by operational factors. Notwithstanding these and other data presented or re-examined in SC/46/NP3, other members believed that the existence of sub-stocks was still a plausible hypothesis.

6.3.3 Future work
The sub-committee agreed that it would be premature to formulate additional Implementation Simulation Trials because that process would be overtaken by the results of new studies which are planned for the coming year (SC/46/NP1, 2, 3 and SC/46/O 22).

SC/46/O 22 described a proposal for Japanese sightings surveys in summer 1994 and January-March 1995 in the North Pacific. The sub-committee welcomed this proposal as an important contribution to its work on minke whales and other species and strongly recommends that these surveys be conducted.

The issue of how to determine what data would be required to distinguish between alternative hypotheses, concerning stock and sub-stock structures was referred to the full Committee.

A further general matter which needs to be resolved is how to interpret the results of trials where sub-stocks are modelled as stocks, as has been done in the initial Implementation Simulation Trials for North Pacific minke whales (IWC, 1994b). Butterworth suggested that attempts should also be made to model sub-stock dynamics directly, in a manner which overcomes problems encountered previously in this regard (IWC, 1993b).

7. ADOPTION OF REPORT
The report was adopted as amended.

(A) INVESTIGATION OF THE EFFECTS OF VARYING STEP SIZE IN THE NUMERICAL
PROCEDURE FOR ESTIMATING THE PRODUCTIVITY PARAMETER \( \mu \)

Trials were conducted last year to investigate the effects of setting values for ‘process error’ (Rep. int. Whal. Commn 44: 75) which were greater than those used in most of the single-stock trials (Rep. int. Whal. Commn 44: 85-88).

Additional trials were conducted to investigate the sensitivity of the trial results to the step size used in the numerical procedure for integration over the prior for the productivity parameter \( \mu \), when very precise estimates of abundance were considered. The nomenclature used and the method of setting the CVs are the same as detailed in Rep. int. Whal. Commn 44: 85-86.

(B) VARIABILITY OVER TIME OF THE ABUNDANCE IN EACH HALF-DAY AREA IN THE
SOUTHERN HEMISPHERE MINKE WHALE TRIALS

Variability over time of abundance in the Southern Hemisphere minke whale trials (run for 30 years, taking zero catch during the management period) is estimated by

\[
\sigma^h = \sqrt{\frac{1}{n-1} \sum_{y=1}^{n} (log P_{h,y} - X_{h}^{y})^2}
\]

where \( X_{h}^{y} = \frac{1}{n-1} \sum_{y=1}^{n} log P_{h,y} \)

and \( P_{h,y} \) is the population size in simulation \( s \) in half-area \( h \) and year \( y \).

The mean value of \( \sigma^h \) is given for all half-areas and for each half-area separately.
The above calculations have also been repeated for Areas instead of half-areas.

(C) A SUMMARY OF IWC METHODS AND RECOMMENDATIONS FOR INTER-ANNUAL COMPARISONS OF SOUTHERN HEMISPHERE MINKE WHALE ABUNDANCE ESTIMATES FROM IDCR CRUISES

D.L. Borchers

A component of what is currently modelled as ‘process error’ in the RMP Southern Hemisphere minke Implementation Simulation Trials is a result of (in estimates from data of the magnitude of this effect (Rep. int. Whal. Commn 44: 90) differences in the proportion of the ocean surface areas between the ice edge and 60°S which were covered by the IDCR surveys of the same Area in different years. A less biased estimate of inter-survey variation in abundance south of 60°S would be obtained on the basis of inter-survey variation in abundance estimates for the same area south of 60°S. However, because not all IDCR surveys covered the whole area between the ice edge and 60°S, some form of extrapolation and/or interpolation of existing IDCR estimates into unsurveyed areas is necessary. This appendix summarizes the methods which have been used for such extrapolation and interpolation in the past, as well as the recommendations made by the Committee regarding extrapolation methods.

Methods used to date
1. Assume density in unsurveyed area to be equal to that in the surveyed stratum immediately to its south
This is the method most frequently used in the analyses of recent years. It provides estimates of abundance for the whole area between the ice edge and 60°S, but in this case a comparison is being made between abundance estimates for areas of different sizes.

2. Adjust abundance estimates to correspond to equal ‘near-ice’ and ‘far-ice’ strata ocean surface areas
This method was first used to compare the 1986/87 and the 1981/82 surveys in Area II because the ice edge extended so far north in 1986/87 that the most southerly strata surveyed were north of the most northerly strata surveyed in 1981/82 as part of the Area. The method is described in SC/40/M19. Essentially it involves multiplying the density estimate in the stratum adjacent to the ice edge in one survey by the surface areas of the corresponding stratum in the other survey and doing the same for the strata not adjacent to the ice edge. This method effectively compares abundance estimates in areas of the same size, although there will generally be inter-survey differences in the boundaries of the areas.

3. Reduction of the effective area of the northernmost surveyed strata
The method involves ‘moving’ southward the northern boundary of the north stratum of the surveys(s) with coverage farthest north, until it coincides with the northern
boundary of the north stratum of the survey with less northward coverage. For inter-survey comparison the abundance estimate in the stratum/strata whose boundary/ boundaries has/have been ‘moved’ in this way is reduced in proportion to the reduction in the area of the stratum. The method uses a constant northern boundary but variable ocean surface area between surveys.

Previous recommendations regarding inter-survey comparisons
In 1988 the Committee recommended ‘further work on the development of procedures for comparing estimates of abundance in the same Area in different years’ (Rep. int. Whal. Commn 39: 74).

In 1989 the Committee recommended that ‘Theoretical considerations of how to compare the results of surveys which differ in their area coverage and in the environmental conditions experienced during the surveys’ should be addressed as a matter of priority in time for the 1990 Comprehensive Assessment’ (Rep. int. Whal. Commn 40: 137). Three approaches were suggested.

1. Use JSV data to extrapolate into unsurveyed northern areas. (This is what is done in SC46/SH24).
2. Use Japanese sightings surveys to estimate abundance in the unsurveyed northern areas.
3. Develop spatio-temporal models of whale density and use these to extrapolate.

In 1990 the Scientific Committee recommended ‘Further work to improve the compatibility of population estimates from the results of IWC/IDCR cruises in the same area’ (Rep. int. Whal. Commn 41:123).

Appendix 3

SIMULATION TRIALS OF THE RMP CATCH LIMIT ALGORITHM IN THE PRESENCE OF ADVERSE EXTERNAL INFLUENCES ON WHALE POPULATIONS

J.G. Cooke

Introduction and methods
The robustness tests of the CLA conducted to date involving changes in the external environment have been limited in scope. They include the case of a gradual decline in carrying capacity of 50% over 100 years, and a limited degree of fluctuation in recruitment (IWC, 1993, p.94-96). This note reports the results of trials covering a wider range of severities of effects.

The parameters and values listed in Table 1 were considered. Factors A-E relate to the adverse external effects while factor F-H relate to other aspects of the scenarios. The parameters of an adverse effect are its time of onset, its speed of onset, its severity, its persistence and the parameters of the whale population that it affects.

The adverse effect is presumed to get worse in a linear fashion during the period of onset (except in B1 where the effect reaches its full extent immediately). The effect then remains at a constant degree for the length of time specified in the B factor, after which time it disappears.

In cases D1 and D2, the reduction in recruitment and survival is assumed to be independent of population size. These reductions will imply a reduction in carrying capacity. In the more severe cases, the implied reduction of carrying capacity will be 100%, in the sense that the population would not be able to persist in the long term even in the absence of a harvest. In case D3, the reduction in carrying capacity is explicit, and is assumed to be mediated through recruitment. A reduction in carrying capacity of 100% means that the population becomes borderline persistent.

The operating model used was a slightly simplified version of the operating model used in the programme MANTST developed by the IWC Secretariat. The initial carrying capacity was 10,000 mature whales. The population model is deterministic except that at low population sizes a Poisson birth/death process is operative (so that extinction is possible).

</table>

For each case, 100 simulation trials of a 100-year period were conducted, with and without catches. In the trials with catches, these were set by the Catch Limit Algorithm using 5-yearly or 10-yearly abundance estimates with a CV of 0.2. Statistics were collected for the median lowest and final populations, and the lower 5%-iles of the lowest and final populations.

Results
The first set of trials looked at the three severities of effect (10%, 50% and 100%) and the parameters affected (recruitment, survival and carrying capacity), with all other factors held at their base values.

Table 2 shows lowest and final populations without catch, the 5%-ile and median lowest and final population sizes with catch, and the ratio of the 5% lowest and final population sizes with and without catch.

In the case of a 50% or 100% reduction in survival, the population disappears whether or not there are any catches.

The lower 5%-ile depletions (ratio of lowest or final exploited to lowest or final unexploited population size) are on average lower with adverse environmental effects than without them. Although in some cases (10% and 50% reductions in carrying capacity), the depletion is slightly less deep than in the case with no adverse effects. The worst depletion occurs for a total loss of recruitment or a total loss of carrying capacity in which case the lowest 5%-ile depletion is 0.623 as compared with 0.747 without environmental effects.

Since this was the worst case, it was used as the base case for the remaining trials, in which the MSY rate, the previous history of exploitation, and the survey frequency were varied. Table 3 shows the results. The timing and speed of onset of adverse environmental effects has little influence on the relative depletions, nor is there much difference between a 25 year and an indefinite persistence.

Table 4 summarises the results of all trials. In this table, depletions are expressed in terms of the ratio of the 5%-ile of the lowest or final population sizes to the corresponding statistic for the control population, whichever is the lower.

Columns 1 and 2 show the depletions due to catches, with and without environmental effects, while column 3 shows the ratio of these. A value of unity in column 3 implies that the effects of catch and environmental effects are without interaction. Columns 4 and 5 show the reductions due to environmental effects, with and without catches.
Summary of interactions between effects of catch and environmental effects. Factor levels not listed implies base case level. Depletion/reduction is defined in terms of the ratio of the 5%-ile of the lowest or final population size to that of the control population, whichever is the lower.

* Denotes base case.

Conclusions

The strongest interaction between the effects of catches and environmental effects is found in the trial with surveys conducted only every 10 years. In that case environmental effects exacerbate the catch-related depletion by 21%, and the catches exacerbate the environmental effects by 21%.

REFERENCE

Appendix 4

CLA RESPONSE CURVES

Graphs showing the response of the CLA to differing levels of certain assumption violations have been produced. These are given in Figs 1 to 11.

Fig. 1 shows the effect of positively biased estimates of abundance from surveys for the R1 case. The following values of the bias are shown:

A: no bias (1.0); B: 1.2; C: 1.4; D: 1.6; E: 1.8; F: 2.0.

Figs 2–5 show the effect of positively biased estimates over the same range as Fig. 1 for the R4, S1, D1 and D4 cases.

Fig. 6 shows the effect of under-reported historical catch levels for the R1 case. The true historic catch and the current (year 0) depletion are the same in all cases. The reported historical catches were the following fractions of the true catch values:

A: 100% (i.e. no under-reporting); B: 80%; C: 60%; D: 40%; E: 20%; F: 1%

Fig. 7 shows the effect of under-reported historical catch levels in a different way. The absolute population size at the start of management and the reported catch are the same in all cases, but the true historic catch took the following values:

A: C; B: 2 C; C: 3 C; D: 4 C; E: 5 C; F: 6 C, where C is the reported historical catch.

The absolute population size at the start of management was fixed at the value from the equivalent base case trial.

This trial was added because it mimics the actual situation in which only the current population size and the reported historical catch are known, and not the current depletion (Figs 6, 8 and 10 keep current depletion at 0.3, 0.3 and 0.6, respectively, for all results shown).

Figs 8 and 10 show the effect of under-reporting catches over the same range as Fig. 6 for the R4 and S1 cases.

Figs 9 and 11 show the effect of under-reporting historical catches over the same range as Fig. 7 when the absolute population size at the start of management is fixed at the value in the R4 and S1 base case trials, respectively.

The following distributions are summarised on the graphs.

(i) Total catch (median, 5% and 96%-iles).
(ii) Final relative population size (median, 5% and 96%-iles). The initial stock size is shown by a *
(iii) Lowest relative population size (5%, 10% and 25%-iles).
(iv) Realised protection level (lowest stock size at which a catch was set) (median and 5%-ile). Only values below 0.54K are shown.
(v) Relative recovery statistic (the stock level in the year when it would have been 0.54K in the absence of catches during the management period) (median and 5%-ile). It has no value if the population size at the start of management is >0.54K. Zero is plotted if the stock does not reach 0.54K during the management period, even in the absence of catches.
(vi) Continuing catch statistic (median, 5% and 96%-iles).
(vii) Average annual variation in catch (AAV).
Fig. 1. R1 Bias ranges from 1 (no bias) to 2.

Fig. 2. R4 Bias ranges from 1 (no bias) to 2.

Fig. 3. S1 Bias ranges from 1 (no bias) to 2.

Fig. 7. R1 Historic catch under-reported (method 2). Range = $C_i$ to $C_i/6$.

Fig. 8. R4 Historic catch under-reported. Range = $C_i$ to 1%$C_i$. 
Appendix 5

FURTHER EXPLANATION OF IMPLEMENTATION SIMULATION TRIALS

The Catch Limit Algorithm (CLA) has shown satisfactory robustness under a wide variety of simulation tests when applied to a model of a single isolated baleen whale stock and to models of generic situations involving multiple stocks. The primary purpose of Implementation Simulation Trials is to investigate how this robustness is maintained in the specific circumstances where multiple breeding stocks of a species may mix in the vicinities where catching and/or sighting surveys may take place in the Region where application of the RMP is under consideration. In these trials the anticipated performances of applying the CLA are evaluated using Small Areas and options under Catch-Capping and Catch-Cascading. Alternative hypotheses on stock structure and mixing should be combined with various other factors such as those investigated in the single stock CLA robustness trials in a set of Implementation Simulation Trials which are relevant to the species in the Region in question.

To date, three sets of Implementation Simulation Trials have been developed, all for minke whales, in the following Regions: the Southern Hemisphere, the North Atlantic and the North Pacific (preliminary). The basic features of the Implementation Simulation Trials have developed as more experience has been gained in their formulation, and further developments will no doubt occur. The general nature of the procedures as they have evolved thus far in developing these trials is described below.

Implementation Simulation Trials have been carried out by applying the RMP to simulated whale populations conforming to a range of plausible hypotheses about stock identity, distribution and mixing, identified on the basis of all the biological information available at the time. These hypotheses have been embodied in simulation models, which usually require the specification of:

- the number of discrete breeding stocks of the species present in the Region (which may contribute to the range of hypotheses when the available data are inadequate to determine this with certainty);
- one or more specifications of the proportion of the animals from a particular stock that are to be found (at a particular time) in a locality (hereafter termed a Sub-Area) – the combination of these proportions for all the stocks is referred to as a ‘catching matrix’; the numerical values of which are set in the manner described in the following section, with a stochastic component usually added to such values to reflect inter-annual variability;
- one or more specifications of the proportion of the animals from each stock present in each Sub-Area, at the time of year a sighting survey takes place, which is referred to as a ‘sightings matrix’, together with specifications for the statistical characteristics for simulating the results obtained from such a sighting survey, including its associated variance (which is also required for CLA input in each trial).
The RMP gives catch limits by *Small Area*. Any trial must therefore specify how the simulated catch taken in a *Small Area* each year is divided among the different simulated breeding stocks when a stock structure hypothesis places animals from more than one stock in that *Small Area*. To this end, the *Region* under consideration is divided into *Sub-Areas*. The equations specifying how catches are taken in the trials have assumed that the catch from each stock in a *Sub-Area* is taken in proportion to the number of animals from each stock present. Care must be taken that these *Sub-Areas* are delineated on a sufficiently fine spatial scale that such an assumption could not be substantially violated in actual catches.

The *Small Areas* considered in trials may be single *Sub-Areas*, or combinations of adjacent *Sub-Areas* (e.g. IWC, 1994, p.136). In cases where *Sub-Areas* have been so combined, the associated trials specify how the catches allocated to the corresponding *Small Areas* are to be divided among the constituent *Sub-Areas*, and robustness of the trial results to variations of this specification also needs to be tested.

In setting up the *Implementation Simulation Trials* for the range of plausible hypotheses for the species and *Region*, the available information on historical catches, sighting survey abundance estimates, genetic data and so on, is used to set the parameters for population simulation models so that they conform to what is both known and hypothesised for the species in the *Region* under consideration. This involves calculating distributions, where possible, for pre-exploitation abundance levels for each of the discrete breeding stocks assumed for each trial and where necessary adjusting elements of the mixing matrices, using numerical procedures in conjunction with the population dynamics models.

If there are parameters (i.e. pre-exploitation levels or mixing matrix elements) for which the available data contribute no useful information, sets of values are chosen from plausible ranges, so that such parameters are included with the factors incorporated in the alternative sets of hypotheses referenced above. Given any such values, the distributions for the remaining parameters required to set up the population models are calculated as follows. Realisations are drawn from available information for each datum (e.g. a ‘true’ population size from the survey estimate and associated CV in a particular year for some *Sub-Area* or set of *Sub-Areas*, or similarly from genetic or other information on mixing — e.g. IWC, 1994, p.140, table 4). Population models for each breeding stock are then fitted to a set of such realisations, using some suitable minimisation criterion to calculate the remainder of the parameters. Repetition of this process provides a Monte Carlo realisation of the distributions required as input to the simulation trials.

In principle, factors additional to those indicated above could (and should where relevant) be included in this process, by expanding the set of trials to take into account other sources of uncertainty relevant to the species and *Region* in question. However, selecting such factors should take account of the fact that some possible factors (e.g. a change in the value of natural mortality assumed in the population model) have been thoroughly investigated in the single stock *CLA* trials, where their effects on performance were shown to make a near negligible difference, so it seems unnecessary to include such factors in every set of implementation trials. Other possible factors (e.g. different survey intervals or possible under-reporting of catches) had larger effects, but which had nevertheless been shown to be within acceptable limits over a range of values. Accordingly, it would not usually seem necessary to include such factors in *Implementation Simulation Trials* unless likely ranges exceed those tested or a combination of factors are considered relevant.

Given the set of trials developed during the course of an *Implementation*, the anticipated performance for various RMP variants (Catch-capping/Catch-cascading options, *Management Area* delineations) is evaluated. The variant for which performance is assessed by the Scientific Committee to be best in terms of the Commission’s objectives for the RMP is then recommended to the Commission.

The specific criteria for judging the performance of the RMP in *Implementation Simulation Trials* have not been developed. The criteria for evaluating the performance of different RMP variants may be more stringent than those used in the single stock robustness trials. The Scientific Committee will need to continue to document fully the results of *Implementation Simulation Trials* and carefully record the basis on which it makes decisions on its advice to the Commission on each implementation.

The Committee may decide to carry out further *Implementation Simulation Trials* when undertaking an *Implementation Review*, taking into account additional data collected since the previous *Implementation* or *Implementation Review*. The additional data may alter the range of hypotheses considered plausible, and thus alter the set of trials requiring consideration. The data may also alter the information for setting up the simulation models. The resultant set of trials then provides results which may lead to proposals to vary *Management Area* designations and RMP *Catch-cascading/*Catch-capping options.

NOTES:

1. Specific criteria for judging the plausibility of hypotheses have not been developed. The range selected may interact with criteria for judging performance (see below). The Scientific Committee will need to document the basis for its judgements of plausibility.

2. Often the sightings and catch mixing matrices are assumed to be identical. Assuming differences (as, for example, in the North Atlantic minke trials) is one approach to testing robustness to the incorrect specification of ‘boundaries’ (in an average sense, given the stochastic components of mixing models) between stocks.

3. For certain trials, the *Sub-Areas* so combined may have identical mixing matrices (for some parts of the season if trials model migration during the whaling season, as for example in the North Pacific minke whale trials), so that this combination itself meets the criteria for a *Sub-Area*, and *Sub-Areas* become identical to *Small Areas*.

4. These values may be for the current abundances in a previously unsurveyed area, which can be equivalent to the assumption of sets of values for the pre-exploitation levels for some of the discrete breeding stocks.

5. In principle, other data, such as a CPUE series for example, could be included in this process if their reliability is acceptable to the Scientific Committee.

6. Factors previously investigated for the *CLA* are indicated in table 3 of IWC (1993), some of which have been more intensively examined (e.g. environmental change, SC/46/Mg12). Factors specifically examined in *Implementation Simulation Trials* to date have included abundance estimate bias and inter-survey interval in
combination (North Atlantic minke trials), spatial differences in density dependence (Southern Hemisphere minke trials) and whaling during migration (North Pacific minke trials).

7 Situations can be envisaged where further Implementation Simulation Trials would not be necessary, for example if no further scientific information had become available since the previous Implementation or Implementation Review. However, even the results from a single additional sightings survey (as would be anticipated under standard operation of the RMP) could constitute new information which may have an impact on the process of setting parameter values for the population simulation models, particularly in the early stages of an RMP application.

Appendix 6
THE ANALYSIS OF DNA FROM HISTORICAL SAMPLES OF TISSUE

C.S Baker

The use of the polymerase chain reaction (PCR) for genetic analyses of ancient and recent historical samples has begun to revolutionize our approach to the study of the evolution and demography of animal and human populations.

Commercial and subsistence whaling has provided a wealth of tissue samples and artifacts that may allow detailed analyses of historical genetic variation or population structure. Potential historical sources of DNA from whales include preserved soft tissues (e.g. skin, liver, kidneys, ovaries, ear plugs etc., stored frozen or dried or preserved in ethanol or formalin), bones, baleen and dried blood. The ease of extracting and amplifying DNA is dependent on a number of factors that influence the degradation (i.e. fragmentation of DNA into short sequences) and biochemical modification of the DNA strands themselves. As a rough ‘rule of thumb’, the chances of amplifying DNA from soft tissue ranges from excellent to fair according to the following rank ordering of storage methods: frozen or in ethanol (excellent), dried (excellent to fair), formalin (fair to poor). It should also be noted that the degree of success in amplification is often relative to the skill and effort required according to the reverse of this rank order. Storage success may be less predictable for hard tissue such as bone, but exposure to water is likely to be destructive except in unusual circumstances. Not all hard tissue contains DNA in sufficient quantities for amplification. Ivory seems to be a poor candidate, for example. I am unaware of attempts to use baleen for amplification but the best chance would seem to be from tissues attached to the growing, rather than the distal end.

Possible applications of PCR to historical samples include identification of stock identity where current samples are unavailable and estimates of genetic variation in populations before and after periods of exploitation. A question was raised during the sub-committee on Aboriginal Subsistence Whaling concerning the historical and current levels of interchange between circumpolar populations of bowhead whales. It is thought that bones, baleen or other artifacts may be available from villages around the Arctic. Analysis of sequence variation (mitochondrial or nuclear) from DNA amplified from these artifacts could provide an indication of isolation or possible periods of interchange, or shifts in distributions of populations. The examination of current levels of isolation is likely best addressed with current samples collected by biopsy darting or from subsistence catches. A limited number of mtDNA control region sequences are now available from the 1992 subsistence catch from the Bering-Chukchi-Beaufort Sea stock of bowhead whales (Baker et al., 1993).

A second question arose during the sub-committee on Management Procedures concerning further analyses of available North Pacific minke whale tissue samples which have been stored frozen for an extended period. Although poorly stored frozen tissue may not be suitable for protein electrophoresis (i.e. allozymes) or for extraction of the entire mtDNA genome by differential centrifugation, this is unlikely to be a serious problem for analysis by PCR. The available number of samples is large (n=875 used in allozyme analysis reported in SC/46/NP2 and SC/43/M132) and could be used for analysis of mitochondrial and nuclear DNA sequence variation (e.g. Baker et al., 1993; Palumbi and Baker, 1994). Given current debate concerning the stock structure of the North Pacific minke whale (e.g. SC/46/NP2 and NP3) additional genetic analyses of these samples may be warranted.

Report of the Sub-Committee on Southern Hemisphere Baleen Whales

1. OPENING REMARKS, ELECTION OF CHAIRMAN, APPOINTMENT OF RAPPORTEURS

The meeting was convened by Bannister, who welcomed the participants and called for nominations for Chairman. Brownell was elected Chairman. Best, M. Brown and Baker agreed to act as rapporteurs.

2. REVIEW AND ADOPTION OF AGENDA

The adopted agenda is given as Appendix 1. It was agreed that discussion of blue whale material and data would be held under Plenary Agenda Item 8.1.1, when matters arising therefrom might be referred to a special sub-group.

3. REVIEW OF AVAILABLE DOCUMENTS

Documents available to the sub-committee included SC/46/SH1, 3-25 and a number of ‘In press’ papers provided for information (Kasamatsu et al., 1994; Pulumbi and Baker, 1994; Baker et al., 1994).

It was decided that relevant aspects of the papers SC/46/SH15, SH24, SH11, SH12, SH13, SH17, SH20 and SH21 would be discussed by this sub-committee, although other aspects of these papers were more appropriate for discussion by other sub-committees (SC/46/SH15, SH25) or in the Plenary (SC/46/SH11-13, SH17, SH20-21).

Following a decision taken in Plenary, it was decided not to discuss SC/46/SH1.

4. REVIEW OF AVAILABLE DATA

4.1 IDCR sightings surveys

Allison reported that data from the 1992/93 cruise were not yet fully validated and that data from the 1993/94 cruise had arrived and had been coded.

4.2 Other sighting surveys

Japanese scouting vessel sightings (JSV) data is already coded and an updated version supplied to the Secretariat during 1993 and is being added to the database being developed under contract. It was reported that sightings data from the most recent Japanese special scientific permit cruises in the Antarctic (JARPA) were still being entered and will be submitted to the IWC Secretariat in the near future. The Secretariat already holds paper copies of sightings surveys carried out by Japan in the periods immediately before and after the IWC/IDCR research cruises and from five dedicated surveys in the Southern Hemisphere but separate from IDCR between 1978/79 to 1982/83. Of this only data from ‘Before-After IDCR’ for the period 1987/88–1991/92 had been coded but it had not been validated. The data prior to 1987 had not yet been coded because it was in a different format.

4.3 Coding progress for catches, marking and effort

Coding of individual catch data for the Southern Hemisphere had continued, concentrating especially on African and Australian catches from the 1920s and 1930s (Appendix 2). Allison requested that anyone knowing the whereabouts of any of the data presently unavailable should please inform the Secretariat. All ‘Discovery’ marking data had been coded, but early data (<1956) had not yet been validated. Allison reported that there had been no progress with entering effort data.

A report on the development of the database for sightings data which had been awarded to SASS, Aberdeen, was referred to the sub-committee on management procedures (Annex D).

4.4 Soviet catch data

Actual catch data for the Southern Hemisphere operations of four Soviet expeditions post WWII had now been received from the Russian Federation (Appendix 3); however, positional data are only available for one expedition thus far.

5. COMPUTING FACILITIES AVAILABLE

Allison described the available facilities, which included the standard microcomputers and link to the Cambridge mainframe.

6. IMPLICATIONS OF CATCH HISTORY REVISIONS ON COMPREHENSIVE ASSESSMENTS

Earlier this year, Yablokov (1994) had reported that official Soviet whaling statistics previously submitted were unreliable in many aspects. During the meeting, the Russian Federation scientist reported that an ongoing examination of original catch records from past Soviet whaling operations in the Southern Hemisphere from 1949/50 was revealing considerable falsifications of the records that had been submitted by the Soviet authorities to the Bureau of International Whaling Statistics (BIWS) and which are held in the IWC Secretariat database. A
summary of the information so far obtained is given in Appendix 3, along with the BIWS data for the same four expeditions for comparison. The sub-committee expressed its appreciation for the efforts of Zemsky and his colleagues in locating and securing these extremely important records which go back many decades.

Zemsky reported that he and his colleagues are continuing their work to find additional catch and positional data for past Soviet catches.

The sub-committee encouraged the Russian scientists to provide the Commission with a report giving the background to the revised catch statistics. Zemsky stated that something of this nature will be provided in future.

The sub-committee reviewed the implications of these new data for the work of the Committee. It noted that further information on the catches is still being sought; in particular, the lack of positional data makes it difficult to be species/area specific with respect to implications. It also noted that the falsification of records was not confined to under-reporting; in some years the catch of certain species were over-reported, whilst others were under-reported – this was presumably related in some way to total production data. The effects of over-reporting will be the reverse of those described below for under-reporting.

6.1 Current abundance
The Scientific Committee now only uses estimates of current abundance based on direct methods such as sighting surveys or on other methods that do not depend on catch data, such as photo-identification. Revisions to past catch data thus have no effect on the estimates of current abundance accepted by the Committee.

6.2 Depletion level
Models such as HITTER/FITTER (and indeed the CLA) estimate depletion levels from estimates of current abundance and historic catch series. In general, if catches are under-reported, the level of depletion (expressed as a percentage of current to initial population size) will be underestimated to some degree, depending on the level of the catches relative to the current stock estimate and their distribution over time (i.e. the true initial population size will be higher than the estimated initial population size; under-reporting in more recent years will have a larger effect than the same level of under-reporting in earlier years). The reverse is true for over-reporting.

6.3 Population recovery
If a population has been reduced to low levels, continued catching after protection may be sufficient to prevent or slow recovery of the population. Such unreported catches may in some cases be sufficient to explain an apparent failure of a stock/species to recover under protection, without recourse to other explanations. Therefore, for populations in which increases have been observed, if these increase rates are back extrapolated over the period protection was assumed (rather than the true period), the lowest absolute population size that the population is estimated to have reached will be lower than the true value.

6.4 The RMP
The RMP uses information on current population size and historic catches to determine appropriate catch levels (and implicitly estimate depletion levels). It has been designed to be robust to misreporting of historic catches by up to 50% each year; it assumes that future catches (i.e. those set under the RMP) will be accurately known. Its performance will be degraded (for example it will take longer to ‘learn’ the true status of the population) if the true historic catches are not known but it will nevertheless perform adequately. In such circumstances, the underestimation of initial level arising from under-reporting noted earlier, will result in higher initial catch limits than if the true catches were used, although of course the CLA is designed to correct for this over time. If it is suspected that under-reporting of greater than 50% might have occurred for any species/area then further trials would be specified at the implementation stage for that species/area.

At present, implementation of the RMP is only being considered for minke whales. Available information for minke whales suggests that the level of misreporting is small compared to 50%.

7. PRIORITY SPECIES – HUMPBACK WHALES

7.1 Stock identity
Baker introduced SC465SH23 and also referred to Baker et al. (1994) and Palumbi and Baker (1994).

Tissue samples were collected by biopsy darting from 114 humpback whales (Megaptera novaeangliae) in six seasonal habitats representing Groups IV (Western Australia), V western component (Eastern Australia), V eastern component (New Zealand and Tonga) and VI-I (the Antarctic Peninsula and the Gorgona Islands, Colombia, South America) of the Southern Hemisphere.

To date, a highly-variable 300-400 base-pair section of the mitochondrial DNA control region has been sequenced from 81 of these individuals. A total of 56 unique sequences (i.e. nucleotides) has been identified among the 81 individuals. Most nucleotides were unique to only one of the four stock components. Of the six nucleotides shared by more than one region, only one was found in all four stock components, three were found in Western Australia and Eastern Australia or Tonga, one was found in Eastern Australia and New Zealand, and one was found in Western Australia and the Antarctic Peninsula. The sex of 88 whales (63 males and 25 females) has been identified by molecular genetic techniques. A strong male bias was found in the samples from Western Australia and the Gorgona Islands. A female bias was found in Tonga.

A preliminary cladistic analysis of gene flow suggests significant genetic divisions among the four Southern Ocean stocks, although a pattern of historic interchange is evident. Considering only the two most distant stocks, Group IV and Group VI-I, a cladistic analysis of gene flow provides an estimated migration rate of only 5–7 females per generation. A permutation procedure suggests that the current distribution of mtDNA nucleotides is significantly structured (i.e. non-random) among the four stock components despite the trans-regional distribution of many clades. Of particular interest is the presence of the previously described North Pacific ‘AE’ clade of nucleotides in the Gorgona Islands. The presence of this clade in the Gorgona Islands is evidence of historic gene flow from the North Pacific to the Southern Hemisphere. The timing of this migration event is likely to have been 3,000–10,000 years ago based on the observed divergence of the Gorgona Islands nucleotides and a previous calibration of the control region ‘molecular clock’ (Baker et al., 1993). The fact that this clade appears only in the Gorgona Island region (the Group VI-I stock) suggests that migration between Southern Hemisphere stocks may be limited over periods of thousands of years.
In discussing the results of these papers, the sub-committee noted that more samples were required from other areas of the range of Southern Hemisphere humpbacks, particularly from feeding grounds, before a comprehensive understanding of stock structure could be obtained. The availability of tissue samples from southern humpback whales, including the question of the disposition of the biopsy samples from IDCRI cruises now held in Japan, was referred to a sub-group under Bannister. This working group was also asked to identify the need for the collection of further material. It was noted that biopsy material collected under JARPA should not be considered as generally available, as Japanese scientists reserved the right to undertake at least initial examination of this material. The report of the working group is attached as Appendix 4.

7.2 Estimates of abundance

7.2.1 IDCRI results

7.2.2 OTHER SIGHTING SURVEYS

The only new information on these agenda items available to the sub-committee was contained in SC/46/SH24. Although this paper included population estimates for a number of species other than humpback whales, the sub-committee felt it was appropriate to consider the results of the analyses in toto under these agenda items because their interpretation required an understanding of how the data for other species were collected.

Butterworth introduced SC/46/SH24, which presented an analysis of estimates of abundance for species other than minke whales sighted on the first 13 IDCRI cruises (1978/79-1990/91). Estimates of abundance had been obtained for the area covered by IDCRI cruises using the ‘standard methodology’ developed for minke whale data from the same cruises. A value for the probability of seeing a group on the trackline (g(t)) of 1.0 had been adopted for all species. Some estimates (those for sei and pilot whales for example) were extremely crude, due to the small number of sightings involved (less than 20 in both cases). In general, the size of the CVs made it impossible to detect any significant difference between the estimates of abundance produced for the first six and the last six cruises (Table 1) with the exception of sperm whales, for which a large and statistically significant increase was evident. Butterworth pointed out that the rate of population growth implied thereby was biologically infeasible and suggested that the apparent trend could be due to (i) an underestimation of the associated CVs for sperm whales, or (ii) a systematic shift in distribution. To this could be added the possibility of a change in the classification of primary and secondary sightings between the two periods, as only primary sightings were used in the estimates. Although a breakdown of the estimates of abundance for each species by the six statistical Areas I to VI had been attempted, this was not really defensible due to the levels of imprecision in the estimates.

The sub-committee agreed that the estimates of abundance for the area covered by the IDCRI surveys which are shown in Table 1 are probably the best possible given the small sample sizes involved. It draws particular attention to the high degree of imprecision of most of these estimates, as evidenced by their associated large CVs and also by the likely negative bias of the sperm whale estimates as g(0) for this species is likely to be rather less than 1 as assumed because of their long dive times.

* During the Committee meeting, an error in the manner in which data from the 1990/91 cruise had been incorporated into the analysis was noted, but Butterworth noted that correcting for this will result in only slight modifications to the results in this Table.

The authors of SC/46/SH24 used the sighting rates obtained from Japanese scouting vessels (JSV) to extrapolate the estimates from the IDCRI cruises to cover the likely whole summer range of the species. These surveys were not undertaken in a random manner, their principal objective being the detection of concentrations of whales, but it was assumed that any biases would be independent of latitude. Other assumptions made were that the effective search width (ESW) of the scouting vessels (and their detection probability on the track midline) would be similar in all latitudes. Because it might be expected that weather conditions in middle latitudes would be worse than in the IDCRI area (and therefore possibly producing lower values for ESW and g(0)), any such effect would result in the extrapolation being negatively biased. Only JSV data for the months of January and February were used, as these corresponded to the timing of the IDCRI surveys.

Extrapolations could be made using either the whole IDCRI area as the basis, or only the northern stratum within it. The latter was considered preferable because it avoided the problem of the varying ice-edge from year-to-year in the southern stratum. Such extrapolations are shown for two periods of JSV data in Table 2 (the nature of the searching strategy and data collection procedures for the JSV differed for these two periods). The authors of SC/46/SH24 suggested that extrapolations for the first period might be considered more reliable because more JSV searching effort was expended during that period and the distribution of effort was better spread over the strata. The resultant CVs are also smaller. One caveat is that the extrapolations for sperm whales in both data sets may be biased if the g(0) for sperm whales should differ with latitude because of the generally larger schools in lower latitudes.

Holt expressed reservations concerning the reliability of the extrapolation process, questioned the assumption of constant ESW with latitude and raised the possibility of ‘double-counting’ of animals because of a seasonal mismatch between the IDCRI and JSV data. Holt was also concerned about the biases that might arise from the non-random nature of the JSV surveys. In particular he felt that the data did not support the assumption that the non-random nature of the JSV surveys was constant with latitude – effort (especially in the lower
Table 2
An extrapolation of the estimates of Table 1 to the area south of 30°S, based upon JSV data and using weighted mean density estimates for the two circumpolar sets of IDCР cruises (from SC/46/SIH24).

* Based upon the assumption that all blue whales reported north of 50°S during the JSV surveys were pygmy blue whales.

Aititudes) appeared to be concentrated where particular species were expected to be found, so that high sighting rates were correlated with high effort. These latter concerns were illustrated in Appendix 5, in which he concluded that unstratified pro-rating can lead to substantial over-estimation of total numbers.

Ohsumi considered the ‘double-counting' problem not likely to be very substantial, given that the data used in the analysis referred to the period (January/February) when feeding was at its height, so that marked latitudinal movements were unlikely. Butterworth also referred to an earlier analysis by Horwood (1986) in which the ‘double-counting' probabilities for blue whales had been considered low.

Kasamatsu and Holt considered that the extrapolation using the later set of JSV data might be more appropriate, given that from 1976/77 the sighting surveys were run independently of whaling operations. Attention was also drawn to the fact that the distinction between sightings of blue and pygmy blue whales had been made on the basis of whether they were above or below a latitude of 50°S, whereas SC/46/SIH10 indicated that a latitude of 55°S would be more appropriate.

It was agreed that pooling of the JSV data by latitudinal strata irrespective of the longitudinal sector in which the sightings were made could lead to bias, as suggested in Appendix 5. It was proposed that if a reanalysis of the data was to be made, it should be on as fine a longitudinal division as possible. Kasamatsu pointed out that he had used such data by Area south of the Antarctic convergence in a paper submitted to the Scientific Committee last year (SC/45/SIH24), from which estimates of humpback whale population size totalling 10,400 (CV 0.23) had been obtained. Extrapolation by Area (or even sub-Area) between 50° and 60°S was suggested, although concerns were expressed that at the finer geographical division, small sample sizes could lead to large CVs.

After discussion, the sub-committee agreed that the sensitivity of the population estimates south of 30°S provided by extrapolation based on JSV data to longitudinal disaggregation be examined. Results should be calculated with this extrapolation carried out at a half-Area and Area level, in addition to the circumpolar aggregation basis of SC/46/SIH24. These results should include an indication of the differences resulting from interpolating densities for regions with minimal JSV effort and considering the population abundances in such regions to be zero.

Baker queried whether the IDCР cruises would ever give data from which a trend in population could be determined and it was agreed that given the current design of the cruises this was unlikely in the medium term for any species other than minke whales; the principal objective being to obtain estimates of population size for relatively large Sub Areas of the Southern Ocean for management purposes. However, a restructuring of the cruises (to concentrate on one Area, for instance) might in principle be able to supply data for trend analysis.

In light of the disagreement over the validity of the extrapolated figures from the IDCР surveys, it was decided to tabulate all independent estimates of current stock size (suitably annotated to indicate their origin, methodology and assumed efficiency in sampling the population) for Southern Hemisphere humpback whales (Table 3).

7.2.3 Land-based sightings
SC/46/SIH22 provided evidence for possible sex-segregated migration in southern humpback whales. Extensive biopsy sampling of the northern and southern migrations of East Australia from May to October 1992 (n = 180) produced a sex ratio of 2.39 males to 1 female, with no indications of a

Table 3
Population estimates for Southern Hemisphere humpback whales. Other on-going studies of southern humpback whales that might lead to estimates of current population size were known to be underway in Brazil, New Caledonia and Tonga.

</table>
bias caused by incomplete sampling of pods or sampling of pods of certain sizes. The proportion of males was similar to that recorded in East Australian humpback whaling (2.1:1) and an excess of males in catches was also recorded for low latitude areas such as West Australia, New Zealand, the Congo, Madagascar, South Africa and the Grenadines. However, catches from high latitudes of the Southern Hemisphere indicated an excess of females. It was concluded that approximately 50% of females in Area V might not migrate to the breeding grounds each year, possibly remaining in feeding areas throughout the winter.

In discussion, Baker commented that the apparent scarcity of females relative to males on Northern Hemisphere breeding grounds had previously been attributed to a shorter residence time, but this study suggested that absenteism could be a feasible alternative explanation. Bannister queried whether the commercial catch sex ratio was not affected by selection against lactating females, even on the northern migration when the whales could distinguish yearlings. M. Brown responded that most yearlings were weaned by the time they reached the latitude of the shore-based surveys and that she doubted whether the restriction against taking lactating females had been totally effective.

Best queried whether the whaling seasons (and the biopsy sampling) had ended before the southern migration was completed, as it was believed that the last component of the migration consisted of cows with calves-of-the-year: a premature termination of whaling/sampling would therefore effectively exclude a significant number of adult females. M. Brown agreed that this might have been the case for the early whaling operations. When the quota might be filled before the southern migration was completed, but would not apply to the later whaling seasons or to the biopsy sampling, as few whales were seen passing Stradbroke Island after October.

The results of an IWC contract study to investigate the parameters of the southern migration of humpback whales on the west coast of South Africa were given in SC/46/SH4. Over a period of 46 days in October/November 1993, 62 sightings of 135 humpback whales were made from the lighthouse at Cape Columbine, a headland on the west coast of South Africa. Theodolite tracking revealed that both net and average bearings for the direction of movement of humpback whale groups were distributed virtually uniformly to all four compass quadrants. Although about 90% of groups showed average speeds exceeding 1.5km/hr, about 70% of these groups had net speeds of less than 1.5km/hr. A migratory index (average speed/net speed) showed that even those groups with low migratory indices (and thus travelling more or less in a straight line) were equally distributed to all four compass quadrants. Twelve groups of 27 humpback whales were intercepted by boat over a period of 20 days and individual identification photographs revealed that some whales were sighted on several occasions over a period of up to 20 days. Apparent feeding behaviour was observed on 13 occasions over 38 days and defecations were seen on seven occasions, three of which when sampled showed crustacean food remains, mainly euphausiids. It appeared that the southern migration had been suspended during the survey period, possibly in response to local abundance of food.

Late in the meeting, the sub-committee received a report on the occurrence and photo-identification of humpback whales in Brazil. Although it was unable to discuss this report it is appended as Appendix 6.

7.3 Assessments
In SC/46/SH5(Rev), assessments of humpback whale stocks in Groups 4 and 5 were attempted in response to the revelation of previously undeclared Soviet catches in the Antarctic. Recent data had indicated fairly rapid increases in abundance on both eastern and western coasts of Australia. If cataloging of humpback whales had stopped at legal protection in 1963, one would have expected the increase to be manifest almost immediately. However, estimates of relative or absolute abundance made in 1962 or 1963 on either coast were not substantially less than equivalent estimates made in the late 1970s/early 1980s. The model was used to estimate the size of the undeclared catch that would be needed to reconcile the 1962 and 1963 data points with the subsequent population trajectory, using MSYR values obtained from the fit of the trajectory to estimates of abundance made from the late 1970s or early 1980s, and with current estimates of stock size as targets. However, the strong bias in favour of males in the historic catches meant that some of the projections resulted in zero numbers of males and only poor fits to the abundance series could be obtained in other projections. Adjusting the sex-ratio at birth from parity to 52% males (as observed in foetuses from the Antarctic) obviated these problems for Area IV. For Area V, it proved necessary to use the upper 95% confidence limit for the estimate provided by the foetal sex ratio data (56% males). Finally, fixed annual undeclared catches from 1963 to 1971 of 49 (Group IV) and 46 (Group V) were sufficient to reconcile the 1962/63 data points with the subsequent trajectories, but these catch estimates had low precision. These simulations were conducted using estimates of current abundance which were crudely adjusted to allow for absenteism of females (SC/46/SH22); however, if these population estimates were adjusted to higher levels still, then the estimates of undeclared catch were even higher.

In discussion of this paper it was pointed out that there were also undeclared catches prior to 1963 and that the sex-ratio of these catches might counter some of the relative male depletion effects seen in SC/46/SH5(Rev). The sub-committee drew attention to new data given in Appendix 7 for the sex ratio of humpback whales taken by one Soviet expedition in the Antarctic area. In addition, the basis for Chittleborough’s (1965) estimate in Area V needed re-examination, as it was based partly on analyses of CPUE and catch data; further assessments should also consider the postulated division of Area V into two substocks (East Australia, New Zealand/Tonga).

The sub-committee then considered how future assessments of humpback whales might proceed. It was agreed that the critical pieces of information needed were (i) estimates of current abundance, (ii) current increase rates and (iii) accurate historical catch series.

(i) Estimates of current abundance were available from the IDC cruise series, but the extrapolation of these to the whole summer range of the species needed some reanalysis as the estimates themselves were of low precision. Estimates of current abundance from shore-based surveys in lower latitudes needed reconsideration following the suggestion of significant absenteism of females.

(ii) Estimates of increase rates were also available from shore-based surveys, but it was unclear whether the rates observed were affected by transient effects such as a changing proportion of the population migrating closer to the coast. A modelling exercise was also required to see if the rates of increase observed were
biologically feasible, but it was unclear whether there was sufficient information on demographic parameters of southern humpback whales for this purpose (although some was available for northern humpbacks). It was agreed that the degree to which increase rates might be influenced by transient age structure effects could be readily examined using existing assessment models.

(iii) Once the final Soviet catch data set was available, a more accurate catch series could be constructed. However, without adequate information on stock identity and mixing it would be difficult to allocate pelagic catches in some areas to specific breeding stocks (if an assessment was done on a breeding stock basis) and conversely, to allocate some catches in lower latitudes to feeding aggregations, if the latter were to be the basic assessment units.

8. ABUNDANCE ESTIMATES, STOCK IDENTITY AND DISTRIBUTION FOR OTHER SPECIES

8.1 Minke whales

A review of information on possible breeding areas and southbound migration routes of southern minke whales by Kasamatsu et al. (1994) was considered. Information from Japanese sighting vessels was used for the months of October-December only (corresponding to the second half of the conception season), during 1976/77-1987/88, with relatively little data from within national EEZs after 1980. Sightings north of 30°S were considered to be indicative of the likely location of breeding grounds. Four areas of high density were identified in this stratum, one in the western Indian Ocean (30°-40°E), one in the eastern Indian Ocean (80°-120°E), one between 170° and 130°W in the southwest Pacific and one between 120°W and 100°W in the southeast Pacific. The animals appeared more dispersed on these grounds than humpback or right whales. Sightings in more southerly latitudes in later months suggested that whales from these breeding grounds moved almost directly south but on reaching waters south of 50°S dispersed in an east-west direction.

The sub-committee noted that this analysis did not include the South Atlantic because a lack of sighting effort in that region, but they believed that at least one other breeding population (off northern Brazil) could be identified in that ocean.

Van Waerebeek introduced his paper with Reyes (SC/46/SH19). The first records of minke whales on the coast of Peru occurred in 1991 (Van Waerebeek and Reyes, 1994). A review of the past and present occurrence of southern minke whales (including the dwarf form) off Pacific Colombia, Ecuador, Peru and Chile (SC/46/SH19) revealed only 15 specimen and sighting records, and the impression gained from many years of fieldwork in Peru is that minke whales are not common in the area. The minke whales in Area I of the Antarctic cannot therefore migrate due north to breeding grounds off the Pacific coast of South America, but must move either to the west or east or both. Van Waerebeek suggested that the longitudinal boundaries of Area I north of 40°S might have to be revised for minke whales.

The sub-committee noted that the rarity of minke whale records from the Pacific coast of South America (SC/46/SH19) was consistent with the low sighting rates for that area presented by Kasamatsu et al. (1994) and felt that it was possible that minke whales in Area I were linked to the ‘breeding ground’ between 120° and 100°W. The sub-committee recommended that NOAA records from the eastern tropical Pacific be summarised and presented to the Scientific Committee. Discussion on the taxonomic status of both forms of minke whale in the Southern Hemisphere relative to each other and to those in the Northern Hemisphere, revealed the need for a comprehensive review of their systematic status. Attention was drawn to recent papers on the genetic relationship between minke whales in at least two of these areas (Arnason et al., 1993; Pastene et al., 1994).

The genetic structure of minke whales in Antarctic Areas IV and V was examined through the analysis of 1,257 samples collected as part of JARPA during the seasons 1988/89 to 1992/93 (SC/46/SH13). The samples had been arbitrarily divided into four longitudinal sectors (Area IV&V, Area VE&W) and two time periods, early (December-January) and late (January-March). Mitochondrial DNA haplotype frequencies were used to determine relationships between these groups. After pooling samples from different seasons, a marked spatial and temporal heterogeneity was found. A group of whales sampled in Area IV&W in the early part of the season was significantly different in haplotype composition from all but one of the other spatial and temporal groups analysed. Furthermore, a group of whales sampled in Area VE late in the season was significantly different from all but one other group. It is possible that these belonged to different breeding stocks. However, of 123 haplotypes identified, 8 were dominant, but were present in all six groups, so that no stock-markers could be identified.

In discussion, Pastene commented that they were considering the use of other genetic techniques, including examination of nuclear DNA. Baker commented that the data presented in SC/46/SH13 were amenable to more powerful statistical analyses to examine relationships (e.g. by clustering and analysis of molecular variance by permutation procedure) and Pastene stated that these were being planned. The sub-committee recommended that further analysis on a temporal basis should be undertaken to examine the distinctions between the apparently different groupings early in Area IV&W and late in VE. It understood that some material was already available from Area IV&W for this analysis.

8.2 Other

As discussions of blue whales had been deferred to the Plenary, the only other estimates of current abundance for southern baleen whales available to the sub-committee were those for sei and fin whales arising out of the IDCR surveys (SC/46/SH24). However, the estimates for sei whales were based on so few sightings that they had very limited reliability.

The coverage of the IDCR surveys had been somewhat too far to the south to cover the summer distribution of fin whales adequately, so extrapolation using the JSV data had been attempted. The authors of SC/46/SH24 considered the estimate based on the earlier JSV data set to be the preferred estimate (15,000, CV 0.30), but the use of the later data set did not give a significantly different answer (22,000, CV 0.42) – Table 1.

The sub-committee expressed the same reservations about the extrapolation process as they had for humpback whales and other species, noting that the bulk of the extrapolation came from JSV sightings in the 50-60°S stratum. Attention was drawn to the illustrative calculations for fin whales in Appendix 5. As the distribution of fin whale density in the 50-60°S stratum was
substantially different between the early and later JSV data sets, it was necessary to exercise caution in deciding which data sets to use for extrapolation. It was also pointed out that the ratio of secondary to primary sightings was the highest of any of the species encountered on the IDC cruises (SC/46/SH24), being 0.92 compared to 0.20–0.64 for the other species considered. This suggested some element of schooling behaviour that was different. Ensor confirmed that fin whales were often found in relatively dispersed groups on the cruises, such that if they were more than a few body lengths apart it was difficult to know whether they should all be classified as a part of the primary sighting. This effect may therefore introduce an element of negative bias into the fin whale abundance estimates.

The sub-committee noted that the current cruise planning for IDC vessels made it unlikely that any useful information on current abundance of sei whales would be forthcoming in the near future. It stressed that it would be difficult to undertake a comprehensive assessment of this species in the Southern Hemisphere without more reliable estimates of current stock size.

9. IDC SOUTHERN HEMISPHERE MINKE CRUISES

9.1 Estimates of abundance from previous cruises

Borchers reported that the data from the 1992/93 IDC cruise had been coded and validation was almost complete; he would analyse the data to provide an estimate by the time of the next annual meeting. The 1993/94 data had been coded but not validated – it would only be analysed if a third year of the IWC contract was awarded.

In view of the time and money already invested and the importance of obtaining the results, the sub-committee recommended that the contract should be extended to enable the 1993/94 data to be analysed.

It was pointed out to the sub-committee that an enormous amount of accessory data had been collected on these cruises, especially environmental and behavioural. Although the latter were not yet in the data base, the sub-committee recommended that studies to look at these data should be actively encouraged. If no interest is shown, those collecting such data may begin to consider their efforts redundant.

9.2 Report of the 1993/94 cruise

The report from this cruise (to Area I) had already been presented to the Scientific Committee in Plenary (SC/46/SH3). The sub-committee expressed its appreciation for the generosity of the Japanese government in providing these vessels along with its gratitude to the cruise leader, Ensor, and other participants for their contribution towards a successful survey. It was agreed that recommendations arising from this cruise would be considered by the ad hoc Working Group on the 1994/95 IDC cruise under Best.

9.3 Plans for 1994/95 IDC cruise

Best requested that the sub-committee hold some initial discussion on the possible choice of a survey Area (and its size) for the forthcoming cruise, as guidance to his Working Group.

It was pointed out that with only two vessels, coverage of an Area up to 60°S would make it very difficult to achieve complete coverage longitudinally of any existing management Area, particularly Areas II and V, where there were deep embayments in the continent (Weddell and Ross Seas) and great uncertainty about pack-ice conformations. In the most recent survey (in Area I) a target of 50° longitude was set, but was not fully achieved. Hence a more realistic target might be 40°, unless the northern limit was dropped to 61°S (or lower).

Although it was realised that Areas I and II were very far from Japan and that Areas II and V presented special problems for a survey with two vessels, support was expressed in principle for the continuation of circumpolar surveys, as these contributed much to our knowledge of Antarctic whale stocks and their ecological relationships.

In reply to a question whether it was necessary to survey Areas IV and V as frequently as the other Areas, because sighting estimates for these areas were being obtained from JARPA, it was pointed out that there were problems of compatibility of methodology between these surveys and those under IDCR, so that Areas IV and V for the present should be considered as full candidates for an IDCR survey. However, it was recognised that calibration across cruises remained a possibility and that this might be considered at the next IWC meeting.

In reply to a question about the desirability of ‘completing’ surveys in Areas that had been only partially surveyed in a recent cruise, it was agreed that such surveys should not be regarded as sufficient for that Area as a whole.

The sub-committee specifically charged the ad hoc Working Group with investigating the implications of collecting ‘accessory’ data (such as biopsies, photo-identifications or environmental monitoring) on the IDCR cruises. A table of ‘trade-offs’ in terms of likely survey time lost was requested from the group.

Komatsu stated the Japanese Government’s position that while ‘accessory’ data should be collected where possible, the priority of the cruises should remain the estimation of whale abundance.

10. FUTURE WORK

The sub-committee first reviewed progress on the topics that had been proposed last year under this agenda item.

Short term

(1) Completion of coding of catch and marking data. Allison reported that (apart from the revised Soviet data), coding of available catch data was virtually complete (Appendix 2). The sub-committee recommended that the marking data for humpback whales under the ‘Discovery’ scheme (especially from Australia and New Zealand) be coded and validated, as a priority. Zemsky stated that the Russians will attempt to locate the original Soviet Southern Hemisphere marking data and transmit it to the IWC Secretariat.

(2) Inventory of biopsy samples from Southern Hemisphere humpback whales. Bannister reported that this task had been completed (see Appendix 4). The sub-committee recommended that member governments be requested to include the numbers of tissue samples collected for genetic analysis (from all species) in their annual progress reports.

(3) The sub-committee reviewed briefly its 1993 recommendations that sources of photo-identification material be identified and progress in development of a central catalogue of Southern Hemisphere photo-id material be reported. Recent studies had included both fluke and lateral photography. It noted that development of a central catalogue may not be
essential and would in any case not be possible unless resources were made available to maintain and operate such a facility. A viable alternative at present appeared to be to ensure that there was good cooperation between active groups, with provision made for long-term archiving of the material. The sub-committee noted that a partial catalogue had been produced for Australian material, based primarily on east coast (Area V) material and that international cooperation in photo-identification work on southern humpback whales was described in SC/46/SH21. Other material, primarily from Area IV (Australian west coast) and from the Antarctic had been included on the humpback database maintained by the US NMFS Seattle laboratory, but support for that has now been discontinued. The sub-committee recommended that those responsible ensure that the existing electronic and reference photographic material be properly archived and maintained as a potentially important resource in the longer term and that information on the status of the system be provided to the committee.

The sub-committee was concerned that, while it had some assessments of abundance based on photo-identification material available, it had not reviewed the more general question of the reliability of photo-identification based population assessments for humpback whales. It noted, however, the potential contribution of natural marking studies in assessments of movement between areas and exchange between populations, site fidelity and seasonal and other movement. It recommended that time be allocated at its 1995 meeting for a critical review of the utility of photo-identification studies for Southern Hemisphere humpback whale assessments and that material should be made available at that meeting that would allow it to:

1. assess sources of error and bias in estimates of Southern Hemisphere humpback whale abundance based on fluke and other photography;
2. review utility of the technique for other studies, such as local and seasonal movements, relationships between breeding and feeding areas, site fidelity and short-term behavioural studies, relating to assessment and management;
3. identify sources, quantity and quality of existing holdings of Southern Hemisphere humpback photo-identification material and arrangements for access and co-operative studies.

Long-term

1. IDENTIFICATION OF TROPICAL BREEDING GROUNDS
It was pointed out that historical catch data such as that presented by Townsend (1935) could provide useful information on the distribution of whales in warmer waters during months believed to correspond to their breeding season, as the 19th century pelagic industry was not subject to the same legal constraints regarding times and locations of whaling as modern whalers. Cawthorn undertook to provide the positions of the humpback whale catches in a subset of the Townsend data that he had obtained and to present it to next year's meeting. The sub-committee recommended that such an analysis should be undertaken.

Lockyer presented a proposal to examine the 'Discovery' and other historical data held by the Sea Mammal Research Unit, the British Antarctic Survey, the Institute of Oceanographic Sciences Deacon Laboratory and the Scott Polar Research Institute, all in the UK (SC/46/SH9). Some of this data pertained to whaling operations in waters outside the Antarctic and so might be of value in considering potential breeding areas. She stressed, however, that nearly all the data was still in its original, voluminous, documentary format and that to make it readily accessible some initial computerisation at least would be required. Upon enquiry she stated that relatively little of the data was relevant to southern humpback whales.

Although not listed in SC/46/SH9, some of these same institutes held collections of biological material from whales that might be of interest and an inventory of such material had been prepared by Sidney Brown some years ago as part of the Data Inventory phase of the comprehensive assessment; this inventory is already be lodged with the IWC Secretariat.

(2) PLANNING OF IDCR CRUISES TO BREEDING GROUNDS
It was noted that a proposed austral winter IDCR cruise was to be considered under the blue whale discussions in Plenary. The sub-committee welcomed this development and recommended that support should be given to such cruises as they had the potential to provide very valuable information on the distribution of southern baleen whales on their breeding grounds.

## SOUTHERN HEMISPHERE CATCH DATA CODING: POSITION AT 1 JULY 1994

The following table lists the Southern Hemisphere catch data in the IWC data base and indicates whether the data were encoded by the IWC or by RIDS (a Norwegian data coding bureau). The data encoded by RIDS are not fully validated and are known to contain errors (these data are currently being checked and corrected as far as possible). The table also lists catches which are not in the data base and indicates whether or not the data are known to be available.

1. Includes S. Georgia, S. Shetlands, S. Orkney and Falkland Islands.
2. No data available. If anyone knows the whereabouts of any of these data please inform the Secretariat.
3. Includes Ross Sea.
4. Includes S. Georgia 1930/31-38/39 and Deception in 1930/31
5. Includes some sperm whales caught N40S.
6. En route home from Antarctic.
7. Chile catch in 1965 unknown.
8. Chile catch in 1982 unknown.

SOVIET ANTARCTIC PELAGIC WHALING AFTER WWII:
REVIEW OF ACTUAL CATCH DATA

V.A. Zemsky, A.A. Berzin, Y.A. Mikhaliey and D.D. Tormosov

Introduction

Some actual Soviet Antarctic pelagic whaling records were made public by D.D. Tormosov and A.V. Yablokov during the plenary session of the Society of Marine Mammalogy's Tenth Biennial Conference in Galveston, Texas in November 1993. These data were from one (Yuri Dolgorukiy) of the four Soviet factory ships that operated in the Southern Hemisphere after World War II. The catches for right, blue and humpback whales were reported as 717, 1,433 and 7,207 respectively (Yablokov, 1994). These catches occurred during the 1960s and had been previously kept secret by the Soviet authorities. This Appendix reviews actual Soviet Antarctic pelagic catches from whaling operations for all four factory ships (SLAVA, Sovietskaya Ukraina, Yuri Dolgorukiy and Sovietskaya Rossiya). The lines which are crossed out are the old numbers, as supplied to the Bureau of International Whaling Statistics and which are included in the IWC database. The lines above give the new Russian data. In the case of the new Yuri Dolgorukiy data, individual records exist.

BIWS database

Records on Soviet whaling catches were submitted to the Bureau of International Whaling Statistics (BIWS). The BIWS database was subsequently transferred to the International Whaling Commission (IWC). These two databases have served as the official record of all whaling by the USSR until last year. These databases are false.

Actual database

The actual records of Soviet whale catches were collected by each of us as follows: V.A. Zemsky and Y.A. Mikhaliey (SLAVA, Sovietskaya Ukraina), A.A. Berzin (Sovietkaya Rossiya) and D.D. Tormosov (Yuri Dolgorukiy). These records were collected by us or our colleagues working on the four factory ships. The collection of these data are not yet complete, but we present these data as provisional at this time to aid the work of the IWC Scientific Committee. Additional data and materials will be presented in the future.

Acknowledgements

We thank Cherry Allison who prepared the tables to compare actual Soviet whale catches with those officially reported to the BIWS in the past.

</table>

Total catch by the Sovetskaya Ukraina 1959/60-1971/72

New | 558  | 3,162 | 7,044 | 16,268 | 16,333 | 13,286 | 569 | 363 | 2,053 | 30 | 73,775
Old | 949  | 0   | 11,077 | 16,921 | 873 | 11,409 | 3 | 383 | 105 | 41,723

1 Note that no new data were available for the period 1972/73 - 1986/87.
2 Adjustments have been made to these new USSR totals as there were discrepancies in the sums.
3 Plus additional catch numbers, unknown at present (indicated by a "?" in the table of catches by year).
