The Committee welcomed an update on international efforts addressing anthropogenic noise and their impacts on cetaceans, particularly regarding the appropriate assessment and protection of acoustic habitat quality as discussed in Annex K (item 5), and commended IWC engagement with organisations such as IMO and the UN.

Guidelines developed by the Convention on Migratory Species (CMS) Secretariat, also on behalf of the ASCOBANS and ACCOBAMS Secretariats, for Environmental Impact Assessments for noise-generating offshore industries were presented to the Scientific Committee. These guidelines had been endorsed through CMS Resolution 12.14 on Adverse Impacts of Anthropogenic Noise on Cetaceans and Other Migratory Species, and provide a pathway to implementing the Best Available Techniques (BAT) and Best Environmental Practice (BEP).

The Committee also considered the results of a study utilising modelling approaches to evaluate relative levels of communication masking for four baleen whale species in the Stellwagen Bank National Marine Sanctuary, in Massachusetts Bay, USA Cholewiak *et al.* (In press).

Attention: SC, G, CG-A

Recalling its previous recommendations on noise and the importance of addressing its impacts on cetaceans, the Committee:

- (1) **welcomes** and **draws attention** to the Convention on Migratory Species Family Guidelines on Environmental Impact Assessments for Marine Noise-Generating Activities (<https://www.cms.int/en/guidelines/cms-family-guidelines-EIAs-marine-noise>), noting that these guidelines will help improve global standards for environmental impact assessments;
- (2) **recommends** that levels of anthropogenic noise and its effects on marine species be explicitly considered in the management of marine protected areas;
- (3) **welcomes** the information received on using marine soundscape planning strategies to reduce interference between hydroacoustic instrumentation (e.g. echosounders and airgun arrays) and marine mammals, and **encourages** work to further develop this approach;
- (4) **recognises** the commonalities identified among the concurrent efforts of multiple international bodies to develop national guidance on noise strategies, and **encourages** continuing efforts to identify synergies and develop priorities for actions to reduce exposure of cetaceans to anthropogenic noise;
- (5) **welcomes** the work on modelling cetacean communication space, and **encourages** scientists engaged in the development of modelling techniques that address multiple anthropogenic impacts, such as noise and entanglement in fishing gear to bring these forward to the Scientific Committee;
- (6) **agrees** that a pre-meeting on noise be organised for SC/68b and that an intersessional steering group be convened (Annex Y) to develop the agenda for that pre-meeting.

15.5 State of the Cetacean Environment Report – SOCER

The Scientific Committee **thinks** the editors of the State of the Cetacean Environment Report (SOCER) for their work and commended them on compiling this information on the Mediterranean and Black Seas. Next year's region will be the Atlantic Ocean. The Scientific Committee would welcome input from the members for information on this region. A 5-year global compendium is being produced in cooperation with the Secretariat that will receive a dedicated webpage on the IWC website in time for presentation to the 2018 Commission meeting.

15.6 Update on other standing topics

15.6.1 Marine debris[litter]

The Committee received and discussed a number of papers relating to several aspects of marine debris as discussed under Annex K (item 7.1). Exposure to marine debris and microplastics in cetaceans is now widespread and common. However the impacts on cetacean health and populations is not fully understood.

Attention: C-A, SC

*The Committee **draws attention** to the fact that marine debris remains a threat, and that in particular, exposure to plastics (including microplastics) is a rapidly emerging area of concern. It therefore:*

*(1) **agrees** that an intersessional workshop on Marine Debris should take place, preferably to coincide with the World Conference on the Biology of Marine Mammals in Barcelona in December 2019.*

15.6.2 Climate change

Climate change was highlighted at SC/67a as being an overarching issue that is important to various topics, and that where relevant its impact should be discussed in conjunction with that topic (see discussion in Annex K, item 7.2). Notwithstanding that, the Committee may want to initiate a specific activity related to climate change in future (see intersessional correspondence group in Annex Y).

Attention: C-A, CG-A, SC

*The Committee **draws attention** to the fact that climate change remains a threat that interacts with other threats and stressors impacting cetacean populations.*

15.6.3 Cetacean diseases of concern

Monitoring health and disease agents in large whales in the Arctic is continuing to provide important information on changing patterns in prevalence, environmental status, and potential impacts. In addition, morbillivirus and Brucella continue to be important pathogens causing disease and increased mortality in cetaceans in the Atlantic.

Remote methods for assessing health and condition using visual and aerial photography (e.g. SC/67b/CMP13), is a major rapidly developing field, due to the widespread availability and reduced cost of unmanned aerial vehicles (UAVs). Standardisation efforts (e.g. see Annex S) for measuring body condition using UAVs for photogrammetry, and for collecting blow samples, should progress to ensure this useful tool can provide comparable data across studies, taking into account the differences between the various platforms available. Cross-validation with current methods for assessing body condition from visual health assessments is essential.

Attention: SC

*The Committee **agrees** to hold a focussed session next year (SC/68a) on our current understanding of the pathology and epidemiology of morbillivirus and Brucella and the potential for identifying and understanding the cumulative effects of exposure to other immunosuppressive stressors in cetaceans.*

15.7 Progress on previous recommendations

15.7.1 Pollution

The SC/67a recommendations were to (a) make the effect of contaminants on cetacean populations (SPOC) model available to the public; (b) review mercury in cetaceans; and (c) include new data into the contaminant mapping tool. These have all been completed.

15.7.2 Cumulative effects

As recommended last year, a workshop on understanding the cumulative effects of multiple stressors was held as a pre-meeting to SC/67b.

15.7.3 Diseases of concern

The Committee noted that the content on the Cetacean Diseases of Concern (CDoC) website will now be utilised and merged with the Strandings Initiative for the development of their training and outreach materials.

Whilst the recommended quarterly CDoC updates remain of interest to the Committee, a means of progressing this on a voluntary basis has not yet been identified although efforts to find such assistance are ongoing.

15.7.4 Strandings

The Strandings Initiative has progressed as recommended at SC/67a and a full progress report can be found in Annex K, Appendix 2.

15.7.5 Noise

In response to a previous recommendation, that Committee has received the recently developed seismic survey guidelines by the New Zealand government, a link to the technical working group reports created during the NZ seismic guidelines review is now available (<http://www.doc.govt.nz/our-work/seismic-surveys-code-of-conduct/work-of-the-technical-working-groups/>). However, these guidelines have not yet been discussed by the Committee.

As recommended and noted earlier under Item 15.5, the intersessional group assisted in the development of a summary of the IWC recommendations relevant to shipping noise for presentation to the International Maritime Organization's Marine Environment Protection Committee in 2018.

15.7.6 Thanks

The Committee would like to thank Teri Rowles for her exceptional support and hard work as Chair of the sub-committee on environmental concerns over recent years. Her extensive knowledge, expertise and guidance has been most appreciated and will be missed.

15.8 Workplan 2019-20

The Committee's workplan on environmental concerns is given as Table 20.

Table 20

Work plan for matters related to environmental concerns (for more details see Annex K, Appendix 4).

Item	SC68a	SC68b
Pollution 2020 (including oil spills)	If new information	Primary topic (including oil spills and mercury), summary report to Commission
Cetacean diseases of concern (incl. HAB toxins)	Primary topic	Primary topic
Strandings	If new information	Primary topic
Noise		Noise focus session
Marine litter	Pre-meeting on litter and plastics focus session	If new information
Cumulative impacts	If new information	If new information
Emerging issues	If new information	If new information
SOCER	Receive report	Receive report
Climate change	Over-arching topic	Over-arching topic

16. ECOSYSTEM MODELLING

The report of the Working Group on Ecosystem Modelling is given as Annex L. This group was first convened in 2007 (IWC, 2008b). It is tasked with informing the Committee on relevant aspects of the nature and extent of the ecological relationships between whales and the ecosystems in which they live.

Each year, that Working Group reviews new work on a variety of issues falling under three areas:

- (1) reviewing ecosystem modelling efforts undertaken outside the IWC;
- (2) exploring how ecosystem models can contribute to developing scenarios for simulation testing of the RMP; and
- (3) reviewing other issues relevant to ecosystem modelling within the Committee.

16.1 Cooperation with CCAMLR on multi-species modelling

The Committee has been considering plans for joint workshops with CCAMLR on ecosystem modelling for some time (e.g. see IWC, 2017c, p.56), although this has not yet happened, the Committee remains interested.

Attention: SC

*The Committee **reiterates** its interest in holding joint workshops with CCAMLR. It **agrees**:*

- (1) that a two-year delay in the occurrence of the workshop will provide the opportunity to pursue and complete the relevant work with input from CCAMLR as needed; and*
- (2) that collaboration between SC-IWC/SC CCAMLR should be on going, and that the revised plan for the workshops (IWC, 2018e) be implemented.*

16.2 Applications of species distribution models (SDMs) and ensemble averaging

The Committee had agreed in 2015 to review the application of species distribution modelling (SDM) and associated techniques as they pertain to the goals of the Committee and to develop good practice guidelines and recommendations. While the review has occurred (IWC, 2016b), there has been no significant progress in the intersessional correspondence group set up to develop the guidelines.

Attention: SC

The Committee **reiterates** the importance of developing good practice guidelines and recommendations for species distribution modelling and **agrees** that this should be pursued by an intersessional correspondence group (Annex Y) with a view to reviewing and adopting guidelines within the next biennium.

16.3 MODELLING OF COMPETITION AMONG WHALES

16.3.1 Individual-based energetic models

Enhancements to an individual-based energetics model (IBEM) were presented to the Committee (SC/67b/EM07). These included the explicit modelling of feeding on migration, individual dives and searching for prey schools. Results showed that carrying capacity and productivity were sensitive to the level of food available during migration, making it important that ecosystem models to cover the entire migratory range of the species. This is an important contribution to the determination of species' function response, which can play a pivotal role in ecosystem modelling. This approach is also discussed under Item 5.1.

16.3.2 Modelling of relationship between whales and prey

The Committee reviewed three papers relevant to modelling of the relationships between whales and prey, SC/67b/EM04, SC/67b/EM06 and de la Mare *et al.* (*in press*). The discussion of these can be found in Annex L (item 3.2).

16.3.3 Modelling of competition among baleen whales

The Committee noted that multi-species individual based energetic models (IBEM) such as those described under Items 16.3.1 and 16.3.2 could be used to model direct and indirect competition of different whale species in the same environment, and that relevant modelling work was nearing completion.

16.3.4 Stable isotope analyses

The Committee received preliminary results of the analysis of stable carbon ($\delta^{13}\text{C}$) and nitrogen isotope ratios ($\delta^{15}\text{N}$) on samples from the edge of baleen plates in Antarctic minke whales (SC/67b/SP09). The details can be found in Annex L (item 3.5).

16.4 Standing topics

16.4.1 Effects of long-term environmental variability on whale populations

How long-term environmental variability might affect stock assessments is of particular interest to the Committee. Given the need for a literature review on the subject to facilitate discussions, an intersessional correspondence group (Annex Y) has been established.

16.4.2 Update on body condition analyses for the Antarctic minke whales

For several years, the Committee has been discussing whether there has been a statistically significant (5% level) decline in the blubber thickness and fat weight of Antarctic minke whales over the course of the JARPA surveys. In 2014, the Committee had agreed that there had been such a decline (IWC, 2015b). Since then, scientists from Australia, Japan and Norway have presented a series of models both supporting and challenging this conclusion. There has been collaboration over this period and significant development in the types of models used. In addition, there have been in-depth discussions regarding the proper handling of data, the explanatory variables to be included in the analysis and the appropriateness of various statistical methods.

New analyses were presented this year and detailed discussions can be found in Annex L, item 2. This year the debate focused on three points; (1) the use of a new variable of primary interest (the 'accumulated blubber thickness in each feeding season); (2) the use of FIC and (3) the appropriate handling of the data.

Attention: SC, G

The Committee has been discussing whether there has been a statistically significant (5% level) decline in the blubber thickness and fat weight of Antarctic minke whales over the course of the JARPA surveys for several years. In conclusion, the Committee **agrees**:

- (1) that, for the data set considered as a whole, all approaches result in point estimates reflecting a decline when fit to a linear trend in time;
- (2) however, the extent of the decline estimated differs amongst the methods, and is not statistically significant at the 5% level for all approaches;
- (3) for some approaches, when the data are disaggregated by gender and/or area, some point estimates of trend are not negative;
- (4) there are some indications of temporal variation that is more complex than linear.

In addition, the Committee:

- (1) **encourages** the authors to publish the results of their study in peer-reviewed journals; and
- (2) **agrees** that this matter will not be considered during the forthcoming biennium.

In discussion of the above, Norwegian scientists stated that since an error in parts of the Australian scientists' calculations has recently been acknowledged by them, and parts of the Australian scientists' conclusion and appendix had recently been withdrawn, the overall position regarding the blubber thickness and fat weight analyses now became as follows. There are no new analyses from the Australian scientists on the five response variables which have been considered and discussed in the Committee from 2011 to 2017. The results presented this year by the Norwegian scientists (SC/67b/EM02), which took into account some of the queries from the Australian scientists from last year, confirmed results presented by the Norwegian scientists earlier. Thus, the conclusions by the Committee in 2014 and 2017 on these variables remain valid. For this meeting the Australian scientists had presented analyses related to a new difficult dependent variable 'increase in blubber thickness during summer feeding in Antarctic waters' estimated from the blubber thickness at position BT11. The conclusion above about variables with a non-significant decline now pertains to the new variables only (points (2) and (3) above). The Norwegian scientists' position is that the conclusion drawn above was heavily influenced by the results of the calculations subsequently withdrawn, so that parts of those conclusion are no longer valid.

In response, the Australian scientists stated that results of some calculations carried out earlier were withdrawn because of a previously unidentified problem with a standard statistical package failing to converge on a solution without giving an error message. Subsequent collaborative checking with the Norwegian scientists led to the discovery of this problem. Withdrawing this calculation (which the Australian scientists had carried out to illustrate a property of the Norwegian scientists' methods) had no effect on the main results which the Australian scientists had presented in SC/67b/EM03. Nor did this retraction affect the results of analyses the Australian scientists had presented in 2017 showing non-significant trends in fat weight and blubber thickness (De La Mare *et al.*, 2017a; 2017b). The Australian scientists held the view that the assertion by the Norwegian scientists that "There are no new analyses from the Australian scientists on the five response variables which have been considered and discussed in the SC from 2011 to 2017" was not correct; the Australian scientists had provided full results of fitting models to BT11 in SC/67b/EM03. The main results in SC/67b/EM03 were based on differences between early- and late-season predictions from models with BT11 as the dependent variable. This difference was a simple measure of feeding in Antarctica. The earlier conclusion should not be materially affected by withdrawing the Australian scientists' compromised demonstration in relation to the Norwegian scientists' methods.

16.4.3 Review the information on krill distribution and abundance by NEWREP-A

The Committee received the results of the krill and oceanographic surveys during the third NEWREP-A survey in Area V-E and VI-W (SC/67b/EM05). Discussion of this information can be found in Annex L (item 6.1).

16.4.4 Ecosystem functioning

Resolution 2016-3 tasked the Committee with investigating the contribution of cetaceans to ecosystem functions. Last year, the Committee noted that its focus would be on scientific aspects of the issue and it established an intersessional correspondence group to progress this work. Progress made by that group, including development of a final terms of reference, can be found in Annex L, item 6.2. The Committee notes that the Conservation Committee will focus on the conservation and social science aspects of this issue.

It was noted that there is broad interest in understanding the role of cetaceans in ecosystem functions, and that the Committee's expertise relates to the scientific aspects of the issue. Given the broad international interest, it is suggested that the Committee work in collaboration with interested parties (e.g. CMS, CCAMLR, SCAR and SCOR) to share information and avoid the duplication of work.

C-A, CC, SC

*Commission Resolution 2016-3 tasked the Committee with investigating the contribution of cetaceans to ecosystem functions. The Committee notes that the Conservation Committee will focus on the conservation and social science aspects of this issue. In responding to the Resolution 2016-3, the Committee **advises** the Commission that with respect to the scientific aspects on the contribution of cetaceans to ecosystem functioning:*

- (1) it is unlikely that the ultimate goal of reliably determining the contribution of cetaceans to ecosystem functioning could be achieved in under a decade, given the complexity of the issue and the data gaps; and*
- (2) a more immediate and achievable goal is the carrying out of a gap analysis to identify knowledge gaps and to develop a plan to address them.*

*To further this work, the Committee **agrees**:*

- (1) to hold a workshop to (a) define short- and medium-term objectives to be addressed and (b) to identify what further research is required in order to begin initial modelling of the contribution of cetaceans to ecosystem function; and*
- (2) that the Secretariat in conjunction with the Steering Group (Annex Y) should contact CMS to determine their interest in participating in such a workshop.*

16.6 Workplan 2019-20

The Committee's work plan on ecosystem modelling is provided in Table 21.

Japan referred to its statement on the adoption of the Agenda (Annex Z) and considered that several of the items for the proposed workshop (Item 16.4.4 and Item (7) in Table 1) are outside the competence of IWC. Therefore, it cannot support the proposed workshop or associated funding from the Committee's budget.

Table 21

Summary of the two-year work plan on matters related to ecosystem modelling

Item	Intersessional 2018/19	2019 Annual Meeting (SC/68a)	Intersessional 2019/20	2020 Annual meeting (SC/68b)
(1) Ecosystem modelling in the Antarctic Ocean	Continue further analyses.	Review results of further analyses	Continue further analyses.	Review results of further analyses
(2) Application of species distribution models (SDMs)	Intersessional group activity (Annex Y)	Review progress		
(3) Effect of long-term environmental variability on whale populations	Continue further analyses. Intersessional group activity (Annex Y)	Review results of further analyses. Review progress	Continue further analyses	Review results of further analyses
(4) Further investigation of individual-based energetic models	Continue further analyses	Review results of further analyses	Continue further analyses	Review results of further analyses
(5) Modelling of competition among whales	Continue further analyses	Review results of further analyses	Continue further analyses	Review results of further analyses
(6) Update of any exercises on krill distribution and abundance	Conduct NEWREP-A krill survey and an international cooperative krill survey. Conduct simulation analyses to resolve issues on survey design.	Review results of survey and analyses.	Conduct NEWREP-A krill survey. Conduct analysis of data taken by the international survey.	Review results of survey and analyses.
(7) Cetaceans & Ecosystem Functioning: a gap analysis workshop or pre-meeting	Review relevant scientific studies before the workshop in addition to preparation of workshop (Annex Y).	Review outcomes of workshop and develop clear work plans with priorities.	Continue analyses	Review results of analyses.

17. SMALL CETACEANS

The report of the Committee on Small Cetaceans is given as Annex M.

17.1 Overview of taxonomy, distribution and abundance for *Inia* and *Sotalia*

In this assessment, two species and two sub species of dolphins were considered, some of which have several common names. In addition, a new species has been proposed but has not yet been recognised (Table 22).

Table 22

Summary of names used in the description of *Inia* and *Sotalia*

Scientific name	Common Name
<i>Inia geoffrensis</i>	boto, Amazon River dolphin
<i>I. g. boliviensis</i>	Bolivian bufeo
<i>I. g. geoffrensis</i>	Common boto
<i>I. araguaensis</i>	Araguaian boto
(proposed species)	(from the Tocantins and Araguaia basins)
<i>Sotalia fluviatilis</i>	tucuxi, delphin gris, bufeo negro
<i>Sotalia guianensis</i>	Guiana Dolphin

The river and estuarine dolphins of South America are subject to various threats from habitat degradation, competition with fisheries, bycatch and direct exploitation. A major threat to river dolphins in South America is population fragmentation, altered habitat productivity and regulation of natural river flow as a result of dam construction. The cumulative impacts from this type of infrastructure at the macrobasin scale exacerbate the threats to river dolphins and their habitat in the Amazon and Orinoco basins. It was estimated that more than 50% of the range of Araguaian *Inia* is affected by damming.

Two genera were discussed in depth, *Inia* and *Sotalia*, from the vast and convoluted systems within the Amazon, Orinoco, Tocantins and Araguaia River basins. In the case of *Sotalia*, two species are recognised: *Sotalia guianensis* (marine) and *Sotalia fluviatilis*, (freshwater) in the Amazon basin. *S. guianensis* in the Orinoco basin likely represents an independent population unit as it is isolated from other coastal populations. Two intersessional workshops have been proposed that aim to elucidate the status of *S. guianensis* and it is that divisions within this genus will be clearer on the completion of this work in 2020. The taxonomy of *Inia* has a complex history and at this time, one species and two sub species are

recognised: *Inia geoffrensis*, the Amazon river dolphin, *I. g. boliviensis*, the Bolivian bufeo, and *I. g. geoffrensis*, the common boto. There is a third putative subspecies, *I. g. humboldtiana*, in the Orinoco basin of Venezuela and Colombia. The information currently available suggests that *I. g. boliviensis* should be elevated to species level and that *I. g. humboldtiana* should be recognised. Another new species, *I. araguaensis*, has been proposed for the dolphins that inhabit the Tocantins and Araguaia basins of central Brazil as this area is geologically and hydrologically separate from the Amazon basin.

Attention: SC, G

Given the incomplete resolution of Inia taxonomy, the importance of clarifying and solidifying recognition (or elevation to species) of the Inia subspecies found in different river basins, the possibility that in such complex habitats localised specialisation is likely, and the need to focus attention on the conservation of demographically independent populations, the Committee encourages support for efforts to resolve Inia spp. taxonomy in light of the significant and diverse threats affecting the populations inhabiting the Amazon-Orinoco-Tocantins/Araguaia drainages.

17.1.1 Inia

For *Inia*, there are estimates of abundance for some rivers, however, there is little information on population trends. It was suggested that new technologies, such as Unmanned Aerial Vehicles (UAV), may help to better refine population survey techniques. From telemetry studies and two long term studies some information on population parameters is available. In particular, the Committee commends an ongoing telemetry study as it begins to address some of the most important scientific questions concerning *Inia* ecology, habitat use, behaviour and, particularly movements.

In addition, and central to IUCN assessments, a generation time for *Inia* has been calculated as 24.8 years from a long-term mark and recapture study. Given the estimated rate of population decline, this equates to a loss of 82% per generation and in excess of 99% over three generations. Such values are well above the threshold for a Red List assessment of a species as Critically Endangered. Concern was also expressed at the high rate of mortality of <1 year calves in one study site, where examined carcasses show evidence of both deliberate killing and net entanglement.

The information presented on population parameters were based on direct observations in a very small geographic area of the Amazon and therefore, a very small proportion of the total range of *I. geoffrensis*. As such, extrapolation to the whole region would be unwarranted, nonetheless these results and their implications for population decline are alarming.

Attention: CG-A, G

The Committee draws attention to declines in Inia numbers documented in two study areas and the lack of abundance surveys in most parts of its range. The Committee therefore encourages the collection of data, calculation of abundance estimates and undertaking of analyses to estimate population trends for Inia throughout its range, for use in assessments of the status of the species, subspecies, and regionally isolated populations.

17.1.2 Sotalia

Sotalia fluviatilis, known as tucuxi (Brazil) delphín gris (Colombia) or bufeo negro (Peru and Ecuador) is restricted to the Amazon basin in Ecuador, Peru, Colombia and Brazil and has a more limited distribution than *Inia*. *Sotalia guianensis*, the Guiana dolphin, occurs mainly in nearshore and estuarine waters of the Atlantic from southern Brazil, along the coast of Central America, to Nicaragua and possibly Honduras. Small populations in Lake Maracaibo and in the lower reaches of the Orinoco River, Venezuela, were highlighted as being heavily impacted.

In the Mamirauá Reserve, Brazil, the population of *S. fluviatilis*, has shown a precipitous decline in abundance over a 22-year study period. Using the average observed decline of 7.4% per year, and, from literature, a generation time estimate of 15.6 years, the Mamirauá population trend equates to a 97% reduction over 3 generations, qualifying this population as Critically Endangered under IUCN Red List criteria. Unlike *Inia*, which is heavily exploited for use as bait in the piractananga fishery, the primary driver of the decline in *Sotalia* in this region is gillnet entanglement.

17.1.3 Threats shared by dolphins in the Amazon and Orinoco River systems and Lake Maracaibo

Throughout the range of both genera, illegal hunting was highlighted as a transnational problem, making it difficult to create and enforce effective conservation measures. This issue is severe for *Inia* throughout its range and, for *Sotalia* in the Orinoco River and particularly in Lake Maracaibo, Venezuela.

Attention: C-A, G, CC

The Committee draws attention to the serious situation reported for Lake Maracaibo in Venezuela, where both directed takes and oil pollution are thought to be having serious impacts on populations of S. guianensis. The Committee therefore recommends that NGOs and researchers focus on documenting the threats to Sotalia and work with local communities to mitigate the impacts on these dolphin populations.

In addition to direct exploitation, there are numerous other threats to both species throughout their habitat in South America: the recent increase in deforestation affects their prey species, as there is no deposition of seeds and fruits into the rivers to support productivity and sustain fish stocks; hydropower developments and channel dredging affects flows regimes, the connectivity of rivers, the migrations of fish and can fragment dolphin populations, as has already occurred in the Tocantins River basin; heavy metals, such as mercury, have been measured in high concentrations in dolphin tissues; negative interactions with fisheries, in addition to directed takes for use as bait and food, also include bycatch, deliberate poisoning and 'control' killing.

Attention: CG-A, G, CC

The Committee **draws attention to** the multiple threats associated with development, habitat degradation and fragmentation, and pollutants facing river dolphins in the Amazon, Orinoco and Tocantins basins. It therefore:

- (1) **advises** the Brazilian, Bolivian and Peruvian Governments, as they carry out their reviews of proposed construction of new dams for hydroelectric energy production, to explicitly consider the potential impacts on river dolphins (e.g. isolation, loss of genetic diversity, habitat degradation);
- (2) **discourages** water pumping in the Araguaia-Tocantins river basin for agricultural use as such a practice causes dramatic decreases in water levels in rivers, thereby increasing the probability that dolphin populations will be extirpated;
- (3) **encourages** range states of the Amazon basin and its tributaries to support and carry out baseline research into the impacts of the development of commercial waterways in the Amazon (hydrovias) and their potential impacts on dolphin populations and habitats, including but not limited to the ecological impacts of dredging, noise pollution, channelisation by embankments, altered sediment suspension and transfer, and changes in turbidity, light, oxygen availability and primary productivity, and (b) work to minimize or at least mitigate these impacts;
- (4) **encourages** (a) a review of the status of dolphins trapped within dammed stretches of the Tocantins and Madeira rivers and (b) evaluation of possible relocation (translocation) of animals when environmental conditions create a high likelihood that they cannot continue to survive in this severely compromised habitat; and
- (5) **encourages** the review of the effects and the scale of contaminant and heavy metal (e.g. mercury) pollution on river dolphins in key areas of the Amazon (Japura/Caquetá, Içá/Putumayo, in Brazil and Colombia) and Orinoco (Venezuela) basins.

17.2 *Tursiops* populations occurring in estuarine areas in southern Brazil

Discussion focused on two populations of Lahille's bottlenose dolphins (*Tursiops truncatus gephyreus*) in Patos Lagoon Estuary (PLE) and Laguna (LGN), Brazil. Both have been the focus of long-term ecological studies that provide a good source of information on the conservation status of the subspecies. Mark-recapture studies indicate year-round residency and permanent emigration is unlikely. Population sizes are small (85 dolphins in PLE and 60 in LGN) with low to moderate genetic diversity (mtDNA and nuclear DNA variation) in both areas. Pollutant analyses indicated moderate levels of persistent organic pollutants (POPs). Of additional concern is a chronic dermal infection which is apparent in 14% of the LGN population, which may be related to pollution but this is not clear. The greatest threat to both populations is bycatch in artisanal gillnet fisheries. Whilst there is no clear evidence of a negative trend in abundance, there is a high probability of population decline in the near future, given the small population, the high degree of residency and the continuing mortality as a consequence of IUU (illegal, unreported, unregulated) fishing and other human activities in these areas.

In Santa Catarina, Paraná, and São Paulo provinces, Brazil, north of LGN and PLE, a total of 119 bottlenose dolphins (sub species unknown) and 442 Guiana dolphins were recorded stranded over 2 years. There was strong evidence that entanglement was indicated as the cause of death for bottlenose dolphins. The Committee was informed that the Brazilian Government is looking into this issue and is seeking ways to improve legislative effectiveness in protecting dolphins and other threatened species in these locations.

Attention: SC, CG-R

The Committee **draws the attention of** the range states (Argentina, Brazil, Uruguay) to its conservation concerns over the entire sub-species of Lahille's bottlenose dolphins (*T. t. gephyreus*) given their relatively small population sizes and constricted ranges, the high levels of bycatch and the high incidence of individuals with chronic dermatitis. The Committee therefore recommends:

- (1) immediate action to reduce the level of bycatch in the southern Brazil populations;
- (2) continued monitoring and photo-identification work on the populations throughout the subspecies' range to refine survival estimates and to assess trends in abundance and the prevalence and etiology of the chronic skin infections; and
- (3) that the conservation status of the subspecies be prioritised for assessment in the future.

17.4 Franciscana CMP

In 2016, the IWC created a Conservation Management Plan (CMP) for the franciscana – see Item 10.1.4. In 2019, a review will be presented to the Committee. The review will be jointly conducted by the SM and CMP sub-committees and will include input from other relevant sub-committees.

17.5 Report of the 2018 *Tursiops* Taxonomy Workshop

In 2014 (IWC, 2015b) it was agreed that the Committee would undertake a review of taxonomy and population structure in the genus *Tursiops*, over several meetings. Understanding whether there is any consistency in the derivation of various local forms across the range, and to which taxonomic or population unit(s) they belong, has been challenging, and the taxonomy of the various forms is still unresolved. An additional aim of this exercise was to develop a widely applicable taxonomy assessment framework for small cetaceans. The review process concluded with an intersessional workshop, held in La Jolla in January 2018.

The 3-year review and workshop brought together researchers and experts from around the world to discuss this topic, motivated focussed research, and promoted new collaborations. Results from studies presented at previous meetings (2015-2017) and at the workshop itself were compiled and formed the basis for evaluation of taxonomic and population distinction issues in each geographic region.

Attention: SC, G

*Having reviewed the extensive information included in the 2015-2017 review and 2018 workshop for evaluation of Tursiops species, subspecies and population distinctions, the Committee **draws attention to** the need for Tursiops research in the areas identified as data deficient (the African coast of the eastern Atlantic, southern and eastern Mediterranean Sea, eastern South Pacific, Pacific coast north of California and off the Mexican mainland, Central American coast of the eastern North Pacific, Central American Atlantic and Caribbean Sea and Atlantic coast of northern and north-eastern Brazil, eastern Australia and in the western Pacific the islands of Micronesia, Melanesia, Polynesia, the Philippines and Vietnam). The Committee therefore **encourages**:*

- (1) collection of additional data, including morphometrics, and high-resolution genetic analyses (e.g. ddRAD which may also be useful in other areas where there are similar questions requiring high-resolution analysis), to better characterise divergence between coastal and offshore forms in the western South Atlantic Ocean, to help confirm whether subspecies or species classification is more appropriate for T. t. gephyreus;*
- (2) further investigation of T. aduncus lineages in the Indian Ocean and western South Pacific to assess potential subspecies recognition, extending the geographic coverage to include eastern Africa, the region between Pakistan and Indonesia, and the region between Australia and China;*
- (3) continued study of the genetics and morphology of southern Australia bottlenose dolphins with the "T. australis" mtDNA lineage, in the context of both T. truncatus and T. aduncus;*
- (4) examination of the level of male-mediated gene flow between the coastal and offshore forms in the western North Atlantic to determine whether the coastal form should be elevated to species or subspecies status;*
- (5) more comprehensive morphometric analyses comparing T. truncatus in the Mediterranean, Black Sea, and eastern Atlantic to integrate with genetic data and evaluate whether any regions in addition to the Black Sea (T. t. ponticus) harbour a taxonomic unit above the level of population;*
- (6) comprehensive morphometric analyses of coastal and offshore T. truncatus in the eastern North Atlantic and comparison to those from the western North Atlantic to better evaluate potential regional differences;*
- (7) morphometric analyses of Gulf of California coastal and offshore dolphins relative to those from California and the eastern tropical Pacific, with a particular focus on the level of divergence of coastal dolphins in the upper Gulf of California to other areas; and*
- (8) the collection of additional genetic and morphological data throughout the eastern South Pacific and further studies to investigate coastal versus offshore forms throughout the region, including coastal and offshore waters from Central America to Mexico, and if possible around the southern tip of South America to Argentina.*

*The Committee also **agrees** to continue compilation of specimen, study, and researcher details, and concentrated effort to improve our understanding of Tursiops in data-deficient areas.*

*Finally, after reviewing the 2018 Tursiops Taxonomy Workshop's evaluation of the support provided for taxonomic (subspecies, species) and population-level distinctions proposed in the publications reviewed, the subcommittee **concludes** that:*

- (1) the current taxonomy provided for Tursiops by the Society for Marine Mammalogy's Committee on Taxonomy is well supported by morphological and molecular genetic data, as well as ecological and distributional data; and*
- (2) discordance in currently available results from morphometric analyses and across different genetic markers of the recently described 'T. australis' from southern Australia calls into question its validity at this time.*

In addition to the information and recommendations on *Tursiops*, the Committee noted that the review provided an opportunity to formulate some generic conclusions on taxonomic issues related to small cetaceans.

Attention: SC, G

After reviewing the development and use of a strategy for objective evaluation of species, subspecies, and population-level distinctions by the 2018 Tursiops Taxonomy Workshop, the Committee:

- (1) **agrees** with the strategy implemented at the workshop for the evaluation of species, subspecies and population level distinctions;
- (2) **encourages** use of the criteria and guidelines in Reeves et al. (2004) for the assessment of species-level taxonomy, in Taylor et al. (2017) for subspecies-level taxonomy, and in Martien et al. (2015) for Demographically Independent Populations; and
- (3) **concludes** that future taxonomic questions should be examined within an appropriately wide and inclusive geographic context and that multiple lines of evidence are necessary when positing taxonomic changes.

The Committee applauded Natoli, Rosel and Cipriano for their considerable work and organisational skills during this effort.

17.6 Poorly documented takes for food, bait or cash and changing pattern of use

17.6.1 Intersessional Workshop on the use of Small Cetaceans for Food and Non-Food Purposes in South America

The poorly documented take of small cetaceans for use as wildmeat has been assigned as a priority topic. An ICG (and see Annex Y) has been tasked with the development of a toolbox of techniques that could guide and co-ordinate research into this topic, and as such a series of workshops were proposed to fulfil this task. The second of these workshops focused on South America and incorporated a detailed review of the use of Amazon river dolphins as bait in the piracatinga fishery, which, in turn, fed into the priority topic of the 2018 meeting.

Information was summarised for all countries, except Guyana and Suriname, and it was recognised that products from small cetaceans have been used throughout the region for both food and non-food purposes. This type of use is referred to as 'aquatic wildmeat'. The usefulness of various tools and techniques was discussed, including data gathering techniques and forensic investigation. A database, comprising more than 3000 references, was used to map existing knowledge and understand data gaps. A framework was also established that had the purpose of standardised future data collection. The workshop participants populated a database from which regional patterns were mapped. Areas that were highlighted as a cause of conservation concern were; Bolivia, Brazil, Colombia, Costa Rica, Ecuador, Peru and Venezuela.

The take of Amazon river dolphins as bait in the piracatinga fishery was also reviewed. All range countries of *Inia* and *Sotalia* have laws in place to protect dolphins and prohibit intentional killing. Fishing for piracatinga is banned in Brazil and its trade is prohibited in Colombia, due to its impact on river dolphins and other wildlife. The practice of using dolphins as bait has recently expanded to Peru, Bolivia and Venezuela, following the imposition of restrictions in Brazil, however, no other range country has developed specific legislative or regulatory action, beyond the general protection of river dolphins, in response to the emergence of this practice.

The workshop concluded that some species and population required urgent attention both due to the extent of their use as wildmeat and from other threats.

17.6.1.1 SCIENTIFIC CONCLUSIONS AND RECOMMENDATIONS

Attention: SC, G, CG-A

*The Committee **endorses** the scientific conclusions and recommendations from the recent intersessional workshop on the use of Small Cetaceans for Food and Non-Food Purposes in South America aimed at improving regional knowledge and conservation research. In particular, the Committee:*

- (1) **agrees** that potential divisions within the genus *Inia* should be evaluated and genetic conservation units established;
- (2) **agrees** that an evaluation of historical data on river dolphins should be undertaken to better understand other threats (e.g., from bycatch), to provide further insights into current trends;
- (3) **encourages** the use of new technologies, such as drones and satellite telemetry, to establish trends, habitat use and dispersion patterns of *Inia* within Amazon River Basin and
- (4) **encourages** new efforts to improve regional research capacity.

*The Committee **draws attention** to the evidence showing that several small cetacean species and/or populations are being negatively impacted by their use as wildmeat in South America, and therefore **recommends** that abundance and distribution surveys, in tandem with investigation into the magnitude of aquatic wildmeat use, be conducted on these species. Appropriate survey designs should be implemented that consider the statistical power required to detect trends and the resultant data should then be used to estimate the impact of deliberate take for wildmeat on the following populations:*

- (1) Boto in Purus and Japurá rivers, Brazil, and Içá/Putumayo river in both Brazil and Colombia, using previously established standardised methods (studies should also be expanded into other areas where take for bait may be a cause for concern);
- (2) Chilean dolphin in Chile;
- (3) Burmeister's porpoises in both Chile and Peru, noting that current evidence suggests that the Peruvian population is distinct;
- (4) Dusky dolphins in Peru, noting that evidence shows that landings of this species has decreased and populations may have been heavily impacted;
- (5) Guiana dolphins and other small cetaceans in Amapá, Pará, Maranhão, Piauí, Ceará, Espírito Santo, São Paulo and Paraná, in Brazil, where there is a documented use of bycatch for wildmeat purposes;
- (6) Bottlenose dolphins and pantropical spotted dolphins in Bahia Solano, Colombia, noting that deliberate takes for a long line fishery is ongoing;
- (7) Tucuxi throughout its range, in Brazil, Colombia, Ecuador, as it shares most of the same threats as *Inia geoffrensis*, and may also be used as bait in the piracatinga fishery; and
- (8) Guiana dolphin (*Sotalia guianensis*) in Lake Maracaibo in Venezuela, noting that deliberate take for food is ongoing.

The Committee also **draws attention to** the Boto dolphins that have been isolated within the dam system of the Tocantins and Maderia Rivers in Brazil. Given the confined condition of the dolphins' habitat, the Committee **agrees** that the status of these dolphins be evaluated, to include abundance, genetic, habitat, prey availability assessments, with a view to developing a translocation protocol, including under what circumstances such a protocol should be enacted.

Finally, given the concerns over the extensive habitat modification that will result from the Mega Project 'Arco Minero del Orinoco', a large scale mining operation proposed along the river and watershed of Venezuela, the Committee **recommends** that population sizes and trends of both *Inia geoffrensis* and *Sotalia guianensis*, in the Orinoco River basin, be monitored before and during this project.

17.6.1.2 CONSERVATION AND MANAGEMENT ISSUES

Attention: CG-R, S, CC

The Committee **draws attention to** the management recommendations within the Report of the Workshop on the Use of Small Cetaceans for Food and Non-Food Purposes in South America, in particular, the need to have a regionally co-ordinated fisheries management plan for the Amazon River basin and a regional strategy for the conservation of river dolphins. Given continued concern over the use of dolphins as bait in the piracatinga fishery, the Committee:

- (1) **commends** the Government of Brazil on its swift action in declaring a moratorium on the piracatinga fishery and respectfully requests that it maintains the moratorium to allow sufficient time to evaluate the effectiveness of protective measures and ensure the necessary protection of river dolphins;
- (2) **reiterates** previous recommendation of the IWC Scientific Committee that range states (Bolivia, Brazil, Colombia, Peru and Venezuela) engage in a co-ordinated effort to strengthen legislative, enforcement, management and scientific efforts to ensure protection of the Amazon River dolphins;
- (3) **encourages** range state authorities to work together and exchange information on the movement of piracatinga products across international borders; and
- (4) **requests** that progress reports be submitted to the Scientific and Conservation Committees.
- (5) **recommends** that the Commission asks the IWC Secretariat to send a letter to the Buenos Aires Group highlighting the issue of dolphins being used as bait in the piracatinga fishery and requesting joint efforts to enhance enforcement on wildlife and trade laws.

17.6.2 Wildmeat Database

In 2016 (IWC, 2017) an intersessional group was established to work with the IWC Global Database Repositories Convenor, to develop an overarching aim for any future cetacean wildmeat database and identify the specific questions that such a database might address. The results of this work were presented, including a research agenda the formulation of key questions that could be addressed through the development and analysis of an aquatic wildmeat database. The Aquatic Wildmeat Database, developed independently of the IWC, was presented again and the Committee was updated on its improvements made following suggestions made last year. The future value of this data repository was highlighted and this and related issues will be considered intersessionally (see Annex Y).

The work of the Steering Group (see Annex Y) will continue and a third workshop, focusing on Africa, will be conducted intersessionally. The framework for an IWC Wildmeat database established at the workshop in South America will be further refined and will be used at the forthcoming workshop.

17.7 Small cetacean task team

The Scientific Committee continues to support the Task Team Initiative and the latest Task Team, for the South Asia River Dolphin, is in the process of being established with Dipani Sutaria and Nachiket Kelkar nominated as co-conveners. The task team currently comprises 14 members with representation from Bangladesh, India, Nepal and Cambodia and includes university associated researchers and NGOs (WWF and the Wildlife Institute of India).

*Under its Task Team Initiative (e.g. IWC, 2016), the Committee **strongly supports** the work of a Task Team for the South Asia River Dolphin and **agrees** that its first meeting which will occur before the 2019 meeting, if sufficient funding is available.*

17.8 Progress on previous recommendations

17.8.1 Vaquita

The Report of the Tenth Meeting of the International Recovery Team for Vaquita (CIRVA-10) was summarised and the results of the acoustic monitoring program for vaquitas were presented (SC/67b/SM01). This shows a continued decline in vaquita detections with no change in the trend since the last report in 2016. A brief review of the VaquitaCPR project was presented. This initiative, conducted in October and November 2017, aimed to capture vaquitas and bring them into human care. Ninety experts from nine countries were involved, including researchers experienced in the capture and handling of harbour porpoises, animal care professional, and veterinarians. Two vaquitas were successfully captured (an immature female [V01F] and an adult female [V02F]). In both cases, medical and behavioural evaluations were conducted to determine the suitability of the animals for transport to the floating pen or shore-based facility. Through the whole process the animals' health was continuously monitored by a team of experienced marine mammal veterinarians. The first vaquita caught (V01F) was in good condition initially, but did not acclimate to either the vaquita care centre pool or to the sea-pen facility, and the vaquita was released. V02F was also considered to be in good condition for transport to the sea-pen, however, after initially showing signs of adapting to the facility, the animal stopped swimming and an emergency release was initiated. The release was unsuccessful and the vaquita was quickly recaptured for administration of emergency care. Following three hours of emergency response, the animal went into cardiac arrest and did not respond to resuscitation attempts. Analyses of tissues and material obtained from VH02 is ongoing and a full report on VaquitaCPR will be reported at SC68A.

The survival of the vaquita depends on gillnet-free habitat and efforts to remove gillnets, both derelict and active, have increased dramatically in the last three years, particularly, during the ongoing 2017-18 totoaba season. The net removal programme demonstrates that illegal totoaba gillnets are still routinely set in great numbers in vaquita habitat. Despite enhanced enforcement efforts, there is a continued failure to prevent illegal fishing. CIRVA have stated that immediate action is needed to improve the situation through implementation of a series of recommendations. In particular, CIRVA recommended that the Government of Mexico establish an enhanced enforcement area, extending the boundaries of the existing vaquita refuge.

Attention: SC, CC, CG-R

The Committee has stressed for many years that the vaquita population is at a critically low level, and the most recent evidence demonstrates that the cause of the decline – use of illegal large-mesh gillnets – continues, making extinction in the wild increasingly likely; *the long-term decline in the vaquita reported previously has continued in 2017*. The Committee yet again **re-emphasises the serious concerns** it has raised on the status of the vaquita, and in particular its recommendations of the past two Committee meetings. Whilst again **commending** the Government of Mexico for its attention and response to the CIRVA findings and recommendations, the Committee:

*(1) respectfully **requests** that reports continue to be provided annually to the IWC Scientific Committee on actions and progress towards saving the vaquita;*

*(2) **strongly endorses** the recommendations of CIRVA10 that:*

(a) the CIRVA10 acoustic monitoring programme, critical for evaluating the effectiveness of conservation actions, be continued as in previous years to provide an annual empirical estimate of population trend;

(b) all Mexican enforcement agencies increase their efforts on land and in water immediately and continue this enhanced enforcement programme for the duration of the period of illegal totoaba fishing (at least until June 2018) to eliminate all setting of gillnets in the range of the vaquita;

(c) emergency regulations be promulgated immediately to strengthen the current gillnet ban and enhance enforcement and prosecution by:

- (i) eliminating all fishing permits for transient fishermen and limiting fishing access to only those fishermen who can demonstrate residency in the fishing villages;*
- (ii) confiscating any vessel that does not have the appropriate vessel identification, permits, and the required vessel monitoring system;*
- (iii) requiring vessel inspection for each fishing trip at the point of departure and landing;*
- (iv) prohibiting the sale or possession of gillnets on land and at sea within the area of the current gillnet ban and on adjacent lands within a specified distance of the coastline.*
- (v) requiring that all gillnets be surrendered or confiscated and destroyed.*

(vi) eliminating the exemptions for all gillnet fisheries, including the curvina and sierra fisheries.
 (d) efforts to remove gillnets from vaquita habitat be continued and enhanced and the numbers and locations of new nets recovered be published monthly;
 (e) the number of inspections, interdictions, arrests, sentences, and other enforcement actions be published monthly, together with information on observed levels of illegal activities obtained from intelligence operations, for example from drones;
 (f) successful prosecution and subsequent penalties be sufficient to deter illegal fishing; and
 (g) development of gillnet-free fisheries be enhanced and linkages to incentivise the conversion of the fleet to gillnet-free operations be strengthened.

17.8.2 Yangtze finless porpoise

A rangewide survey of Yangtze finless porpoises (*Neophocaena asiaeorientalis asiaeorientalis*) was conducted in 2017, giving a preliminary abundance of around 1,000 individuals. This indicates that the rapid decline observed between 2006 and 2012 has now slowed, and that numbers may even be increasing in some areas. Nevertheless, the Critically Endangered status of this species remains unchanged. The survey results were encouraging and regarded as a possible indication that *in situ* conservation of Yangtze finless porpoises is feasible, given the marked increase of the number of individuals in Dongting and Poyang Lakes. For the population to make a sustained recovery in both numbers and range, current measures directed towards improving the habitat in the Yangtze River as well as the Dongting and Poyang Lakes must be continued and expanded. The Government of China was commended for the efforts undertaken to improve the YFP habitat. Nevertheless, concern remain over threats such as vessel strikes, bycatch, underwater noise and bridge construction. In addition, the planned construction of a dam across the channel connecting Poyang Lake to the river is an additional concern.

Attention: SC, CG-R

Given the extensive and pervasive nature of the threats facing the Yangtze finless porpoise population, the Committee:

- (1) **commends** the efforts of the Government of China to improve its habitat; and
- (2) **reiterates** that the primary conservation actions should focus on (a) restoring and maintaining suitable habitat throughout the Yangtze River and associated lakes, including the maintenance of a network of *in situ* reserves and (b) ensuring that genetic diversity is preserved and that harmful human activities are limited.

17.8.3 Maui Dolphin

The Government of New Zealand reported that its review of management measures is scheduled for later this year. An update was provided on observer coverage of the set net fishery in Taranaki and the trawl fisheries adjacent to existing closure areas (95.5%, and 88.3%, respectively). Outside of this target coverage area, an additional 114 trawl fishing days were observed. No captures of Māui dolphins were reported by observers or fishermen in commercial fisheries in the 12-month reporting period to 31 March 2018. A species-specific, spatially explicit, multi-threat risk assessment is being developed for Māui and Hector's dolphins, the results of which will inform an updated Threat Management Plan later in 2018.

Attention: SC, CG-R, CC

The Committee notes that no new management action regarding the Māui dolphin has been enacted since 2013. It therefore concludes, as it has repeatedly in the past, that existing management measures in relation to bycatch mitigation fall short of what has been recommended previously and expresses continued grave concern over the status of this small, severely depleted subspecies. The human-caused death of even one individual would increase the extinction risk. In addition, the Committee:

- (1) **re-emphasises** that the critically endangered status of this subspecies and the inherent and irresolvable uncertainty surrounding information on most small populations point to the need for precautionary management;
- (2) **reiterates** its previous recommendation that highest priority should be assigned to immediate management actions to eliminate bycatch of Māui dolphins including closures of any fisheries within the range of Māui dolphins that are known to pose a risk of bycatch to dolphins (i.e. set net and trawl fisheries);
- (3) **notes** that the confirmed current range extends from Maunganui Bluff in the north to Whanganui in the south, offshore to 20 n. miles, and it includes harbours - within this defined area, fishing methods other than set nets and trawling should be used;
- (4) **welcomes** the update on Maui dolphins provided and looks forward to receiving the species-specific, spatially explicit, multi-threat risk assessment in 2019.
- (5) **respectfully encourages** the New Zealand Government to commit to specific population increase targets and timelines for Māui dolphin conservation,
- (6) **respectfully requests** that reports be provided on progress towards the conservation and recovery goals as updates become available.

17.8.4 Cruise report from North Western Africa

For the third year, survey results were reported from cruises conducted in north western Africa waters. Fourteen schools comprising some five species and totalling 433 individuals were sighted, including bottlenose dolphins, both pantropical and Atlantic spotted dolphins and, spinner dolphins. This area is poorly surveyed and the continuation of this work was encouraged. The Committee **suggests** that a more substantive analysis of the data from all surveys be conducted and reported back next year, particularly as SC68A priority topic will be on African small cetacean species.

17.8.5 Monodontids Workshop Report

NAMMCO hosted a workshop and produced a Global Review of Monodontids. Researchers and subsistence hunters from across the Arctic and subarctic participated. Several IWC scientists also participated, including Litovka, Reeves, and Suydam. The report⁹, summarises what is known about the status of 12 stocks of narwhals and 22 stocks of white whales. There may be more stocks than this as information on stock structure is incomplete for some areas. The summary information and identification of threats and concerns within the report will be helpful in prioritising future research. Some stocks are doing well, but conservation actions are desperately needed for some others. The IUCN Red List status and documentation for both species was updated to Least Concern in December 2017 and that the information summarised in the NAMMCO review was very useful for those assessments.

Attention: C-A

*The Committee **welcomes** the report of the NAMMCO workshop reviewing the monodontids⁹. It **draws attention to** the recommendations contained in the report and **encourages** their implementation, particularly those pertaining to the stocks of greatest concern.*

17.9 Takes of small cetaceans

17.9.1 New information on takes

The Committee received the summary of takes of small cetaceans in 2016–17 extracted from the online National Progress Reports and prepared by the IWC Secretariat, in addition to information obtained online.

No direct takes of small cetaceans were reported in the 2017 National Progress Reports. The Committee **notes** that it would be helpful if the Secretariat encouraged all member countries and IGOs (e.g. NAMMCO) to submit information on direct takes as a routine procedure.

The content of the Japan Progress Report on Small Cetaceans, a public document available from the website of the Fishery Agency of the Government of Japan¹⁰, was summarised. It was noted that catch statistics in the Japan Progress Report on small cetacean cover catches in the calendar year, that is, from 1 January to 31 December, following the guidelines for IWC National Progress Report, while the catch quota of small cetacean fisheries are set seasonally. Thus, in some cases, the calendar yearly catch may exceed the seasonal (yearly) catch in appearance, but in such cases, the actual seasonal catch is aligned with the allocated catch quota. The Committee noted that the catch of 1,057 Dall's porpoises in the hand harpoon hunt was significantly lower than previously recorded reported and below the quota. It was stated that this is a result of the destruction of the community that conducts this hunt, rather than a change in the cetacean population, following the earthquake and tsunami of 2011.

17.9.2. Live captures

The Pacific Scientific Research Institute of Fisheries and Oceanography (TINRO) will consider a quota of 13 killer whales for 2018 and a public hearing was held on 3 May 2018 to make comments on this plan. This proposed new quota considers killer whales in the Sea of Okhotsk as one population, which is estimated to have an abundance of over 3,000 individuals. This number is considered minimal as only 50% of the sea was surveyed. In addition, the information available to the Russian Government on colour and fin patterns, feeding behaviour and distribution do not allow clear identification of different ecotypes, and that all genetic samples analysed to date belong to a single population. It was noted that most published information on Okhotsk Sea killer whale abundance and stock structure is in Russian-language literature, or as part of internal documentation.

Attention: C-A, CG-A

With respect to live captures, and specifically the capture of killer whales from the Sea of Okhotsk, the Committee:

- (1) **reiterates** its long-standing recommendation that no small cetacean removals (live capture or directed harvest) should be authorised until a full assessment has been made of their sustainability;*
- (2) **notes** that this is especially important for killer whales because populations are generally small and have strong social bonds and removals have unknown effects on their demographic structure; and*
- (3) **reiterates** its concern that removals of killer whales are occurring from the Okhotsk Sea population.*

⁹https://nammco.no/wp-content/uploads/2018/05/report-global-review-of-monodontids-nammco-2018_after-erratum-060518_with-appendices_2.pdf

¹⁰ http://www.jfa.maff.go.jp/j/whale/w_document/attach/pdf/index-9.pdf

In light of the verbal report received at this meeting that Russian authorities intend to proceed to consider limits of allowable live-capture removals of killer whales in the Sea of Okhotsk on the basis that there is no stock structure and there are no ecotype differences between the populations in this region, the Committee:

- (1) **encourages** more extensive effort to examine these issues; and
- (2) **requests** that relevant analyses be provided for the Scientific Committee's consideration at its next meeting.

17.10 Status of the voluntary fund for small cetacean conservation research

In 2017, donations for the Voluntary Fund for Small Cetacean Conservation Research totalling £13,122 were received from the Government of Italy. At the end of the financial year 2017, this brought the total of the fund to £81,077.

The Committee **expresses its sincere gratitude** for Italy's contributions and notes that these funds support critical conservation research projects of direct relevance to the work of the Committee.

Five projects were offered funding in 2016 and were implemented in 2017. One of the projects has since been withdrawn and one project, the Indus river dolphin abundance survey, was completed and reported on in 2017. The remaining three projects, on the 'Chilean Dolphin' in Chile, the 'Use of small cetaceans as wildmeat in China' and the 'Development of a business model for sustainable fisheries in the Upper Gulf of California, Mexico', are all near completion and will be reported on fully next year. Updates are available on the IWC website.

17.11 Work plan and budget requests

17.11.1 Priority topics for 2019 to 2024

The sub-committee on Small Cetaceans discussed ongoing priorities and will continue the development of these intersessionally; however, given the location of the meeting it is likely that the focus will be on African species or areas during 2019-20. Other potential priorities identified in discussions were *Inia* (e.g. taxonomy), *Sotalia guianensis*, *Phocoena phocoena*, *Delphinus delphis*, southern hemisphere beaked whales, *Steno bredanensis*, Northwest Pacific *Orcinus orca* and 'the Caribbean'.

17.11.2 Work plan for 2019 – 2020

The workplan on issues related to small cetaceans is given in Table 23.

Table 23
Work plan on small cetaceans

Topic	Intersessional 2018/19	2019 Annual Meeting (SC/68a)	Intersessional 2019/20	2020 Annual meeting
Franciscana CMP	ICG (Annex Y) to co-ordinate outcomes of CMP across sub-committees	Report	ICG (Annex Y) to synthesis actions from 2019 SC report and develop a work plan	Report
Wildmeat	ICG (Annex Y) to plan and conduct African Workshop.	Report	ICG (Annex Y) group to summarise workshop series and develop future work plan.	Report
Small Cetacean Task Team	Intersessional Workshop on South Asian river dolphins.	Report	Act on recommendations from 2018/19 River dolphin workshop.	Report
Sotalia	SG (Annex Y) to plan and conduct workshop #1 (at SOLOMAC)	Report	SG (Annex Y) to plan and conduct workshop #2	Report

18. WHALE WATCHING¹¹

The report of the sub-committee on whale watching is given as Annex N.

18.1 Assess the impacts of whale watching and swim-with-whale operations on cetaceans

18.1.1 Review progress of Modelling and Assessment of Whale Watching Impacts (MAWI)

Modelling and Assessment of Whale Watching Impacts (MAWI) has been on the Committee's agenda for several years. In April 2018, an intersessional workshop was held to identify the key research questions for understanding the potential impacts of whale watching on cetaceans (SC/67b/Rep03). A number of issues were highlighted, including: (a) the need to better understand the impact of recreational whale watching vessels as compared to commercial vessels; (b) the importance of looking at the potential impact of whale watching at short-term (e.g., behaviour change), mid-term (e.g., shift in habitat use) and long-term (e.g., population dynamics) time scales; (c) the use of existing and new data to explore the mid- and long-term impacts, as opposed to replicating short-term studies; and (d) the importance of building scientific capacity in the locations where the research would take place. More information can be found in Annex N, item 2.1.

¹¹ In response to a request from the Chair of the Whale Watching Working Group of the Conservation Committee, we have changed our past practice of treating whalewatching as a single word to the use of two words.

Attention: SC, C-R

The Modelling and Assessment of Whale Watching Impacts (MAWI) initiative held a workshop in Italy in April 2018, in conjunction with the 32nd European Cetacean Society conference.

The Committee **endorses** the following recommendations from this workshop:

- (1) the incorporation of both social and natural sciences to better understand whale watching impacts;
- (2) the development of a Strategic Framework, supported by a Decision Tree, to aid in the prioritisation of policy and research choices;
- (3) the development of toolkits and resources that can be accessed globally; and
- (4) the standardisation of data collection.

The Committee also **agrees** that a third MAWI workshop be held intersessionally, ideally just before or after the 2nd World Marine Mammal Science Conference in 2019, in Barcelona, with the following objectives:

- (1) to determine in detail which data should be collected to best answer the natural and social science research questions developed in SC/67b/Rep03;
- (2) to identify the best locations for conducting research projects that address these questions; and
- (3) to continue to develop modelling approaches for assessing the long-term impacts of whale watching on cetacean populations (using data on short- and mid-term impacts).

18.1.2 Review specific papers assessing impacts

The Committee received several papers regarding impacts to cetaceans from whale watching activities. Those papers included (1) efforts to assess stress hormones in baleen of southern right whale calves, (2) 'solitary sociable' cetaceans, (3) land-based observations in the Canary Islands to assess and mitigate potential impacts of whale watching vessels on cetaceans, (4) a Whale Welfare Assessment Tool (also presented and discussed in Plenary) and (5) the 15th year of a summary of papers published in the previous year related to a better understanding of impacts, mitigation and compliance to regulations. Additional details on these papers and projects can be found in Annex N, item 2.2.

Attention: SC, CG-A

The term 'solitary sociable dolphin' or cetacean is usually taken to apply to cetaceans that have little or no contact with conspecifics and who regularly closely approach humans, often including touch, social, sexual and play behaviours (Wilke et al., 2005). Given that solitary sociable cetaceans often end up in circumstances where they are harmed and killed and that they may come to present a threat to human swimmers, the Committee:

- (1) **agrees** to continue intersessionally to monitor the phenomenon of solitary sociable cetaceans as part of its work;
- (2) **advises** that, where these animals occur, research be conducted to determine whether the emergence of harmful behaviours either to the animal or to people can be reversed; and
- (3) **advises** local authorities and other concerned parties to keep people away from them in order not to encourage behaviour that may prove harmful to the animal or swimmers.

In addition, the Committee **agrees** that the Whale Welfare Assessment Tool (currently being developed at the Royal Veterinary College, University of London, in the context of the IWC Whale Killing Methods and Welfare Issues Action Plan), for which a hypothetical whale watching case study was trialled (Annex N, item 2.2), be applied to real-world whale watching situations. The southern resident killer whales in Washington, USA and the bottlenose dolphins in Bocas del Toro, Panama were proposed. These two populations are subject to intense whale watching pressure and may be suffering welfare and health impacts related to this pressure. Both locations have data relevant to the assessment tool and therefore seem ideal as pilot projects for its application.

18.1.3 Consider documented emerging areas of concern (e.g., habituation, new areas/species, new technologies, in-water interactions) and how to assess them

The Committee received several papers about emerging areas of concern regarding whale watching, including (1) human-induced behavioural changes, (2) impacts from recreational in-water interactions with cetaceans and (3) purposeful and inadvertent feeding by humans.

The Secretariat for the Convention of Migratory Species (CMS) submitted several documents to SC/67b including a global review of in-water interactions with aquatic mammals. That review had resulted in a CMS resolution that encouraged Parties to facilitate research allowing for an assessment of the long-term effects and biological significance of disturbances from 'swim-with-marine-mammal' programmes. The topic of swimming with cetaceans is also addressed under Item 18.6.

The Committee received reports about several studies to assess the impacts and compliance with regulations of commercial 'swim-with-whale' operations in Australia. The discussion of this issue can be found in Annex N, item 2.3.

Attention: SC, CC, S

The Committee **agrees** that the habituation intersessional correspondence group, now named human-induced behavioural changes of concern, should continue (see Annex N, table 3).

Given the substantial effort the Convention on Migratory Species (CMS) Secretariat has made in preparing several documents for the Committee to consider this year, the Committee:

- (1) **recommends** a continuation and an expansion of this exemplary collaboration between the IWC and CMS Secretariats and their various committees;
- (2) **endorses** the intention of CMS to work with the IWC Scientific Committee on guidelines for in-water interactions with aquatic mammals and **offers** to provide the scientific underpinning for these guidelines;
- (3) **agrees** that the Committee's intersessional correspondence group on swim-with-whales work intersessionally with the CMS Aquatic Mammals Working Group to develop draft guidelines; and
- (4) **offers** to review draft guidelines when they are ready, with a view to **agreeing** a joint product of the IWC and CMS and hosted by both websites as a global resource.

See also Item 18.6 for additional recommendations related to swimming with cetaceans.

18.2. Consider information from platforms of opportunity of potential value to the Scientific Committee

The Committee received examples of several platforms of opportunity where data have been collected concerning habitat use, behaviour, changes in distribution and potential risks from shipping for multiple different species in several different areas. Of particular interest was Peninsula Valdés, Argentina, where approximately 460,000 photographs have been taken from whale watching boats and provided to researchers from the Instituto de Conservación de Ballenas and Ocean Alliance (SC/67b/WW04). See Annex N, item 3.

The Committee offered numerous suggestions as to how to handle the large number of images and **encourages** the researchers to network with other researchers around the world, particularly humpback whale researchers dealing with similarly large numbers of photographs and multiple catalogues, to improve the processing time of the photographs.

18.3 Whale watching in east Africa and the wider Indian Ocean

A proposal for Concerted Action for Arabian Sea humpback whales was passed by CMS with strong support from range states. This was discussed in Annex N, item 4.

Attention: CC, S, CG-A

Noting the Committee's discussions over several years on the status of the Arabian Sea humpback whales (see Item 10.2.1), the Committee:

- (1) **welcomes** the CMS proposal for Concerted Action for Arabian Sea humpback whales;
- (2) **notes** that humpback whales are the target of one emerging whale watching operation in the south of Oman and **highlights** the likelihood that the population could become the target of future whale watching activities;
- (3) **emphasises** the need for regulators and scientists to work with the industry to ensure that whale watching does not add to the many other pressures on this small, isolated, non-migratory and endangered population.

The Committee therefore:

- (1) **recommends** that building capacity to conduct needed research and to ensure consistent training of whale watching operators be a high priority for Omani authorities and other parties working on the recovery of the endangered Arabian Sea humpback whale population;
- (2) **notes** that boat operators for cetacean watching operations appear to turn over at a high rate in this area, and **recommends** that training workshops should be regularly offered and conducted;
- (3) **welcomes** the offer from the Pacific Whale Foundation to help organise and conduct another training workshop, but **recommends** a more comprehensive plan be implemented by the Omani authorities, working with the IWC and other interested parties, to build local capacity for such training; and
- (4) **agrees** to retain a review of whale watching in east Africa and the wider Indian Ocean region in its work plan (see Annex N, table 4) and to conduct an intersessional review of whale watching in these areas, to be presented at SC/68a.

18.4 Review Whale Watching Strategic Plan (2018-2024) and joint work with the Conservation Committee

18.4.1 Review and provide recommendations on the draft Strategic Plan

At SC/67a, the Conservation Committee's SWG on Whale Watching requested the Scientific Committee to review a draft of the next iteration of the IWC's Strategic Plan (2018-2024) on Whale Watching (see SC/67b/WW02). This was accomplished primarily during a SC/67b pre-meeting and then further discussed in Annex N (item 5 and appendix 2).

Attention: CC

The Committee **draws the attention** of the Conservation Committee's Standing Working Group on Whale Watching (SWG) to Annex N, appendix 2, which provides a full set of comments on the draft Strategic Plan (2018-2024) on Whale Watching. The most important comments and recommendations from the appendix are highlighted below:

(1) The addition of an Action 1.5: Develop a communications strategy to actively promote IWC whale watching resources (e.g., the Handbook, reports and training opportunities), with approaches tailored to target key audiences. These audiences include the public and whale watching managers, researchers, operators, and on-board naturalists. Communication actions could include preparing publicly accessible summaries of IWC whale watching reports, improving the whale watching pages on the IWC website (which is already underway with the new Whale Watching Handbook, see Item 18.5), and promoting resources on social media, at key meetings and via press releases to industry bodies and trade publications. The implementation of this action could be coordinated intersessionally via the Secretariat. A joint intersessional working group, which includes key Secretariat staff, could develop a communications strategy for consideration at IWC/67 (the Brazil Plenary meeting) and/or the joint session of the CC/SC at SC/68a.

(2) The replacement of the actions of Objective 2 in the draft Strategic Plan with the following:

- a) Action 2.1 – Continue the Modelling and Assessment of Whale Watching Impacts (MAWI) initiative, to develop tools and methodologies to assist researchers and managers in their efforts to assess potential impacts of whale watching on cetaceans and to mitigate them. This initiative is ongoing and could focus on:
 - i) Investigating modelling methods to link short- (e.g., behavioural reactions) and medium-term (e.g., changes in population distribution) responses with potential impacts from whale watching to long-term (i.e., >10 to 20 years) consequences (e.g., vital rates).
 - ii) Establishing standard data collection methodologies, including from platforms of opportunity.
 - iii) Identifying key locations for whale watching research projects and programmes, taking into consideration logistics, capacity and management urgency;
- b) Action 2.2 – Develop a long-term integrated research programme to better understand the potential impacts of whale watching on the demographic parameters of cetacean populations. Seek to:
 - i) Investigate whether there is a causal relationship between whale watching exposure and the survival and vital rates of exposed cetacean individuals and populations;
 - ii) Understand the mechanisms involved in causal effects, if they exist, in order to define a framework for improved management;
- c) Action 2.3 – Develop processes and mechanisms for whale watching activities to collect and provide scientifically robust and useful data to researchers and research programmes; and
- d) Action 2.4 – Develop an approach (e.g., hold an intersessional workshop; establish a joint intersessional working group) to integrate social and ecological scientific research within the IWC to inform whale watching management and promote potential benefits. This is a coordinated action between the SWG and the sub-committee.

In particular, Action 2.2 will require a dedicated person to guide and coordinate the development and implementation of a research programme or plan. The best option would be for the SWG to contract with someone, full- or part-time, to carry out this task, whilst recognising the budgetary concerns. Therefore, the Committee **recommends** that the search for funding for this and all other actions in the Strategic Plan be focused, broad-ranging, and innovative. An alternative, if budgetary issues are prohibitive, is to have the research programme developed intersessionally by an intersessional correspondence group or the convenor and co-convenor of the Committee's sub-committee on whale watching.

Lastly, the Committee **reiterates** its previous recommendation to improve the coordination between the SWG and the Committee's sub-committee on whale watching in the development and implementation of a Strategic Plan on Whale Watching. This year's 21 April pre-meeting to review the draft Strategic Plan was intended to improve coordination and provided an opportunity to contribute to the draft Strategic Plan but it did not completely achieve the goal of coordination, as a limited number of SWG members were able to attend the pre-meeting.

18.4.2 Develop procedures to provide scientific advice as requested in the plan (including the online handbook) and make the Committee more effective at providing information to the Commission

The revised Actions 2.1-2.4 in Item 18.4.1 outline how the sub-committee on whale watching will collect information needed to inform the Conservation Committee's SWG on Whale Watching. Procedures for providing this advice will be discussed and determined cooperatively with the Conservation Committee, during the joint meeting immediately after SC/67b and intersessionally through the intersessional correspondence group (see Annex N, table 3,).

18.5 Whale watching handbook

18.5.1 Review and provide comments on the IWC's Whale Watching Handbook

The Whale Watching Handbook (Handbook) was presented. Before being made available to the public it will also be translated into French and Spanish with support from CMS. Annex N (item 6) provides additional comments and suggestions for fine-tuning and improving the already-admirable Handbook.

Attention: CG-R, SC, S, CC, C-R

The Committee **welcomes** the presentation of the online Whale Watching Handbook and **agrees** that it is comprehensive, scientifically substantive, user-friendly and well designed.

To ensure the IWC Whale Watching Handbook comes to the attention of the international whale watching community, including managers, operators and the public, the Committee **recommends** that all Contracting Governments provide a link to the Handbook on the relevant agency pages of their own government websites once the Handbook goes 'live'.

The Committee also **recommends** that the Conservation Committee and the Commission develop a plan for identifying and securing long-term funding for the further development (e.g., translations into additional languages, writing additional case studies or country profiles) and the ongoing maintenance (e.g., periodic reviews of content) of the IWC Whale Watching Handbook. The Handbook must be updated regularly to remain a vibrant, living document.

18.6 Review reports from intersessional correspondence groups

The Committee received information from the intersessional correspondence groups (ICG) of swim-with-whale operations and communication with IORA. Annex N provides details of (1) the discussion related to the intersessional work of the ICG on swim-with-whale operations (item 7.1) and (2) the discussion related to the intersessional work of the ICG on IORA communication (item 7.2).

Attention: S, SC, CC, CG-A, CG-R

Regarding swim-with-cetacean operations, the Committee:

(1) **agrees** that the intersessional correspondence group on swim-with-whale operations (Annex N, table 3) should continue;

(2) **draws attention** to guiding principles for whale watching, including in-water interactions, that are being or have been developed by various regional bodies, such as the Convention on Migratory Species and UNEP in the Wider Caribbean (see Annex N, item 2.3 and UNEP-CEP, 2012), that advise that swimming with cetaceans be discouraged where it is not already established; and

(3) **recommends** that, in jurisdictions where swim-with-cetacean activities have not been occurring or are just starting, this practice be prohibited until there is scientific evidence that supports allowing it, noting that the risks to both humans and cetaceans are substantial if operators are inexperienced and not following any relevant guidelines; and

The Committee also **welcomes** the increased communications between IORA and the IWC over the past year. The IORA Sustainable Whale and Dolphin Watching Tourism Network was established and Australia will convene the Network in its first year of operation and will produce a biannual newsletter. Consequently, the Committee:

(1) **agrees** that the intersessional correspondence group on communication with IORA (Annex Y) should continue; and

(2) **encourages** greater engagement between the IWC and IORA on whale watching, beyond the exchanges amongst the intersessional correspondence group (Annex N, table 3).

18.7 Review progress on scientific recommendations

18.7.1 Global influence of recommendations

The Committee received information about the influence of previous recommendations in numerous countries. Details can be found in Annex N, item 8.1.

18.7.2 Tracking progress on previous recommendations

The sub-committee on whale watching reviewed 27 of its recommendations and agreed statements from the past two years. Of those, 15 were completed or partially completed, nine are on-going, and three have not yet been addressed. Annex N, item 8.2, provides details about those recommendations and agreed statements. There is also ongoing work to update and finalise the terms of reference for the sub-committee on whale watching.

18.7.3 Update on dolphin watching in Bocas del Toro, Panama

Concern continues about the number of dolphins from the small population in Bocas del Toro, Panama that are found dead. Nine deaths in 2016 and 2017 are known to have occurred, five of them confirmed boat strikes. These losses are unsustainable. Research to better understand impacts on the population includes measuring stress hormones in biopsy samples and acoustic monitoring. A regulatory update to strengthen management of whale and dolphin watching in Panama, including Bocas del Toro, was released in October 2017, with the support of the Ministry of Environment.

Attention: SC, C, CG Panama

The Committee **reiterates** its grave concern regarding the intense and uncontrolled dolphin watching in Bocas del Toro, Panama. This concern has been expressed and reiterated for several years due to continuing mortalities, including from vessel strikes, in this small population (probably fewer than 100 animals). In this regard, the Committee:

(1) **welcomes** the ongoing research to monitor this dolphin population and the impacts it is facing from dolphin watching;

(2) **reiterates** its welcome of Panama's increased responsiveness to protect the local dolphin population by minimising negative impacts from dolphin watching (IWC, 2018a) and **welcomes** the regulatory update, supported by the Ministry of Environment, which is meant to lead to stronger management of whale and dolphin watching in Panama, including Bocas del Toro; and

(3) **expresses serious concern** at the number of deaths reported in 2016 and 2017 and **recommends** action from the Government of Panama as a matter of urgency, including the immediate and committed implementation of the updated regulations.

18.8. Work plan and budget requests for 2019-2020

18.8.1 Work plan for 2019-2020

The work plan for matter related to whalewatching is shown in Table 24.

Table 24

Summary of the work plan for matters related to whale watching. Many of these items have intersessional correspondence groups (ICG) or intersessional advisory groups (IAG). Those groups will work intersessionally and provide updates at SC/68a (see Annex X)

Topic	Intersessional 2018/19	2019 Annual Meeting (SC/68a)	Intersessional 2019/20	2020 Annual meeting

19. SPECIAL PERMITS

19.1 General considerations on improving the evaluation process

This issue is considered as part of the process to revise ‘Annex P’ (see discussion in Item 28.3).

19.2 NEWREP-A

Summaries of NEWREP-A papers are given in Annex U1.

19.2.1 Report on ongoing research

In plenary, the Committee received and briefly discussed four papers on ongoing work – as indicated below, some of these were discussed more fully in sub-groups.

SC/67b/SP08 presented the results of the third biological field survey of NEWREP-A during the 2017/18 austral summer season. In discussion, it was noted that the high apparent pregnancy rate (95.3%; 122 of 128 mature females) of Antarctic minke whales was consistent with previous results (e.g. from JARPA and JARPA II).

SC/67b/ASI07 presented a summary of results of the NEWREP-A dedicated sighting survey during the 2017/18 austral summer season whilst SC/67b/ASI11 presented the research plan for the next systematic vessel-based sighting survey in the Antarctic under NEWREP-A 2018/19. The new NEWREP-A 2018/19 sighting survey plan has been endorsed by the Committee; Annex Q (item 4.2) provides more details on both these papers.

SC/67b/EM05 presented results of the krill and oceanographic surveys undertaken during the third NEWREP-A survey in Area V-E and VI-W (see Annex L, item 6.1 for details).

19.2.2 Update on previous recommendations

19.1.2.1 AGE DATA AND RMP/IST (RECOMMENDATION 1)

SC/67b/RMP03 provided updated draft specifications for an RMP/IST type simulation exercise to evaluate management procedures based on modified catch limit algorithms that use information on recruitment inferred from age data from Antarctic minke whales. Details and discussion are given in Annex D, section 2.3.2.

Attention: S

The Committee **agrees** that methods currently used or proposed to be used in the Committee that use age data should (as necessary) be investigated to evaluate the relationship between their results and the accuracy and precision of the age data that they use where this is pertinent to the results of import from these methods. The Committee **agrees** to include this as an agenda item for next year’s meeting.

19.1.2.2 BIOPSY SAMPLING AND TELEMETRY FEASIBILITY STUDIES (RECOMMENDATIONS 4 AND 5)

SC/67b/SP04 summarised the results of a feasibility study on biopsy sampling and satellite tagging of Antarctic minke whales under NEWREP-A. The authors concluded that in the context of the NEWREP-A objectives, (a) the efficiency of biopsy sampling is much lower than that of lethal sampling for Antarctic minke whales and (b) that the amount of tissue derived from biopsy samples is insufficient to conduct the suite of biomarkers targeted by NEWREP-A. They therefore concluded that biopsy sampling was not a feasible approach to fulfil the objectives of NEWREP-A.

This paper prompted considerable discussion in the Committee, both with respect to ‘efficiency’ of the method and the amount of material required.

One issue raised was that there was the need for better clarification of terminology used in the paper (e.g. ‘sampling’ versus ‘killing’) in order, for example, to interpret properly the conclusion that biopsy sampling took approximately three times longer than lethal sampling. It was not clear, for example, whether the median times for biopsy and lethal sampling provided were truly comparable because of the lack of information on when the time for these methods started and ended. In particular, handling time for lethal sampling appeared to not be included in the total time calculations.

The authors responded that in SC/67b/SP04 ‘the efficiency’ of sampling techniques was defined as ‘Success Proportion’ rather than ‘Time of Experiment’ because ‘Success Proportion’ represents a better indicator of the efficiency. To fulfil the purposes of NEWREP-A, random sampling is required in which generally only one animal from a school is sampled. Notwithstanding this clarification, they provided definitions of ‘Time of Experiment’ (see details in Yasunaga *et al.* in Annex U2).

Another issue raised was that the NEWREP-A review workshop (ref) had suggested ‘involving people with expertise in successfully biopsy sampling common minke whales in the North Atlantic’, meaning collaborating in the field with experienced foreign experts. However, Table 2 of SC/67b/SP04 showed an ongoing decline in success proportion (number of biopsy samples / number of targeted whales which were chased for sampling by the SSVs) between 2015/2016 and 2017/2018 rather than the increase one would expect with increasing experience. The authors responded that they had consulted with foreign scientists although they were not on the vessels, that they used experienced marksmen and that the decline was an artefact of weather and sea state conditions under which samples were collected. However, the counter-comment was made that in authors’ analyses, the best model did not include “weather conditions” as a significant factor.

In response the authors provided results of a GLM analysis based on the binomial distribution assumption to examine the differences in success proportion in the biopsy sampling experiment using research seasons as explanatory variables. The coefficients for each year were not significant, suggesting that the differences of success proportions among the seasons are not statistically significant and consequently provide no evidence that shooters’ efficiency has decreased significantly over the three research seasons (see details in Yasunaga *et al.* in Annex U2).

Some Committee members (see Clapham *et al.* I, in Annex U2) disagreed with the authors’ conclusion that the study revealed that biopsy sampling was not feasible for the NEWREP-A programme. Rather, they believed that it showed that it was both feasible and appropriate. They also disagreed that the amount of tissue obtained was insufficient, citing the large number of research programmes that successfully use biopsy samples to fulfil research objectives including using a single sample for a variety of biomarkers (e.g. stable isotopes, fatty acids, hormones, genetics).

In response, the authors agreed that the amount of epidermal tissue collected by biopsy sampling is enough for the requirement of genetic, epigenetic and stable isotope analyses. However, they stressed that the amount of adipose tissue collected by biopsy sampling was not large enough to measure progesterone, lipid content and fatty acid in the context of the objectives of NEWREP-A (see details in Yasunaga *et al.* in Annex U2).

In their closing comments, the authors stated that in response to the recommendation of the Expert Panel, dedicated experiments for biopsy sampling of Antarctic minke whales had been carried out which had generated the results presented at this meeting and from which the authors had drawn their conclusions. No further dedicated time for biopsy experiments was planned at this stage, but this could be reconsidered at the mid-term review. Meanwhile, NEWREP-A will only collect additional biopsy samples opportunistically.

With respect to the best approach to assess the efficiency of biopsy versus lethal sampling, a standard approach for measuring the efficiency of biopsy sampling and to compare this to the process of lethal sampling was proposed (Clapham *et al.* II, in Annex U2).

Attention: S

*The Committee had last year agreed on establishing an intersessional Advisory group tasked ‘to provide advice on developing an experimental protocol for ascertain whether it is possible to reliably biopsy minke whales and, if so, under what circumstances (experience, vessel type, equipment, environmental conditions, etc.). This group could use as starting point the advice provided by the Expert Panel’ (JCRM 19 suppl:431-490). Due to a clerical error the group did not convene. Attention was drawn to a protocol to evaluate non-lethal techniques presented to SC66b (Mogoe *et al.*, 2016). This protocol included four questions to help identify the feasibility and practicability of non-lethal methods.*

*The Committee **agrees** to re-establish the Advisory group (Annex Y), under Palka for consideration at SC68a. It also **agrees** that suggestions for refining questions in the method used by Mogoe and colleagues (2016) should be added to the tasks of this group.*

19.1.2.3 EPIGENETIC AGEING (RECOMMENDATION 8)

Recently, epigenetic (DNA-methylation) ageing has been successfully used to estimate age in humpback whales (Polanowski *et al.* 2014). As noted under Item 11.4.4, this year, the Committee invited Jarman, the leading specialist in this technique to give an overview presentation to the Committee as a special night session. This covered topics such as current and future prospects for this class of methods (see Annex I, item 5.5).

SC/67b/SDDNA04 presented a feasibility study on epigenetic ageing in Antarctic minke whales in response to Recommendation 8 from the Expert Panel (for details see Annex I, item 5.5).

Some suggestions were made on how to improve resolution (in particular, evaluate more loci and then restrict to those loci highly correlated with age); the current set of loci do not provide sufficient precision for use in the population dynamics modelling exercise recommended for NEWREP-A. Given that there is an upper limit to the degree of precision that can be achieved using this technique, the Committee noted that the utility of epigenetic age estimation (and other methods of age determination) will depend on the degree of precision needed for the specific application of interest (see recommendation under Item 11.4.1).

19.1.2.4 DETERMINING SEXUAL MATURITY IN BLUBBER (RECOMMENDATION 9)

SC/67b/SCSP05 presented results from the NEWREP-A research component focused on determining sexual maturity in female Antarctic minke whales, during the feeding season based, on concentrations of progesterone in blubber. The authors concluded that the progesterone concentration in blubber samples cannot be used as a diagnostic index to discriminate between mature and immature female Antarctic minke whales and that lethal sampling is required to obtain information on sexual maturity for use in population dynamic models.

Some members of the Committee disagreed with that conclusion, as they demonstrated that the amount of misclassification in immature versus mature females would be small (~1%, see Wade *et al.* in Annex U2) and thus that progesterone levels in biopsy samples would allow discrimination between mature and immature animals.

They noted that the stated purpose of the study was to discriminate between immature and mature females for fitting population dynamics models such as the catch-at-age analysis; the only misclassification that occurred was a total of 3 (out of 230) whales between the resting and the immature classes, and therefore the only misclassification rate that is important remains ~1% of the total sample.

Some other members noted, also in relation to recommendation 10, that misclassification for discriminating between resting and immature animals was higher and thus the method less reliable for that task.

In response to a request, the authors provided a histogram showing the numbers of immature, resting, ovulating and pregnant animals (Figure 1 of Yasunaga *et al.* in Annex U2). Based on the assumption of cut off values (1.0 ng/g) of progesterone set in Wade *et al.* (see in Annex U2), six of 56 immature whales and three of 11 resting whales were misclassified. Misclassification ratios were thus 10.7% and 27.2%, respectively, and these were not considered negligible by the authors (see details in Yasunaga *et al.* in Annex U2).

19.1.2.5 SAMPLE SIZES REQUIRED TO DETECT CHANGE IN ASM (RECOMMENDATION 26)

SC/67b/SCSP01 focused on the need to complete NEWREP-A recommendation 26 on the calculation of sample size. The Committee discussed its previous conclusions in this regard. In 2016, the Committee assessed that three of six aspects of the Expert Panel's recommendations had been adequately addressed in relation to sample sizes. Some members of the Committee consider that until the proponents fully implement the Expert Panel recommendations for calculating sample sizes, the proponents have not demonstrated that they are able to meet their stated objectives in relation to the NEWREP-A programme. The proponents' position and that of some Committee members is that the work has been completed to a reasonable level and that any further work on sample sizes will be afforded a low priority.

The Proponents reiterated their position regarding the work on and status of recommendation 26 ('Provide a thorough power analysis of sample sizes required to detect change in ASM and follow the other recommendations in this item') from the NEWREP-A Review Workshop (IWC, 2016). In view of the proponents, the work on recommendation 26 has been completed to a reasonable level. Details can be found in GOJ (2015; 2016a) and GOJ (2016b). The IWC SC has already concluded that the approach being taken to address the recommendation is appropriate (IWC 2018). Consequently, the proponents have concluded that the reasonableness of the proposed sample size (333) has been adequately demonstrated. The proponents recognize that in 2016 the Scientific Committee suggested some further refinement work; however, they consider that such refinement work goes beyond the original scope of recommendation 26 from the NEWREP-A review workshop. Nevertheless, in deference to the Committee, it was the proponent's intention to address the refinement work for this year's Scientific Committee. However, because of unanticipated specialist personnel unavailability, this has had to be postponed. The proponent's intention is to continue contributing to this work subject to logistical constraints and the availability of specialist analysts.

19.1.2.6 COMMITTEE'S ADVICE

The table in Annex U4, provides a detailed update of the Committee's view of progress on previous recommendations. An overview is given in Table 25.

Table 25

NEWREP-A – Overview on progress with recommendations.

Recommendations in are not in priority order. Recommendations that relate to purposes A, B, C and D are higher priority for completion. Recommendations coded uniquely as “E: Relevant to improve existing components of the proposed programme” are excluded from this table as they were optional. Key for ‘Purpose’: A: To evaluate the contribution of a particular objective or sub-objective of the programme to meet conservation and management needs; B: To evaluate the feasibility of particular techniques (whether lethal or non-lethal); C: Relevant to a full evaluation of whether any new lethal sampling is required; D: Relevant to issues related to sample size (irrespective of method used to obtain data).

Recommendation	Purpose	Deadline	Proponents self-evaluation on progress as of SC67b	Committee’s comments
(1) Age data and RMP/IST	A, C, D	August 2016	Completed to a reasonable level	SC66b: A range of opinions as to the extent to which this recommendation has been addressed. SC67a: No new information. SC67b: Some information presented (See section 19.1.2.1).
(2) Stock definition	A, D	May 2016	In progress.	SC66b: No progress. SC67a: As in SC66b. SC67b: As in SC66b.
(3) Mixing rates (simulations on precision and bias)	A, D	May 2016	To be completed by the mid-term review.	SC66b: No progress. SC67a: As in SC66b. SC67b: As in SC66b.
(4) Biopsy feasibility study	B, C, D, E	Field season 2017-2018	Completed.	SC66b: Some progress (SC/66b/IA05). SC67a: Some progress (SC/67a/ASI07). SC67b: Partially completed, further refined analysis is needed (see 19.1.2.2). A WG was formed to review and improve methods.
(5) Telemetry feasibility study	B, E	Field season 2018-2019	Completed.	SC66b: Some progress (SC/66b/IA05). SC67a: Some progress (SC/67a/ASI07). SC67b: Completed.
(8) DNA methylation ageing technique	B, C, D	March 2017	Completed.	SC66b: No progress. SC67a: As in SC66b. SC67b: Partially completed, further refined analysis is encouraged. See section 19.1.2.3.
(9) Hormones in blubber and sexual maturity	B, C, D	March 2018	Completed.	SC66b: No progress. SC67a: As in SC66b. SC67b: Blubber hormones analysis completed. On accuracy see section 19.1.2.4.
(10) SCAA and misassignment ‘resting’ females/immature females.	A, C, D	August 2016	To be completed by the mid-term review*.	SC66b: No progress. SC67a: As in SC66b. SC67b: New information presented (SC/67b/SCSP05).
(11) SCAA, density- dependence, and stock mixing	A, C, D	May 2016	Completed*.	SC66b: Partially completed: updates on stock mixing and mixing rates still necessary. SC67a: As in SC66b. SC67b: As in SC66b.
(12) Time-varying natural mortality and SCAA	A, C, D	August 2016	To be completed by the mid-term review*.	SC66b: No progress. SC67a: As in SC66b. SC67b: As in SC66b.
(13) Time varying ASM data and SCAA	A, C, D	May 2016	To be completed by the mid-term review*.	SC66b: No progress. SC67a: As in SC66b. SC67b: As in SC66b.
(15) Krill acoustic sampling	B, E	March 2017	Completed.	SC66b: Completed.
(17) Power analysis for krill abundance	A, E	August 2016	To be addressed.	SC66b: Will be addressed in consultation with CCAMLR specialists SC67a: No progress. SC67b: As in SC66b.
(18) Stomach contents vs krill survey	A, B, C	May 2016	To be addressed.	SC66b: Will be addressed in consultation with CCAMLR specialists SC67a: No progress. SC67b: As in SC66b.
(22) Energy intake (requirements)	A, B, D	August 2016	To be addressed. Need clarification from the IWC SC	SC66b: No Progress. SC67a: As in SC66b. SC67b: As in SC66b.
(23) Stable isotopes in baleen plates	B	August 2016	Completed.	SC66b: Will be addressed in consultation with other research institutions. SC67a: Some progress presented. SC67b: Completed.
(26) Sample sizes required to detect change in ASM	D	May 2016	Completed to a reasonable level	SC66b: Overall, the approach being taken to address the recommendation is appropriate, but some further refinements are required. SC67a: No Progress. SC67b: As in SC67a.

*See note in Table #, Annex U4.

19.3 JARPN II

The new information provided on JARPN II is relevant only to the discussion of the NEWREP-NP ‘non-lethal vs lethal’ feasibility study (see Item 19.3).

19.4 NEWREP-NP

19.4.1 Report on ongoing research

Three papers were presented on progress made during the 2017 surveys of different aspects of the NEWREP-NP programme (SP03, 06, 07, see Annex U3 for summaries).

In particular, SC/67b/SP03 reported the results of the satellite tagging of North Pacific sei whales. A total of 44 tagging attempts were made using SPOT6 tags with the LKArts attachments system. A total of 15 tags were deployed on sei whales, and eight whales were tracked. Two sei whales were tracked for more than 35 days, and both showed longitudinal movement. The authors concluded that the tagging experiment showed that deploying such tags from sighting/sampling vessels was practical, but identified technical improvements to try to increase the tracking period.

In discussion, it was noted that the proportion of successful deployments was low (7 failures in 15 attempts); and suggestions on how to improve this included: (a) strategic placement of tags on the upper body of whales to ensure tag longevity and reduce potential physical impacts (e.g. lesions) and (b) replacement of the current screw-on anchor system with an integrated tag design to decrease the possibility of tag breakage. It was noted that guidelines for cetacean tagging should become available within the next year and published in the IWC Journal. It was noted by the authors that the cause of the failures in SP03 were difficult to evaluate since a tag in an optimal position on the whale had also failed. New tags with a modified anchor system and stopper will be used during the next season.

The Committee welcomes new information on the feasibility of satellite tagging sei whales and notes the valuable movement data collected from two of the longer-term (>35 days) deployments. The Committee **encourages** the collection of more telemetry data and notes that this may help improve abundance estimation (by providing information on correction factors) and provide inferences on stock structure.

SC/67b/ASI10 presented a summary of results of the NEWREP-NP dedicated sighting survey in the western North Pacific in 2017 whilst SC/67b/ASI06 presented the research plan for the next systematic vessel-based sighting survey in the western North Pacific under NEWREP-NP in 2018 and 2019. As indicated under Item 24.3, the new NEWREP-NP sighting cruise plan has been endorsed by the Committee; Annex Q (item 4.2) provides more details on both these papers.

19.4.2 Update on previous recommendations

The table in Annex U4, provides a detailed update of the Committee's view of progress on previous recommendations. An overview is provided in Table 26 (see next page).

Table 26

Summary of status of recommendations relevant to NEWREP-NP

No. of recommendation	Priority by the Committee	Timeline	Proponents self-evaluation on progress as of SC67b	Scientific Committee Evaluation
(1) Lethal vs non-lethal quantitative review of data	Very high	Before start	SC67a: Completed.	SC67a: Different opinions as to whether the recommendation has been met. SC67b: No progress.
(3) Sexual maturity (blubber and serum)	High	Before start	SC67a: Completed.	SC67a: The Proponents demonstrated intention to include analysis of blubber for progesterone, but there are few details of how. SC67b: Partially addressed.
(4) Sightings surveys	High	Before start and annually	Addressed and ongoing.	SC67a: Completed: survey plan was presented. SC67b: Completed: survey plan was presented.
(5) Stomach contents	High	Before start	SC67a: Completed.	SC67a: Completed.
(7) Immune function assays	High	Before start	SC67a: Completed.	SC67a: Completed.
(8) Lipophilic compounds	High	Before start	SC67a: Completed.	SC67a: Completed.
(10) Coordination with IWC-POWER	High	Before start and annually	Addressed and ongoing	SC67a: Completed annually.
(11) Coastal component: sampling strategy	High	Before start	Disagree with Panel	SC67a: No progress as proponents disagree with Panel. SC67b: No progress.
(12) Offshore components: sampling strategy	Very high	Before start	SC67a: Completed.	SC67a: Completed.
(13) downweight historical age-composition data	Very high	Before start	Disagree with Panel.	No progress.
(15) efficiency of biopsy sampling (additional captures unnecessary)	Very high	High priority ASAP in 2017	Disagree with Panel.	No progress.
(17) Telemetry	High	Before start	Ongoing	SC67a: Partially addressed. SC67b: New information (SC/67b/SCSP03).
(21) Sample size (potential reduction of lethal sample size)	Very high	Before start	To be considered by the mid-term review.	SC67a: The possibility for further work has been considered. SC67b: No progress.
(22) Sample size (in general)	Very high	Before start	Not relevant.	SC67a: Small progress. SC67b: No progress.
(23) Impact of catches on common minke whales (subset of 2013 <i>Implementation</i>)	Very high	Before start	Disagree with Panel.	SC67a: Major concerns addressed. SC67b: Completed. Refined analyses were presented. It could be reconsidered in the next <i>Implementation Review</i> .
(24) Impact of catches on common minke whales (new abundance)	Very high	Before start	Disagree with Panel.	SC67a: Major concerns addressed. SC67b: Completed. Refined analyses were presented. It could be reconsidered in the next <i>Implementation Review</i> .
(25) Sei whale (abundance, $MSYR_{1+}=1\%$, $MSYR_{mat}=4\%$)	Very high	Before start	SC67a: Completed.	SC67a: Completed.
(27) Higher priority to analyses and modelling	High	Before start	Ongoing	SC67a: It is not clear that additional qualified personnel have been hired. SC67b: No progress.
(28) Sample and data archiving, relational database(s)	High	Before start	Ongoing	SC67a: Partially addressed for DNA data and associated biological information.
(29) Contingency plan	High	Before start	Ongoing	SC67a: Partially addressed.

20. WHALE SANCTUARIES

20.1 Review of the Southern Ocean Sanctuary Management Plan

The Schedule amendment establishing the Southern Ocean Sanctuary (SOS) requires the Sanctuary to be reviewed at succeeding ten-year intervals, unless otherwise revised by the Commission. The first review of the SOS took place in 2004 (IWC, 2005) and the second review was completed in 2016 (IWC, 2017). In 2014 (IWC, 2015c), the Commission adopted eight objectives for the SOS (summarised in Annex R, item 3). The Commission also provided terms of reference for the review to be undertaken by the Scientific and Conservation Committees. The Scientific Committee review made several recommendations (IWC, 2017c). These recommendations were taken into account in a draft Southern Ocean Sanctuary Management Plan (SC/67b/SAN01) developed by Australian scientists and discussed in Annex R (item 3). It was noted that, while the draft Plan does contain performance measures, it does not contain criteria for its own review.

The purpose of the draft Management Plan is twofold: (1) to inform the Commission and public about the sanctuary objectives and actions planned for the next ten years; and (2) to propose strategies toward the achievement of the SOS's goals using the best means available and provide clear performance measures for each proposed action.

The operative part of the Plan is a Research and Action Plan that involves assessing and addressing threats and research on the recovery of whale populations and their habitats. The Research and Action Plan is structured based on the Commission's agreed objectives for the SOS. Each objective is linked directly to a measurable objective, action or approach and performance measure.

The Committee also discussed the potential contributions that data and results from the Japanese whale research programme in the Southern Ocean (NEWREP-A) could make to the objectives and goals of the Plan and the Committee agrees to incorporate reference to NEWREP-A under Objectives 4-6.

The amended Plan, with Objectives 1 and 8 (relating to policy) and the chapeau of Objective 5 redacted to clarify that the Committee did not address these elements of the Plan, is given as Annex R (Appendix 2).

A statement from the Government of Japan regarding its position on the SOS and this draft Management Plan is attached as Annex R, Appendix 3.

Attention: C-A, CC, SC,

The Committee reviewed the components of a draft Management Plan for the Southern Ocean Sanctuary (SOS) that are related to science and therefore within its remit and:

- (a) **endorses** the measurable objectives, approach/actions and performance measures of Objectives 2 -7 of the amended draft Southern Ocean Sanctuary (SOS) Management Plan (Annex R, appendix 2); and*
- (b) **agrees** to include a new standing item on the agendas of all relevant sub-committees and working groups: 'new information relevant to the SOS Management Plan' in order to assist the Commission in monitoring and measuring progress on the scientific objectives of the Plan.*

21. SATELLITE TAGGING DEVELOPMENT AND BEST PRACTICES

21.1 Tag Workshop Meeting, Silver Spring, MD, USA 6-8 September 2017

A workshop on cetacean tag development, tag follow-up and tagging best practices was held at the National Marine Fisheries Service in Silver Spring, Maryland, USA from 6-8 September 2017. The workshop was co-sponsored by the Office of Naval Research (ONR), the International Whaling Commission (IWC), and the National Oceanic and Atmospheric Administration's National Marine Fisheries Service (NOAA/NMFS). The purpose of the workshop was to review and evaluate progress in tag design and attachment since the 2009 ONR Cetacean Tag workshop (ref - attached), with an emphasis on (a) recent tag attachment improvements, (b) follow-up studies that examined the effects of tagging, and (c) reviewing and providing input on draft cetacean tagging best practices guidelines.

Several presentations were made, with a focus on sharing information and discussion of the best available science of design and effects of tagging to facilitate future advancements in tag design and application, maximising attachment durations to the extent required to answer the questions being posed, whilst minimising potential impacts to the animals.

Discussion on the status of tag attachment development and follow-up studies occurred, along with extensive discussion regarding the cetacean tagging best practices guidelines. While much was accomplished towards the collective goals of the workshop, one item not covered in sufficient detail was discussion on the future directions in tag attachment technology. Therefore, a second smaller workshop will be convened in June of 2018 with a subset of the original attendees that focus specifically on tag attachments. The final report will merge the results of the September 2017 workshop and the June 2018 workshop.

22. IWC LIST OF RECOGNISED SPECIES

The Committee has agreed to follow the guidance of the Society for Marine Mammalogy's Committee on Taxonomy. This year (see Item 17.5), in completing its review of the taxonomy of *Tursiops*, the Committee noted that the current taxonomy provided by the SMM Committee for *Tursiops* was well supported by morphological and molecular genetic data, as well as ecological and distributional data.

23. IWC DATABASES & CATALOGUES

23.1 Guidelines for IWC catalogues and photo-ID databases

At last year's meeting, the Committee agreed IWC Guidelines for Photo-identification Catalogues (IWC, 2018f), noting that adding technical Appendices would be valuable in the future. Draft items for inclusion as Appendices were discussed by the *Ad hoc* Working Group on Photo-identification (Annex S, item 5.1) covering five issues: (1) cataloguing software; (2) image matching software; (3) seminal papers defining individual identification, by species; (4) photo quality guides; and (5) photo/data collection apps. Work will continue on developing these appendices intersessionally (Annex Y).

23.2 Progress with existing or proposed new catalogues

23.2.1 Integration of eastern South and Central Pacific blue, humpback, and fin whale photo-catalogues

There was no new information specific to this item this year.

23.2.2 Southern Hemisphere and Indian Ocean humpback whale catalogues

23.2.2.1 ANTARCTIC HUMPBACK WHALE CATALOGUE

The Antarctic Humpback Whale Catalogue (AHWC), maintained at College of the Atlantic, USA, was established in 1987 and during the past 30 years its data have been used in dozens of studies and publications (Stevick *et al.*, 2017). With a recent loss in funding, the catalogue database is now 'frozen' and is not being actively updated. The Working Group expressed strong disappointment at this news as well as the hope that the AHWC's funding situation will change and enable the catalogue to continue.

Attention: SC, G

The Scientific Committee has been informed that due to a loss of funding, the Antarctic Humpback Whale Catalogue curated by the College of the Atlantic, USA will no longer be updated. The Committee:

- (1) **draws attention** to the great value this catalogue (established in 1987) has provided to the Committee, including receiving photographs from the IWC IDCR and SOWER cruises and providing information for the Committee's Comprehensive Assessment of Southern Hemisphere humpback whales;*
- (2) **welcomes** news that the existing catalogue will remain a resource for scientists; and*
- (3) **encourages** potential funders to support future continuation of the catalogue.*

The Committee also received an update on the development and status of 'Happywhale', a web-based marine mammal photo-ID crowd-sourcing platform (SC/67b/PH05)¹². This is discussed in Annex S (item 2.2). In recent months Happywhale provided images to catalogues relevant to the IWC and IWC-SORP of Southern right whales, Antarctic blue whales, and Antarctic killer whales. It will also contribute to the ongoing in-depth assessment of North Pacific humpback whales (see Annex F item 4.2.1).

23.2.2.2 ARABIAN SEA WHALE NETWORK'S FLUKEBOOK

In 2016 (IWC, 2017), the IWC approved funding for the development of a regional data platform for the Arabian Sea Whale Network (ASWN), to be implemented in collaboration with Wild Me, the developers of Flukebook. This year the Committee received information SC/67B/PH/03 that described Flukebook, a non-profit, open source cetacean data archiving and photo matching tool as discussed in Annex S (item 2.1; SC/67B/PH/03). The ASWN is joining Flukebook with two primary objectives: (1) to consolidate and more effectively manage humpback whale and other cetacean data collected in Oman over the past 20 years; and (2) to provide an online platform that will allow comparison and regional-level analysis of cetacean data collected by different research groups throughout the Arabian Sea (so far photographs are mainly from Oman, with a few from Pakistan and India). The Committee **looks forward** to updates on this work.

23.2.3 Southern Hemisphere Antarctic and pygmy blue whales: Catalogues and databases

23.2.3.1 SOUTHERN HEMISPHERE BLUE WHALE CATALOGUE (SHBWC)

The SHBWC has become the largest repository of Southern Hemisphere blue whale photo-identifications. It now includes a total of 1,519 individual blue whale photo-identifications from areas off Antarctica, Chile, Peru, Ecuador-Galapagos, Eastern Tropical Pacific (ETP), Australia, Timor Leste, New Zealand, southern Africa, Madagascar and Sri Lanka. The Committee received information on the progress made with the catalogue (SC/67B/PH/04), especially in light of the recommendations made last year to conduct catalogue comparisons in the Indo-Australian region (IWC, 2018b). This is discussed in more detail in Annex S (item 3.2). Comparison work (SC/67B/SH16) found (a) no matches between Australia, New Zealand and Sri Lanka, reinforcing the hypothesis of separate populations; and (b) exchange within Australia, suggested a single population; and (c) re-sights found in New Zealand suggest some site fidelity. Additional work is underway. The relevance of the catalogue to population assessments is discussed in Annex H Item 7.1.1.2.

23.2.3.2 ANTARCTIC BLUE WHALE CATALOGUE (ABWC)

In 2017, the Antarctic Blue Whale Catalogue compared photographs from the IWC IDCR/SOWER cruises in 1989/1990, 1993/1994, and 1997/1998 as well as opportunistic photographs collected by collegial scientists, naturalists, and tourists 2015-2018. The catalogue now contains almost 460 individuals. The results of the comparison of new Antarctic blue whale identification photographs to the ABWC is summarised in SC/67B/PH02 and discussed in Annex S (item 3.1); 17 new individual blue whales were identified. The collection of Antarctic blue whale identification photographs provide data for capture-recapture estimates of abundance (SC/67B/SH08) as well as information on the movement of individual blue whales within the Antarctic region. The relevance of the catalogue to population assessments is discussed Annex H, Item 7.1.1.1.

Attention: SC

- (1) The Southern Hemisphere Blue Whale Catalogue provides data useful for estimating abundances and examining connectivity between feeding and breeding grounds. The Committee **agrees** that the catalogue continue.*
- (2) The Committee **agrees** that the Antarctic Blue Whale Catalogue continue its work collecting adding photo-identification data to the catalogue in order to assist with developing estimates of population abundance for Antarctic blue whales.*
- (3) The Committee **agrees** that the development of a simple guide (physical and electronic versions) to help tourists and naturalists take photos that are suitable for photo-identification should be undertaken. This will support the photo-ID*

¹² <https://happywhale.com>

catalogues from the Antarctic region for use in population assessments by the IWC, particularly for blue whales, right whales, fin whales, and humpback whales.

23.2.4 Southern Hemisphere fin whale photo catalogues

The Committee received information on a new photo-identification catalogue of Antarctic fin whales. Photographs from SOWER cruises 2004-2008 are included as well as those collected opportunistically near the South Orkney Islands during a Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR) fisheries research voyage (SC/67B/PH01). This is discussed in Annex S (item 4.1). The catalogue serves as a foundation for future photo-ID studies, especially those proposed for the western Antarctic Peninsula. The relevance of the photo-identification of fin whales to population assessments is discussed Annex H, Item 7.1.2.

Attention: S, SC

*1) The Committee **encourages** continuation of the Antarctic Fin Whale Catalogue which can potentially provide data toward estimating abundance or identifying movement patterns.*

*2) The Committee **agrees** that an exhaustive search be conducted to locate SOWER photos that are missing from the IWC archives, including those of fin whales.*

23.2.5 Western Pacific gray whale photo catalogues

The Committee received information on two photo-identification catalogues relating to the Sakhalin Island feeding aggregation: one (SC/67B/ASI04), based on work undertaken as part of an industry-sponsored Exxon Neftegas Limited-Sakhalin Energy Investment Company joint monitoring program discussed in Annex S, item 4.2); and the other conducted by the Russia gray whale project (SC/76b/CMP/7) discussed in Annex O (item 2.1.3). The Committee welcomed news that the two catalogues would be unified under the auspices of the IWC.

23.3 Work plan

The work plan on work related to catalogues is provided in Table 27.

Table 27

Work plan on issues related to catalogues.

Topic	Intersessional 2018/19	2019 Annual Meeting (SC/68a)	Intersessional 2019/20	2020 Annual meeting
Appendices for IWC Guidelines for Photo-identification	Continue compilation	Appendices ready for review	Continue compilation	Appendices ready for review
Upload all available New Zealand blue whale identification photographs to SHBWC (also pertains to Annex H item 7.1.1)	Cross-reference between separate area catalogue holdings before uploading to SHBWC avoid duplication; intersessional correspondence group (Annex Y)	Included in SHBWC report	-	-
Development of how-to photo-ID materials for naturalists and citizen scientists (also pertains to Annex H item 7.1.1.2)	Prepare hard copy and PPT photo-ID guides	Guide completed and available (pending funding)		
4) Search for missing SOWER photographs, especially fin whale photos from 2006/2007	Search Secretariat archives and contact SOWER researchers for personal copies of photos	Report		

23.4 Potential future IWC databases

23.4.1 Global database for disentanglement activities

As discussed under Item 13.2, development of a dedicated entanglement database will be considered further at the June 2018 meeting of the Global Whale Entanglement Response Network (see Annex J, item 2.3).

23.4.2 Global bycatch database

No new information was presented on the development of a global bycatch database was presented this year. Consideration of such a database could take place as part of the Bycatch Mitigation Initiative and should it be taken further, follow the guidelines for the proposal of new databases developed last year (IWC, 2018, pp. 403-404).

23.4.3 Development of simple technical guidelines for new proposals

No changes were suggested to the guidelines developed at last year's meeting (IWC, 2018, pp. 403-404).

24. IWC MULTINATIONAL RESEARCH PROGRAMMES AND NATIONAL RESEARCH CRUISES THAT REQUIRE IWC ENDORSEMENT

24.1 IWC-POWER

The Committee received the results of the 8th annual IWC-POWER cruise conducted between 3 July and 25 September 2017 in the eastern Bering Sea. Researchers from Japan, USA and IWC participated on the surveys (SC/67b/ASI12). The Committee also received the report of the planning meeting for the 2018 IWC-POWER cruise, which will be conducted in the central Bering Sea, and cruise plans for the 2019 and 2020 cruises (SC/67b/Rep02). Details and preliminary results of the 2017 IWC-POWER survey and future plans for 2018, 2019 and 2020 are provided in Annex Q, item 4.1.

Attention: SC, C-A, CG-R

The Committee reiterates to the Commission the great value of the data contributed by the IWC-POWER cruises which cover many regions of the North Pacific Ocean not surveyed in recent years and so address an important information gap for several large whales. The Committee:

- (1) thanks Japan who generously supplies the vessel and crew, for their continued support of this IWC programme;*
- (2) thanks the USA who provided an acoustician and acoustic equipment for the 2017 cruise and will do so for the 2018 cruise;*
- (2) agrees that the 2017 cruise was duly conducted following the requirements and guideline of the Committee (IWC, 2012) and looks forward to receiving abundance estimates based on these data;*
- (3) endorses the plans for the 2018, 2019 and 2020 POWER cruise and recommends a meeting of the Technical Advisory Group along with the planning meetings for 2019 and 2020 cruises;*
- (4) strongly recommends that Russia facilitates the proposed research by providing permits for the IWC-POWER cruise to survey the Russian Exclusive Economic Zone in 2019;*
- (5) looks forward to receiving a report from the 2018 survey at the next SC meeting.*

24.2 Southern Ocean Research Partnership (IWC-SORP)

The Southern Ocean Research Partnership (IWC-SORP) was established in March 2009 as a multi-lateral, non-lethal scientific research programme with the aim of improving the coordinated and cooperative delivery of science to the IWC. The Partnership currently has 13 member countries: Argentina, Australia, Belgium, Brazil, Chile, France, Germany, Italy, New Zealand, Norway, South Africa, the United States of America, and Luxembourg was welcomed at this meeting. New members are warmly welcomed.

There are five ongoing IWC-SORP themes:

- (1) 'The Antarctic Blue Whale Project';
- (2) 'Distribution, relative abundance, migration patterns and foraging ecology of three ecotypes of killer whales in the Southern Ocean';
- (3) 'Foraging ecology and predator-prey interactions between baleen whales and krill';
- (4) 'Distribution and extent of mixing of Southern Hemisphere humpback whale populations around Antarctica?' focused initially on east Australia and Oceania; and
- (5) 'Acoustic trends in abundance, distribution, and seasonal presence of Antarctic blue whales and fin whales in the Southern Ocean'.

Bell presented the IWC-SORP Annual Report 2017/18 on the continued progress of research undertaken researchers involved in the five themes since last year (SC/67b/SH21). This progress includes the production of 33 peer-reviewed publications during 2017/18, bringing the total number of peer-reviewed publications related to IWC-SORP since the start of the initiative to 126. In addition, 125 IWC-SORP related papers have been submitted to the Scientific Committee, 22 of them this year.

Fieldtrips were undertaken to a variety of places during the past year, including the western Antarctic Peninsula, Marion Island, the Ross Sea, the Chesterfield-Bellona Reef complex west of mainland New Caledonia, and the Great Barrier Reef, Australia. Thousands of images for photo-identification have been collected; a variety of satellite tag-types deployed on Antarctic minke whales, humpback whales and killer whales as well as biopsy samples collected from these same species; video suction cup tags have been deployed on Antarctic minke whales and humpback whales; and hundreds of hours of acoustic recordings have been made and analysed. The support of tour companies in providing opportunistic research platforms to facilitate these activities and external data contributors were acknowledged by the Committee.

Attention: SC, G

The Committee reiterates the great value of the IWC-SORP (Southern Ocean Research Partnership) programme to its work. The Committee:

- (1) **encourages** the continuation of the Southern Ocean Research Partnership programme;
- (2) **commends** the researchers involved who are key to the overall success of the Partnership in IWC-SORP for:
 - (a) the impressive quantity of work carried out across diverse member nations;
 - (b) their contributions to the work of the Committee; and
- (3) **encourages**:
 - (a) the continued development, testing and implementation of leading edge technology; and
 - (b) the continued development of collaborations between ships of opportunity and external bodies that can provide platforms for research and/or contribute data, inter alia, photo-identification data, to IWC-SORP and the wider Committee

24.2.1 Workplan

The work plan for issues related to IWC-SORP is given in Table 28.

Table 28
Workplan for the Southern Ocean Research Partnership.

Topic	Intersessional 2018/19	2019 Annual Meeting (SC/68a)	Intersessional 2019/20	2020 Annual meeting
Analyses	Continued analysis of data/samples from previous IWC-SORP voyages/fieldwork	Report	Continued analysis of data/samples from previous IWC-SORP voyages/fieldwork	Report
Voyages	Argentine coastguard 'Tango' voyage along Western Antarctic Peninsula (early 2019)	Cruise report		
	Almirante Maximiano voyage along Western Antarctic Peninsula (early 2019)	Cruise report		
	Australian-led RV Investigator voyage to Ross Sea (early 2019)	Cruise report		
	New Zealand-led RV Tangaroa voyage to Ross Sea (early 2019)	Cruise report		
	German-led RV Polarstern voyage to Scotia Sea (early 2019)	Cruise report

Acoustics	Retrieval and redeployment of passive acoustic recorders	Report	Retrieval and redeployment of passive acoustic recorders	Report
	Completion of annotated library of acoustic detections	Report		

24.3 National cruises that require IWC oversight

The Committee welcomed plans for national research cruises to be conducted in the intersessional period of 2018-2019. Details on the cruise plans and cruise reports are presented in Annex Q, item 4.2.

Attention: SC, C-A

The Committee **recognises** the great value to its work provided by data from national cruises. The Committee:

- (1) **endorses** the proposed sighting survey plans for cruises to be conducted with IWC oversight in the southwestern Okhotsk Sea by Russia, and in the North Pacific and the Antarctic by Japan; and
- (2) **encourages** submission of abundance estimates from these studies the future.

24.4 Review of cruise reports from national programs with IWC oversight

The Committee considered a process to optimise the review of cruise reports from national research programs with IWC oversight. Details are given in Annex Q, item 2.7

Attention: SC, CG-R

The Committee **recognises** the value of information provided by national cruises with IWC oversight. The Committee noted that a process to optimise the review of national cruise reports is needed and

- (1) **recommends** contracting governments to submit reports of multi-year cruises with IWC oversight biennially, in years between Commission meetings (e.g., SC “A” years);
- (2) **agrees** that cruise reports will be summarised in a table;
- (3) **notes** that that in certain circumstances, cruise reports may require additional evaluation; and
- (4) **agrees** that the ‘Requirements and Guidelines for Conducting Surveys and Analysing Data within the Revised Management Scheme’ should be modified at next year’s meeting to accommodate procedural changes with respect to the submission and review of national cruise reports.

24.5 Work Plan

The Committee’s work plan for continuing the IWC-POWER programme in 2019 and 2020 is provided below in Table 29.

Table 29

Workplan for issues related to IWC-POWER.

Item	Intersessional 2018-19	SC68a	Intersessional 2019-20	SC68b
IWC-POWER Cruise	Conduct 2018 survey and planning meeting for the 2019 Cruise (Bering Sea)	Review cruise report, report from the planning meeting and new abundance estimates from IWC-POWER cruises.	Conduct 2019 survey and planning meeting for the 2020 Cruise	Review cruise report, report from the planning meeting and new abundance estimates from IWC-POWER cruises.

25. SCIENTIFIC COMMITTEE BUDGET FOR THE CURRENT BIENNUM

25.1 Status of previously funded research, workshop proposals, data processing and computing needs

25.1.1 Funded proposals for the current biennium 2017-2018

Table 30 summarises the status of the work funded by the Committee last year. The majority have been completed, but several remain ongoing. The projects all contributed considerably to the work of the Committee and the Committee thanked all of those involved.

25.1.2 Funded proposals in previous years still ongoing

A number of projects from previous years are still ongoing (see Table 30). These are all still of great value to the Committee and should be completed before the next meeting. Details of all ongoing projects can be found in SC/67B/01 Rev1.

25.1.3 Report on funds reallocations and contingencies for the Research Fund, Voluntary Fund for Small Cetaceans and SORP Voluntary Fund

SC/67b/01Rev1 provides information on the actual position against budget for the Research fund for 2017 as well as the position to 31st March for the 2018 financial year. The paper gives summary level and detailed information for the Research fund as well as the expected level of contingency available, which remains static at around 10% of the Research budget, or £32k. The document also provides details of the reallocations of budget amongst budget headings for 2017 and the 2018 year-to-date. Annex 1 gives a detailed position along with a status report for each budget line. Section 3 also provides details of voluntary funds which relate to Scientific Committee business – the Gray Whale Tagging Fund, the Small Cetaceans Fund and the SORP fund. For each there is an update of 2017 expenditure and 2018 to-date information along with details of commitments to future work in these funds.

Table 30

Summary of progress on proposals funded at SC67a

SC/67a no.	RP Title	Status
SC01	Invited Participants - SC/67b	Completed
IA01(67a)	Workshop for an in-depth assessment of North Pacific humpback whales	Ongoing (Annex F)
EM01	Two joint SC-CAMLR and IWC-SC Workshops	Ongoing (Annex L)
AWMP01	AWMP first intersessional Workshop and genetic work	Completed (SC/67b/Rep06)
AWMP02	AWMP second intersessional Workshop	Completed (SC/67b/Rep06)
CMP01(67a)	5 th Workshop on the rangewide review of population structure and status of North Pacific gray whales	Completed (SC/67b/Rep07rev1)
BRG04	Satellite tagging best practices Workshop	Ongoing, Item 21
WW01	Intersessional Workshop: data gaps and modelling requirements for assessing the impacts of whale watching	Completed (SC/67b/Rep03rev1)
RMP01	Intersessional Workshop: <i>Implementation Review</i> of North Pacific Bryde's whales	Completed (SC/67b/Rep02)
RMP01(67a)	Intersessional Workshop: <i>Implementation Review</i> for Western North Pacific minke whales	Completed (SC/67b/Rep05)
WW01(67a)	Review CC Strategic plan on whalewatching pre-meeting on intersessional workshop	Completed (Annex N)
E05/E01(67a)	Cumulative impacts - pre-meeting or intersessional meeting	Completed (Annex K)
SM01	Intersessional Workshop: resolving <i>Tursiops</i> taxonomy	Completed (SC/67b/SM18rev1)
SM01(67a)	Intersessional Workshop: boto mortality	Completed (SC/67b/Rep01)
SH07	Defining blue whale population boundaries and estimating associated historical catches, using catch data in the Southern Hemisphere and northern Indian Ocean	Completed (SC/67b/SH23)
AWMP02	AWMP developers fund	Completed (Annex D)
IA02	Assessment modelling for an in-depth assessment of North Pacific sei whales	Ongoing (SC/67b/IA01)
RMP02	Essential computing support to the Secretariat for RMP	Completed (Annex D)
Research		
BRG01	Aerial photographic survey of southern right whales on the South Africa Cape nursery ground	Completed (SC/67b/SH01)
BRG03	Passive acoustic monitoring of the eastern South Pacific southern right whales, improving CMP outputs	Completed (SC/67b/CMP18)
SH03a	Northern Indian Ocean humpback subspecies determination-genetics	Ongoing (Annex H)
IA03	IWC-POWER cruise	Completed (SC/67b/Rep04)
SH01(67a)	Coding for Australian blue whale photo catalogue	Ongoing (Annex PH)
E02(67a)	Mercury in cetaceans (requested by the Commission)	Ongoing (SC/67a/E08)
SH02	Southern Hemisphere Blue Whale Catalogue	Completed (SC/67a/PH04)
SH08	Development of a permanent blue whale song reference library	Completed (SC/67a/SH11Rev1)
HIM01	Ship Strike Database Coordinator	Completed (SC/67a/HIM11)
E01	Cetacean Diseases of Concern	Ongoing (Annex K)
E03(67a)	IWC strandings initiative	Ongoing (Annex K)
E04	SOCER (State of the Cetacean Environment Report)	Completed (SC/67a/E01)

The Committee received a brief report on the IWC-SORP Research Fund. Following an open, competitive Call for Proposals (26 July to 17 August 2016) a total of £144,058 GBP was allocated from the IWC-SORP Research Fund to 10 research projects, ahead of the 2016-2017 austral summer survey season. Progress on these projects is detailed in SC/67b/SH18.

The Committee also noted that since SC67a, substantial vessel time has also been secured by IWC-SORP researchers for the 2019 and 2020 austral field seasons.

Attention: C, F&A, S

A full report on the new Call for Proposals, opened in September 2017 and closed in January 2018, was also received. A total of 19 proposals were received and evaluated by the Assessment Panel under the coordination of the Chair of the Scientific Committee. The Committee thanks Fortuna for convening the Assessment Panel and expressed its gratitude to the Panel members who all provided valuable and thoughtful input into the assessment process. The Committee welcomes the outcome of the Assessment Group and agrees with the allocation of a total of £493,544 GBP from the IWC-SORP Fund to 15 projects (Table 31).

The Committee agrees on these recommended allocations and requests the Secretariat to submit them to the Finance and Administration Committee, as soon as feasible, for its consideration. Should the Commission endorse these financial recommendations, the Committee requests the Secretariat to inform successful and unsuccessful proponent immediately after the next Commission's meeting.

Table 31
List of the funding allocations by project recommended by the IWC-SORP Assessment Panel

ID	Chief Investigator	Title	Requested amount (£)	Recommended amount (£)	Level of funding (Partial/Full)
1	Baker & Steel	Is migratory connectivity of humpback whales in the Central and Eastern South Pacific changing? A decadal comparison by DNA profiling	27,598	26,375 (deducted in house instrument expenses)	P
2	Charrassin	Application of satellite telemetry data to better understand the breeding strategies of humpback whales in the Southern Hemisphere	21,200	21,200	F
3	Branch	Modelling somatic growth and sex ratios to predict population-level impacts of whaling on Antarctic blue whales	32,594	32,594	F
4	Friedlaender & Constantine	Pregnancy rates in Southern Ocean humpback whales: implications for population recovery and health across multiple populations	29,334	19,984 (equipment deducted and some analytical costs)	P
5	Herr	Recovery status and ecology of Southern Hemisphere fin whales (<i>Balaenoptera physalus</i>)	82,300	81,900 (equipment deducted)	P
6	Friedlaender & Constantine	A circumpolar analysis of foraging behaviour of baleen whales in Antarctica: Using state-space models to quantify the influence of oceanographic regimes on behaviour and movement patterns	34,711	34,711	F
7	Buchan & Miller	A standardized analytical framework for robustly detecting trends in passive acoustic data: A long-term, circumpolar comparison of call-densities of Antarctic blue and fin whales	43,369	41,369 (publication costs)	P
8	Lang & Archer	Inferring the demographic history of blue and fin whales in the Antarctic using mitogenomic sequences generated from historical baleen	22,710	22,710	F
9	Zerbini & Clapham	Assessing blubber thickness to inform satellite tag development and deployment on Southern Ocean whales	22,646	22,426 (supply costs deducted)	P
10	Širović & Stafford	Acoustic ecology of foraging Antarctic blue whales in the vicinity of Antarctic krill studied during AAD interdisciplinary voyage aboard the <i>RV Investigator</i>	34,183	30,107 (airfares deducted)	P
12	Kelly & Maire	Development of statistical and technical methods to support the use of long-range UAVs to assess and monitor cetacean populations in the Southern Ocean	30,576	30,576	F
13	Reisinger & de Bruyn	An integrative assessment of the ecology and connectivity of killer whale populations in the southern Atlantic and Indian Oceans	33,650	33,650	F
14	Bengston Nash	Implementation of humpback whales for Antarctic sea-ice ecosystem monitoring; Inter-program methodology transfer for effective circumpolar surveillance	91,202	51,555 (equipment costs deducted)	P
17	Carroll, Torres, Graham	Circumpolar foraging ecology of southern right whales: past and present	21,290	21,290	F
18	Infíguez Bessega	Habitat use, seasonality and population structure of baleen and toothed whales in the Scotia sea and the western Antarctic Peninsula using visual and passive acoustic methods and genetics	26,579	23,097 (equipment costs reduced, communication & network costs deducted)	P
TOTAL			693,195	493,544	

Finally, the Committee was informed that the next Call should open prior to SC/68b (i.e. late 2019/early 2020) in readiness for IWC68 (2020). This timing would allow strategic prioritisation of the research toward which the Call is directed in order to meet IWC-SORP and IWC/SC priorities; allow knowledge gaps to be identified; and allow the IWC-SORP SSC to seek additional funding to augment the funds available in the IWC-SORP Research Fund.

26. COMMITTEE PRIORITIES AND INITIAL AGENDA FOR THE BIENNium 2019-2020

The Committee's priorities and work plan by broad subject matter are provided in Tables under the relevant agenda items.

The Committee agrees that the Chair, Vice-Chair and Head of Science, in co-operation with the Convenors, should examine the individual work plans by topic and develop an overall Committee biennial workplan and priorities taking into account the overall work load, meeting venues and efficiency. This should be submitted to the Commission meeting as an Annex to their two-year overview.

27. SCIENTIFIC COMMITTEE BUDGET FOR THE BIENNium 2019-2020

27.2 Budget for the next biennium

As in 2016, the Committee has developed a two-year budget, based on the proposed work plans. The process given in Annex S IWC, (2016) was applied, with extensive discussion carried out in each of the sub-committees and Working Groups to establish priorities among the presented proposals. Funding was not approved for one project (*Gulf of Penas, Southern right whales*) as further information is needed before funding can be agreed. The savings from 2018, some self-reductions and adjustments between years allowed inclusion of all funding proposals for 2019 and 2020 in the new budget of £315,800 per year.

Table 32
Workshop proposals agreed during this meeting (TBD: to be decided).

Title	Relevance	Date	Venue
Western gray whale update of CMP and conservation issues within modelling framework	CMP		
Marine debris	E	December 2019	Barcelona, Spain
Noise pre-meeting	E	Pre-meeting 2020	TBD
Cetaceans & ecosystem functioning: a gap analysis*	EM	TBD	TBD
Joint IWC-IUCN workshop to evaluate how the data and process used to identify Important Marine Mammal Areas (IMMAs) can assist the IWC to identify areas of high risk for ship strike	HIM	April 2019	Greece
Comprehensive Assessment of North Pacific humpback whales	NH		
Comparative biology, health, status & future of NA right whales	NH	Late 2019	Boston, USA
<i>Implementation Review: North Pacific minke whales</i>	RMP		
Catch series: Southern right whales	SH	Pre-meeting 2020	TBD
Intersessional workshop of the task team on South Asian River dolphins	SM	Feb 2019	TBD
Guiana dolphin pre-assessment	SM	October 2019	Curitiba, Brazil
Modelling whale watching impacts (MAWI)	WW	December 2019	
POWER planning meeting	ASI	Oct 2018	Tokyo, Japan
Wildmeat workshop	SM	Late 2019/early 2020	Africa
Tagging best practices	ASI	Jun 2018	Seattle, USA

* Japan referred to its statement on the adoption of the Agenda (Annex Z) and considered that several of the items for the proposed workshop (Item 16.4.4) are outside the competence of IWC. Therefore, it cannot support the proposed workshop or associated funding from the Committee's budget.

Table 33 shows the Committee budget requests for the biennium for each of the proposed priority activities.

27.2.1 Invited Participants

INVITED PARTICIPANTS

Invited participants (IPs) are a vital component of the working of the IWC's Scientific Committee. IPs contribute in many ways including as sub-committees and Working Groups Convenors, co-Convenors and rapporteurs, subject area experts and Convenors of intersessional groups. All sub-committees and Working Groups benefit from this budget item. This year under this budget item, 62 scientists from Australia, Argentina, Belgium, Brazil, Canada, Chile, China, Colombia, France, Germany, Italy, Japan, Mexico, Netherlands, Norway, Oman, Peru, Slovenia, South Africa, Spain, UK, USA were supported.

27.2.2 Workshops

RP16 WESTERN GRAY WHALE UPDATE OF CMP AND CONSERVATION ISSUES WITHIN MODELLING FRAMEWORK

The CMP is over 10 years old and requires updating. Initial work has been undertaken but the results of the rangewide workshop need to be incorporated and conservation-related questions need to be developed that can be addressed within the new population modelling framework developed as a result of the Committee's work. This is primarily related to the CMP and AWP groups, however, it is also of importance to the work of IA and ASI in terms of precedents for future assessments and the work of HIM in terms of examining scenarios that take into account bycatch and the uncertainty associated with estimating it.

RP06 MARINE DEBRIS WORKSHOP

There remains an urgent need to better understand and address the threats posed by marine debris to cetaceans. The most effective way to do this, building on earlier work by the IWC and taking into account the greatly expanded interest in this topic by many other international bodies, is to hold a workshop. It is proposed that the workshop is held in Barcelona in December 2019 just before the World Conference on Marine Mammalogy (the joint meeting of the SMM and ECS).

RP05 NOISE PRE-MEETING

The sub-committee on Environmental Concerns will address Anthropogenic Noise as a focus topic during the Scientific Committee meeting in 2020. A pre-meeting workshop is proposed for SC68b, to address emerging issues related to the management of underwater noise and its impacts on marine species.

RP08 CETACEANS & ECOSYSTEM FUNCTIONING: A GAP ANALYSIS

Experts on the role and impact of cetaceans on ecosystem functioning will participate in a workshop/pre-meeting to discuss the current state of knowledge on the ecosystem functioning provided by cetaceans as requested by the Commission in Resolution 2016-3. This Resolution directed 'the Scientific Committee to further incorporate the contribution made by live cetaceans to ecosystem functioning into [its] work' and asked 'the Scientific Committee to screen the existing research studies on the contribution of cetaceans to ecosystem functioning, to develop a gap analysis regarding research and to develop a plan for remaining research needs'.

RP17 JOINT IWC-IUCN WORKSHOP TO EVALUATE HOW THE DATA AND PROCESS USED TO IDENTIFY IMPORTANT MARINE MAMMAL AREAS (IMMAs) CAN ASSIST THE IWC TO IDENTIFY AREAS OF HIGH RISK FOR SHIP STRIKE

The identification of 'high risk areas' for ship strikes of cetaceans is a key step toward establishing mitigation actions, through scheduling, re-routing or speed reduction. IUCN's proposed initiative to identify Important Marine Mammal Areas (IMMAs), would likely assist this effort. The SC has encouraged cooperation with the IUCN Task Force on this. The IUCN TF has completed three regional IMMA workshops, including the Mediterranean Sea. This proposed joint workshop will focus on identifying overlap between shipping and the IMMAs identified in the Mediterranean Sea.

Table 33
Summary of budget requests for the 2019-20 period. For explanation and details of each project see text.

RP no.	Title	Sub-committee/ working group	2019 (£)	2020 (£)

Notes: ¹Budget was reduced from £22,200, ²£20,300 was the expected financial need for 2019 but savings from 2018 allowed for the reduced budget of £0; ³£11,400 was the expected financial need for 2019 but savings from 2018 allowed for the reduced budget of £1,000; ⁴£15,000 was the expected financial need for 2019 but savings from 2018 allowed for the reduced budget of £13,000. ⁵Budget was reduced from £8,958, ⁶£20,000 was the expected financial need for 2020 but financial savings for 2018 allowed for the reduced budget of £17,000, ⁷£32,500 was the expected need for 2019 but financial savings from 2017 allowed for the reduced budget of £22,500, ⁸£32,500 was the expected need for 2020 but financial savings from 2018 allowed for the reduced budget of £22,500, ⁹The requested budget was £15,000 but further information is required before funding can be considered. The project will be re-evaluated at the 2019 SC meeting, ¹⁰£6,185 was the expected financial need for 2019 but financial savings from 2018 allowed for the reduced budget of £0, ¹¹budget was reduced from £10,000, ¹²budget was reduced from £10,000, ¹³funding of approximately £7,280 may be requested for 2020 next year depending on progress, ¹⁴£4,000 was the expected financial need for 2019 but savings from 2018 allowed for the reduced budget of £0, ¹⁵budget was reduced from £4,000, ¹⁶budget was reduced from £4,000.

27.2.1 Invited Participants

INVITED PARTICIPANTS

Invited participants (IPs) are a vital component of the working of the IWC's Scientific Committee. IPs contribute in many ways including as sub-committees and Working Groups Convenors, co-Convenors and rapporteurs, subject area experts and Convenors of intersessional groups. All sub-committees and Working Groups benefit from this budget item. This year under this budget item, 62 scientists from Australia, Argentina, Belgium, Brazil, Canada, Chile, China, Colombia, France, Germany, Italy, Japan, Mexico, Netherlands, Norway, Oman, Peru, Slovenia, South Africa, Spain, UK, USA were supported.

RP19 COMPREHENSIVE ASSESSMENT OF NORTH PACIFIC HUMPBACK WHALES

At SC67a, following discussion of the results of an assessment workshop held in April 2017, a Steering Group was established to facilitate a second North Pacific humpback whale assessment workshop, and to coordinate work required for this meeting. This meeting was not held prior to SC67b and the workshop is now planned for prior to the 2019 meeting of the Scientific Committee, with a view to completing or significantly advancing the assessment.

RP37 BALAENID WORKSHOP: BIOLOGY, HEALTH, STATUS

The North Atlantic right whale's population rate of increase is much lower than that of all other well-studied balaenid populations. This workshop will compare reproductive biology, health and status of North Atlantic right whales with those of other balaenid populations with the goal of determining their potential for growth and assessing the role of anthropogenic mortality as a driver of current population decline. Possible causes of the NARW's lower reproductive rate need reassessment include: sub-lethal effects of entanglements; environmental contaminants or marine biotoxins; inadequate prey base; stress from noise; genetic factors; and infectious diseases. This review will also help understanding of population changes for other balaenid populations.

RP21 IMPLEMENTATION REVIEW: NORTH PACIFIC MINKE WHALES

These workshops are essential in order for the Committee to conduct a full *Implementation Review* for Western North Pacific common minke whales following the Committee's Requirements and Guidelines. Conducting *Implementation Reviews* are a required activity under the RMP.

RP29 CATCH SERIES: SOUTHERN RIGHT WHALES

A new review of available catch data for measuring regional takes of southern right whales is overdue and the availability of new sources suggests that it is timely to do this. The expected outcome of this workshop is updated regional estimates of southern right whale catches, which can be used to conduct regional assessments of southern right whale past exploitation and develop population trajectories to measure past abundance and current recovery levels.

RP25 INTERSESSIONAL MEETING OF THE TASK TEAM ON SOUTH ASIAN RIVER DOLPHINS

The South Asian river dolphin, *Platanista gangetica*, is listed as an endangered cetacean species by the IUCN Red List assessment. Across its range, in the countries of India, Pakistan, Nepal, and Bangladesh, the species remains highly threatened by a range of anthropogenic activities at multiple scales. These range from localised threats caused by hunting, fisheries bycatch, or local disturbances as well as from large-scale alterations of the rivers by dams, barrages, waterways and river-linking schemes. In particular, large-scale and rapidly accelerating water development in the Indo-Ganges-Brahmaputra floodplains make the outlook for the South Asian river dolphin conservation grim. In recognition of this situation, the Scientific Committee has established a Task Team for the species and the team of experts will meet in person and discuss how to go forward.

RP26 GUIANA DOLPHIN PRE-ASSESSMENT (*SOTALIA GUIANENSIS*)

An intersessional workshop will assess the geographic extent of Guiana dolphin threats and conservation measures needed in both national and international contexts. The outcomes of the workshop shall include: (1) a Comprehensive Assessment of the status of Guiana dolphins; (2) recommendations to potentially improve management actions and the monitoring efforts associated with the current conservation plans of actions; and (3) a consolidated report to be presented to the SC at next year's meeting for review.

RP27 MODELLING WHALE WATCHING IMPACTS (MAWI)

There is little research on the potential mid- and long-term impacts of whale watching on cetacean populations. This is due to the complexity of the required modelling approaches, lack of clarity regarding the data needed to inform them, and the need to identify locations suitable for data collection. Without addressing these issues understanding the potential mid- and long-term impacts of whale watching is not possible. The workshop will bring together modellers and field researchers to achieve the following outcomes: (1) identify existing modelling approaches that could be used to understand the potential mid- and long-term impacts of whale watching, and determine whether new approaches are required; (2) determine which data currently being collected are suitable for answering questions regarding the mid- and long-term impacts of whale watching, and what new data are required; and (3) determine the feasibility of data collection, and identify locations where this has already been done or could be achieved.

27.2.3 Modelling/computing

RP20 ASSESSMENT MODELING FOR AN IN-DEPTH ASSESSMENT-NORTH PACIFIC SEI WHALES

The IA sub-committee is currently conducting a Comprehensive Assessment for North Pacific sei whales. This involves evaluating the status of a population using a population dynamics model that is specific to the biological parameters and movement behaviour of that particular population and is fitted to monitoring data. During the intersessional periods after

the 2018 SC meeting and possibly also after 2019 SC meeting, it is expected that population dynamics models will be finalised and run using the existing data. This will result in an assessment of the status of the population.

RP22 DEVELOP AN AGE-STRUCTURED EMULATOR FOR THE INDIVIDUAL-BASED ENERGETICS MODEL (IBEM)

An IBEM provides an alternative population dynamics model to the usual cohort models, particularly because density dependence in births, growth and age-specific mortality are emergent properties of a species in a given environment (which can be stochastic). The IBEM is computationally infeasible for conducting *ISTs*; the proposal is to develop a computationally efficient cohort model (emulator) which uses demographic parameters and their covariances generated using the IBEM.

RP23 ESSENTIAL COMPUTING SUPPORT TO THE SECRETARIAT

Regular *Implementation Reviews* are required under the RMP and AWMP. Computing support is also required for Comprehensive and in-depth assessments. The Committee is currently about to undertake an *Implementation Review* for the North Pacific common minke whales, and more will follow. The Committee has developed a complex trials structure for *Implementation Reviews*. A key task in this process is to develop and validate the code for the simulation trials that are the core component of this process. Experience has shown that the Secretariat staff alone cannot handle this complete process themselves, so computing support is needed.

RP36 SIMULATING LINE TRANSECT DATA TO INVESTIGATE ROBUSTNESS OF NOVEL ANALYSIS METHODS

The IWC SC has already invested time and money in developing simulated line transect data to evaluate the robustness of the Norwegian minke whale and Antarctic minke whale survey data. This project will update the old code for the simulator to make it more user-friendly so that it can be made available to all SC members and to produce some standard data sets in accordance to the specifications of the ASI sub-committee.

27.2.4 Databases/catalogues

RP01 IWC-POWER CRUISE

The Committee has strongly advocated the development of an international medium- to long-term research programme involving sighting surveys to provide information for assessment, conservation and management of cetaceans in the North Pacific, including areas that have not been surveyed for decades. This is one of the most important international collaborations undertaken by the IWC and the cost to the IWC is minimal given the generous contribution of a vessel by Japan and acoustic equipment by the USA. Committee objectives have been developed for the overall plan and requested funding will allow for the continuing work of the initial phase and progress on developing the medium-term phase. The IWC contribution is for: (1) IWC researchers and equipment; (2) to allow the Committee's Technical Advisory Group to meet to review the multi-year results thus far and develop the plans for the next phase of POWER based on the results obtained from Phase I; and (3) to enable analyses to be completed prior to the 2020 Annual Meeting.

RP11 ABUNDANCE ESTIMATES OF THE FRANCISCANA DOLPHIN IN BUENOS AIRES PROVINCE, ARGENTINA

Abundance estimates of franciscanas will be based on a series of aerial surveys along the coast of Buenos Aires Province, with the same survey design of surveys carried out in 2003 and 2004 (Crespo *et al.*, 2010). The new estimate will allow comparing density values with those obtained in the previous surveys. This item represents only one third of the funds required for the project, with the remainder being provided by the Government of Argentina.

RP09 GULF OF PENAS, SOUTHERN RIGHT WHALES

Eastern South Pacific (ESP) Southern right whales (SRW) are classified as critically endangered as there are no more than 50 SRW in this population and there is no information on the ESP SRW breeding and feeding grounds. Gulf of Penas is one of the most remote and exposed areas in Chile, with limited access and wild weather that have prevented its exploration. The largest baleen whale mass mortality of almost 400 sei whales occurred in this area and almost remained unnoticed. Recently, a local living nearby the Gulf of Penas recorded the presence of SRWs, including several calves. The Gulf might be the unknown breeding ground of the ESP SRW. This area will be explored during the austral winter breeding season with a group of researchers and government officers to confirm this finding and if so, start immediately working towards the protection and management of the species and the area.

RP10 POPULATION DYNAMICS OF SOUTHERN RIGHT WHALES AT PENÍNSULA VALDÉS, ARGENTINA: THE INFLUENCE OF KELP GULL LESIONS ON THE HEALTH, CHANGES IN INCREASE AND MORTALITY RATES IN THE CONTEXT OF A DENSITY-DEPENDENT PROCESS

The recent mortality of southern right whales at Península Valdés, Argentina is the highest ever recorded for the species. Understanding the causes is critical to propose management and mitigation actions. Preliminary results from glucocorticoids in baleen from stranded calves show that stress from injuries due to Kelp Gull attacks negatively affects their physiological homeostasis, potentially leading to death. Also, aerial counts show an important reduction in population rate of increase as a whole (from 7% in the past to 0.5% at present), and changes in distribution (mainly of adults) and density along the Argentinian coast.

RP12 PASSIVE ACOUSTIC MONITORING OF THE EASTERN SOUTH PACIFIC SOUTHERN RIGHT WHALE

The Eastern South Pacific southern right whale population is Critically Endangered and in 2012 the IWC adopted a Conservation Management Plan (CMP). Over the years, few opportunistic sightings have been recorded and no breeding area has yet been identified. Until a breeding ground is found many CMP priority actions cannot be implemented. Thus, in 2016 the IWC Scientific Committee decided to support this passive acoustic monitoring (PAM) project to facilitate the identification of potential breeding areas along the coast of Chile and Peru. This project seeks to obtain temporal coverage over a complete annual cycle and spatial coverage depending on the number of sites. The PAM project is likely the most

cost-effective way to investigate the seasonal and temporal distribution of southern right whales along the coast of Chile and Peru. The information will be crucial to identify aggregation areas and facilitate the implementation of CMP for this population.

RP13 SAMPLE THE HOLOTYPE SPECIMEN OF *MEGAPTERA INDICA* (GERVAIS, 1883) AT THE MUSÉUM NATIONAL D'HISTOIRE NATURELLE (PARIS)

Several lines of evidence suggest that humpback whales in the Arabian Sea/Northern Indian Ocean comprise a discrete, isolated and non-migratory population that merits a taxonomic revision. Genetic analyses of available samples are now underway in order to determine whether sub-species/species designation is merited. The resultant nomenclature will necessarily draw on a description of the type specimen of *Megaptera indica*, which is held at the Muséum National d'Histoire Naturelle in Paris. This work will develop an approach for examining and sampling this specimen so that the taxonomy of Arabian Sea humpback whales can be accurately defined, better informing regional conservation efforts, highly relevant to the IWC's stated interest in the establishment of a Conservation Management Plan for Arabian Sea humpback whales.

RP14 ASSESSING ISOLATION OF THE ARABIAN SEA HUMPBACK WHALE POPULATION AND CONTINUITY ACROSS THE ARABIAN SEA THROUGH GEOGRAPHIC VARIATION IN SONG

A study of geographic variation in humpback whale song indicates that the Arabian Sea song from Oman is distinct from the Southwest Indian Ocean (SWIO) song, and evidence from a small Indian sample suggesting continuity in song between the western and eastern Arabian Sea. This work will be followed up on with a detailed comparison of song across the Arabian Sea and continued assessment of song differences with the SWIO: The project will (1) assess the connectivity of Arabian Sea humpback whales from Oman to India by comparing existing samples of song between the two regions from several different years; and (2) assess and re-examine the differences in song exhibited between Oman and the SWIO with more recent data, particularly in light of evidence that SWIO singers were found off Oman during the Boreal summer of 2012.

RP15 A QUANTITATIVE ASSESSMENT OF THREATS TO ARABIAN SEA HUMPBACK WHALES USING EXISTING PHOTOGRAPHIC AND UAV DATA

The research will assess the prevalence of anthropogenic and natural threats to Arabian Sea humpback whales through a robust and quantitative assessment of available photographic data. These data include the entire Oman photo-ID catalogue, imagery recently acquired using UAVs (drones) and images provided by third parties. The latter include several images from elsewhere in the populations range. The project will provide an assessment of the relative prevalence of a suite of indices typically associated with major threats (fisheries entanglements, ship-strikes, other scars) as well as scars associated with natural sources (barnacles, cyamids, *Penella* sp., killer whales). Project outcomes will include assessment of the risks posed by each threat, as well as the development of a set of metrics with which further changes can be monitored. Project results will be reported to the IWC SC in 2019 and will contribute to the development of a draft Conservation Management Plan for this population.

RP24 COLLABORATIVE ANALYSIS OF WNP MINKE WHALE STOCK STRUCTURE USING JAPANESE MICROSATELLITE DNA DATABASE AND SPATIALLY EXPLICIT POPULATION STRUCTURE ANALYSES.

This item will help address the recommended 'analysis 2' from the report of the workshop on Western North Pacific common minke whale stock structure (SC/67b/Rep05) in support of the next intersessional meeting on WNP common minke whale stock structure. This specific aspect of the work will apply spatially explicit population structure analyses that provide greater power than the program STRUCTURE together with geographic context. The data will be analysed as a total dataset (not based on any assignment in STRUCTURE), but also include temporal subdivision to assess possible seasonal changes in patterns of connectivity. The latter aspect may be critical to understanding the true pattern of structure, but it will also be the most time-consuming, requiring extensive replication of the analyses. The results of these analyses will provide an assessment of structure in the context of biogeography using methods that have considerably more power than the program STRUCTURE and using an approach that will consider temporal patterns of movement.

RP28 UPDATED CATCH SERIES AND ASSESSMENTS OF FOUR PYGMY BLUE WHALE POPULATIONS

The SH sub-committee is conducting in-depth assessments of populations of Southern Hemisphere blue whales. Assessments have previously been conducted for two of the six populations (Antarctic blue whales, and Chilean blue whales), but not for the four pygmy blue whale populations addressed by this research. This project will provide crucial catch separation data and associated uncertainty needed to conduct stock assessments and provide the first stock assessments for each of the four populations. Such data are critical inputs for the assessments planned by the SC.

RP30 MULTI-OCEAN ANALYSIS OF SOUTHERN RIGHT WHALE DEMOGRAPHIC PARAMETERS AND ENVIRONMENTAL CORRELATES

This study aims to compare population demographics of southern right whales in Southern Hemisphere wintering grounds and investigate correlations between reproductive success and abundance trends, and environmental variables. This study is a component of the proposed SORP project - The right sentinel for climate change: linking foraging ground variability to population recovery in the southern right whale.

RP 31 ANALYSIS OF FIN WHALE SONG VARIABILITY ACROSS SOUTHERN HEMISPHERE

Fin whale songs consist of short pulses repeated at regular interpulse intervals (IPIs). These songs have been suggested as a tool to distinguish populations. Features that have been used for fin whale song separation include: spectral structure of individual pulses; their patterning; the IPIs; and presence of a higher frequency component of the pulses. Based on this higher frequency component, there appear to be two fin whale song types in the Southern Ocean. We propose to use a

combination of song feature measurements to identify whether fin whale songs in the Southern Hemisphere could be indicative of population structure. Data to be used include recorders deployed in the Western Antarctic Peninsula, Weddell Sea, and Eastern Antarctica (Kerguelen and Casey) from 2014-16. Additional SH lower-latitude recordings are available in southeastern Pacific and South Indian Ocean. Overall, the analysis will enable a comprehensive review of fin whale song variability across the SH.

RP34 PHOTO-IDENTIFICATION INFORMATION PLACARDS FOR NATURALISTS AND CITIZEN SCIENTISTS

Pre-cruise training and reference placards describing examples of photo-identification subjects (large whales) will be developed for distribution to the tourist vessel industry in the South Georgia and Antarctic Peninsula region. Information will include primary ID features used for seven species likely to be encountered; right, blue, sei, fin, humpback, sperm and killer whales (key species). A Powerpoint presentation will be developed for distribution to naturalists working on tourist vessels, to orient them and their clients to the basics of whale identification photography. Minimal training is required for a considerable improvement to the quality of identification photographs that are collected by naturalists and citizen scientists and ultimately provided to the established photo-ID catalogues from the region. A formal collaboration with the global photo-ID platform, HappyWhale will be established.

RP07 IWC STRANDINGS INITIATIVE – EMERGENCY RESPONSE AND INVESTIGATIONS

Over the next two years, the Emergency Response and Investigations fund will support response, collection of data to determine the cause(s) or contributing factors for the event and/or to fill critical data gaps identified by the SC or Commission. The Initiative will be evaluated annually and policies and procedures adapted according to feedback from responses and through Steering Group/Expert Panel advice.

27.2.5 Databases and catalogues

RP18 SHIP STRIKE DATABASE COORDINATOR

The ongoing development of the IWC ship strike database requires data gathering, communication with potential data providers and data/database management. This project will provide support for expanding and maintaining the database.

RP33 ANTARCTIC BLUE WHALE CATALOGUE: COMPARISON OF NEW PHOTOGRAPHS FROM 2014-2020

In year one (2019) this project will compare the identification photographs of an estimated 45 individual Antarctic blue whales collected during ICR cruises 2014-17, to the Antarctic Blue Whale Catalogue. These identifications would increase the size of the catalogue (458 individuals) by almost 10%. In year two (2020) additional photos representing approximately 12 IDs are expected from collaborating scientists and citizen scientists that will be compared to the catalogue. The expected outcome is an expanded dataset that may improve estimates of population abundance and reveal new information on movement patterns.

RP32 SOUTHERN HEMISPHERE BLUE WHALE PHOTO CATALOGUE

The Southern Hemisphere Blue Whale Catalogue (SHBWC) is an international collaborative effort to facilitate cross-regional comparison of blue whale photo-identifications catalogues. To date more than 1,500 individual blue whales have been contributed to the SHBWC from researchers groups working on areas off Antarctica, Chile, Peru, Ecuador-Galapagos, Eastern Tropical Pacific, Australia, Timor Leste, New Zealand, Madagascar and Sri Lanka. Therefore, the SHBWC has become the largest repository of Southern Hemisphere blue whale photo-identifications. Results of comparisons among different regions will improve the understanding of basic questions relating to blue whale populations in the Southern Hemisphere such as defining population boundaries, migratory routes, visual health assessments, and to model abundance estimates. The results will contribute primarily to the IWC Southern Hemisphere blue whale assessments.

RP38 DATABASE MANAGEMENT

The IWC Secretariat hosts several databases for the SC. These have annual service costs associated with them including, web/database servers, storage, backups, software licences and other associated infrastructure or costs.

27.5.6 Reports

RP03 MERCURY IN CETACEANS: BIOGEOCHEMICAL CYCLING, TOXICOLOGICAL IMPACTS

In response to the Commission resolution on mercury, the objective of the work is to complete the global review of mercury in cetaceans, resulting in the documentation and mapping of decadal trends. The Scientific Committee will also invite experts in mercury in the environment and its cycling and in mercury and selenium cetacean toxicology to participate to provide further detail and interpretation of the current status and potential impact of mercury on cetacean populations at an ocean basin scale.

RP04 PRODUCTION OF ANNUAL STATE OF THE CETACEAN ENVIRONMENT REPORT (SOCER) FOR THE SCIENTIFIC COMMITTEE AND COMMISSION (2019 AND 2020)

SOCER is a long-standing effort to provide information to Commissioners and Committee members on key current global developments that are affecting the cetacean environment. Focus will be on the Atlantic Ocean (2019) and the Pacific Ocean (2020). It will, in both years, also present key current global developments that are affecting the cetacean environment. It will also contain a glossary of technical terms used and species names. A 5-year compendium spanning all regions is also being produced.

RP02 AMENDMENT OF THE RMP GUIDELINES TO INCORPORATE SPATIAL MODELLING APPROACHES TO ESTIMATE ABUNDANCE

The 'Requirements and Guidelines for Conducting Surveys and Analysing Data within the Revised Management Scheme', referred to as the 'RMP Guidelines' (IWC, 2012) constitutes a document prepared by the Scientific Committee to state the requirements and to guide the collection and analysis of survey data to compute abundance estimates for use in the Revised Management Procedure (RMP). Currently this document provides detailed guidance for developing estimates using design-based line transect shipboard and aerial surveys. Amendments are required to consider other methods, for example, model-based analysis of survey data and mark-recapture models. This project will update the RMP Guidelines as required by the Scientific Committee. This update will be completed in consultation with the project's steering committee and presented for consideration of the SC by SC68b. The expected outcome is a new, revised document of with the 'RMP Guidelines'.

27.5.7 General items

IMPLEMENTATION: RESOLUTIONS AND INSTRUCTIONS FROM COMMISSION & FOLLOW UP FROM PREVIOUS YEARS' RECOMMENDATIONS

This line is required to accommodate additional work requested by the Commission at IWC67 and work generated by meetings, workshops and projects funded and concluded in the first year (2019). This line can also accommodate new project proposals generated during the 2019 Scientific Committee meeting.

28. WORKING METHODS OF THE COMMITTEE

28.1 Rules of Procedure of the Scientific Committee

Attention: C, S

*As per usual practice in the last biennium the Committee has been reviewing its working methods to improve transparency and align its processes with the biennial pace of the Commission. These changes and a number of changes that were made in previous years and approved by the Commission (i.e. SORP Voluntary Fund, new process to allocate and manage the Research Fund and the Small Cetacean Voluntary Fund Rules of Procedure) require a number of adjustments and additions to the Commission Rules of Procedure, Financial Regulations and Scientific Committee Rules of Procedure. The Committee **agrees** to submit all proposed amendments to the Commission for its consideration (Annex W).*

*The updated Rules also refer to the online 'Scientific Committee Handbook' that has been updated at this meeting. The Committee **requests** the Secretariat to post the updated version online as soon as feasible. The Committee also **agrees** to that a pdf version of the Handbook be made available as a document for the Commission meeting.*

28.2 Biennial reporting and related matters

At its 2015 meeting, the Joint Conservation Committee and Scientific Committee Working Group (Joint CC/SC WG) agreed to undertake a collation and analysis of conservation-relevant recommendations from the Scientific Committee and organise these recommendations into key issues/areas highlighting those that feature regularly, including the creation of a pilot database. Double, Convenor of the Global Databases and Repositories Steering Group (GDR), presented an update on the development of this database. The Scientific Committee is fully engaged in this process and, this year, a standing agenda item was added to all sub-committee agendas to ensure a regular, more formal review of progress in delivering recommendations than was the case in the past.

Attention: SC, CC

*The Committee **welcomes** the development of the IWC Database of Recommendations, noting that this tool will give recommendations more prominence and improve the ability to measure progress. The Committee **agrees** to:*

- (1) continue to improve its standardised way to present recommendations to include core information¹³ to facilitate input into the database; and*
- (2) to work closely with the Secretariat to assist with the overall process of data entry.*

28.3 Additional proposals for revisions to 'Annex P'

The Committee continued this year the work begun last year to update Annex P in response to Commission Resolution 2016-2 and recommendations by previous Expert Panels.

Attention: C-R, SC,

*The Committee **recommends** the revisions to the previous Annex P reported in Annex P in response to Resolution 2016-2 and recommendations made by Expert.*

¹³ IWC/MAY18/CCSC/01

28.4 Succession plan for key Scientific Committee experts

Last year, the Committee had identified the need to consider ‘succession planning’ for key participants, particularly in relation to the *Implementation Reviews* and assessment processes. Informal discussions continued informally during the intersessional period and invitations were issued to three modellers to evaluate their interest in becoming active members of the IWC Scientific Committee, but only one could attend. Concern regarding succession planning of these other key positions on the Committee still remains and an intersessional group has been re-established to look at this and report back to the Committee next year (Annex Y).

The Committee also refers to its discussion related to a Deputy Head of Science in its review of the governance report (see Item 28.6.2).

28.5 Update on Data Availability requests

Suydam provided a summary of requests received under the Data Availability Agreement shown in Table 34.

Table 34

Summary of requests under the Data Availability Agreement.

Date	Requested by	Objective/Subject	Outcome
June 2015	de la Mare (Australia) – Procedure B	(a) Consistent with recent advice of the Scientific Committee with particular respect to minke whale nutritive condition analyses, to develop a set of models that best capture the Committee’s previous recommendations, taking into account the structure of the underlying processes giving rise to the data; and (b) To provide analyses relevant to the determination of sample sizes for detecting specified trends in the age at sexual maturity (ASM).	SC/66B/EM/02, SC/67A/EM/01, SC/67A/EM/02, SC/67A/EM/03, SC/67A/EM/04, SC/67A/EM/07, SC/67A/EM/08, SC/67B/EM/01 Rev1, SC/67B/EM/02, SC/67B/EM/03, SC/67B/EM/08, See EM Annexes, 2016 to 2018. Differing results between research groups about changes in body condition of Antarctic minke whales
January 2018	Baker (USA)	The intent of the request is to examine plausible stock hypotheses. Analyses will rely primarily on tests of Hardy-Weinberg expectations, exact tests of differentiation, randomized Chi-squared tests (contingency tables), Analyses of Molecular Variance (AMOVA), as well as mixed-stock analyses, clustering methods and kinship (parent offspring pairs), to investigate dispersal and differences in haplotype frequencies, genotypes and sex for various geographic and temporal strata.	On-going

28.6 Any other matters

28.6.1 Welfare Assessment Tool

Since our last discussion in 2015 on animal welfare related matters relevant to the Committee (IWC, 2016, p.86), Dr. Nicol (Professor of the Royal Veterinary College, London) developed a ‘Welfare Assessment Tool’ following the recommendations of the Workshop to ‘Develop Practical Guidance for the Handling of Cetacean Stranding Events’ (South Africa, 2016) on this matter. This year, the Committee received a report from Nicol on the latest phase of the development of such a tool, that is being developed to help assess non-hunting related threats in the context of the IWC’s Welfare Action Plan and in a joint project between the RVC and Humane Society International, supported by the UK Department for Environment, Food and Rural Affairs (Defra). The approach is based on application of the ‘five domains model’ (Beausoleil and Mellor, 2015; Mellor *et al.*, 2015) and two hypothetical case studies have been explored, one related to marine debris and the other to whale-watching.

Trial assessments were presented and the Scientific Committee was asked for assistance and advice in the development of real examples for consideration. The Committee welcomed the information provided and further discussions were held informally. The Tool was also considered by the Whale Watching Subcommittee (see Annex N) and will be presented for consideration by the Commission at the next meeting of the Working Group on Whale Killing Methods and Associated Welfare Issues.

28.6.2 Review of the IWC review report

The final report from the Governance Review was released on the 16th April 2018 (downloadable here: <https://archive.iwc.int/?r=6890>). The Independent Review Panel report represents the view of the three panellists, based on a survey, in-person interviews and analysis of documents. It represents only the first step of the Governance Review process. The Chair of the Operational Effectiveness Working Group of the Finance and Administration Committee asked the Scientific Committee to provide a voluntary feedback to the Commission on recommendations related to the Committee.

The Scientific Committee formed an *ad hoc* Working Group to develop an initial response, which was then discussed in Plenary. The initial WG membership was restricted to the Scientific Committee Chair and Vice Chair, all Heads of Delegations present at the meeting, sub-groups Convenors that are also delegates, and former Scientific Committee Chair present at the meeting. This subset represented the view of Committee members that, given their roles, had a strong knowledge on the current and past structure and procedures of the Committee. More delegates and invited participants joined the discussion in Plenary. The final version of this preliminary feedback, which has the support of all 32 delegations attending the meeting and additional members of the Scientific Committee is provided in Annex X.

The Scientific Committee organised its discussion and feedback on Review Panel's recommendations and comments around five mutually exclusive subject areas (pre-eminence of the Scientific Committee, IWC strategic planning, communication, Scientific Committee function in relation to Commission and other subsidiary bodies, Secretariat function in relation to the Scientific Committee). Within each subject area, those recommendations of perceived importance to the WG were identified. Where feasible, a timeline for developing a response was proposed.

Attention: C, SC

*Given the fact that both the Chair of the Commission (Morishita) and the Chair of the F&A Working Group on Operational Effectiveness (Phelps) reminded the Committee that the Commission has not yet decided the fate of the 'IWC review report', nor has yet requested a full engagement by the Committee, the Committee **agrees** to submit the preliminary feedback on the report (Annex X) for the Commission's consideration.*

*In addition, given the productive exchange of opinions and ideas on several aspects of the Committee working methods that occurred in during its discussions, the Committee **agrees** to establish an Intersessional Correspondence Group on 'Improving on-going working practices of the IWC Scientific Committee' under DeMaster (see Annex Y). The ICG will provide a written summary of its proposals to the Scientific Committee 60 days prior to the start of the annual meeting of the Scientific Committee in 2019. This ICG will also be in charge dealing with the preparation of a draft document for the follow-up on Governance Review, should the Commission instruct the Committee to do so at its next biennial meeting.*

28.6.3 Additional discussion on other issue related to the Committee working procedures

A number of suggestion for improving the ability to follow a topic during the Scientific Committee meeting were discussed by the Committee and the Convenors group. In order to facilitate the full participation of members of the Committee to various sub-groups and, especially, to the discussion of cross-cutting issues relevant to different groups, the Committee **agrees** that next years the Convenors should: (a) organise joint-sessions early in the meeting and release draft reports of those discussion, as soon as feasible; (b) adopt a simple coding system for 'hot topics' (e.g. North Pacific common minke whales: NPMW, Antarctic minke whales: AMW; biopsy sampling; etc.), which will be included in the daily timetable together or instead of the Agenda item. The Convenors group will carefully consider these issues intersessionally.

29. PUBLICATIONS

The Secretariat reported on the excellent progress made with the *Journal* this year, and in particular that the previously noted backlog has now been dealt with. This has been particularly assisted by the excellent work of the new Associate Editors including Fortuna, Leaper, New, Jackson, Punt, Tiedemann, Zerbini. The Committee **thanked** the Publications Team for its dedication and hard work and **reiterated** the importance of the *Journal* and *Supplements* to its work.

30. ELECTION OF OFFICERS

This was the final year of office for the Chair (Fortuna) and the Vice-Chair (Suydam). In accordance with its Rules of Procedure, the Vice-Chair becomes the new Chair for the next three years. The Committee elects Zerbini (Brazil) to be the new Vice-Chair by consensus. The outgoing Chair will provide the formal report to IWC67 in Florianopolis, Brazil of the SC Reports from the 67a and 67b SC meetings.

The Committee rose in appreciation to thank the outgoing Chair. It wished to formally record its immense gratitude for her excellent leadership over the past three years. Dr. Fortuna's scientific and organizational skills provided a lasting legacy to the Committee. She adeptly faced the many complex and challenging issues during her term and tremendous progress has been made for the benefit of the entire Commission in meeting its science and stewardship objectives. The Chair, Head of Science, and Executive Secretary of the Commission added their thanks and congratulations to the many participants expressing their appreciation to Dr. Fortuna.

The Committee also welcomed with enthusiasm the new team of Suydam and Zerbini and looked forward to working with them over the next three years.

31. ADOPTION OF REPORT

The Committee adopted the report at 17:45 hrs on 6 May 2018, apart from the final items discussed during the last session. As is customary, these items were agreed by the Chair, rapporteurs and convenors. The Chair thanked the participants for

their scientific contributions as well as their constructive dialogue. Given the sensitivity of several agenda items, this positive approach helped ensure that all views could be presented and rigorously discussed for a productive outcome. The Chair especially thanked the convenors, rapporteurs, Head of Science, and Vice-Chair for their excellent assistance. Finally, she reiterated her thanks to the government of Slovenia and the hotel staff for the facilities and great service, which contributed greatly to the success of the meeting.

Fortuna concluded that it had been an honour to serve as the IWC Scientific Committee Chair over the past three years. She expressed her gratitude for all the support provided by so many as she led this effort. She voiced her thanks for the Secretariat, and in particular her deep appreciation for the guidance provided by the Head of Science (Donovan) without whom she could not have accomplished her work.

Suydam congratulated Fortuna for having expertly led the Scientific Committee as their Chair over the past three years. He noted that the praise and applause from the participants in the room were well very much deserved given her outstanding leadership. Suydam noted that it will be a particular challenge to follow the incredible example set by Fortuna and thanked her for her mentorship. The Executive Secretary (Lent) added to these words of gratitude and commendation on behalf of the Secretariat and wished her all the best. She also offered the full support of the Secretariat to the incoming SC Chair Suydam.

Echoing the sentiments raised under Item 30, participants thanked the Chair for her adept, fair and efficient handling of the meeting, her unflagging dedication and her great contribution to the effective working of the Committee.

Fifth Rangewide Workshop on the Status of North Pacific Gray Whales

IWC

INTERNATIONAL
WHALING COMMISSION

Fifth Rangewide Workshop on the Status of North Pacific Gray Whales¹

1. INTRODUCTORY ITEMS

1.1 Convenors' opening remarks

The Workshop was held at the Granite Canyon Laboratory (Big Sur, California) of the Southwest Fisheries Science Center from 28-31 March 2018. The list of participants is given as Annex A. Brownell welcomed the participants and explained the history of the facility, which has been used for almost five decades to census gray whales during their southbound migration. Donovan and Punt (co-convenors) noted that the primary tasks of the workshop were to review the results of the modelling work identified at the Fourth Workshop and SC67a, to examine the new proposed Makah Management Plan (submitted by the USA – see Annex X) for gray whaling off Washington state and to update as possible (and develop a workplan for) updating the scientific components of the Conservation Management Plan (CMP) for western gray whales.

1.2 Election of Chair

Donovan and Punt were elected Chairs (Donovan chaired from the 28-30 March and Punt on 31 March).

1.3 Appointment of rapporteurs

Calambokidis, Cooke, Lang, Punt, Reeves, Scordino and Weller served as rapporteurs.

1.4 Adoption of Agenda

The Adopted agenda is given as Annex B.

1.5 Documents and data available

The documents available to the meeting are listed in Annex C. Annex D summarizes the terminology used to designate breeding stocks and feeding aggregations.

2. PROGRESS ON 'NON-MODELLING' RECOMMENDATIONS AND NEW DATA

2.1 Updated information from co-operative genetics studies

Bickham presented the results of a multi-authored study of SNPs using samples from approximately 50 whales feeding off Sakhalin Island ('western' gray whales) and approximately 100 whales from the Mexican wintering grounds (assumed 'eastern' gray whales); the full study was to be presented at SC67a. The methods used are described in DeWoody *et al.* (2017). Bickham stated that a finished version of the paper will be presented at the 2018 IWC SC meeting. The authors believe that the results will have implications for prioritising the various stock structure hypotheses being modelled in the Rangewide Review (see below).

Multiple duplicate biopsies were found within both the Sakhalin and Mexico sample sets, but none were shared between the two localities. SNP genotypes were also presented for two mitochondrial and two sex-linked loci (Zfx and Zfy). One of the sex-linked SNPs (ZFY_342) had an apparent fixed heterozygosity in the Mexican whales and thus only the second locus could be used for determining the sex of the whales. The Workshop noted that whilst there is no single explanation of this, one possibility is that there was a translocation (duplication) of the Y-linked SNP to the X or to an autosome.

Bickham also presented the results of the STRUCTURE analyses for the SNPs. In the cases with locality as a prior and without locality as a prior, $K = 2$ genomes (or populations) was the best solution; the plot with geography as a prior showed better differentiation with one predominating in the east (Mexico) and the other predominated in the west (Sakhalin). All eastern samples showed admixed ancestry (including some with predominantly the "western" genome) but the western samples showed a much higher proportion of admixture including individuals of nearly 'pure' eastern and western genomes. He also presented results for an analytical approach called Landscape and Ecological Associations (LEA)². The LEA analysis also identified $K = 2$ genomes but with greater separation. In the Sakhalin sample set the western genome still predominated but there were both individuals with pure western and others with pure eastern genomes as well as admixed individuals. The more equal proportions

¹ Not all attendees have had a chance to comment on this final version although much of the report was agreed at the Workshop itself.

² <http://membres-timc.imag.fr/Olivier.Francois/LEA/tutorial.htm>

of western and eastern genomes in the Sakhalin samples was consistent with an Mxy estimate of genetic similarity (the Sakhalin sample set had a notably higher variance for genetic relatedness between paired samples than was observed in the Mexican sample set).

The authors of the working paper concluded that the Sakhalin population might be comprised of two types of individuals representing two breeding stocks (i.e., two different genomes), along with individuals of mixed ancestry (admixture). The proportions of the two genomes are vastly different in the two sample sets.

The Workshop **agreed** that incorporating photo-id data into the genetic results will greatly improve interpretation of stock structure and movements and **recommended** that the genetic dataset should be examined comparing whales seen only once off Sakhalin with those whales seen in multiple years.

Lang gave a brief update of her work on SNPs, using the next-generation sequencing approach ddRAD. She is analysing approximately 200 gray whales representing approximately equal sample sizes of PCFG (Pacific Coast Feeding Group), western gray whales, and Northern Feeding Group whales. She expects to present the results of at the 2019 gray whale *Implementation Review*.

The Workshop **welcomed** news from Bickham that a request to the government of Japan to obtain gray whale samples for genetics studies (including of the possible extant western breeding stock).

It was noted that the extent of mixing of gray whales in the past had probably fluctuated in response to changes in sea ice (glacial versus interglacial periods). Bickham responded that additional genome sequencing was planned and that the reconstruction of the historical demography of western and eastern gray whales is one goal of that study. Analyses may reveal associations with the climate cycles of the Pleistocene.

2.2 Updated information from photo-identification studies including consolidation of WGW catalogues

SC/MP/CMP/02 reviewed the results of long-term photo-identification studies conducted between 2002-2017 off northeast Sakhalin Island by the Joint Monitoring Program of two oil and gas companies³. The photo-identification catalogue resulting from this work contains 283 identified individual gray whales, including: (a) 175 whales that use the Sakhalin Island feeding area on a regular annual, (b) 27 occasionally-sighted whales (recorded at intervals greater than 3 years), and (c) 71 individuals that have been recorded only once. Forty-eight of the one-time visitors were recorded as calves, excluding the nine calves first identified in 2017. There are 29 identified mothers and 127 whales first identified as calves in the catalogue. Six mother-calf pairs were identified in 2017, along with three unpaired calves. Whale no. KOGW127 (aka “Agent”), was identified as a calf in 2005 and was first recorded as a mother in 2017 at the age of 12 years. Agent was satellite tagged in 2011 and her winter migration was tracked to the Gulf of Alaska before the transponder stopped working (Mate et al., 2015).

Drone-based photography was incorporated into the joint-programme field program in 2017. In most cases, the drone was used at an average distance of about 800 m from shore with a standard altitude of 8 meters. The range of the drone presently in use is 2.5 km from the shore. With the collection of aerial photographs from drones, a new body aspect (“back”) was added to the photo-identification catalogue. Also, a new supplemental catalogue of drone-collected video was created for 35 individuals.

The catalogues of the ENL-SEIC joint programme and the Russian Gray Whale Programme (previously the Russia-US programme) were last cross-matched using data available through 2011. At that time, the two Sakhalin photo-identification catalogues contained a total of 222 whales, of which 186 were common to both. Seventeen whales were found only in the Russian Gray Whale Programme catalogue and 19 only in the ENL-SEIC catalogue (IUCN, 2013). An updated catalogue comparison, under the auspices of the IWC, is being discussed as is the concept of a common shared catalogue and database.

In discussion, the Workshop **agreed** on the importance of the long-term nature of the research programmes being conducted off Sakhalin. The concept of a common catalogue and database was welcomed and several measures to ensure data compatibility were mentioned, including the important step to standardize reporting of effort and protocols used to designate calves versus yearlings. It was further mentioned that sighting histories of whales photo-identified off Kamchatka should be evaluated to determine patterns of annual occurrence. Finally, the availability of a shared catalogue and regular updating of such was highlighted with respect to the research component of the hunt management plan proposed for the Makah hunt.

2.3 Gray whales off Korea

SC/M18/CMP/04 reported the possible occurrence of a gray whale off Korea in 2015. Video footage of what

³ Exxon Neftegas Limited (ENL) and Sakhalin Energy Investment Company (SEIC)

appears to be a gray whale was uploaded on YouTube in 2015⁴. The whale was swimming near a port facility in Samcheok, on the east coast of Korea. While the poor quality of the video prevented positive identification to species, some features of the whale suggest that it was a gray whale. Additional information is being sought to confirm the species identification. If this sighting was indeed of a gray whale, it would be the first record from Korea since 1977. The workshop thanked D. Yasutaka Imai for alerting Kim to the existence of this video.

3. UPDATING SCIENTIFIC ASPECTS OF THE CMP

Donovan reported recent progress on the “Rangewide Review of the Status of North Pacific Gray Whales” and the ‘Western Gray Whale Conservation Management Plan’ (CMP). Since 2004, the IUCN and IWC have emphasized the need for a comprehensive international CMP to mitigate anthropogenic threats facing gray whales throughout their range in the western North Pacific. This CMP was initiated at an IUCN-convened international workshop in Tokyo in summer 2008 (IUCN 2009). A draft of the CMP was completed in 2010 (Brownell *et al.* 2010) and this was endorsed by both the IWC and IUCN. The first successes of the CMP included completion of a telemetry project conducted off Sakhalin and a Pacific-wide photo-identification catalogue comparison. The results of these projects showed that some of the whales sighted off Sakhalin in the summer migrate east, across the Pacific, reaching portions of the North American coast between British Columbia, Canada and the wintering lagoons off Baja California, Mexico. In light of this new information, the IWC has been engaged in the present rangewide review.

In support of the CMP initiative, in 2014 a ‘Memorandum of Cooperation Concerning Conservation Measures for the Western Gray Whale Population’ (the MoC), was signed by Japan, Russian Federation and the USA. In 2016, the memorandum was signed by Mexico and the Republic of Korea and Prof. Hidehiro Kato of the Tokyo University of Marine Science and Technology was appointed as coordinator of the memorandum. It is hoped that in time the other remaining range states will also sign the memorandum.

3.1 Review of existing sections

The Workshop noted that the work to complete the computing specifications, especially taking into account the new Makah Management Plan, meant that there was insufficient time to update the CMP sections, also recognising that this could best be completed after the modelling results became available, ideally at SC67b. Attention was drawn to the updated seasonal maps⁵ and participants were asked to send any comments or suggestion for modification to Donovan and Reeves.

The Workshop **recommended** that the Scientific Committee considers establishing a small drafting group comprised of at least the national co-ordinators of the MoC, Reeves (IUCN) and Donovan be convened to meet intersessionally (e.g. at IUCN headquarters) to provide an updated version of the plan after SC67b.

3.2 Consideration of future stakeholder workshop

An important component of the CMP effort is the need for a stakeholder workshop (tentatively forecast to occur in 2019) that helps to finalize the CMP and develops a strategy for its implementation (IWC, 2017b). The workshop, which would be co-sponsored by IWC, IUCN and the signatories to the Memorandum of Cooperation, should be broad-based and include representatives of national and local governments, industry (e.g. oil and gas, fishing, shipping and tourism), IGOs and NGOs. Objectives of this meeting should include: (1) review and updating of the CMP taking into account any new scientific results from the rangewide workshops, (2) establish a stakeholder Steering Group to monitor CMP implementation, (3) arrange for a coordinator of the CMP and (4) establish a work plan and consider funding mechanisms to implement the actions of the plan. The IWC has a Voluntary Fund for Conservation, to which donations can be specifically directed towards the gray whale CMP and related work. It is expected, however, that after the first year of CMP implementation, range states will contribute the necessary funds to advance the conservation actions listed in the plan. The Workshop welcomed the support offered by IUCN with respect to organising the stakeholder workshop.

4 UPDATE ON MODELLING FRAMEWORK AND RUNS

4.1 Progress of modelling since SC67a including validation

⁴ <https://www.youtube.com/watch?v=dJ4J7luGgcE>

⁵ <https://iwc.int/western-gray-whale-cmp>

4.1.1 General progress, including validation

Punt informed the Workshop that code implementing the specifications agreed at the 4th Rangewide Workshop and modified during SC67a had been written and used to condition the reference trials based on stock hypotheses 3a, 3e and 5a, along with the sensitivity tests that implement stock hypotheses 3b and 6b.

Brandon summarized progress on validating the code implementing the operating model and the conditioning process. SC/M18/CMP/03 provides an update on code validation, including a brief overview of the code and input files, and a list of verification steps taken to date. The main focus of the validation process has been on the FORTRAN procedures necessary for the conditioning phase. Conditioning the operating model is the first and most computationally expensive phase of the Rangewide modelling effort because this code involves the bulk of calls to numerical methods to estimate parameters given model fits to the data. To this end, the conditioning code has been checked against the mathematical and statistical model specifications, to ensure that the procedures as implemented are consistent with the specifications (see Annex D for the specifications of the Rangewide model). Likewise, diagnostic output from the code has been checked against expected values. No errors in the coding were identified.

4.1.2 Modelling related to the proposed Makah management plan

Punt informed the Workshop that code implementing the Makah Management Plan (Annex X) had been developed and initial results presented to the March 2018 AWMP meeting. However, Brandon has yet to validate this code. The code implementing the Makah Management Plan needs to be validated prior to SC67b.

During the Workshop, the Makah Management Plan was clarified/updated as shown below.

- (1) It was clarified that the hunt will be stopped if the PCFG 10-yr strike limit less number of PCFG-designated animals drops below 1 or if the PCFG 10-yr female strike limit less number of PCFG-designated females drops below 1. The initial implementation only stopped the hunt only when these differences were less or equal to zero.
- (2) It was agreed to incorporate an 'unknown identity' component for landed whales because it may not be possible to obtain a useable photograph of landed as well as struck and lost whales (although at a lower probability).
- (3) It was agreed to allowing for the fact that the amount that unidentified whales count towards the PCFG 10-year strike limit will be updated based on available data rather than always being assumed to be 0.4. The error associated with the estimate of the proportion of PCFG whales in even-year hunts needs to be accounted for (see Item 4.4.1).

4.2 Review of stock hypotheses

The Workshop reviewed how the three baseline stock hypotheses (3a, 3e and 5a) and the two stock hypotheses considered as tests of sensitivity (3b and 6b) had been implemented, noting that some of the 'limited' movements (light arrows in Annex E) had been omitted from the baseline hypotheses, but would be considered in tests of sensitivity (e.g. the PCFG in sub-area BSCS). The omission of the associated links was due to lack of mixing data to allow the links to be modelled. It was also noted that there are no data (abundance estimates, mixing proportions, catches) for some of the sub-area (e.g. the OS sub-area), which implies that the results will be identical no matter how such regions are treated in the modelling.

The Workshop noted that the current implementation of hypothesis 5a did not include the WBS in the SKNK sub-area. This is because there was currently no basis to specify a mixing proportion for WBS vs WFG animals in the sub-area. Cooke provided abundance estimates by breeding stock / feeding group (see Item 4.3.1), which means that it is no longer necessary to specify mixing proportions for the SKNK sub-area.

The Workshop **agreed** that stock hypotheses 3a and 5a would form the references for the analyses as they appear to be most plausible, while trials would also be conducted for stock hypotheses 3b, 3c, 3e and 6b. Annex E shows the final stock hypotheses considered in the trials graphically, while Annex D, Table 2 shows the resulting mixing matrices. The γ values in Annex D, Table 2 indicate parameters that are estimated during the model fitting process.

4.2.1 Plausibility of stock hypothesis 6b

SC/M18/CMP/01 aimed to reopen discussion on the plausibility of the stock hypotheses previously considered as high priority for modelling, with special emphasis on stock hypothesis 6b. Stock hypothesis 6b assumes that the WBS has no fidelity to wintering ground and uses both wintering grounds in both Asia and Mexico. SC/M18/CMP/01 argued that this hypothesis was elevated to high priority due to discussions regarding the movements of humpback whales and the social aggregating hypothesis of Clapham and Zerbini (2015). This hypothesis involves humpback whales learning of new wintering grounds, likely through hearing other humpback whales, and temporarily immigrating. SC/M18/CMP/01 argued that this hypothesis does not apply well to gray

whales because they are much quieter than humpback whales and there is a large distance between the distribution of WBS and eastern breeding stock whales (as portrayed by hypothesis 6b) preventing communication between whales. Furthermore, humpback whales and gray whales have very different breeding behaviour, with humpback whales aggregating on modified leks (Clapham and Zerbini 2015). There does not appear to be a functional benefit for WGW to justify shifting their migration to go to wintering grounds in Mexico instead of Asia given the extra 4,000 km of travel required (Villegas-Amtmann *et al.*, 2015). Furthermore, it does not appear likely that the WBS used both wintering grounds without fidelity prior to commercial whaling given that whaling occurred off Japan and Korea during a period when the whales using the Mexican wintering grounds were depleted. Bickham *et al.* (2013) has also presented arguments based on genetics on why hypothesis 6b has low plausibility. SC/M18/CMP/01 also suggested that hypothesis 3e has low plausibility because it assumes that WBS whales occur in their historical feeding range but do not use the Piltun Lagoon area of Sakhalin Island, which has proved to be an important feeding area since the mid-1980s. It is more likely that if the WBS exists, that this breeding stock would spend at least some time feeding near Piltun Lagoon. SC/M18/CMP/01 concluded the trials based on stock hypotheses other than 3a and 5a should be sensitivity tests.

In discussion, it was noted that gray whales that feed off Sakhalin and traditionally used wintering grounds in the western North Pacific could be driven to occasionally use migratory routes and wintering areas in the Eastern North Pacific. While the Rangewide model does not explicitly account for breeding so does not incorporate information on when or where whales breed, this hypothesis could provide an explanation for the observations of Sakhalin whales in the eastern North Pacific. There is evidence showing that whales from the same feeding groups migrate together; both Sakhalin and PCFG whales have been photographically identified in the same groups and in localized areas while on migratory routes (Weller *et al.* 2012, Calambokidis and Perez 2017). This could provide a mechanism by which whales that feed together, but have traditionally used different wintering areas, could learn new migratory routes.

Although the possibility that gray whales use multiple wintering grounds could not be ruled out, the Workshop **agreed** that stock hypotheses 6b would be considered as a sensitivity test. It was also **agreed** that stock hypothesis 3e would be considered a sensitivity test.

4.3 Confirm final data sets

4.3.1 Removals (*direct and incidental*)

IWC (2018) referenced records of gray whale deaths from entanglement/entrapment, ship strike, and unknown causes in Japan from 1982 until the present (Nakamura *et al.*, 2017). A small group (Scordino, Reeves, Brownell) met to confirm and update what had been stated previously on removals in Japan (and elsewhere), recalling that the adult that ‘died off Hokkaido in 1996’ was killed deliberately (Brownell, 1999).

The Workshop **endorsed** the conclusions of the small group as summarised below.

(1) Of the six gray whales reported as beached in Japan between 1990 and 2016 but with cause of death undetermined, some proportion should be assumed to have died from either entanglement/entrapment or ship strike. The under-reporting factor (usually x4 but with sensitivities of x10 and x20; Annex D, tables 8 and 9) used in the model to convert observed mortality to true mortality in the case of bycatch and ship strike would account for this.

(2) There was no reason to believe there had been any change in fishing effort (e.g. set net fishing) in Japan between 1930 and 1982. Therefore, the removal rate from 1982 to the present should be extended back to 1930 for modelling purposes.

(3) Finally, with respect to commercial set gillnet fishing in California prior to 1981, as noted last year (IWC, 2018), a seabass fishery operated in northern Mexico and southern California prior to the 1980s (e.g. landing 412,000 pounds of black seabass and 873,000 pounds of white seabass in 1953; Marine Fisheries Branch, 1956). In fact, this fishery was active and overall fishing effort ‘fairly constant’ from before 1930 until the early 1980s (Vojkovich and Reed, 1983). There was no observer effort in this fishery before 1981, nor was an official stranding record of cetaceans maintained in California before that time. However, a coordinated reporting system for stranding was established in the early 1960s under the auspices of the American Society of Mammalogists, and stranded gray whales were regularly reported. For example, 24 dead gray whales were reported as stranded in California between 1960 and 1968, of which seven were confirmed or suspected of having been either entangled in fishing gear or struck by a ship; Brownell, 1971). A gray whale that stranded at Ocean Beach, California, on 19 February 1953 was missing its flukes and bore ‘several gashes’ on the body – all suggestive of an entanglement death (Robert Orr, pers. comm. to R. Brownell, April 1964).

At last year’s workshop, it was assumed that set gillnet fishing effort for halibut in California declined linearly from 1982 to no effort in 1975. To model the effect of this assumption, it was decided to assign all records of gray

whales recorded as injured or killed in halibut or other set gillnet fisheries to a single fishery and modelled separately from all other California fisheries. It was also decided to examine both a low case that assigned no deaths to set gillnet fisheries and a high case that considered all bycatch reports related to gillnet, set gillnet, net, and halibut fisheries in California as if they came from a single fishery (IWC, 2018). A recently found publication (Bureau of Commercial Fisheries, 1936) reported that both set gillnets and trammel nets were used in the 1930s in California for halibut and white seabass fishing. Based on this new information, the Workshop **agreed** to drop the assumption that fishing effort declined linearly to zero from 1982 to 1975 and therefore there was no reason to evaluate high and low scenarios as a way of accounting for bycatch in California prior to 1975.

Set gillnetting effort off California changed markedly in 1991 due to regulations passed in November 1990 intended to eliminate gillnet fishing within 3 n.miles of the mainland and within 1 n.mile of any offshore island in southern California by 1994 (Barlow *et al.*, 1994). To address this, a second set gillnet fishery was added to the model starting in 1991 and the set gillnet fishery described in the preceding paragraph was modelled as having ended in 1990.

4.3.2 Abundance estimates

There were no updates to the estimates of abundance for the PCFG or the ENP stock. New abundance estimates for western gray whales had been presented to the last GWAP meeting (Cooke *et al.*, 2017), which will also be presented to the SC67b. Estimates for the WFG were extracted at the Workshop that would correspond to the stock structure hypotheses listed in Annex E (table 1). The larger estimates for the WFG correspond to the hypothesis that all whales visiting SE Kamchatka and/or Sakhalin belong to the WFG, while the smaller ones correspond with the hypothesis that only whales that visit Sakhalin belong to the WFG (regardless of whether these individuals also visit Kamchatka).

For the hypotheses where a proportion of the WFG belongs to the western breeding stock (WBS), this proportion is highly uncertain (and could be zero) even though the estimate for the total WFG is reasonably precise. The estimates of the numbers of WFG animals in each of the two breeding stocks are, therefore, highly negatively correlated. In these cases, the multi-stock model uses as inputs the estimate of the total WFG and the estimated proportion of this that belongs to the WBS.

4.3.3 Mixing proportions

Table 2 lists the updated mixing proportions. The mixing proportion for the EJPI sub-area is unchanged from that specified at the 4th Rangewide Workshop because none of whales encountered recently in this sub-area had adequate photographs to allow for matching (Table 3).

New mixing proportions were calculated for PCFG whales by sub-area for the winter/spring (migrating) and summer/fall (feeding) seasons (Table 4). The sub-regions of the BCNC region used for the analysis were northern Oregon, southern Washington, and northern Washington because they were thought to have the least chance of bias in calculated mixing proportions. Updated data through 2015 based on matches to the PCFG catalogue were used. There was considerable discussion about how to calculate the mixing rate for the Oregon-Washington outer coast area due to a dramatic change in proportion of PCFG whales in northern Washington from surveys in early April 2015. Those surveys identified a large number of whales in a previously poorly sampled area that had very few PCFG whales. Identifications in spring 2015 (heavily influenced by these April surveys) reduced the overall proportion of PCFG whales based on pooled proportions through 2015 to 24% (it had been 36% based on data through 2014). To provide a value less influenced by these two days of surveys, the proportions of PCFG whales were averaged over sub-region and month to compute an overall average of 28% (an average of the eight values presented in Table 4).

The Workshop **agreed** to adopt 28% for the proportion of PCFG whales in the BCNC sub-area during the migrating season for the bulk of the trials, and that sensitivity would be evaluated to 17%. This value is obtained by restricting the analysis of mixing rates of PCFG whales during the winter/spring to just northern Washington where the hunt would occur (based on the unweighted average of the 4 months where there were at least 10 photo-IDs, table 4). Pooling all 622 photo-IDs for December to May would result in a rate of 20%, although this approach weights values towards periods with more photo-IDs.

Considering some of the uncertainty around the estimate for the portion of PCFG whales present in the spring off the Washington-Oregon coast and the variation by location, month, and year, the Workshop **agreed** the current best estimate of 28% to be $\pm 20\%$ (8-48%) for the true PCFG mixing rate. The rationale for the choice is that very different results would be obtained in different areas such as 1) the recently sampled zone north of Tatoosh Island in the early spring where migrating whales appear to gather in some years where recent efforts revealed almost no PCFG whales, compared to 2) areas along the Northern Washington Coast or for example in Barkley Sound

that are feeding areas for PCFG whales and where their proportion compared to migrating whales would be highest.

4.4. Confirm final trial structure and conditioning

4.4.1 Changes to the trials specifications, including stock structure

Annex D lists the specifications for the model that will form the basis for drawing final conclusions regarding the implications of alternative stock structure hypotheses and of the implementation of the Makah management plan. The specifications (see also Annex D and Table 5 and 6) reflect changes to how the stock hypotheses are implemented as well as how the abundance estimates for the western Pacific are used in conditioning. The Workshop also agreed that the following additional changes will be made the trials specifications:

- (1) the base-case survival rate for animals aged 1 and older would be assumed to be 0.98, which reflects the estimates obtained by Cooke (ref) and Punt and Wade (2012); the values used in previous trials was 0.95;
- (2) the SET1 and SET2 fleets (set gillnets off California in the feeding and migration seasons) would be split between 1990 and 1991 given the changes in regulations in the associated fisheries that appear to have changed bycatch rates;
- (3) the survey plan for the California counts were updated to reflect the current plan (two surveys in every five-year block); and
- (4) the periods used to calculate average bycatch rates to infer bycatch prior to the establish of monitoring networks into the future as generally but the earliest and most recent five years, but a longer period is specification for sub-areas (e.g. EJPJ and SI) with limited data (Annex D, table 3)

Evaluation of the Makah Management Plan requires specification of the probability of photographing a landed or struck and lost whale, as well as the probability of correctly deciding that such a whale is from the PCFG or the WFG. In addition, it is necessary to specify the probability of striking and losing a whale and assigning a sex to an animal for which a match has been made. These probabilities are specified as follows:

- (1) *Probability of obtaining a photograph of sufficient quality to allow it to be matched to the catalogue.* For struck and lost whales, this probability is estimated to be a 0.6 for winter/spring and 0.8 for summer/fall (due less favourable light and weather in winter/spring compared to summer/fall). For landed whales, it is estimated to be 0.9 for all seasons.
- (2) *Probability of struck and lost.* The review of the Makah whale SLA concluded in 2013 was based on a value for this probability of 0.5, which was informed by two strikes that occurred during the Makah 1999 hunt in which one strike resulted in a landing and the other contacted the whale but did not penetrate the skin. The Workshop agreed to retain the assumption of a 50% struck and lost rate for hunts during the winter and spring. It was decided that hunts occurring during the summer and fall were much less likely to have struck and lost due to better weather conditions and more predictive movement behaviours of whales in the normal feeding depths of PCFG whales. The Workshop therefore agreed that the struck and lost rate for summer and fall hunts would be 0.1 and that sensitivity would be explored to a value of 0.5.
- (3) *False positive rate for PCFG (i.e. probability of a non-PCFG being identified as from the PCFG given a good quality photograph).* The probability that a non-PCFG whale might be falsely identified as a PCFG whale is estimated to be 0.05. Normally, there is a near 100% confidence for matches that are identified to Cascadia's PCFG catalogue because these are double checked and photographs of poorer quality where there is some ambiguity are treated as Poor Quality and not used. The value of 0.05 is based on the assumption that a slightly different set of circumstances would exist for comparison of a whale struck or landed because there would be pressure to try to match regardless of the quality of the photograph and it would be hard to justify not reporting as a match something where there was a relatively high degree of confidence (i.e. 95% confident of the match to a PCFG whale).
- (4) *False negative rate for PCFG (i.e. i.e. probability of a PCFG whale not being identified as such given a good quality photograph).* This probability is estimated to be 0.25 for a hunt in the winter/spring, and zero for a hunt in summer since all struck whales are assumed to be of the PCFG. This value of 0.25 accounts for several factors, including whales only seen in fewer in two years in the PCFG because of a combination of being young, not being photographed, and the one year lag in available catalogue. In addition, there could be a matcher error in missing a match due to things like changed markings.
- (5) *False positive rate for WFG (i.e. probability of a non-WFG being identified as from the WFG given a good quality photograph).* This probability is estimated to be 0.01 based on the WFG catalogue being smaller and more well-known. Also, it is suspected that the matcher would likely only declare a match when there was a high level of confidence given the infrequent rate of these matches.
- (6) *False negative rate for WFG (i.e. i.e. probability of a WFG whale not being identified as such given a good quality photograph).* On the assumption that calves and lactating mothers will not be hunted, the proportion of hutable WFG whales that would not be known as WFG whales if taken during the spring

northward migration was estimated using the population model fit to the Sakhalin and Kamchatka photo-id data. An animal that has been seen off Sakhalin is assumed to be a WFG animal if seen or taken in the eastern North Pacific. An animal seen off eastern Kamchatka but not Sakhalin is not assumed to be a WFG animal, because it might be an NFG animal. The estimated proportion, averaged across the posterior distribution of the population trajectory, was 4-5% depending on the hypothesis. These estimates used data through 2011 only, that being the last season for which the catalogues were cross-matched. If only a single catalogue were used, the rate would be higher. The values used in the trials are: stock hypotheses 3a, 3c, 3e, and 6b: 0.041; stock hypothesis 3b: 0.040; stock hypothesis 5a: 0.049.

- (7) *Probability of not assigning a sex to a struck and lost animal that has been identified to the PCFG.*
 - a. This probability is estimated at 19% for the feeding season based on 81% of encounters of PCFG whales from June-Nov through 2015 for the Oregon and Washington outer coast having known sex. For those with known sex in this sample 58% were female and 42% male, but this could be biased by some directed sampling toward females so the sex ratio should be treated as 50:50 in the management plan.
 - b. This probability is estimated at 27% for the migrating season based on 73% of encounters of PCFG whales from Dec-May through 2015 for the Oregon and Washington outer coast having known sex. For those with known sex in this sample 46% were female and 54% were male. This male-biased sex ratio is in the opposite direction of the bias from intentionally sampling females, which suggests males are actually more abundant and available in the spring off the Oregon and Washington outer coast likely as a result of females with calves migrating later and being less available in spring. Given the bias for trying to sample known females, it is likely that the sex ratio in spring is likely closer to 60:40 male:female. If hunters avoid taking mothers with calves it would further reduce the chances of taking a female.

Estimates of the proportion of PCFG whales used in the Makah management plan for assigning a struck unidentified whale in the winter/spring hunt are subject to uncertainty due to for example shifting proportions based on sampling differences and these should be considered subject to a bias (which depends on trials) that ranges from -0.1 to 0.1.

4.4.2 Base-case trials and sensitivity tests

The 4th Rangewide workshop specified a series of trials. However, it had not been possible to implement all of these trials during the intersessional period. The Workshop reviewed the set of trials and made the following changes (trial numbers relate to revised numbering system):

- (1) stock hypothesis 3e is now treated as a sensitivity test as it is a variant of stock hypothesis 5a (with no WBS animals in the SI sub-area);
- (2) a new sensitivity test (18C) based on stock hypothesis 3c has been added as agreed at the 4th Rangewide workshop (IWC, 2018);
- (3) the sensitivity test exploring a higher proportion of WBS whales in sub-area SI (3B) involves increasing the estimates of abundance for the WBS by 50% and correspondingly reducing the estimates of abundance for the WFG;
- (4) the trials involving PCFG whales in the BSCS sub-area (12A/B) are based on assuming that all PCFG whales are in the BSCS sub-area. The assumption will be conservative given that most PCFG whales are located elsewhere when the aboriginal hunt off Chukotka occurs;
- (5) the trials involving WFG whales in the BSCS sub-area (13A/B) are based on assuming that all WFG whales are in the BSCS sub-area. The assumption will be conservative given that most WFG whales are located elsewhere when the aboriginal hunt off Chukotka occurs;
- (6) the trials exploring the sensitivity of how the California set gillnet catches were modelled (trials 14 and 15 in Table 8 of IWC (2018)) were dropped as the approach for modelling the SET1 and SET2 fleets was modified (see Item 4.3.1);
- (7) the trials with MSYR estimated and a higher pulse were dropped as these trials are unlikely to be informative (trials 14A/B and 8A/B examine these factors individually);
- (8) variants of trials 5A/B and 16A/B (trials 18A/B and 19A/B) that have net immigration of 1 to the PCFG were added because the assumption of zero immigration into the PCFG is unlikely given the results of Lang and Martien (2012);
- (9) trials 7A/B and 16A/B exclude the PCFG abundance estimates for 1998-2002 as a low pulse would not allow the model to mimic these data – this change in model specifications mimics the adoption in the trials used to evaluate the SLA for a Makah hunt by IWC (2013) of a time-varying survey bias;
- (10) trials 22A/B have been added to examine the future consequences of a catastrophic events in the NFG – these events occurs randomly once in the first 50 years and randomly once in the second 50 years, with a magnitude equivalent to that of the mortality event in 1999/2000; and

- (11) trials 23A/B and 24A/B have been added to explore sensitivity to the struck and lost rate for a Makah hunt in the feeding season, and the false negative rate for a Makah hunt in summer.

4.4.3 Conditioning statistics

The Workshop reviewed the diagnostic plots for evaluating the conditioning developed for the trials specified at the 4th Rangewide Workshop. The Workshop **agreed** that the following plots should be produced for each trial and provided to the Intersessional Steering Group for review:

- (1) The estimates of absolute abundance (with 90% sampling intervals) and the median, 50% and 90% intervals for the time-trajectory of the model estimates of 1+ population size.
- (2) The time-trajectory of the model estimates of the number of mature females.
- (3) The distributions (median, 50% and 90% intervals) for the generated mixing proportions and those for the model-predicted mixing proportions.
- (4) The distribution for the net immigration rate from the NFG to the PCFG and the target value (black vertical bar).
- (5) The estimates of average bycatch over the period for which reporting is considered adequate [Annex D, table 3] (with 90% sampling intervals) and the median, 50% and 90% intervals for the model-estimate of the average bycatch over the period.
- (6) The distributions (median, 50% and 90% intervals) for the generated survival rates for PCFG whales and those for the model-predicted survival rates for PCFG whales.
- (7) The time-trajectories of removals, including the recorded removals (adjusted for under-reporting) and the bycatch inferred for the years for which reporting is not considered adequate.

4.4.4 Projection scenarios

Previous projections for the Sakhalin population (J. Cooke in Reeves *et al.*, 2005) considered a scenario in which there is future bycatch of 1.5 mature females off Japan based on inferences from bycatch at that time. The Workshop noted that observed bycatch off Japan has declined since then. The Workshop **agreed** that a projection scenario with 1 mature female taken each year in the EJPI sub-area should to be conducted.

In addition, the Workshop **agreed** that, if possible, projections should be conducted for the current Makah SLA, although it was recognised this may not be feasible to achieve before 67b.

The Workshop noted that care needs to be taken to compare the results from the previous *Implementation Review* with those based on the Rangewide review because the population structure hypotheses have changed and the Rangewide review has more fully accounted for bycatch and its uncertainty.

4.4.5 Performance statistics

4.4.5.1 TIME-TRAJECTORIES OF POPULATIONS

The results of the model fits and the projections will be summarized by time-trajectories of 1+ numbers of breeding stock / feeding group and by sub-area

4.4.5.2 MAKAH MANAGEMENT PLAN

The results of the projections to evaluate the performance of the Makah management plan will be based on the standard statistics used by the Committee to evaluate the performance of Strike Limit Algorithms

- (1) D1. Final depletion of 1+ and mature female numbers by breeding stock / feeding group (median, lower 5th and upper 5th percentiles)
- (2) D8. Rescaled final depletion: P_T/P_0 (1+ and mature female numbers by breeding stock / feeding group; median, lower 5th and upper 5th percentiles) where P_0 is number of 1+ / mature female animals had there been no future Makah hunts.
- (3) D10. Relative increase. The ratio of the 1+ and mature population size after 10 and 100 years to that at the start of the projection period by breeding stock / feeding group (median, lower 5th and upper 5th percentiles)
- (4) N9. Need satisfaction. The proportion of the total number of requested strikes that were taken over the first 10 years and the entire 100-year period (median, lower 5th and upper 5th percentiles).

Results are provided for both 10 and 100 years for the D10 and N9 statistics because (a) the Makah management plan current only operates for 10 years, and (b) previous evaluations of the performance of management procedures (RMP and AWMP) have considered performance over 100 years. Population-related statistics should be also be provided for the case there is no future Makah hunt (only bycatch and hunting off Chukotka).

5. WORKPLAN

Before / during 67b

- (1) Update the code for the operating model (Punt)
- (2) Validate any changes to the historical (conditioning) component of the operating model (Brandon)
- (3) Conduct conditioning and distribution of conditioning diagnostics to the Steering Group (Punt)
- (4) Review of the conditioning results (Steering Group)
- (5) Code the revised Makah management plan and the associated testing code (Punt)
- (6) Validate the revised Makah management plan and the associated testing code (Brandon)
- (7) Conduct the projections and assemble the projection results (Punt)

After 67b

- (1) Complete drafting of the CMP.

6. ADOPTION OF REPORT

The co-chairs thanked Brownell and his colleagues for the excellent and historic facilities provided at the laboratory in the beautiful setting of Granite Canyon (complete with gray whales migrating by). The report was adopted by email.

Table 1. Abundance estimates (1+) for the WFG feeding aggregation and the western breeding stock

<i>Year</i>	<i>Group</i>	<i>Hypothesis</i>	<i>Estimate</i>	<i>SD</i>	<i>CV</i>
1995	WFG	3a/3c/3e/6b	75.1	3.8	0.051
1995	WBS	3b	25.8	7.3	0.282
1995	WFG	3b	75.5	3.3	0.043
1995	WBS	3e	30.0*	15.0	0.500
1995	WBS	5a	26.6	6.9	0.259
1995	WFG	5a	47.8	7.7	0.160
1995	WBS+WFG	5a	74.4	3.9	0.052
1995	WBS/(WBS+WFG)	5a	0.358	0.093	0.259
2015	WFG	3a/3c/3e/6b	199.8	5.4	0.027
2015	WBS	3b	63.8	15.8	0.248
2015	WFG	3b	198.9	5.7	0.029
2015	WBS	3e	30.0*	15.0	0.500
2015	WBS	5a	64.4	14.0	0.218
2015	WFG	5a	135.6	14.1	0.104
2015	WBS+WFG	5a	200.0	5.7	0.029
2015	WBS/(WBS+WFG)	5a	0.322	0.069	0.200

* Guestimate because the WBS cannot be distinguished given the available information.

Table 2. Mixing proportions for use in the trials

Sub-area	Season	Stock / Feeding aggregation	Mixing proportion
EJPI	All	WBS/NFG	0.33
SEA	Feeding	PCFG	0.57 ¹
SEA	Migration	PCFG	0.1 ²
SEA	Migration	WGW	0.002 ³
BCNC	Feeding	PCFG	0.93
BCNC	Feeding	WGW	0
BCNC	Migration	PCFG	0.28
BCNC	Migration	WGW	0.002
CA	Feeding	PCFG	0.60
CA	Feeding	WGW	0
CA	Migration	PCFG	0.1
CA	Migration	WGW	0.002 ³

1: Not used in the conditioning as no bycatch is recorded for the SEA sub-area during the feeding season.

2: Assumed value owing to lack of data to estimate mixing proportions.

3: Set to the value calculated for BCNC by Moore and Weller 2013)

Table 3. Updated information on matches between whales encountered off Japan and those photographed off Sakhalin (D. Weller, SWFSC).

Date	Location and source	Conclusion
April 2016	Shizuoka, beached	no useable photos/no match
February 2017	Kanagawa, sighting	poor quality video only/no match
April 2017	Chiba, sighting	poor quality video only/no match
March 2017	Aogashima, sighting	no useable photos/no match
February 2018	Aogashima, sighting	no useable photos/no match

Table 4. Proportion of PCFG whales by region and Month for cells with >10 IDs through complete through 2015 for OR-WA Jan to May (no Dec data)

Region	Jan	Feb	Mar	April	May
NWA	0.09		0.09	0.10	0.41
SWA			0.38	0.21	0.33
NOR					0.63

Mean of above cells for OR to WA: **Unweighted = 28%**, Pooled = 24%

Mean of above for just N WA: Unweighted = 17%, Pooled = 20%

Table 5

Factors considered in the model scenarios. The bold values are the base-levels and the values in standard font form the basis for sensitivity analyses.

Factor	Levels
Model fitting related	
Stock hypothesis	3a , 3b, 3c, 3e, 5a , 6b
MSYR ₁₊ (western)	As for WFG
MSYR ₁₊ (north)	4.5% , 5.5%, Estimated (common); estimate (separately)
MSYR ₁₊ (WFG)	4.5% Estimated (common); estimate (separately)
MSYR ₁₊ (PCFG)	2%, 4.5% , 5.5%, Estimated (common); estimate (separately)
Mixing rate (migration season in BCBC)	0.28 , 0.17, 1.00
Immigration into the PCFG	0, 1, 2 , 4
Bycatches and ship strikes	Numbers dead + M/SI, dead x 4 ; dead x 10; dead x 20
Pulse migrations into the PCFG	10, 20 , 30
Projection-related	
Additional catch off Sakhalin (mature female)	0, 1
Catastrophic events	None , once in years 0 – 49, and once in years 50-99
Northern need in final year (from 150 in 2014)	340
Struck and lost rate	(0.1; odd-years; 0.5 even years) , 0.5 all years
Future effort	Constant , Increase by 100% over 100 years
Probability of a photo (struck and lost whales)	0.8; odd-years; 0.6 even years
Probability of a photo (landed whales)	0.9
Probability of false positive rate PCFG	0.05 , 0.1
Probability of false negative rate PCFG	0.25
Probability of false positive rate WFG	0.01
Probability of false negative rate WFG	0.041 (stock hypotheses 3a , 3c , 3e , 6b); 0.040 (stock hypothesis 3b); 0.049 (stock hypothesis 5a)
Probability of a sex assignment given a PCFG match	0.81

Annex D

Terminology Used With Respect to Stock Structure Hypotheses

Table 1

Feeding groups or aggregations.

	Feeding groups or aggregations	Abbreviation	Definition (may vary with hypothesis)
1	Western Feeding Group	WFG	Animals that feed regularly off Sakhalin Island* according to photo-identification data.
2	Pacific Coast Feeding Group	PCFG	Animals that feed regularly in the PCFG area according to photo-identification data.
3	North Feeding Group including	NFG	Animals found in other feeding areas (and for which there is relatively little information photo-identification).

*May need revising with regard to southern Kamchatka animals given information in SC/A17/GW08.

Breeding stocks. There are up to two extant breeding stocks: Western (WBS) and Eastern (EBS).

Feeding groups or aggregations. There are up to three feeding groups or aggregations. There is dispersal between the Pacific Coast Feeding Group (PCFG) and North Feeding Group (NFG), but the Western Feeding Group (WFG) is demographically independent of the other two feeding

groups (i.e. there is no permanent movement of animals from the NFG or PCFG to the WFG).

Sub-areas. The model includes 11 geographical sub-areas that are used to explain the movements of gray whales (breeding stocks and feeding groups) in the North Pacific and two 'latent sub-areas' used to link model predictions to observed indices of abundance.

Schematic diagrams of the hypotheses being considered are found on pp.534-536.

Table 2 Sub-areas.

	Sub-area	Abbreviation
	Vietnam-South China Sea	VSC
1	Korea and western side of the Sea of Japan	KWJ
2	Eastern side of the Sea of Japan and the Pacific coast of Japan	EJPJ
3	Northeastern Sakhalin Island	SI
4	Southern Kamchatka and northern Kuril Islands*	SKNK
5	Areas of the Okhotsk Sea not otherwise specified	OS
6	Northern Bering and Chukchi Sea	BSCS
7	Southeast Alaska	SEA
8	British Columbia to northern California	BCNC
9	California	CA
10	Mexico	M
11	Latent sub-area	Calif-3
12	Latent sub-area	BC-BCA-3

*New at this Workshop – replaces the old East Kamchatka and Kuril Islands sub-area to recognise the information from telemetry and photo-identification.

ABSTRACT

Gray whales (*Eschrichtius robustus*) are divided into western and eastern populations. This study is the first to present the genetic data obtained from the gray whales migrating to or from the breeding ground of the western population along the Japanese coast. We conducted mitochondrial DNA analysis on the samples of gray whales from Japan (western, N=6) and Russia (eastern, N=7) and analyzed the generated data in comparison to those of Leduc *et al.* (2002) and Lang *et al.* (2004) to better understand the genetic characteristics of these whales at the wider geographic area. The Japanese gray whales were those either stranded on beach or bycaught on set net along the Japanese coast from 1995 to 2007, and the Russian gray whales were those legally caught during the Chukotka aboriginal subsistence whaling in 2008. All of the mtDNA haplotypes found in the Japanese (five) and Russian (six) samples matched to some of the previously reported haplotypes. The level of genetic diversity of these samples described as haplotype diversity and nucleotide diversity were surprisingly high, suggesting either gene flow between the western and eastern populations or retention of ancient polymorphism without gene flow. No statistically significant difference in haplotype frequencies was detected between the JPN and RUS samples possibly due to the small sample sizes. The phylogenetic analysis of the mtDNA haplotypes found in this study and the past studies detected no distinct cluster for the Japanese whales, supporting the past observation that the western and eastern gray whales were indistinguishable at the evolutionary time scale.

KEYWORDS: GRAY WHALES, PACIFIC OCEAN, GENETICS

INTRODUCTION

Gray whales (*Eschrichtius robustus*) distribute along the North Pacific coast from Asia and Russia to United States and Mexico and are divided into the western (Okhotsk-Korea) and eastern (Chukotka-California) populations (Rice, 1998). The eastern gray whales breed in the Baja California waters in winter and feed in the Bering and Chukchi Seas during summer, while the western gray whales breed in the coastal waters near China and feed in the Okhotsk Sea off Sakhalin Island. After severe reduction of the population size during the commercial whaling period, the eastern population recovered its abundance to near pre-exploitation level but the western one has been believed to still remain small

(IWC, 1998). Conservation and management of this species has been of concern for the range countries.

Identification of population structure is essential for effective management. Past genetic studies based on the genetic variations at mitochondrial DNA (mtDNA) and microsatellites demonstrated that the western and eastern populations were genetically distinct at the population level but not at the evolutionary level (Leduc *et al.*, 2002; Lang *et al.*, 2004). The population structure of the species hasn't been fully resolved yet, however, partly because the sample of what they call the western population in these past studies limited to the individuals from the narrow part of feeding ground off Sakhalin Island. These whales could have been the mixture of whales from both populations (e.g., Lang *et al.*, 2004) or could have come from the eastern population (e.g., Ilyashenko, 2009). Lang *et al.* (2004) found high genetic diversity within the samples and the differences in the level of genetic differentiation between males and females, that made the authors suspect extended migration of some eastern gray whales, especially males, to the area off Sakhalin Island. Ilyashenko (2009) proposed that the current gray whale population migrating to the area off Sakhalin Island was originated from the eastern gray whales recolonized after the extinction of the species in this area during the commercial whaling period. In order to address this issue and to conduct effective management of gray whales, it is important to analyze gray whales obtained from the entire range of the species.

This study is the first to present the genetic data obtained from the gray whales migrating to or from the breeding ground of the western population along the Japanese coast (Fig. 1; Kato *et al.*, 2010). We conducted mtDNA analysis on the samples of gray whales from Japan (western, N=6) and Russia (eastern, N=7) and analyzed the generated data in comparison to those of Leduc *et al.* (2002) and Lang *et al.* (2004) to better understand the genetic characteristics of these whales at the wider geographic area.

MATERIALS AND METHODS

Samples

Three stranded gray whales on beach and three bycaught ones on set net along the Japanese coast from 1995 to 2007 were used for this study (JPN; Table 1). Detailed information on these six animals can be seen in Kato *et al.* (2010). Seven gray whales caught during the Chukotka aboriginal subsistence whaling in 2008 were also used (RUS; Table 1).

mtDNA analysis

Total DNA from each of the whales was extracted from 0.05 g of skin or muscle tissue using the protocol of Sambrook *et al.* (1989). Extracted DNA was stored in TE buffer (10 mM Tris-HCl, 1 mM EDTA, pH 8.0). The first half (486 bp) of the mtDNA control region was amplified through the polymerase chain reaction (PCR) using the following primer set: light-strand MT4 (Árnason *et al.*, 1993) and heavy-strand Dlp 5R (5'-CCATCgAgATgTCTTATTAAggggAAC-3'). PCR products were purified by MicroSpin S-400HR columns (Pharmacia Biotech). Cycle sequencing was performed with the same primers, using BigDye terminator cycle sequence Kit (Applied Biosystems, Inc). The cycle sequencing products were purified by AutoSeq G-50 spin Columns (Pharmacia Biotech). The labeled sequencing fragments were resolved by electrophoresis through a 5% denaturing polyacrylamide matrix on an ABI3100™ Automated DNA Sequencer (Applied Biosystems, Inc) following the protocols of the manufacture. For each sample both strands were sequenced.

Data analysis

Published mtDNA sequences in Leduc *et al.* (2002) were extracted from GenBank for haplotype designation and data comparison. The published data was generated from analyzing eastern gray whale sample (N=120) collected from the several locations along the coast from Chukotka to California and western gray whale sample (N=45) collected from the northeastern coast of Sakhalin Island. Because analyzed length of the sequence in our study was 37 bp shorter than that of Leduc *et al.* (2002), the haplotype G and O (hereafter, G/O), L and U (L/U), W and X (W/X) in the original paper became indistinguishable, reducing the total number of the haplotypes from 36 in the original paper to 33.

The number of haplotypes and haplotype diversity were calculated following Nei (1987). The nucleotide diversity (Nei, 1987: equation 10.5) and its standard error (se) for population sampling and stochastic processes were calculated from the pair-wise differences between the mtDNA sequences using the Kimura's 2- parameter adjustment (Kimura, 1980). The randomized chi-square test of independence (Roff and Bentzen, 1989) was used to investigate the level of genetic differentiation. In each test a total of 10,000 permutations of the original data were performed. The level of genetic differentiation expressed as H_{ST} was calculated based on Hudson *et al.* (1992).

Phylogenetic reconstruction of the mtDNA sequences was made using the neighbor-joining method implemented in the PHYLIP version 3.5c program (Felsenstein, 1993). Genetic distance among haplotypes were estimated using the program DNADIST of the PHYLIP based on Kimura's 2- parameter model (Kimura, 1980) with an observed transition:transversion ratio of 1:20. The obtained tree was visualized using TreeView PPC (Page, 1996).

RESULTS

On the basis of sequence variation at the 486 bp of control region, five different mtDNA haplotypes were found from the six Japanese gray whales, while six different haplotypes were found from the seven Russian gray whales (Table 2). These haplotypes of the JPNs matched to haplotypes A (N = 1), B (1), G/O (1), L/U (2), and Z (1) in Leduc *et al.* (2002), whereas the haplotypes of the RUSs matched to C (2), H (2), R (1), V (1), AE (1), so that total number of haplotypes found from the two studies was still 33. Haplotype diversity and nucleotide diversity within samples was 0.933 and 0.0185 (se = 0.0058) for the Japanese sample and 0.952 and 0.0163 (se = 0.0032) for the Russian sample, respectively. The level of genetic differentiation between the Japanese and Russian samples expressed as H_{ST} was 0.0316 which was not significantly different from 0 ($p=0.164$). Statistical test failed to detect statistically significant difference in the haplotype frequencies between the JPN and RUS ($p=0.211$). Because it was difficult to extract the exact number of haplotypes within the western and eastern population samples from Lang *et al.* (2004), no statistical comparison was conducted between the samples from this study and the past study.

The neighbour-joining tree was constructed for 33 haplotypes (Fig. 2). No geographically specific cluster was detected.

DISCUSSION

We analyzed the sample of the gray whales collected along the Japanese coast. Therefore, significance of this study is that these analyzed whales definitely came from the western population. We did not have

Do not cite without written permission from the authors

to worry about that we might have collected the individuals from the eastern population that migrated to the feeding ground of the western population.

The results of this study were very same to those of the past genetic studies (Leduc *et al.*, 2002; Lang *et al.*, 2004): the genetic diversity within each of the two samples was high and the eastern and western populations were phylogenetically indistinguishable. As already presented by the past genetic studies, the level of genetic diversity within the western population was surprisingly high as compared with a typical small population. Four possible explanations can be raised. Firstly, individual(s) from the eastern population could have been wrongly sampled as the western population. Secondly, there may be gene flow between the two populations. Thirdly, because of the long life and historically large abundance, the western population may still retains considerable amount of genetic diversity after severe, but recent, population reduction. Finally, the population size of the western population may not be as small as it has been estimated (e.g., Cooke *et al.*, 2008). Among these, the first one is the most unlikely because our sample came from migratory corridor between the feeding and breeding grounds of the western population. The site fidelity of gray whales during the breeding migration has been believed strong. If all of the western gray whales feed at the area off Sakhalin Island and have been completely covered through photo-identification, the population size of the western population is indeed small as estimated (Cooke *et al.*, 2008) and thus the fourth reason raised above becomes unlikely. Among the remained two, it is hard to decide. Because of the small sample size as no statistically significant genetic differentiation was detected between the Japanese and Russian samples, it was difficult to reliably estimate the level of gene flow in this study. The population reduction during the commercial whaling period was quite severe biologically but might not have been genetically, allowing the western population to retain ancient diversity. Continued population monitoring and survey is important to estimate population size and describe migration pattern of gray whales.

Five of the six individuals in the Japanese sample had the different haplotypes and those haplotypes were widespread in the phylogenetic tree. Although two (L/U and Z) of the haplotypes found in the Japanese sample were referred as the eastern population types in Leduc *et al.* (2002), the analysis of the additional individuals in Lang *et al.* (2004) detected these two in the sample collected from the area off the Sakhalin Island. Contrary to the large differences in the numbers and frequencies of the different haplotypes within the samples from the same region among the different studies (i.g., Leduc *et al.*, 2002; Lang *et al.*, 2004; this study), the total number of the different haplotypes found from these studies did not changed as much. This indicated that the inference drawn from the phylogenetic analysis in this study should reflect gray whales' evolutionary history. Sharing of quite many haplotypes between the two populations and their positions in the phylogenetic tree indicated recent divergence of the populations within the species.

During the last year's scientific committee meeting (IWC, in press), population status of the gray whales feeding at the area off Sakhalin Island, whether the whales were the member of the eastern, western or mixture of both populations, was discussed (Brownell *et al.*, 2009; Ilyashenko, 2009). On the basis of the results from mtDNA and microsatellite analyses, Lang *et al.* (2004) showed that the Sakhalin gray whale sample was genetically different from the eastern gray whale sample but raised at the same time the possibility of extended migration of the eastern gray whales to the area off the Sakhalin Island.

Do not cite without written permission from the authors

With increase of the sample size, the newly analyzed individuals in the Sakhalin sample tended to have the haplotypes originally found only in the eastern sample but not newly discovered (see Leduc *et al.*, 2002 and Lang *et al.*, 2004). This could reflect the level of the ancient polymorphism retained in the Sakhalin sample or this could indicate that the number of the eastern gray whales migrating to the area off Sakhalin Island is more than we have anticipated. Use of our Japanese gray whales as a reference base sample is suitable to address this kind of issue. However, it is unfortunate that its sample size is small and only mtDNA data is available at this moment. We are thus planning to analyze our samples with more than ten microsatellite markers that should overcome the reluctance for population structure analysis attributable to the small sample size.

ACKNOWLEDGMENTS

We wish to express our sincere appreciation to the following people for their assistance and advice during the sample collection and manuscript preparation: J. Morishita, K. Ueda, and T. Uoya from Fisheries Agency of Japan, H. Kato from Tokyo University of Marine Science and Technology, T. Bando, Y. Fujise, H. Hatanaka, H. Ishikawa, T. Isoda, T. Mogoe, and S. Otani from Institute of Cetacean Research, I. Mikhno from Chukotka Government and A. Ottoy - Aboriginal whalers captain from Lorino village in Chukotka.

ABSTRACT

This study analysed post-1900 published and unpublished records of gray whales in the western North Pacific. Modern whaling recorded a peak annual catch of 100-200 whales in the 1910s, followed by a rapid decline in the 1920s and 1930s and a continued low level (perhaps 10-20 whales/year) for over 40 years to the 1960s. Catches made during the last phase could have been the major factor suppressing recovery until recently. There are reasons to believe that this gray whale stock breeds in Hainan waters.

KEYWORDS: GRAY WHALE; MIGRATION; WHALING-MODERN

INTRODUCTION

In contrast to the recovery of the eastern North Pacific stock of gray whales (Darling, 1984), no significant sign of recovery has been detected in the 'Asian' or western North Pacific stock (e.g. IWC, 2002). The present study attempts to clarify the catch history of this stock by reviewing published and unpublished records of catches. It also considers some possible reasons for the stock's lack of recovery.

MATERIALS AND METHODS

Published and unpublished records of gray whales taken in Korean and Japanese waters were reviewed, in addition to unpublished records of sightings in the same area.

The major sources of published catch records and the periods covered are as follows: (1) 1890-1903, 1906-1945, 1948 and 1957-1966 Park (1987); (2) 1911-1945 Kasahara (1950); and 1945-1966 Brownell and Chun (1977).

Some data are common between the studies —Park (1987) cited all the statistics (1911-1945) in Kasahara (1950) and the 1957-1966 statistics in Brownell and Chun (1977).

Unpublished catch records were obtained from the private log of an ex-whaling gunner, Mr Toraichiro Emoto, covering the coastal seasons 1923/24-1933/34 and 1941/42-1944/45. They include sightings and catches by species and other information on the operation such as area and whales taken by other vessels. Between 1934 and 1941, Emoto was employed in the Antarctic fleet.

A further source of sightings data was the daily records of whale sightings recorded for the Fisheries Agency of Japan by whaling captains operating in the western North Pacific, East China Sea, Sea of Japan and Okhotsk Sea (Fig. 1). The records cover the periods 1971-1987 (large-type whaling) and 1977-1988 (small-type whaling) and are kept at the National Research Institute of Far Seas Fisheries (Far Seas Fisheries Research Laboratory).

¹ A version of this paper was originally presented as SC/A90/G19.

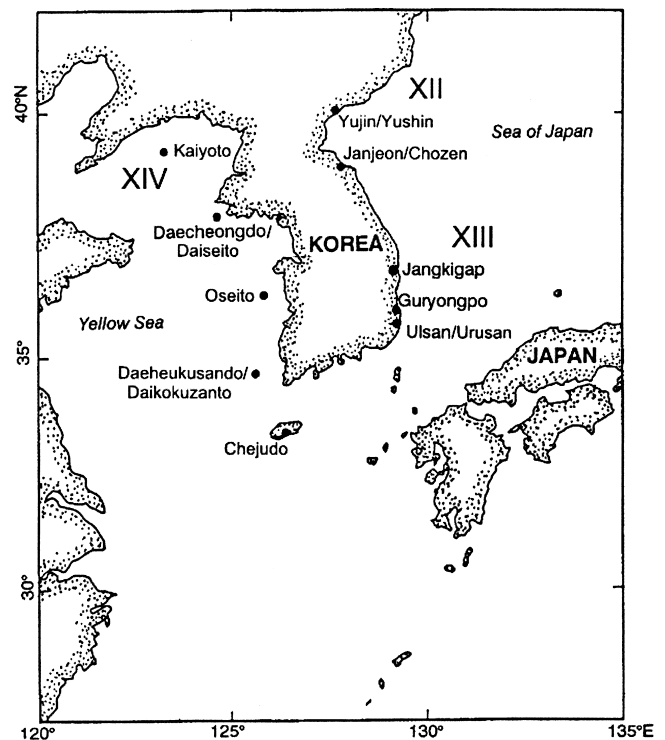

Fig. 1. Land stations (closed circle) used by modern whaling fleets in Korean waters.

Kasahara (1950) grouped the 11 pre-war Korean coastal whaling stations into three areas: (1) Area XII (the northeastern coast bordering the Sea of Japan, the Jangjeon ground of this study); (2) Area XIII (the southeastern coast bordering the Sea of Japan, the Ulsan ground); and (3) Area XIV (the Yellow Sea ground). His classification has been used in the following analysis. Some of the previous studies used Japanese geographical names in Korean waters, but in this study local names have been used as far as possible.

RESULTS

Catch history

A total of 1,750 gray whales (44 individuals by net whaling) were reported to have been taken from the western North Pacific stock in the 77 years from the start of modern whaling in 1891 to 1966 (Table 1): 1,704 (97.4%) were from the east coast of the Korean peninsula (Jangjeon and Ulsan ground); 3 from the west coast (Yellow Sea ground); and the remaining 43 from elsewhere. It is unclear when the exploitation of gray whales ceased in Asian waters, but it certainly lasted until 1966 (Brownell and Chun, 1977).

Just before modern whaling began off the Korean coast, Japanese net whalers took 16, 15 and 13 gray whales off Pusan (southeastern lower Korean peninsula) in 1890/1891, 1891/1892 and 1898/1899 respectively (Park, 1987). A Russian vessel, from the Pacific Whale Fishing Co., began whaling off the Korean coast in 1890 (Tonnessen and Johnsen, 1982, p.131). This marked the start of modern whaling in Asian waters. The operation continued until February 1904 and the outbreak of the Russo-Japanese war (Akaishi, 1910). Statistics are available for only three seasons in the period 1889/1900-1902/03, i.e. 116, 114 and 96 whales, respectively (Park, 1987). Catches by species are only known for the 1902/03 season, with a take of nine gray whales (about 10% of the total) off Jangjeon (Park, 1987). On the assumption that the Russian whaling fleet took about 100 whales/season and 10% of them were gray whales, the total estimated gray whale take in the 13 seasons 1891/92-1902/03 would be around 130 individuals; these are not included in Table 1, which represents the minimum estimate.

Japanese modern whaling started in Korean waters in February 1900, expanded to wider areas along the Korean and Japanese coasts after the Russo-Japanese war (Akaishi, 1910; Park, 1987) and continued in Korean waters until the end of the Second World War in 1945. Catch statistics by species are available from 1906 onwards. Although no statistics before then give the species composition, at least 37 gray whales are known to have been taken on the Jangjeon ground between 1900-1905 (Park, 1987).

High catches occurred during 1907-1918 with a maximum annual take of 193 whales in 1912. Of the total of 674, 546 (81%) were taken on the Ulsan ground. From 1920, the catch declined annually, but it is clear from the Emoto log that catches continued at a very low level on the Ulsan and Jangjeon grounds until 1945. Although the log does not cover the 1934/35-1940/41 seasons, it is a reasonable assumption that other Japanese vessels will have taken some gray whales in the area. A gray whale was reported in 1942 from a land station on Paramushiro Island in the northern Kuril Islands (Mizue, 1951) which may have originated from the Californian or eastern stock of gray whales.

There are some inconsistencies between the published statistics and the Emoto log. Emoto recorded the take of seven gray whales off the east coast of Korea in 1942/43-1944/45 (Table 1), but none are recorded in the official statistics used by Kasahara (1950) and cited in several studies. Since Emoto's records only covered about half of the total fin whales caught on the Ulsan ground during this period, the total gray whale catch there could have been higher. Additionally, if the operation off northeastern Korea (the Jangjeon ground) is taken into account, the total take of gray whales on the Korean coast could have been higher. During the war years, in the face of threats from enemy submarines, there would have been increased demands on local food sources such as gray whales.

After the Second World War, whaling resumed in the Republic of Korea in 1946 (Park, 1987) and possibly also in the Democratic Peoples Republic of Korea (North Korea). Brownell and Chun (1977) report a total of 67 gray whales taken on the Ulsan ground in the period 1948-1966. Information is not available on catches made in the Democratic Peoples Republic of Korea.

The Peoples Republic of China began modern whaling in 1964 using a catcher boat and there is a recorded catch of at least three gray whales, one each in September 1949, June 1958 and April 1960 (Wang, 1978).

Sightings of gray whales on the Ulsan ground

According to the Emoto log, the catcher boat operated up to 40 n.miles from the coast, mainly for minke and fin whales. There were no gray whale sightings beyond 10 n.miles from the coast.

Emoto recorded 17 sightings (36 individuals) of gray whales on the Ulsan ground during the winter (December and January) in the period 1923-1944. Positions are available for 11 sightings. Most occurred at a depth of ≤ 100 m and between Jangkigap and Wejeulgap (Fig. 2). The Emoto log records that the majority frequented the waters off Sogi. School sizes were: 7 singles; one school each of 2 and 3 whales; and 2 schools of 4 animals. There were no records of cow and calf pairs, but it is uncertain whether such schools were either not sighted or not recorded as such.

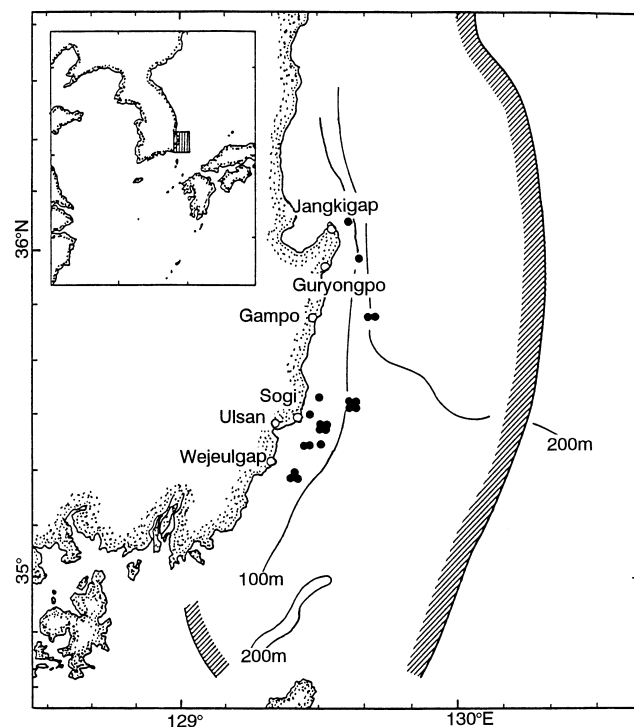

Fig. 2. Sighting positions of gray whales (closed circle) in the Emoto log (1923/1924-1933/1934; 1941/1942-1944/1945) and the ordinary daily rate of operation for fin and minke whales (inside of the shaded area).

Monthly changes in the catch

Table 2 provides monthly catch data from the Ulsan and Jangjeon grounds from published records. These occurred from November-April, with a major peak in December/January and another, smaller peak some three months later, in March/April. Although the discrepancy in magnitude of the two peaks could be due to the general operational pattern of taking fin whales in the Yellow Sea in early spring this could also be interpreted as a reflection of migratory movement south to the breeding ground.

In contrast to the Ulsan ground, the Jangjeon ground recorded two distinct peaks in December and April (about four months apart) and the discrepancy in magnitude of the two peaks is less distinct. The greater time interval on the northern ground (Jangjeon) reflects the difference in timing of the gray whale migration.

Post-war records of gray whales in the northwestern North Pacific

Positions of gray and right whale sightings from Japanese catcher boats are given in Fig. 3. Japanese small-type whaling vessels operated from April-September usually within 60 n.miles of the coast; whale sightings were reported for the seasons 1977-88. Some right whales but no gray whales were recorded by those operations.

Japanese large-type whaling vessels usually operated within 300 n.miles from the coast and reported sightings of whales throughout May-March in the years 1971-87. Records included 'one like gray whale' at 34°31'N, 145°43'E (about 250 n.miles from the nearest coast). The record appears in the Japanese progress report to the International Whaling Commission (IWC) (Anon., 1981) as 'a gray whale'; however it is ignored here as the species identification may be incorrect. The large-type whalers reported nine sightings of right whales, concentrated off Sakhalin, mostly in 1974, suggesting that gray whales wintered much further to the south of the Korean peninsula possibly for breeding.

In addition to the above, there have been five sporadic records (Fig. 3) of gray whales on the Pacific coast of Japan during the period 1968-90 (one whale sighted off the Kii Peninsula; *ca.* 33°30'N-135°30'E) in June *ca.* 1959

(Nishiwaki and Kasuya, 1970); one taken off the Kii Peninsula, February 1968 (Nishiwaki and Kasuya, 1970), one sighting in Ise Bay (34°30'N-136°E), March-April 1982 (Furuta, 1984); one sighting off the Kii Peninsula (*ca.* 33°30'N-136°E), April 1985 (Kasamatsu and Ishikawa, 1990); one stranding on the coast of Sagami Bay (*ca.* 35°N-139°E), February 1990 (Kasamatsu and Ishikawa, 1990).

More recent sightings, of two individuals, were off Izu-Oshima Island (*ca.* 34°30'N-139°30'E) in April 1993 (K. Nakamura and A. Mochizuki, pers. comm.). One animal was stranded at Suttu Town (*ca.* 43°N-140°E), Hokkaido (Kato and Ishikawa, in prep.).

Information on recent sightings of this species in the waters of the Russian Federation is detailed in Weller *et al.* (1999). One juvenile was sighted off the Pacific coast of Kochi, southwest Japan (*ca.* 33°N, 133°E; Kato and Tokuhiro, 1997).

DISCUSSION

The minimum total take of gray whales by modern whaling from the Asian stock since 1891 is estimated to be 1,750 individuals, including 44 caught in net whaling in the 1890s. However, taking into account species uncertainties in the Russian records (100-200 whales) and possible under-recording during the Second World War (10 or more), a better estimate would be between 1,800 and 2,000 individuals. The rapid annual decline to 10-20 whales/season following the peak catches of 100-200 individuals/year at the turn of the century, probably reflected a decline in stock size.

Although it has generally been believed that the catch of gray whales ceased from 1933-1945 (Kasahara, 1950; Mizue, 1951; Omura, 1988), small scale exploitation continued during that period until the mid 1960s. Low level exploitation after World War II has already been documented (Brownell and Chun, 1977). Thus, this stock of gray whales was the focus of low level, but presumably significant, catches for over 60 years following earlier high catches and rapid decline; this may explain the apparent lack of recovery of this stock (and see Weller *et al.*, 2002).

Analysis of available data has identified two distinctive migration peaks along the east coast of the Korean peninsula. These peaks uphold the probability of a breeding area to the south of the Korean peninsula, the first peak in December/January due to southbound migration for winter breeding and the later March/April peak accounting for northbound migration for summer feeding. The waters

Fig. 3. Position of sightings of gray and right whales reported by Japanese coastal whaling catcher boats and some additional records of gray whales (for details see text). Species key: closed circle = right whale; star = gray whale.

around Hainan Dao island (ca. 20°N, 100°E) were considered by Brownell and Chun (Brownell and Chun, 1977) as the most probable breeding site for the western stock of gray whales. Comparing migration times to those of the eastern stock, the four-month period between southbound and northbound migration for the western stock upholds the possibility of Hainan Dao Island as the southern destination for the migrating whales.

ACKNOWLEDGEMENTS

We are greatly indebted to the late T. Emoto for permission to use the 'Emoto Log' for the present study and to S. Ohsumi, Director of the National Research Institute of Far Seas Fisheries for valuable suggestions. Koo-Byong Park (National Fisheries University of Pusan, Republic of Korea) and the late K. Nasu (National Research Institute of Far Seas Fisheries) kindly reviewed the manuscript. R. Shige assisted with the artwork.

Retrophylogenomics in rorquals indicate large ancestral population sizes and a rapid radiation

Fritjof Lammers^{1,2,3}, Moritz Blumer¹, Cornelia Rücklé¹ and Maria A. Nilsson^{1,2*}

Abstract

Background: Baleen whales (Mysticeti) are the largest animals on earth and their evolutionary history has been studied in detail, but some relationships still remain contentious. In particular, reconstructing the phylogenetic position of the gray whales (Eschrichtiidae) has been complicated by evolutionary processes such as gene flow and incomplete lineage sorting (ILS). Here, whole-genome sequencing data of the extant baleen whale radiation allowed us to identify transposable element (TE) insertions in order to perform phylogenomic analyses and measure germline insertion rates of TEs. Baleen whales exhibit the slowest nucleotide substitution rate among mammals, hence we additionally examined the evolutionary insertion rates of TE insertions across the genomes.

Results: In eleven whole-genome sequences representing the extant radiation of baleen whales, we identified 91,859 CHR-SINE insertions that were used to reconstruct the phylogeny with different approaches as well as perform evolutionary network analyses and a quantification of conflicting phylogenetic signals. Our results indicate that the radiation of rorquals and gray whales might not be bifurcating. The morphologically derived gray whales are placed inside the rorqual group, as the sister-species to humpback and fin whales. Detailed investigation of TE insertion rates confirm that a mutational slow down in the whale lineage is present but less pronounced for TEs than for nucleotide substitutions.

Conclusions: Whole genome sequencing based detection of TE insertions showed that the speciation processes in baleen whales represent a rapid radiation. Large genome-scale TE data sets in addition allow to understand retrotransposition rates in non-model organisms and show the potential for TE calling methods to study the evolutionary history of species.

Keywords: Evolution, Phylogenetics, Whales, Transposable elements, Retrotransposon

Background

The bifurcating tree of life, where at each speciation event one ancestral lineage split into two new species, is a concept deeply rooted in the field of evolutionary biology. The opposite, that several new lineages diverge from the same speciation event, a so called polytomy, is mostly regarded as an artefact of limited phylogenetic information [1]. The sequencing and analyses of complete genomes was expected to

finally resolve ambiguous relationships by providing enormous amounts of data [2]. Instead of resolving long standing phylogenetic controversies, genome-scale datasets revealed a lot of natural complexity in the phylogenetic data that previously had been deemed as noise [3, 4].

The evolutionary history of baleen whales (Mysticeti) is a prominent example of a phylogeny that lacked a scientific consensus for a long time [5–8]. In particular, the relationships among rorquals (Balaenopteridae) and gray whales (Eschrichtiidae) were contentious. While some studies showed that the only extant species of gray whales (*Eschrichtius robustus*) is phylogenetically placed within rorquals [6–8], others placed the gray whale as a sister group to rorquals, which was expected given its different morphology and feeding behaviour [5, 9].

Recently, whole-genome sequencing (WGS) of nearly all extant baleen whale species suggested that the rapid radiation of rorquals might represent a hard polytomy [10]. To further explore if the baleen whale phylogeny contains a polytomy, we use transposable element (TE) insertions. TEs are a robust and independent type of phylogenetic markers, that overcomes many limitations of sequence based phylogenetics, i.e. based on single nucleotide variants (SNV) [11]. Furthermore, TEs evolve neutrally and occur interspersed throughout the genome. Hence, they avoid potentially biased phylogenetic signals from gene tree error or linkage disequilibrium that can occur in sequence-based multi-locus analyses [12]. In addition, TE insertions are virtually homoplasy-free because parallel insertions in the large genomic space are very rare [11]. Also, they are less prone to reversals or mutational saturation that can affect SNV-based phylogenetic inference [11].

In baleen whale genomes, the most abundant TEs are short and long interspersed nuclear elements (SINEs and LINEs), covering 24.5% of the bowhead whale genome [10, 13]. The most abundant SINE family in baleen whales are CHR2 elements, which are named after their presence in Cetacea, Hippopotamidae and Ruminants [14] and emerged at least 56 million years ago (Mya). Like most other SINEs, the non-autonomous CHR2 elements are derived from a tRNA sequence. They are mobilized by the enzymatic machinery of LINE1 elements via an RNA intermediate that is reverse transcribed to cDNA and reintegrated into the genome. Compared to LINEs, their relatively high insertion frequencies make SINEs ideally suited for phylogenetic inference in mammalian genomes [11]. TEs have a long history of being used as phylogenetic markers for different cetacean groups [15–17].

Due to advances in genome sequencing and software development thousands of TE insertions can be inferred from multiple genomes across species and individuals [18, 19]. Thus, genome-scale TE detection was successfully applied to analyze retrotransposition in several vertebrate clades outside humans [20–23]. Furthermore, WGS based approaches proved extremely valuable in phylogenetic inference because they can increase the number of discovered TE insertions a thousand-fold, providing enhanced statistical power and the possibility to detect processes of reticulate evolution [23]. By contrast, PCR-based approaches have relied on tedious and time-consuming experimental work to find a few dozens of phylogenetically informative TE insertions from hundreds to thousands of candidate loci [24, 25]. Selection of candidate loci using an experimental approach was often based on a single genome sequence, introducing an ascertainment bias in the phylogenetic signal [17, 26,

27] that can be avoided by the use of large scale WGS sequencing and bioinformatic pipelines.

Here, we identified 91,859 CHR2 insertions in the available baleen whale genomes. This dataset was used to reconstruct the rorqual species tree and allowed us to quantify evolutionary conflict originating from their rapid radiation that took place approximately 8 Mya, coinciding with the onset of modern global oceanic circulation.

Results

WGS mapping and TE variation discovery

We mapped 11 WGS datasets from baleen whales with a coverage depth between 7 and 30 X to the bowhead whale (*Balaena mysticetus*) genome sequence [13] (Additional file 1: Table S1). From the mapped data, the Mobile Element Locator Tool (MELT) [19] called 488,373 non-reference (i.e. absent from the bowhead whale genome) CHR2 insertions, of which 327,488 (67.1%) passed stringent quality filtering. The bowhead whale is a natural outgroup to rorquals and gray whales, hence we focused on calling non-reference insertions in the 11 baleen whales to obtain an ascertainment bias free marker set for rorquals and gray whales. The total number of extracted CHR2 insertion calls per species ranged between 27,994 and 38,182, except for the North Atlantic right whale (*Eubaleana glacialis*), for which 6608 were found (Table 1). The North Atlantic right whale diverged from the bowhead whale about 4.4 Mya, hence fewer variable CHR2 loci reflect a closer genetic distance. In comparison, the divergence time of right whales and the bowhead whale to rorquals and gray whales is ~28 Ma. For clarity, we follow the nomenclature by ref. 10 to include the gray whale within rorquals sensu lato (Balaenopteridae + Eschrichtiidae).

Table 1 Numbers of all CHR2 insertion calls, as well as the amount of heterozygous insertions (Het) in baleen whale genomes compared to the bowhead whale genome

Sample	No CHR2 calls	Het
Blue whale	37,133	26,942
Fin whale	27,994	13,712
Gray whale (eastern) A	36,064	14,648
Gray whale (eastern) B	38,182	17,449
Gray whale (western) A	32,057	24,922
Gray whale (western) B	32,735	22,544
Humpback whale	28,618	14,622
Minke whale	28,606	12,089
North Atlantic right whale	6608	4221
Sei whale A	29,874	11,242
Sei whale B	29,617	11,079
Total	327,488	173,470

Extensive simulations to test the performance of MELT on our dataset showed that a sequencing depth of 5 X or higher is sufficient to reach true positive rates (TPR) of 99% for CHR2 insertions (Additional file 1: Figure S1A). Similarly, 92% of called CHR2 insertions were correctly recognized as homozygous indicating a high genotype accuracy on our dataset (Additional file 1: Figure S1B). MELT's internal filtering reduced sensitivity slightly (Additional file 1: Figure S1C, D), however, our simulations showed that the most effective filters affected all mapped genomes equally because they were based on properties of the reference genome, e.g. the presence of low-complexity regions (Additional file 1: Figure S2). Hence, these filters are not expected to create biases between samples that would influence phylogenetic inference. Furthermore, MELT-Split, which jointly genotypes all genomes, highly improved the detection of orthologous insertions compared to analyzing each genome individually and later combining the results. In summary, the simulations showed that our

approach generated a dataset of high-quality baleen whale TE insertions with the corresponding orthology information that are suitable for evolutionary analyses.

TE phylogenomics recovers rorqual speciation history

By creating a presence-absence matrix from 327,488 genotyped CHR2 insertion sites in all genomes, 91,859 orthologous integration events were identified that took place during the evolution of baleen whales. Based on the presence-absence matrix, phylogenetic trees were reconstructed using Dollo parsimony, Bayesian inference (BI), and Neighbor-Joining (NJ) methods. The three reconstruction methods indicated a common monophyletic origin of Balaenopteridae and Eschrichtiidae (Fig. 1a, Additional file 1: Figure S3) and placed the gray whale as the sister species to the fin whale (*Balaenoptera physalus*) and humpback whale (*Megaptera novaeangliae*) clade. The minke whale (*Balaenoptera acutorostrata*) was reconstructed as the most basal rorqual species. In the NJ and BI trees, blue whale (*Balaenoptera musculus*) and sei

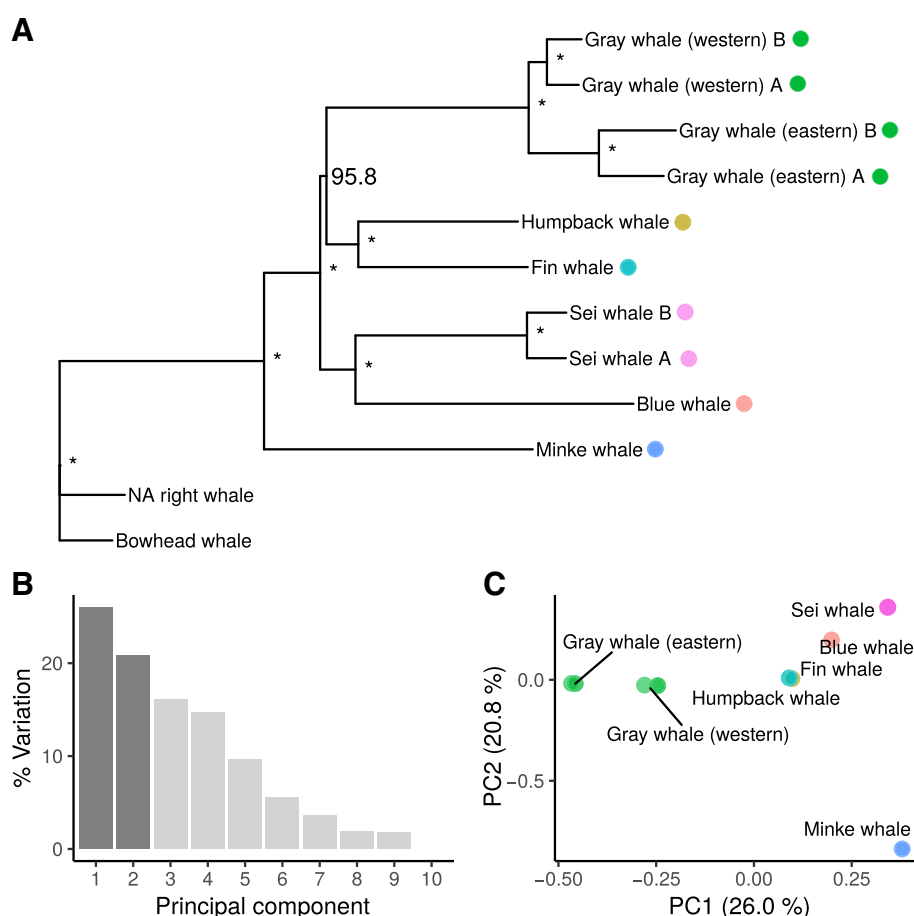

Fig. 1 Phylogenetic signal calculated from 91,859 CHR insertions in baleen whales. **a** Neighbor-Joining tree based on CHR2 insertions. All nodes received bootstrap values of 95% or higher (100% shown as asterisk). **b** Percentage of variation explained by principal components 1–10 in the PCA. **c** Scatterplot of the first two principal components (PC1 and PC2) among baleen whale genomes

whales (*Balaenoptera borealis*) formed a monophyletic clade as a sister group to the fin, humpback and gray whales. The CHR2 Dollo parsimony tree differed slightly from this topology because it reconstructed blue and sei whale as two separate lineages outside the fin, humpback and gray whale clade (Additional file 1: Figure S3 A). All trees received high node support with bootstrap values > 0.95 (Dollo parsimony, NJ) and 100% posterior probabilities (BI).

Although these tree reconstruction methods can by design only yield bifurcating topologies and cannot take conflicting genomic signals into account, considerable amount of phylogenetic conflict is indicated by low consistency indices (CI) (ranging between 0.629 and 0.646). The CI is a measure for tree support that indicates the fraction of minimum character changes compared to the observed number of changes, i.e. the tree length. If all character changes are consistent with the reconstructed tree, the CI is 1.0.

Analyzing the phylogenetic signal from CHR2 insertions among rorquals sensu lato using a principal component

analysis (PCA) resulted in only the minke whale being clearly separated from the other species in the first two components, which together explained more than 50% of the variance in the dataset (Fig. 1b and c). While most species were found to be distinct along the first component, gray, fin and humpback whale were nearly indistinguishable on the second component. Furthermore, on the second component, the intraspecific differentiation between the two gray whale populations was as high as between other species pairs (Fig. 1c).

Network analysis reveals phylogenetic conflict

The low CIs of the phylogenetic trees indicate considerable amounts of phylogenetic conflict in the baleen whale genomes. To further explore these evolutionary signals, a median-joining network was calculated in order to uncover signals that otherwise remain hidden by traditional bifurcating tree-reconstruction algorithms. The phylogenetic network of CHR2 insertions showed a star-like web in the center of *Balaenoptera* and *Eschrichtiidae* (rorquals sensu lato) (Fig. 2a). Edges in the network that cluster the

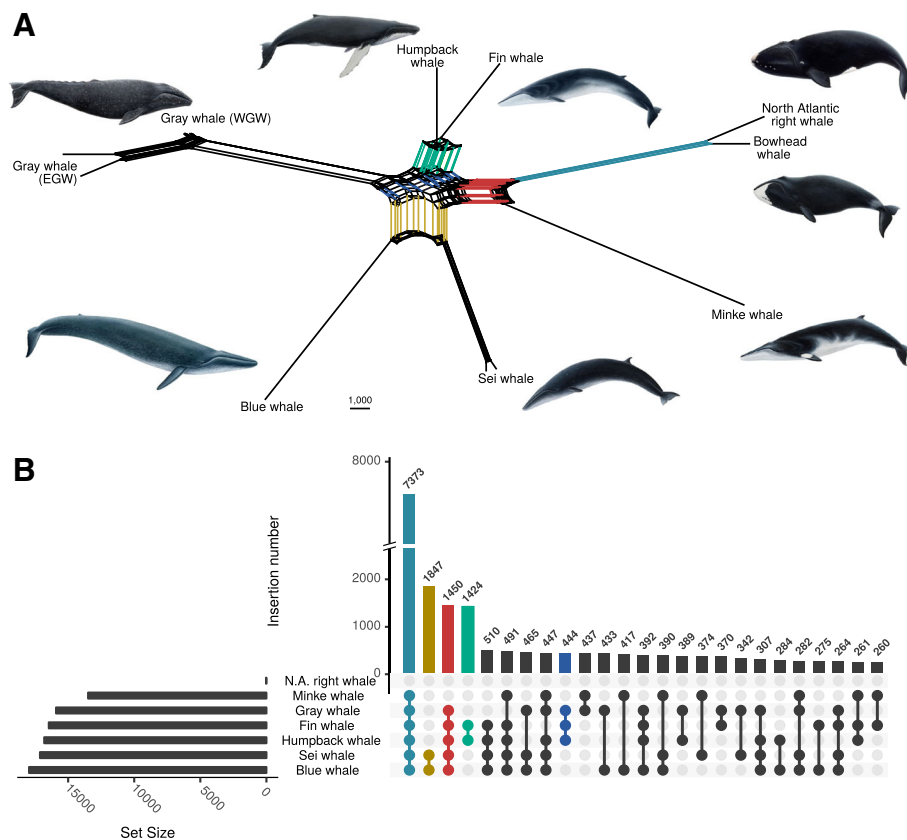

Fig. 2 Phylogenetic conflict among baleen whales inferred from CHR2 insertions. **a** Phylogenetic median-joining network based on 91,859 CHR2 insertions. **b** Distribution of phylogenetic signals in the dataset. Each synapomorphic CHR2 insertion is considered a phylogenetic signal for the common ancestry for the taxa carrying the insertions. The x-axis shows synapomorphic CHR2 insertions between species listed on the left-hand side. Bars on the y-axis show the number of insertions for the respective synapomorphies. The set sizes on the left-hand side show the total number of insertions present per species. Whale paintings are by Jon Baldur Hildberg (www.fauna.is)

gray whale with either the blue and sei whales and/or fin and humpback whales had similar lengths, thus indicating equally strong phylogenetic signal for both topologies.

A quantification of shared CHR2 insertions in baleen whales showed that the four strongest phylogenetic signals support the NJ tree (Fig. 2b) and are in agreement with the evolutionary history of rorquals inferred from genomic sequence analyses [10]. For example, the strongest signal consisted of 7373 synapomorphic CHR2 insertions shared by all rorquals *sensu lato* and supports a common ancestry of this clade. Within rorquals, 1450 insertions support that the gray whale diverged after the minke whale, confirming the paraphyly of rorquals *sensu stricto*. The monophyly of blue and sei whale as well as of fin and humpback whale was supported by 1847 and 1424 insertions, respectively. These strong signals match the well supported nodes in the reconstructed phylogenetic tree (Fig. 1a): the minke whale is clearly distinct from the other rorquals, and the sister group relationships of blue and sei whale as well as of fin and humpback whale are strongly supported. In contrast to other phylogenetic signals incongruent to the species tree, the numbers of TE insertions for the different phylogenetic positions of the gray whale among rorquals are highly similar and make a differentiation between evolutionary scenarios difficult. A ratio of 510:465:444 CHR2 insertions place the gray whale outside a fin, humpback, blue and sei whale clade (510), as sister clade to blue and sei whale (465) or as sister clade to fin and humpback whale (444), respectively (Additional file 1: Figure S4). Hence, this speciation event in the phylogenetic tree appears intuitively as unresolved and in fact a polytomy was only marginally rejected by the KKSC bifurcation test ($p = 0.0204$) [26]. In addition, a plethora of alternative phylogenetic signals of similar strengths illustrate the star-like radiation of Balaenopteridae and Eschrichtiidae. For example, the gray whale shares 433, 374 and 370 CHR2 insertions exclusively with the blue, humpback and fin whale, respectively. With regard to the previously established species tree, these insertions appear to be signals for ILS, however, they can not be considered by the KKSC test [26]. The KKSC test updates the statistical framework introduced by Waddell et al. [28] to test for the significance of conflicting phylogenetic signals from TE insertions to distinguish between ILS and introgression scenarios.

TE insertion dynamics

To explore the insertion dynamics of CHR2 in baleen whales, we investigated the genetic diversity and the insertion rates across time. We mapped the insertion points of all 91,859 CHR2 insertions on the baleen whale species tree [10] and calculated the frequency of heterozygous insertions on basis of the genotyping information provided by MELT. This allowed us to track how many insertions from each ancestral branch were fixed over

time. Not surprisingly, several terminal branches exhibit high rates of heterozygous CHR2 insertions such as the two gray and sei whale populations and the blue whale (Additional file 1: Figure S5). High rates of heterozygous insertions originate also from the ancestral branches that led to the ancestor of gray, fin, humpback, sei and blue whales as well as from the ancestral branch to the fin, humpback and gray whale clade. The genomic heterozygosity of CHR2 insertions was lower in the sei whale branch and the fin and humpback whale clades, branches that exhibit less phylogenetic conflict (Fig. 2).

CHR2 insertion rates were calculated by mapping the insertion numbers on the species tree and using previously estimated divergence times [10] and an average generation time of 24.4 years for extant baleen whales [29]. The estimated insertion rates were relatively stable across the evolutionary lineages and ranged between 0.013–0.138 CHR2 insertions per generation (Additional file 1: Figure S6). The insertion rates at the terminal and shallow branches were relatively low and varied between 0.013 and 0.035. For the ancestral branch to gray, fin, humpback, blue and sei whale a ~ 10-fold increase in insertion rate was observed compared to other branches. The majority of CHR2 insertions that occurred on this branch are incongruent to the bifurcating species tree. Repeat landscapes of minke and bowhead whale genome assemblies illustrate the evolution of TE sequences over time, by plotting the frequencies of sequence divergence to the TE consensus sequences. Both whale species show an increase in frequency of low-divergent SINEs (5–10% CpG-adjusted divergence), that could indicate an amplification burst of these elements (Additional file 1: Figure S7). The presence of a similar peak in both species at the same divergence indicate it must have occurred before their divergence at ~ 28 Mya.

Discussion

Here we have performed the first genome-scale analysis of TE insertions in whales based on next-generation sequencing technology. The included dataset, consisting of 91,859 insertion events across eight baleen whale species, exceeds the dataset size from a previous experimental approach by several magnitudes [16]. Our dataset made it possible to reconstruct the baleen whale evolutionary history and a detailed quantification of phylogenetic conflict.

Many previous studies have attempted to resolve the phylogeny of baleen whales and to clarify the evolutionary origin of the gray whale (family Eschrichtiidae). The gray whale is ecomorphologically derived from the family Balaenopteridae [5, 9] because it is the only bottom-feeding species within a clade of strictly lunge-feeding species [30] leading to confusion about its taxonomic position among baleen whales. Using TEs as virtually homoplasy-free and independent phylogenetic markers overcomes limitations from single-nucleotide based phylogenies [11] and should

provide a more detailed understanding about the evolution of baleen whales. Thus, we expected that a detailed analysis of TE insertions would finally settle the baleen whale relationships and also add additional information about the rate of retrotransposition in the slowest evolving mammals.

An evolutionary network analysis together with a detailed analysis of phylogenetically incongruent CHR2 insertions suggests that the speciation of rorquals represents a divergence that might not be entirely dichotomous. This is in spite that the TE based phylogenies were well supported and highly identical to the multi-locus coalescent tree generated from 34,192 sequence based gene trees [10] and a supermatrix tree [7]. However, careful interpretation is warranted given that bootstrap support and posterior probability were designed to assess sampling error of single genes, not genome-scale datasets and might lead to wrong conclusions about the species relationships [31]. Using bootstrap replicates and Bayesian probabilities to infer branch support is common practice, however, well-supported branches might merely be the result of an oversimplified evolutionary model if the dataset is large and the phylogenetic signal is not tree-like. Our in-depth analysis of conflicting synapomorphic TE insertions in baleen whale genomes show that the high statistical support in the phylogenetic trees is based on marginal numeric differences. Unfortunately, methods and models to reconstruct phylogenies from genome-scale multi-locus TE insertion datasets are not as developed as for nucleotide substitutions.

The presence of several equally strong conflicting phylogenetic signals in the CHR2 dataset can be caused by a) insufficient character sampling leading to an unresolved divergence (soft polytomy), b) near-instantaneous speciation and subsequent incomplete lineage sorting (ILS), or c) speciation under genetic exchange. Given the data presented here, it is highly unlikely that the divergence of the gray whale and its sister lineages represent a soft polytomy (a), as our extensive dataset of 91,859 CHR2 insertions is distributed across the near complete 2.3 Gb genome sequence of baleen whales and each node in the phylogeny is supported by several hundred insertions (Fig. 2b). In addition, a confounding effect from incorrect phylogenetic signal is marginal because SINE insertions are virtually free from homoplasy.

ILS (b) is the persistence of ancient polymorphisms across speciation events and has been observed in several TE-based phylogenomic studies [32–34], including a study investigating baleen whale relationships [16]. Several factors, such as a rapid radiation, large or expanding ancestral effective population sizes (N_e) and consequently a slow evolutionary fixation rate favor the occurrence of ILS [33]. The gray whale and the ancestors of

the blue- plus sei whales and fin- plus humpback whales rapidly diverged from each other within less than one million years, as is evident from the star-like phylogenetic network (Fig. 2a) and previous divergence time estimates [10, 35]. In addition, a large ancestral N_e is suggested by the high number of species-tree incongruent CHR2 insertions and the large fraction of evolutionary old and still unfixed, heterozygous insertions that integrated on the ancestral branches with the highest degree of ILS (Additional file 1: Figure S5, and S6). The genome-wide analysis of CHR2 insertion thus strongly indicates that the ancestral rorqual population exhibited large population sizes and radiated rapidly. Also, explicit modeling of the demographic histories of baleen whales based on genomic data indicates large ancestral population sizes of whales [10]. However, these estimates do not reach back enough in time to cover the timeframe of the radiation.

Whales are the largest living animals and known for their slow physiological and evolutionary rate [36]. They exhibit the slowest nucleotide substitution rate among mammals, estimated to be 10 times slower than among primates [37]. Our estimates indicate that the rate of SINE insertions is about 50% slower than in humans, for which a mean rate of 0.046 Alu insertions per generation per genome was estimated [38]. However, we also observe a 10-fold increased CHR2 insertion rate on the branch to the fin, humpback, gray, blue and sei whale clade. Similar strong fluctuations in SINE insertion rates across evolutionary time, like estimated within baleen whales, were also reported for great apes [20].

Finally, a potential third cause for a conflicting phylogenetic signal (c) is that the emerging whale species might have exchanged genetic material for a long time because vicariance is more difficult to maintain in the marine than in the terrestrial environment. Hence, also speciation with genetic exchange of baleen whales might have caused trans-species polymorphisms [10, 39]. Whether the resulting genomic mosaicism is a result of speciation with genetic exchange or from ILS is however not possible to determine [40] and both processes are plausible for baleen whales. Either process or a combination of both could have created the observed phylogenetic signals that are incompatible with a strictly bifurcating tree. More detailed investigation of these processes require new methods that examine patterns of phylogenetic signals from TE insertions with respect to speciation processes and gene flow.

Conclusions

This study demonstrates the suitability of WGS datasets to infer TE insertions, one of the largest contributor to genomic variation in mammals [41]. Thus, TE insertions are a highly valuable source for

comparative genomics and for reconstructing phylogenies. In line with the first application of TE-based phylogeny of baleen whales [16] and a recent nucleotide-based study [10], the radiation of rorquals sensu lato appears to represent a hard polytomy when depicted as a phylogenetic tree because alternative phylogenetic scenarios are equally well supported. Therefore, a better representation of the rorquals' evolutionary history would be to represent the divergences in a phylogenetic network [10], allowing for the incorporation of ILS and genetic exchange between species as horizontal reticulations. We anticipate that a population-wide sampling of baleen whales might illuminate the divergence processes in more detail.

Materials and methods

WGS mapping

Whole-genome sequencing data from ref. 10 plus additional samples of two gray whales and a fin whale [42, 43] were quality-checked with FastQC (<https://www.bioinformatics.babraham.ac.uk/projects/fastqc/>), trimmed if necessary with Trimmomatic [44] and mapped to the bowhead whale genome with BWA [45] (Additional file 1: Table S1). The bowhead whale (*Balaena mysticetus*) genome assembly [13] was chosen for reference mapping over the more continuous minke whale genome because it is a natural out-group to the rorqual species and thus eliminates TE detection bias between samples [23].

TE detection

The Mobile Element Locator Tool (MELT) [19] was run in the Split mode on all scaffolds larger than 100 kb. A consensus file for TE detection was created according to the MELT manual. We chose the general consensus sequence of the CHR2 SINE family, that was active during the evolution of Cetacea [46]. Seven different subfamilies of CHR2 have been described for cetaceans [47], that contain indels compared to the general CHR2 consensus sequence. Using the full length general consensus of CHR2 [14] and allowing for 10% mismatches makes a broader detection of CHR2 insertions in MELT possible. To annotate all copies of the CHR SINE family elements in the bowhead whale genome, the genome sequence was repeat-masked (<http://www.repeatmasker.org/>) with the Cetartiodactyla repeat library. BEDOPS [48] converted the RepeatMasker output into BED format.

Simulation and sensitivity analysis

Prior to TE calling, we performed a sensitivity and specificity analysis using our custom-made TE calling assessment pipeline ESAT (Element Simulation Analysis Tool) using sequences and parameters matching our whale

dataset. We selected the longest scaffold (5 Mb) from the bowhead whale assembly to serve as a sample genome for our sensitivity analysis. We randomly integrated 200 CHR2 SINEs in the sample genome sequence and simulated paired-end Illumina reads from the resulting sequence with SimSeq (<https://github.com/jstjohn/SimSeq>) at sequencing coverage levels ranging from 1 to 30 X coverage. For read simulation we generated an error-profile typical for our whale resequencing datasets. Reads were mapped to the sample genome with BWA [45] as described above and MELT was used to call the CHR2 SINE insertions from our simulated genome. We generated 10 replicates per simulation. To analyze the performance of MELT, we assessed if the detected non-reference TE insertions matched the simulated TE locations using BEDtools [49]. The detection rate (DETR) reflects the sensitivity of MELT to successfully identify a TE insertion. True positive rate (TPR), false positive rate (FPR) and false negative rates (FNR) were calculated from the detected TEs to estimate MELT's accuracy on the whale dataset. Finally, the proportion of correctly genotyped insertions among the detected variants was recorded. We made ESAT publicly available on <https://github.com/crueckle/ESAT>.

Phylogenomic analysis

Orthologous TE insertion calls across the taxon sampling were identified using the GroupAnalysis and Genotype algorithms in MELT. TE insertion calls passing internal MELT filters were extracted with bcftools filter (www.htslib.org). A NEXUS-formatted presence absence matrix of orthologous TE insertions was created with a modified version of vcf2phyloip [50]. Phylogenies were reconstructed using Neighbor-Joining and Dollo Parsimony in PAUP* [51]. Under Dollo Parsimony, only character state changes from absence to presence (0 to 1) are allowed, thus matching the evolutionary model of TE insertions. Heuristic tree search was conducted with random addition of sequences and 100 repetitions using Tree Bisection and Reconnection (TBR) as branch swap algorithms. Bootstrap support values were calculated from 1000 replicates. Likelihood scores for each tree were calculated using the 'lscores' command. A Bayesian inference tree was calculated in MrBayes v.3.2.6 [52] using "irreversible" character type (ctype irreversible:all) with 10e7 generations and sampling every 1000th generations, 25% of the samples were discarded as burn-in. Principal component analysis (PCA) for the filtered CHR2 datasets were conducted with the SNPRelate package for R. Phylogenetic median joining networks were generated in SplitsTree4 [53]. The intersection diagram was created with UpSetR [54]. For gray and sei whales, only TE insertions present in all individuals of the respective species were considered.

Insertion rates

Per-branch insertion rates were calculated from the number of CHR2 insertions that we had mapped to the species tree from ref. 10. This tree was used because it is the best available bifurcating representation of the baleen whales evolutionary history and is congruent with other recent studies on baleen whale phylogeny [7]. Species-tree incongruent CHR2 insertions were assumed to be the result of ILS and accordingly mapped to the most recent ancestral branch leading to the affected species. The insertion rate was calculated by the equation $\mu = \eta_{CHR2} * b / 24.4$ with η_{CHR2} for the number of CHR2 insertions and b as the branch length in years. The mean generation time of 24.4 years was calculated for from recent generation time estimates of the studied species [29].

ACKNOWLEDGEMENTS

The completion of this dissertation would not have been possible without the assistance and support of a large number of people along the way. First of all, I would like to thank the members of my committee, which included Dr. Bill Perrin, Dr. Ron Burton, Dr. John Hildebrand, Dr. Rick LeDuc, Dr. David Weller, and Dr. David Woodruff, for their valuable guidance and support. Bill Perrin's breadth of knowledge in the field of cetacean biology and conservation is truly remarkable, and I am honored to have had the opportunity to be one of his students. Ron Burton graciously welcomed me into his lab and included me in his lab meetings, and he was always willing to provide guidance when needed. John Hildebrand and David Woodruff have been great to work with and were always willing to contribute their thoughts and perspective at committee meetings.

Rick LeDuc completed the first genetic studies of western gray whales and graciously passed along his thoughts and ideas to me when I started. Much of what is written here stemmed from discussions I had with Rick, who not only has great insight into the complexities of understanding population structure in whales but also has a truly wonderful talent for explaining and sharing his knowledge with others.

Without Dave Weller's support, encouragement, and faith in me I would not have had the opportunity to work on this amazing and unique project. Dave has been a mentor to me since my very first day as a marine mammal intern, when I was fortunate to be assigned to work with him at Texas A&M University when he was finishing his own PhD. Since that time, Dave has played an integral role in guiding me through the many transitions between that first internship and the completion of this degree, acting as an

advisor on my master's thesis research, helping me through the process of finding a PhD program, and then finally contributing his insight and support to the work presented here. His understanding of and respect for the animals we work with is unparalleled, and I've learned much not only from his direct guidance but also by the example he sets as a researcher in this field.

As part of my doctoral research, I spent six summers in a remote field camp on Sakhalin Island, Russia, where I had many of the most rewarding and challenging experiences of my life. My gratitude goes out to the many members of the western gray whale research team with whom I shared these experiences. Dave Weller has put an incredible amount of time and energy into the success of this project; much of what has come out of the study would not have been possible without his dedication and leadership. Alexander Burdin organized the Russian contribution to the project and has been vital to its success, and his work to make sure that the samples we collected eventually arrived in the US (not an easy task!) is very much appreciated. A special thank you goes to Amanda Bradford, Yulia Ivashchenko, Hyun-Woo Kim, Max Sidorenko, and Grisha Tsidulko, who formed the core field team during the time I was in Sakhalin. Amanda, Yulia, and Grisha were kind enough to guide me through my first years in camp, and Amanda, Max, Hyun-Woo and I went on to share many wonderful and at times difficult experiences. All of these people contributed to the collection of samples utilized in this project, and their dedication to and hard work for the conservation of western gray whales was inspiring. In addition, during my time in the Russian Far East I experienced firsthand the hospitality and generousness of many other Russian friends and colleagues. Although too numerous to name, a particular thank you goes to Yuri

Shvetsof, who faithfully carted our team in and out of camp numerous times in his trusty jeep.

Many thanks go to Bob Brownell, who has played an integral role in the western gray whale project and has contributed a lot of his thoughts and ideas to the work presented in this dissertation. On a more personal level, over the years I have really come to appreciate Bob's insight into and dedication to cetacean conservation, and I have learned a lot from working with him.

When I began volunteering at the Southwest Fisheries Science Center (SWFSC), my understanding of how genetic tools could be used to study marine mammal populations was limited, and my lab skills were nonexistent. Many thanks go to Sergio Escorza, who took me on as a volunteer working on his postdoctoral project despite my lack of experience. Carrie LeDuc gave me much more than my first job at SWFSC; she also provided encouragement and support in the early years of my dissertation work and is missed greatly at our lab.

I am fortunate to have spent the last several years as part of the Marine Mammal Genetics Group at SWFSC. Eric Archer, Karen Martien, Phil Morin, and Barb Taylor have provided advice on various aspects of this project, and their innovative approach to answering questions continues to be an inspiration to me. In particular, my gratitude goes to Barb for welcoming me into her group. Amanda Bowman and Vicki Pease, as the lab manager and lab manager's assistant, respectively, have helped with numerous questions and general needs of this project. Thanks also go to Kelly Robertson, who was very helpful in facilitating the import of our samples into the US from Russia, and to Gaby

Serra-Valente, who has been instrumental in archiving and maintaining the samples that were used in this project.

Lisa Ballance, as the director of the Protected Resources Division of SWFSC, has kindly included me as part of the division, and Jeremy Rusin has been the go-to person for numerous questions and concerns over the past several years. Wayne Perryman has integrated me into several different projects over the years, all of which were enjoyable and rewarding experiences. On a more personal level, I am grateful for all the support and encouragement he has provided along the way, and for the opportunities to spend time in what have become two of my most favorite places along the California coastline, Piedras Blancas and Granite Canyon.

Brittany, Vicki, and Erin – you all have been great co-workers but even better friends – your encouragement and support through all of this is much appreciated!

A big thank you is also due to my fellow SWFSC/SIO graduate students. John Hyde and Nick Kellar provided much advice that helped me to navigate through the waters of graduate school. Nick has been my officemate for almost the duration of this experience, and has been the source of much encouragement over the years. Particularly in the last couple of years, John played a big role in helping me keep my priorities (i.e. finishing!) straight and provided a much-needed pep talk that gave me the push I needed to make this happen. Carolina Bonin has been both a good friend and a good labmate over the years, and her positive attitude in the face of challenges has been inspiring.

Many thanks also go to R.H. Defran; as my master's thesis advisor he provided much advice and guidance in those early years which laid the foundation for my more

recent endeavors. Given the tremendous number of students who want to work with marine mammals, I will always be grateful that he was willing to take the chance on me.

My love of the ocean and the animals in it is in many ways an inheritance from my parents, who have spent countless hours walking the beaches of Georgia, often in search of sea turtles. My parents always taught me to believe in myself and in the power of hard work, and encouraged me to pursue my dreams. At the time, I'm pretty sure they didn't think that pursuit would lead me to spend so many months in a remote part of Russia working off a small inflatable boat, but despite the worry I must have caused them, my parents never wavered in their support. Many thanks also go to my sisters, Jen and Lindsey, and to Jen's husband Scott for their support and encouragement over the years, as well as the good times we shared along the way.

Last but certainly not least, my gratitude goes out to my family here in La Jolla. More than anyone, Jeremy had to deal with the daily ups and downs that completing this dissertation entailed. He patiently listened to my thoughts and ideas about this work, as well as to the insecurities and doubts I faced along the way, and provided wonderful guidance on both counts. His love, support, and encouragement of me both personally and professionally never wavered. Teddy's quiet presence has been a source of calm throughout my years as a doctoral student, and she never complained about all the plane trips to and from San Diego that she had to endure while I traveled to Russia. And this last year and half wouldn't have been the same without Finn and Otto, whose spirit and charm never fail to bring a smile to my face and some perspective to my life!

Many groups have provided support and funding for western gray whale studies. A special thank you goes to the Protected Resources Division of the Southwest Fisheries

Science Center, which provided support for me during the first and last years of this work and also provided for the analysis of samples utilized in this study. I am also grateful to have received the NOAA Dr. Nancy Foster Scholarship, which provided four years of support for me during this process. Other groups which have provided support and funding for western gray whale studies include (in alphabetical order): Alaska SeaLife Center, Animal Welfare Institute, American Museum of Natural History Lerner Gray grant, Exxon Neftegas Limited, the International Fund for Animal Welfare, the International Whaling Commission, the Marine Mammal Commission, the Marine Mammal Research Program at Texas A&M University at Galveston, the National Fish and Wildlife Foundation, the National Marine Fisheries Service, Ocean Park Conservation Foundation Hong Kong, Sakhalin Energy Investment Company, the U.S. Environmental Protection Agency, and the Washington Cooperative Fish and Wildlife Research Unit. This project was conducted as part of the Marine Mammal Project under Area V: Protection of Nature and the Organization of Reserves within the U.S.-Russia Agreement on Cooperation in the Field of Environmental Protection.

The material found in Chapter Two is being prepared for submission for publication. I was the primary researcher and author. The co-authors D. Weller and A. Burdin supervised the field effort through which the genetic samples were collected. The co-authors D. Weller, R. LeDuc, and R. L. Brownell, Jr. supervised the research.

The material found in Chapter Three is being prepared for submission for publication. I was the primary researcher and author. The co-authors D. Weller and A. Burdin supervised the field effort through which the genetic samples were collected. The co-authors D. Weller, R. LeDuc, and R. L. Brownell, Jr. supervised the research.

Some or all of the material found in Chapter Four and in Chapter Five will be submitted for publication. I was the primary researcher and author. The co-authors D. Weller and A. Burdin supervised the field effort through which the genetic samples were collected. The co-authors D. Weller, R. LeDuc, and R. L. Brownell, Jr. supervised the research.

ABSTRACT OF THE DISSERTATION

The population genetics of gray whales (*Eschrichtius robustus*) in the North Pacific

By

Aimée R. Lang

Doctor of Philosophy in Marine Biology

University of California, San Diego, 2010

Professor William F. Perrin, Co-Chair

Professor Ronald S. Burton, Co-Chair

Within the North Pacific, gray whales (*Eschrichtius robustus*) are recognized as distinct eastern and western populations. Although both populations were severely reduced by whaling, the eastern population is generally considered to have recovered while the western population has remained highly depleted. This study expanded on previous work supporting differentiation between eastern and western populations using mtDNA and utilized a panel of 13 microsatellite loci to provide additional insight into the population structure of gray whales. Comparison of microsatellite allele frequencies indicated that

eastern and western populations are genetically distinct. Although highly statistically significant, the level of nuclear differentiation between the two populations was relatively low, and the results of sex-specific analyses and assignment testing suggested that some degree of male-biased dispersal may occur between populations. Within the set of samples collected from animals on the primary western feeding ground, relatedness analyses revealed that, consistent with field observations, the fidelity of females and their offspring to this area have been important in shaping the structure of the population. Furthermore, analysis of the paternity of animals first identified as calves, with known and sampled mothers, in the western population between 1995 and 2007 identified 18 males as putative fathers, providing evidence that many of the animals identified on the Sakhalin feeding ground interbreed with each other, presumably while sharing a common migratory route. However, the success of the paternity assignment was lower than expected given the high proportion of sampled animals in this population, suggesting that some males which are contributing to reproduction may not use the primary western feeding ground on a regular basis. The combination of these results suggests that the population structure of gray whales in the North Pacific is more complex than previously thought, and that some movements between the eastern and western populations may take place. However, the maintenance of genetic differences between the two populations supports their recognition as separate eastern and western populations. Future efforts should focus on elucidating the nature and extent of any dispersal which is occurring in order to better understand factors potentially influencing the recovery of the small western population.

I. INTRODUCTION

The overall objective of this dissertation is to utilize molecular approaches to elucidate factors shaping the population structure of gray whales (*Eschrichtius robustus*) in the North Pacific. Any genetic patterns that may be delineated, however, must be put into the context of what is known about the distribution, history of exploitation, and current status of the gray whales on both sides of the North Pacific. As such, a general review of the current understanding of these topics, as well as a summary of findings from previous genetic studies, is provided below. Following this review, the rationale behind the current study is described in more detail and the specific objectives of each chapter are outlined.

Distribution

Although gray whales were first described based on subfossil remains from the coasts of England and Sweden (Lilljeborg 1861, 1867; Gray 1865), the population in that ocean basin is thought to have gone extinct by the early 18th century (Mead and Mitchell 1984). The current distribution of the species is limited to the eastern and western margins of the North Pacific (*Figure 1-1*), where two populations are recognized.

Eastern population

The population in the eastern North Pacific spends its summers feeding in the northern Bering and southern Chukchi Seas (Moore and Ljungblad 1984), although sightings in the eastern Beaufort Sea (Rugh and Fraker 1981) and as far west as the East Siberian Sea (Miller *et al.* 1985) have been recorded. In addition, a small number of animals, referred to as the Pacific Coast Feeding Aggregation (PCFA) of gray whales,

show fidelity to more southern feeding grounds located in the coastal waters between northern California and southeastern Alaska (Gilmore 1960, Pike 1962, Hatler and Darling 1974, Patten and Samaras 1977, Darling 1984, Calambokidis *et al.* 2002). Starting in November (Rugh 1984), animals migrate south along the west coast of North America. The primary wintering grounds for this population are located in the lagoons and coastal waters of Baja Mexico (Gilmore 1960, Swartz 1986, Urban *et al.* 2003), with some animals sighted in the Gulf of California (Findley and Vidal 2002). Animals return to the Arctic feeding grounds between May and June.

Western population

Although whaling logbook records indicate that gray whales once had a fairly extensive summer distribution within the Okhotsk Sea (Reeves *et al.* 2008), the majority of recent sightings of gray whales in the western Pacific during summer months have been confined to waters off the northeastern coast of Sakhalin Island, Russia (Weller *et al.* 1999, 2008). The primary feeding ground for the population is located in the shallow waters (<20 m depth) adjacent to the channel connecting Piltun Lagoon to the Okhotsk Sea (*Figure 1-2*; Weller *et al.* 1999, 2008). Animals have also been documented feeding in an area further offshore during some years (Miyashita *et al.* 2001, Burdin *et al.* 2002), and sporadic sightings of western gray whales have been made in other areas of the Okhotsk Sea and western Bering Sea (Weller *et al.* 2002, 2003). More recently, the occurrence of gray whales, some of which are known to have utilized the primary feeding ground off Sakhalin, has also been documented off the southeastern coast of Kamchatka (Tyurneva *et al.* 2009).

Understanding of the current distribution of western gray whales outside of their summertime range is limited. Some records of sightings, strandings, and entrapments of gray whales off Japan exist (Kato *et al.* 2007), suggesting that these regions may be used by migrating whales. The majority of these records are derived from the Pacific coast, although a few (n=4) have been recorded from the Sea of Japan coast (Kato *et al.* 2007). At least one of the whales entrapped off the Pacific coast of Japan has been matched photographically to an animal known to utilize the primary Sakhalin feeding ground (Weller *et al.* 2008b), providing a link between these two areas. Although no gray whales have been sighted off Korea since 1968 (Brownell and Chun 1977), peaks in the whaling catch records indicate that Korean waters were utilized by gray whales as part of both their northbound and southbound migratory routes (Kato and Kasuya 2002). The wintering grounds for this population have yet to be confirmed, but a limited number of sightings, strandings, and catches between 1933 and 1996 have suggested that western gray whales may overwinter in the coastal waters of southern China, including around Hainan Island (Wang 1984, Henderson 1990, Zhu 1998).

Temporal Changes

Although the distribution of the eastern and western populations are generally considered to be geographically separate, past Arctic environmental changes may have played a role in influencing patterns of mixing and separation between eastern and western animals, as has been proposed for bowheads in the Canadian Arctic (Dyke *et al.* 1996, SaVelle *et al.* 2000). Sea ice expansion during the Neoglacial (~4700 to 2500 years ago) may have limited access to parts of the Bering Sea and has been hypothesized to

have altered the distribution of North Pacific pinnipeds and cetaceans (Crockford and Frederick 2007). Most recently, the “Little Ice Age” (~400 – 750 years ago), which caused Arctic-wide cooling and widespread glaciation (Overpeck *et al.* 1997), may have shifted the distribution of sea ice further south and potentially facilitated mixing between the two populations during that time. It is also possible, however, that increases in sea ice cover could have led to population declines by limiting the extent of shallow water habitat available for feeding.

There are several indications that the distribution and habitat use patterns of eastern gray whales may have changed over the last few decades as a result of the increasing size of the population and/or habitat alterations associated with sea ice reduction and warming in the Arctic. Limited surveys conducted in 2002 found that the density of whales utilizing the Chirikov Basin, once considered a primary foraging habitat, was markedly lower than the densities recorded in the early to mid-1980s (Moore *et al.* 2003). Declines in abundance of amphipods, generally considered a preferred prey species for gray whales, were also documented within this region over that time period (Coyle *et al.* 2007). Given that the reduced density of whales utilizing the Chirikov Basin occurred while the eastern population was still growing, it is likely that these changes were reflected in an expanded foraging range for the population (Moore *et al.* 2003). Several other observations further suggest that some combination of environmental changes and the increased abundance of whales may be influencing foraging patterns of eastern gray whales. These observations (reviewed in Moore *et al.* 2008) include 1) median migration dates of southbound whales are approximately one week later than those observed prior to 1980, suggesting a potential redistribution of

whales on the feeding grounds (Rugh *et al.* 2001), 2) the number of calves born north of Mexico has increased over the last several decades (Sheldon *et al.* 2004), and 3) a positive correlation has been found between reproduction in the eastern population and the amount of time primary feeding areas are free of ice in the preceding year (Perryman *et al.* 2002). In addition, although similar behaviors may have been difficult to detect in the past when the population size was smaller and research efforts were more limited, gray whales have been observed foraging on atypical prey (cumaceans) off Kodiak Island, an area formerly considered part of the migratory route, since 1999 (Moore *et al.* 2007), and some gray whales are known to have remained at high latitudes in the western Beaufort Sea during winter months in 2003-2004 (Stafford *et al.* 2007).

These observations suggest that in the face of population recovery and a changing environment, gray whales may respond by shifting patterns of habitat use on their feeding grounds. Such shifts could be reflected in increased opportunities for mixing between the eastern and western populations. Importantly, however, mixing on the feeding ground does not necessarily denote gene flow. Studies of eastern gray whales have indicated that breeding occurs primarily while animals are on the migratory route, with females coming into estrous during a three week period extending from late November to early December, which coincides with the initiation of the southward migration from summer feeding areas (Rice and Wolman 1971). Females which fail to conceive during this first phase of mating may experience a second estrous approximately 40 days later, when whales would be at or near the wintering areas.

History of exploitation

Eastern population

Aboriginal harvesting of gray whales in the eastern Pacific has been occurring since at least the 16th century (Krupnik 1984). Commercial hunts for eastern gray whales on the population's wintering grounds, which began in 1845, peaked between the 1854/1855 and the 1864/1865 seasons, with an average of 486 whales taken per year (Henderson 1984). The number of whales killed per year declined over the next decade, averaging 214 per year until 1873/1874, after which whaling in lagoons largely ended due to the low number of remaining whales (Henderson 1984). These hunts were particularly devastating to the population due to the large number of females killed in lagoons, which greatly reduced the reproductive potential of the population. During the latter half of the 19th century, gray whales were also being taken via shore whaling from stations along the coast of California (Sayers 1984). By the turn of the century, the small number of remaining whales had made whaling no longer commercially viable (Henderson 1984).

Modern "industrialized" whaling for eastern gray whales was limited to a relatively short time period between 1914 and 1946, during which a total of 940 takes were recorded (Reeves 1984). The signing of the International Agreement for the Regulation of Whaling in 1937 provided protection of gray whales from commercial takes by at least some countries. In 1946, the International Convention for the Regulation of Whaling was established and banned commercial whaling by nations which were members of the International Whaling Commission (IWC). Since Russia (then the USSR) was a member of the IWC, eastern gray whales then received protection from commercial

whaling throughout their range. However, aboriginal subsistence whaling of eastern gray whales by the native people of Chukotka (Russia) and Washington State is allowed under the agreement. The current aboriginal catch limits allow for the take of 620 whales between 2008 and 2012, with a maximum of 140 permitted in a given year (www.iwcoffice.org).

Western population

Aboriginal whaling in the western North Pacific, which was active during the 18th century and probably began much earlier, was conducted by Koryak natives in the northern Okhotsk Sea and likely took some gray whales in that area (Krupnik 1984). Although the species taken were not well-documented, gray whales may also have been taken via hand harpoon by the Japanese as early as the 16th century (Omura 1984). By at least the late 17th century, gray whales were being taken by Japanese net whaling, which continued through the late 19th centuries (Omura 1984). Yankee-type whaling by American and European fleets in the Okhotsk Sea took gray whales from the late 1840s through at least the 1880s; the number of whales taken was estimated to be similar to those recorded for the Bering Sea and the Arctic, which numbered in the several hundreds (Henderson 1984).

Japanese net whaling continued to take some gray whales between 1890 and 1899 (Park 1987, Kato and Kasuya 2002), and modern-type commercial whaling for gray whales, most of which occurred off the Korean Peninsula, began in 1891 (Kato and Kasuya 2002). Although large numbers of gray whales were taken as early as 1907, catches peaked between 1911 and 1919, when up to 193 whales were taken in a single

year (Kato and Kasuya 2002). The mean annual catch dropped to 29 whales/year in the 1920s, and only 48 whales were taken between 1930 and 1933 (Kato and Kasuya 2002). The lack of recorded takes between the mid- to late-1930s indicates that the population had reached commercial extinction, and it was considered by some to have been extirpated by that time (Mizue 1951, Bowen 1974). However, the probable existence of the population was later described based on records of additional catches off the Korean coast between 1948 and 1966 (Brownell and Chun 1977), as well as the sighting of a small number of gray whales in the western Okhotsk Sea in 1967 (Berzin 1974, described in Brownell and Chun 1977) and a mother-calf pair in Korean waters in 1968 (Brownell and Chun 1977). The estimated total catch of western gray whales between 1890 and 1966, including both net whaling and modern-type whaling, was 1800-2000 animals (Kato and Kasuya 2002).

As aforementioned, gray whales first received protection from commercial whaling in 1937; however, none of the countries which border the western population's range were signatories to that agreement, resulting in much more recent exploitation of gray whales in the western North Pacific compared with that of whales in the eastern North Pacific. Some protection was afforded the western population in 1946, as Russia was a member of the IWC at that time. Japan joined the IWC in 1951, although South Korea and China did not join the IWC until 1978 and 1980, respectively. North Korea is not currently a member.

Abundance, current status, and potential threats

Eastern population

Shore-based counts of the eastern North Pacific population of gray whales have been conducted by the National Marine Fisheries Service since 1967/1968. Based on the population's abundance and trends in the population growth rate (Buckland *et al.* 1993), the eastern North Pacific stock of gray whales was removed from the List of Endangered and Threatened Wildlife and Plants in 1994. As required under the Endangered Species Act, the population was monitored over the next five years, after which a comprehensive status review was conducted (Rugh *et al.* 1999). Based on the population's continued growth and the lack of evidence indicating that eastern North Pacific gray whales were facing imminent threats, this review supported the continued classification of eastern North Pacific gray whales as non-threatened, although continued monitoring of the population's abundance was recommended (Rugh *et al.* 1999). The current size of the population is estimated at approximately 22,000 animals (Rugh *et al.* 2008, Wade and Punt 2010).

In 1999 and 2000, however, the eastern North Pacific population of gray whales experienced an "unusual mortality event", during which the number of animals stranding in each of those years ($n = 283$ and $n = 368$, respectively) was greater by an order of magnitude than those recorded in previous years (mean = 41 strandings/year between 1995 and 1998; Gulland *et al.* 2005). Although the cause of this mortality event remains in question, the emaciated condition of many of the stranded whales suggested that starvation may have been a contributing factor (LeBouef *et al.* 2000, Gulland *et al.* 2005) and led to speculation that the eastern North Pacific gray whale population may have

reached carrying capacity (Moore *et al.* 2001). However, several factors have indicated that the high mortality rate observed during these two years represented a short-term, acute event rather than a chronic trend (Rugh *et al.* 2005), including the return of stranding rates to levels observed prior to the event (Gulland *et al.* 2005) and calf counts which, a year after the event ended, were similar to the averages for previous years (Perryman *et al.* 2004).

Debate over the delisted status of the eastern population has also been derived from recent molecular estimates of historic abundance, which suggested that prior to exploitation gray whales in the North Pacific numbered ~96,000 animals (Alter *et al.* 2007). Given that the current abundance is approximately 20% of the genetically derived estimate, the authors recommended that the eastern gray whale population should be listed as “depleted” under the Marine Mammal Protection Act. Considerable debate over the interpretation of genetic estimates of historic abundance exists (*e.g.*, Palsboll *et al.* 2007). In addition, given that the contemporary carrying capacity of the environment may not be representative of the carrying capacity during the time period(s) for which these historic estimates are valid, the relevance of using such genetic estimates in determining the current status of populations has been questioned (Angliss and Allen 2008).

In part because of their largely coastal distribution, eastern gray whales may be subject to a variety of threats, including but not limited to vessel collisions, entanglement in fishing gear, habitat degradation, disturbance from anthropogenic noise, and disturbance from whale-watching (Angliss and Allen 2008). As well, in recent years Chukotkan subsistence hunters have noted that some whales (*i.e.*, “stinky whales”) have a strong medicinal odor. The cause of this phenomenon is not well understood, although it

has been hypothesized that changes in the whales' metabolism (potentially correlated with changes in prey) or contamination by bacteria, fungi, or biotoxins may be responsible (Rowles and Ilyashenko 2007, Rosa *et al.* 2009).

Western Population

The western population of gray whales was likely never as large as its eastern counterpart. Although reliable estimates of pre-exploitation size of the population are not available, back-calculation of population size using whaling catch records suggest that by 1900, after the population may have already been reduced by centuries of pre-modern whaling, approximately 1000-1200 individuals remained (Bradford 2003). Mark-recapture models have estimated that the population's abundance in 2003 was 99 animals (95% CI = 90-109), and population assessment using an individual-based model and data collected through 2007 predicted that the median non-calf population size in 2008 would be 130 animals (confidence limits 120-142; Cooke *et al.* 2008). These estimates indicate that the current size of the population is approximately 10% of that at the turn of the century. The population is currently listed as Endangered under the Endangered Species Act and Depleted under the Marine Mammal Protection Act. Internationally, it is listed as Critically Endangered by the International Union for Conservation of Nature (IUCN, Hilton-Taylor 2000, Baillie *et al.* 2004).

The small size of the western gray whale population leaves it vulnerable to numerous threats. Of particular concern for this population is the low number of reproductive females which have been documented (n=24 between 1995 and 2007, Weller *et al.* 2008a), some of which appeared to be experiencing longer-than-normal

intervals between successive calvings, particularly during the early years of the study (Weller *et al.* 2009). A male-biased sex ratio has also been identified among animals sampled on the western feeding ground (58.5% males) in the population; this sex-ratio is particularly pronounced among calves, approximately 66% of which are male (Weller *et al.* 2009). Given that the growth of the population is restricted by the rate at which calves are produced by females, this male-biased sex ratio could be a limiting factor in the population's recovery.

The onset of large-scale oil and gas development in waters proximate to the primary feeding ground in the mid-1990s has raised concern for the western gray whale population's survival (Weller *et al.* 2002, Reeves *et al.* 2005, IISG 2006). Activities associated with this development put western gray whales at risk for behavioral disturbance due to noise, ship strikes or collisions due to increased boat traffic in the area, disturbance to the benthic environment, and exposure to oil and other chemicals (reviewed in Reeves *et al.* 2005, IISG 2006).

Incidental catches in coastal net fisheries along the whales' migratory routes pose another significant threat to the population's survival (Weller *et al.* 2002; Brownell *et al.* 2007, Weller *et al.* 2008). This threat was highlighted by the loss of four whales, all females, to entrapment in nets off Japan between 2005 and 2007 (Brownell *et al.* 2007, Kato *et al.* 2007, Weller *et al.* 2008). Recent population assessment models have shown that if this rate of mortality continues, the population has a high probability of becoming extinct (Cooke *et al.* 2008). Photographic examination of scarring patterns indicate that at least 18.7% of whales identified between 1995 and 2005 showed scars consistent with

entanglement in fishing gear (Bradford *et al.* 2009), emphasizing the risk this threat poses to the population.

The limited information available on the areas used as migratory routes or wintering areas for western gray whales restricts understanding of the threats western gray whales face on other parts of their range. However, it is likely that whales are exposed to hazards associated with nearshore industrialization, shipping congestion, and pollution in these areas (Weller *et al.* 2002).

Previous genetic work

Most of the genetic work that has been conducted thus far on gray whales has focused on examining the potential for sub-structuring within the eastern gray whale population. These studies have indicated that fidelity to natal lagoons may create some degree of structuring within the eastern population, with small but significant mtDNA differentiation detected between cows (mothers with calves) utilizing two of the primary calving lagoons and females sampled in other areas (Goerlitz *et al.* 2003). An additional study, utilizing both mtDNA and microsatellites with samples collected from all three of the primary calving lagoons, also identified small but significant departure from panmixia between two of the lagoons using the nuclear data, although no significant differences were identified using mtDNA (Alter *et al.* 2009).

Sub-structuring within the eastern population could also be generated by fidelity of whales to particular feeding regions. Feeding ground fidelity has been observed in individuals belonging to the PCFA, which utilize coastal waters between northern California and southeast Alaska to feed during summer months (Darling 1984,

Calambokidis *et al.* 2002). Within these waters, photo-identification research, which commenced in the early 1970s, has identified some whales which demonstrate annual return to specific areas within this larger region, although movements between areas within the region also occur regularly (Hatler and Darling 1974, Darling 1984, Calambokidis *et al.* 2002, 2004). Recent estimates of the annual abundance of animals utilizing this region range from ~250 to ~300 animals (Calambokidis *et al.* 2004, Calambokidis 2007). Concern for this group of animals has stemmed in part from the resumption of subsistence whaling by the Makah tribe in northern Washington, an area used by both migrating and feeding whales. Genetic studies of the PCFA whales have focused on determining whether fidelity to this area is derived matrilineally, as internal recruitment of animals into this aggregation would require separate management to ensure that local extirpation would not result in a loss of part of the natural range. Initial work utilizing a simulations-based approach indicated that if the PCFA of whales was derived from a single colonization event in the past 40 to 100 years, detectable mtDNA genetic differentiation would be generated (Ramakrishnan and Taylor 2000). Subsequent empirical analysis, however, failed to detect such a signal when comparing 16 samples collected from known residents utilizing Clayoquot Sound, British Columbia, with samples (n=41) collected from animals presumably feeding in more northern areas (Steeves *et al.* 2001). Additional genetic analysis utilizing an extended set of samples (n=45) collected from whales within the range of the PCFA indicated that the level of genetic diversity and the number of mtDNA haplotypes identified were inconsistent with measures which would be expected if the aggregation was an exclusive maternal isolate (Ramakrishnan *et al.* 2001). However, both studies focused on evaluating only the

hypothesis of founding by a single colonization event and recognized that alternative scenarios, such as limited dispersal of whales from other areas into the PCFA, could also require separate management (Ramakrishnan and Taylor 2000, Ramakrishnan *et al.* 2001).

In addition, differentiation between the eastern and western populations has been explored using mtDNA (LeDuc *et al.* 2002). This study utilized 45 biopsy samples collected between 1995 and 1999 from animals utilizing the primary western feeding ground located in the coastal waters of northeastern Sakhalin Island, Russia, as well as 120 samples collected primarily from animals which stranded along migratory routes in the eastern Pacific. Significant differences in mtDNA nucleotide diversities and haplotype frequencies were identified ($\phi_{st} = 0.117$, $p < 0.001$; $F_{st} = 0.087$, $p < 0.001$), supporting recognition of the eastern and western populations as separate stocks. MtDNA haplotype diversity was substantially reduced in the western population ($h=0.70$) when compared to the eastern population ($h=0.95$). This reduction was derived from differences in the distribution of haplotypes between the two populations. While the 33 haplotypes identified in the eastern population were distributed relatively evenly, the distribution of haplotypes in the western population was highly skewed, with two haplotypes found in very high frequencies (44.4% and 33.3%) and the eight remaining haplotypes found in only one or two individuals.

The number of mtDNA haplotypes ($n=10$) found among western gray whales was surprisingly high given what is known about this population's small size and history of exploitation. This finding was inconsistent with a scenario in which the western gray whale population, then estimated to contain approximately 100 individuals, had been

growing at the expected rate over the past 30+ years, and raised the possibility that little to no growth occurred in the population between the end of whaling in 1966 and the time of the study (LeDuc *et al.* 2002). However, the occurrence of some degree of male-biased dispersal could also explain the high number of haplotypes found in the western population (LeDuc *et al.* 2002). Given the maternal inheritance patterns of mtDNA, such dispersal could occur without having a substantial impact on the extent of mitochondrial genetic differentiation observed. Some support for this possibility was derived from examination of the distribution of mtDNA haplotypes among the sexes. Of the eight western haplotypes which were found in only one or two individuals, six were found only in males. Given the greater number and diversity of haplotypes found in the eastern population, any animals dispersing from the east into the western population would be likely to carry a haplotype not previously found in the west, suggesting that some of those males which carry haplotypes found in only low frequencies in the western population could represent possible dispersers between the two populations (LeDuc *et al.* 2002).

Objectives

The overall objective of this study is to utilize information from genetic markers to add to our understanding of factors shaping the structure of gray whale populations in the North Pacific. Although the previous genetic study identified significant levels of genetic differentiation between eastern and western gray whale populations, it also raised questions about potential movements of some males between the two populations (LeDuc *et al.* 2002). Additional insight into these questions may be provided by integrating information obtained from nuclear bi-parentally inherited markers with that provided by

mtDNA. In Chapter Two, a panel of 13 microsatellite markers is used to determine if significant nuclear genetic differentiation can be detected between the eastern and western populations. Sex-specific comparisons are used to specifically address the possibility that some male-biased dispersal is occurring. This chapter also compares levels of genetic diversity that have been maintained in the two populations, to determine if a substantial amount of genetic diversity has been lost in the much smaller western population.

The use of microsatellites has the additional advantage of facilitating genetic discrimination between individuals, allowing patterns of relatedness between individuals to be assessed. In the third chapter, the microsatellite data are used to conduct a paternity analysis for animals first identified as calves on the western feeding ground. The results of this analysis are used to determine the number of males contributing to reproduction in the western population, as well as to assess the distribution of reproductive success among those males. Given that this is the first study examining patterns of male reproductive success among gray whales, the results are evaluated in terms of our overall understanding of the mating system of mysticetes. The patterns identified are also discussed in light of their implications for the size and the extent of isolation of the western population.

The goal of the fourth chapter is to assess the role that intermixing between eastern and western populations may play in creating genetic heterogeneity among animals sampled on the western feeding ground. The potential for within population processes, such as differential reproductive success among females, to create substructuring within the feeding ground is also explored.

The fifth chapter discusses the incidental identification of two pairs of samples which are genetically identical using the markers utilized in this study. In both cases, one sample of each pair was collected in the eastern Pacific while the other sample was collected in the western Pacific, suggesting the potential for genetic detection of movements of individuals between the two populations. The caveats of using such methods to identify movements are discussed, as well as the implications for population connectivity that might be derived from assuming such movements are real.

II. CHAPTER TWO

Genetic differentiation between the western and eastern gray whale (*Eschrichtius robustus*) populations using microsatellite markers

ABSTRACT

Within the North Pacific, gray whales (*Eschrichtius robustus*) are recognized as distinct eastern and western populations. Although both populations were severely reduced by whaling, the eastern population is generally considered to have recovered while the western population has remained highly depleted. Previous studies have documented genetic differentiation between the two populations on the basis of mtDNA haplotype frequencies. Since mtDNA represents only maternal inheritance patterns, the present study used bi-parentally inherited microsatellite markers (n=13) to measure differentiation between populations as well as to compare levels of nuclear genetic diversity retained in each. Mean levels of genetic diversity, as measured by the microsatellites, were similar between the eastern and western populations, indicating that the western population has retained relatively high levels of nuclear genetic diversity despite its small size. Comparison of microsatellite allele frequencies confirmed that eastern and western populations are genetically distinct. Although highly statistically significant, the level of differentiation between the two populations is relatively low, and sex-specific analyses suggest that some amount of male-biased dispersal may occur between populations. While these results suggest some movements between the eastern and western populations may take place, the maintenance of genetic differences between the two populations supports their recognition as separate eastern and western populations. Future efforts should focus on elucidating the nature and extent of any dispersal which is occurring in order to better understand factors potentially influencing the recovery of the small western population.

INTRODUCTION

Although gray whales (*Eschrichtius robustus*) once inhabited the North Atlantic Ocean (Mead and Mitchell 1984), the current distribution of the species is limited to the eastern and western margins of the North Pacific (Rice and Wolman 1971). Within this region, gray whales are recognized as having distinct eastern and western populations. Eastern gray whales winter in the lagoons and adjacent waters of Baja California, Mexico and then migrate north along the west coast of North America to feed in the Bering and Chukchi Seas during summer (Rice and Wolman 1971), with small numbers remaining in more southern waters between northern California and southeastern Alaska during summer months (Darling 1984, Calambokidis *et al.* 2002). For western gray whales, the primary feeding ground is in the coastal waters off northeastern Sakhalin Island, Russia (Weller *et al.* 1999, 2002). The location of the wintering ground(s) for this population remains unknown, but limited information from sightings, strandings, and catches shows that some animals winter in the coastal waters of southern China (Wang 1984, Henderson 1990, Zhu 1998).

Both gray whale populations were greatly reduced by intensive commercial whaling during parts of the 19th and 20th centuries, but the two populations have exhibited different trajectories in abundance following exploitation. Commercial whaling for eastern gray whales ceased in 1936 (Brownell and Swartz 2006), and the population's size has increased since that time (Rugh *et al.* 2005). Eastern gray whales were removed from the U.S. List of Endangered and Threatened Wildlife and Plants in 1994, and recent abundance estimates indicate that the population contains approximately 22,000 animals (Rugh *et al.* 2008, Punt and Wade 2010). In the western population, however, hunting

continued through at least 1966 (Brownell and Chun 1977). Although likely never as large as its eastern counterpart, this population was reduced to a much smaller size than the eastern population and was considered by some to be extinct as recently as the 1970s (Bowen 1974). Today western gray whales exist only as a small remnant population. Recent population assessment utilizing a Bayesian individually-based stage-structure model and photo-identification data collected between 1994 and 2007 projected a median non-calf population size of 130 individuals in 2008, assuming current demographic and population trends continue (Cooke *et al.* 2008). This population was listed as Critically Endangered by the IUCN in 2000 (Weller *et al.* 2002, Baillie *et al.* 2004), and its continued survival is jeopardized by problems associated with small population size (reviewed in Clapham *et al.* 1999), as well as by a wide range of potential anthropogenic threats, including the rapid expansion of oil and gas development on its summer feeding ground off Sakhalin Island, Russia (Weller *et al.* 2002, Reeves *et al.* 2005, IISG 2006) and mortality due to net entrapment while on the migratory route off Japan (Brownell *et al.* 2007, Weller *et al.* 2008b).

Concern for the conservation status of the western population led to the initiation of a joint Russia-U.S. research program in 1995. This program is based on the summer feeding ground off Sakhalin Island, Russia and has incorporated both photo-identification studies and biopsy sampling (Weller *et al.* 1999, 2002). Photo-identification research has shown that most whales demonstrate high rates of annual return and pronounced seasonal site fidelity to the Sakhalin feeding ground (Weller *et al.* 1999, 2002). The majority (83% of identified whales (n=169) have also been genetically sampled, allowing a male bias (58% males) to be documented among sampled individuals (Weller *et al.* 2002, 2008).

This male bias is particularly pronounced in individuals first identified as calves, of which 66% are males (Weller *et al.* 2008).

Biopsy samples collected between 1995 and 1999 have been used to show that the eastern and western populations are genetically distinct based on mitochondrial DNA (mtDNA) haplotype frequencies (LeDuc *et al.* 2002). This study found that western gray whales have retained a relatively high number of mtDNA haplotypes for such a small population. Genetic differentiation between the eastern and western populations was based on differences in the frequency distributions of haplotypes within each population. While haplotypes were apportioned relatively evenly among the eastern gray whale samples, the haplotype distribution found within the western gray whale samples was highly skewed, with two haplotypes found in very high frequencies and the remaining haplotypes identified in only one or two individuals (LeDuc *et al.* 2002).

The work presented here used thirteen microsatellite markers to further examine population structure of gray whales. Unlike mtDNA, which is maternally inherited and provides information about historic gene flow of females only, microsatellites are nuclear bi-parentally inherited markers and reflect gene flow of both males and females. The primary goal of this study was to examine genetic differentiation between eastern and western populations using microsatellites, as well as to assess factors which might contribute to that differentiation. Secondly, levels of nuclear genetic diversity were compared between the two populations to determine if substantial genetic variability has been lost in the much smaller western population and could thus be affecting its ability to recover. Finally, since additional western gray whale samples have been collected since

the LeDuc *et al.* (2002) study, further analysis of population structure and genetic diversity using mtDNA was also conducted.

METHODS

Sample collection and DNA extraction

One hundred forty-two western gray whale samples were collected between 1995 and 2007 via biopsy darting of free-ranging whales on the population's feeding ground off Sakhalin Island, Russia. All except for one of the western gray whale samples are linked to a photographically identified animal, and this sample set represents 83.4% of all animals (n=169) identified on the western feeding ground through 2007. One hundred thirty-seven eastern gray whale samples obtained from the archive at the Southwest Fisheries Science Center were used for comparison to the western population. These samples were taken primarily from stranded animals (n=105), with some samples obtained from directed subsistence takes (n=12), fisheries bycatch (n=3), and biopsies (n=17) from free ranging whales. Collection locations ranged from southern California north to the Chukotka Peninsula in Russia.

DNA had been previously extracted for 120 of the eastern gray whale samples and 45 of the 142 western gray whale samples (those collected between 1995 and 1999) for use in an earlier study (LeDuc *et al.* 2002). For the remaining samples, whole genomic DNA was extracted using either the QIAGEN DNeasy™ tissue kit or the Corbett Robotics X-tractor Gene robot with the recommended protocols.

Molecular sexing and mtDNA control region sequencing

For those samples (n=114) not analyzed in the prior study by LeDuc *et al.* (2002), molecular sexing and mtDNA control region sequencing were conducted. For all of the eastern gray whale samples as well as the western gray whale samples which were collected prior to the 2006 season (n=94), a polymerase chain reaction (PCR) was used to determine sex utilizing primers described in Fain and Lemay (1995) and following the methods described in Gilson *et al.* (1998). For western gray whale samples collected in 2006 and 2007 (n=20), the protocol described in Morin *et al.* (2005) was used to determine the sex of individuals.

PCR was used to amplify a 523-base-pair fragment from the mtDNA control region using the primers 5'-TACCAAATGTATGAAACCTCAG-3' (H00034, Rosel *et al.* 1995) and 5'-CCTCCCTAAGACTCAAGGAAG-3' (L15812, Escorza-Trevino *et al.* 2005). Amplification products were cleaned through purification columns (QIAquick, Qiagen) and then sequenced using standard protocols with ABI-PRISM[®] Dye-DeoxyTerminator Big Dye[™] v3.1 (Applied Biosystems) and the same primers. Following ethanol precipitation, sequenced products were run on an ABI 3100 or ABI3130 capillary sequencer. Consensus sequences for both strands were generated using ABI SEQSCAPE v2.5 software.

Microsatellite genotyping

Thirteen microsatellite loci isolated from other cetacean species were used to genotype the samples (*Table 2-1*). Reactions were performed in 25-uL volumes containing approximately 100 ng of genomic DNA and 2.5 uL of 2.0 mM MgCl₂ buffer,

1.5 uL of 10 mM dNTPs, 0.75 uL of each primer (at 10uM concentrations, with the forward primer of each pair fluorescently labeled), and 0.25 uL Taq. The thermal cycling profile included an initial hot start of 94°C for 2 min followed by 35 cycles of 94°C for 45 s, 1 min at the annealing temperature (see *Table 2-1*), and 1.5 min at 72°C, with a final 5-min extension at 72°C. Amplified products were mixed with a size standard and loaded onto an ABI 3100 or ABI 3130 sequencer. Sizing and binning of allele fragments using ABI GENESCAN and GENOTYPER analysis software were automated and relied on the use of internal lane standards, with subsequent manual evaluation of all labeled peaks.

Microsatellite scoring errors and identification of replicate samples

Prior to inclusion in this study, photo-identification data collected during biopsy sampling were used to identify and remove any duplicate samples (*i.e.*, samples taken from the same individual) from the western population sample set. Genotypic data were used to search for duplicates within the eastern gray whale sample set using MS Excel Toolkit v3.1 (Park 2001); one duplicate was identified and removed prior to analyses, leaving a total of 136 eastern gray whale samples. Microsatellite data were also examined for signs of large-allele dropout and null alleles using MICRO-CHECKER v2.2.1 (van Oosterhout *et al.* 2004).

Genetic variability within populations

ARLEQUIN v3.01 (Excoffier *et al.* 2005) was used with the mitochondrial control region data to calculate standard indices of genetic variation (nucleotide diversity, π , and haplotype diversity, h ; Nei 1987) for each population. Genetic diversity

at the nuclear level was characterized by generating the number of alleles, observed heterozygosity, and expected heterozygosity for each microsatellite locus in each population using ARLEQUIN. Within each sample set, a Markov-chain approximation of an exact test, as implemented in GENEPOP v3.4 (Raymond and Rousset 1995a), was used to test for departures from Hardy Weinberg expectations and for linkage disequilibrium between all pairs of loci.

Bottleneck analyses

Populations which have undergone recent bottlenecks are expected to exhibit genetic signatures characteristic of a reduction in effective population size (Cornuet and Luikart 1996, Luikart and Cornuet 1998, Luikart et al. 1998, Garza and Williamson 2001). One such signature is a transient excess of heterozygosity (H_e) relative to that expected in a population of constant size, which results from the rapid loss of rare alleles contributing little to overall heterozygosity (Cornuet and Luikart 1996). Here we utilized the program BOTTLENECK v1.2 (Piry *et al.* 1999) to determine if the gray whale microsatellite data demonstrated evidence of population bottlenecks. As recommended (Piry *et al.* 1999), a two-phase model assuming 95% single-step mutations and 5% multiple-step mutations was employed, with the variance among multiple steps set to 12. The distribution of gene diversity at equilibrium was estimated using a coalescent process with 10,000 simulations, and a one-tailed Wilcoxon test was used to determine if an excess of heterozygosity, relative to that expected in populations at equilibrium, was present (Cornuet and Luikart 1996).

The loss of rare alleles during a population bottleneck may also result in gaps in the size distribution of microsatellite alleles. This can be measured as the mean ratio (M) of the number of alleles to the allele size range across all loci (Garza and Williamson 2001); bottlenecked populations demonstrate reduced M values. Here we used ARLEQUIN to calculate M for both gray whale populations and then compared our values to those reported for reduced and stable populations by Garza and Williamson (2001).

Genetic differentiation among populations

Two approaches were used to assess the degree of genetic differentiation between the two sampling regions. In the first approach, samples were divided *a priori* into populations based on the geographic location in which they were collected. The extent of genetic differentiation between populations was then examined using both mtDNA sequences and microsatellite data. For mtDNA data, an analysis of molecular variance (AMOVA, Weir and Cockerham 1984, Excoffier *et al.* 1992) was used to generate frequency-based (F_{ST}) estimates of differentiation using the program ARLEQUIN (20,000 permutations were used to test for significance). For microsatellite loci, genetic differentiation was examined using an AMOVA (ARLEQUIN) and allelic frequencies (with 20,000 permutations to test for significance) to generate F_{ST} values (Weir and Cockerham 1984). Modified exact tests based on genotype counts, as implemented in GENEPOP v3.4 (Raymond and Rousset 1995b), were also utilized to measure levels of differentiation. Significance was tested using 10,000 permutations. Since the western gray whale sample set included 57 mother-calf pairings, analyses of genetic

differentiation were repeated after removal of the sample representing the calf in each pair, in order to avoid biasing the results by including known first-degree relatives.

As an alternative to *a priori* stratification of samples by geographic location, population structure was also explored using a Bayesian model-based clustering approach (STRUCTURE v2.2, Pritchard *et al.* 2000) with the microsatellite data. STRUCTURE assumes that within a set of samples there are K populations, each of which is characterized by allele frequencies at each locus. The program then divides all samples into K genetically distinct clusters by assigning individuals to putative populations such that deviations from Hardy-Weinberg and linkage equilibrium are minimized within each group. Five independent runs of K=1-5 were performed with a burn-in period of 50,000 iterations followed by 100,000 Markov-chain Monte Carlo repetitions, using a model based on admixture with correlated allele frequencies (Falush *et al.* 2003). After averaging across runs, the log probability of the data given K ($\ln P(X|K)$) was used as the criterion to infer the number of clusters (K) most compatible with the our data.

Detection of sex-biased dispersal

The potential for sex-biased dispersal between populations was investigated using the microsatellite data with the methods described by Goudet *et al.* (2002) and implemented in FSTAT v2.9 (Goudet 2001). Since the signal of sex-biased dispersal disappears with mating (Goudet *et al.* 2002), animals first sampled as calves in the western population were omitted prior to analysis. This program generates a number of statistics aimed at identifying patterns of sex-biased dispersal. The statistics utilized here were 1) F_{st} , the proportion of genetic variation among populations; 2) the mean corrected

assignment index (mAIC) and 3) the variance around the assignment index (vAIC) (Favre *et al.* 1997, Mossman and Waser 1999). The p values were estimated using 10,000 randomizations, and a one-tailed test was utilized based on the expectation that, as in most mammals, dispersal is biased toward males. F_{st} and mAIC are expected to be higher in the more philopatric sex, while vAIC should be lower (Goudet *et al.* 2002).

To further explore the potential for sex-biased dispersal between populations, sex-specific estimates of genetic differentiation were generated using the methods outlined above with both the mtDNA and microsatellite data. In addition, values of cluster membership (Q) produced by the STRUCTURE model assuming K=2 clusters were compared between males and females.

RESULTS

Genetic diversity

Forty haplotypes defined by 39 variable sites were identified from the 278 gray whale samples. Thirty-five haplotypes were found among the eastern gray whale samples, while 22 haplotypes were found in the western gray whale sample set. Seventeen haplotypes were shared between the two populations. The frequency of haplotypes in each population is shown in *Table 2-2*. When all samples were combined, nucleotide diversity (π) was 0.018 (SD=0.0092), while haplotypic diversity (h) was 0.89 (SD=0.012). When subdivided by population, nucleotide diversity was relatively similar in both populations ($\pi=0.016 \pm 0.0081$ SD, eastern population; $\pi=0.018 \pm 0.0093$ SD, western population), while measures of haplotype diversity were higher in the eastern ($h=0.95 \pm 0.006$ SD) than the western ($h=0.77 \pm 0.025$ SD) population (*Table 2-3*). Sex-

specific diversity measures indicated that although haplotypic diversity was similar between the male ($h=0.96$) and female ($h=0.95$) subsets of the eastern population, lower levels of haplotype diversity were found among the western female subset ($h=0.77$) when compared to the western male subset ($h=0.83$).

No signal of large-allele dropout or null alleles was identified by MICROCHECKER for any locus in either of the two populations. No deviation from Hardy-Weinberg Equilibrium was detected in either population after controlling for the False Discovery Rate (FDR, Benjamini and Hochberg 1995). After correcting for the FDR, only one loci combination was found to be in significant linkage disequilibrium in the eastern population. However, significant linkage disequilibrium was detected for eight loci combinations in the western population. Given that the same loci pairs were not in disequilibrium in both populations, it is unlikely that this result was derived from physical linkage. Linkage disequilibrium can result from inclusion of related individuals within a sample set. Therefore, known relatives were removed and the tests were rerun on the remaining genotypes. Six loci combinations remained in linkage disequilibrium after controlling for the FDR.

After averaging across loci, measures of microsatellite diversity were higher in the eastern population ($H_o=0.74$, $H_e=0.74$, $K=9.8$) than in the western population ($H_o=0.71$; $H_e=0.70$, $A=8.8$); however, these differences were relatively small (*Table 2-4*). A total of 18 private alleles were observed in the eastern population, while only 5 private alleles were found in the western population.

Statistical analysis of the microsatellite allele frequency data using the program BOTTLENECK did not detect evidence of a recent ($2-4N_e$ generations) bottleneck in

either population. Under the model utilized, heterozygosity excess was not observed in the eastern (Wilcoxon test, $P=0.989$) or the western population (Wilcoxon test, $P=0.999$). In addition, the calculated M values (0.823 ± 0.15 and 0.808 ± 0.17) in the eastern and western populations, respectively) were more consistent with those described for stable populations and were considerably higher than the upper bound (0.70) that Garza and Williamson (2001) derived for reduced populations.

Genetic differentiation among populations

Significant genetic structuring between eastern and western populations on the basis of both mtDNA haplotypes and microsatellite allele frequencies was observed (*Table 2-5*). Similar results were also observed for the microsatellite data when genetic differentiation was assessed using the exact test; the overall results were significant ($p \leq 0.001$), with 11 of the 13 loci showing significant differences when analyzed independently (data not shown). These comparisons remained significant ($P \leq 0.001$) after known relatives ($n = 57$ calves which had sampled mothers) were removed from the analysis (*Table 2-5*); however, only three of the thirteen loci showed significant differences when analyzed independently.

STRUCTURE analyses (Pritchard *et al.* 2000, Falush *et al.* 2003) supported the presence of two populations ($P \sim 1.0$), with a clear increase in the log-likelihood of the data for $K = 2$ when compared to that for other numbers of clusters (*Table 2-6*). The probability that the data contained only one cluster was < 0.001 , suggesting that eastern and western populations are not panmictic. When Q values, which represent the proportion of each individual's genotype that can be attributed to each of the clusters,

were used to assign individuals into clusters, 80% ($n = 109$ of 136) of animals sampled in the east were grouped into the same cluster while 65% ($n = 92$ of 142) of animals sampled in the west were grouped into a cluster (*Figure 1*). However, average source population Q values were relatively low for both populations; they averaged $0.69 (\pm 0.209SD)$ for animals sampled in the east and $0.60 (\pm 0.296SD)$ for animals sampled in the west.

Sex-specific comparisons

Sex-specific estimates of differentiation were much more marked among females than among males. Using mtDNA haplotype frequencies (*Table 2-5*), both the male and female comparisons were highly significant, although the F_{st} value estimated for females ($F_{st} = 0.078$) was more than twice as high as that estimated for males ($F_{st} = 0.033$). Interestingly, while the male-specific comparisons remained significant ($P = 0.029$) in the microsatellite exact test, F_{st} estimates based on microsatellite allele frequencies suggested no significant differences between eastern and western males. The sex-biased dispersal tests in FSTAT also supported greater philopatry among females when compared to males. While difference in males and females were not significant for the mean assignment index ($P = 0.365$) or the variance in the mean assignment index ($P = 0.9262$), females demonstrated significantly higher F_{st} values ($P = 0.0176$).

Results of the STRUCTURE analysis provided further evidence that male-biased dispersal may be occurring. After removing animals first identified as calves, average Q values were similar between eastern males ($Q_{EM} = 0.70 \pm 0.211SD$) and females ($Q_{EF} = 0.67 \pm 0.208SD$, $P = 0.26$, t-test); 80% and 87% of males and females were assigned to

their source population. In contrast, average Q values were lower for western males ($Q_{WM} = 0.47 \pm 0.339SD$) than for western females ($Q_{WF} = 0.63 \pm 0.250$; $P = 0.010$, t-test). Only 40% of western males had $Q \geq 0.50$ for the cluster representing the western population, in contrast to 75% of western females.

DISCUSSION

Genetic variability

Populations reduced to small sizes can suffer from a loss of genetic diversity, which in turn may compromise their ability to respond to changing environmental conditions (Willi *et al.* 2006) and negatively influence long-term viability (Spielman *et al.* 2004, Frankham 2005). Although little is known about the level of genetic diversity maintained in the western gray whale population prior to its depletion by commercial whaling, comparison of the levels of diversity found in this small population with those maintained in the much larger population in the eastern Pacific can provide some insight into whether reduced genetic diversity may influence its recovery. Previous studies utilizing mtDNA indicated that although the western gray whale population had retained a relatively high number of mtDNA haplotypes and levels of nucleotide diversity which were similar to those found in the eastern population, the population had reduced haplotype diversity when compared to its eastern counterpart (LeDuc *et al.* 2002). Our results, using an extended sample set that included ~83% of photographically identified western gray whales, support these earlier findings. As previously noted, the reduced haplotype diversity found in the western population was not a reflection of the number of haplotypes present but rather of the skewed distribution of those haplotypes (LeDuc *et al.*

2002). This skew was even more marked with the added samples. While the frequencies of the two most common haplotypes changed little, new low frequency haplotypes were added, with 14 of the 22 western gray whale haplotypes being found in only one or two animals.

While approximately half (49%) of the mtDNA haplotypes identified in the eastern population were shared with animals sampled in the western North Pacific, a much larger proportion (77%) of the mtDNA haplotypes found in the western population were also identified in eastern animals. Given the relatively thorough sampling of animals on the western feeding ground, it is likely that most if not all haplotypes present in that area have been identified, indicating that the mtDNA haplotypes found only in the eastern Pacific are likely to be unique to that population. In contrast, the low proportion of animals sampled in the eastern population suggests that those haplotypes currently identified only among western animals (n=5) might also be discovered in the eastern population with additional sampling.

Although the relationship between population size and mtDNA diversity is not straightforward (Bazin *et al.* 2006; Nabholz *et al.* 2008), the number of haplotypes (n=22) found in the western gray whale population is surprising given its small size and history of exploitation. In a similar study of endangered North Atlantic right whales (*Eubalaena glacialis*), which are thought to number approximately 400 individuals, only five haplotypes have been documented (n = 180 samples, Malik *et al.* 2000). While sampling in other populations has been less comprehensive, similar patterns have been found in other small mysticete populations, including the Okhotsk Sea bowhead whale population (*Balaena mysticetus*), in which only four different haplotypes were found (n = 25

samples, LeDuc *et al.* 2005), as well as the Sea of Cortez fin whales (*Balaenoptera physalus*), in which three haplotypes have been identified (n = 56 samples, Berube *et al.* 2002).

Although the number of haplotypes currently found in the western population is higher than might be expected, this pattern may not persist into the future. Eleven of the 14 haplotypes found in low frequencies have been identified only in a single male. Although little specific information is available on gray whale longevity, they are generally thought to live for approximately 40 to 60 years. It is possible that some of these “rare haplotype” males could be animals that escaped being killed by whalers which hunted gray whales until at least 1966. Given the maternal inheritance pattern of mtDNA, and assuming that these males are indeed the only animals in the population with these haplotypes, the eventual loss of these individuals has the potential to substantially decrease levels of mtDNA diversity in the future.

The level of nuclear genetic diversity found in the western population was slightly lower than, but similar to, that found in the much larger eastern population. The number of microsatellite alleles found exclusively in the eastern population, however, was markedly higher than the number found in the western population. Given that the western population has been relatively thoroughly sampled, these results suggest that the western population’s depletion and continued small size may have resulted in the loss of rare alleles from the population. No genetic signature of a bottleneck was detected in the western population using the microsatellite data. However, simulations have shown that detection of bottlenecks using genetic methods is dependent on a wide range of conditions, including duration of the bottleneck, mutation rate, pre-bottleneck size, and

post-bottleneck recovery (Williamson-Natesan 2005), and many studies have failed to detect the genetic signature of a bottleneck even when demographic data indicate population size collapse (*e.g.*, Queney *et al.* 2000, Spong and Hellborg 2002).

Overall, the western population appears to have retained relatively high genetic diversity despite its history of exploitation and continued small population size. In other populations, the maintenance of genetic diversity in the face of population decline has been attributed to long generation times (Dinerstein and McCracken 1990, Hailer *et al.* 2006, Lippe *et al.* 2006), which are characteristic of baleen whales and may have buffered the population against the rapid loss of variation. However, the relatively high level of genetic diversity that appears to have been maintained in the western population could also be the result of dispersal of eastern animals onto the western feeding ground. Even at low levels, dispersal has been shown to obscure bottleneck signatures (*e.g.*, Kellar *et al.* 2001, Busch *et al.* 2007) and genetically “rescue” populations from the loss of genetic diversity (Vila *et al.* 2003). Further exploration of this possibility is detailed below.

Population structure

The inclusion of additional samples to analyses employing mtDNA supported the previous conclusion that the two populations are genetically distinct (LeDuc *et al.* 2002). Nuclear differentiation estimates further confirm differences between the two populations and indicate that genetic separation between populations is not derived solely from female philopatry. These measures of differentiation remained significant after known first degree relatives (*i.e.*, the calf from sampled mother-calf pairs) were removed from

the dataset, suggesting that such differences are not solely an artifact of the inclusion of highly related individuals in the analysis.

Although highly significant, the degree of nuclear differentiation, as measured by F_{ST} values, between the two populations is relatively small. This pattern of differentiation is similar to that found in North Pacific bowhead whale populations, which also demonstrate a significant but small degree of differentiation between a smaller western population inhabiting the Okhotsk Sea and a much larger eastern population in the Bering-Chukchi-Beaufort Seas (LeDuc *et al.* 2005). The relatively small but highly significant genetic differences observed in gray whales, particularly when combined with the similar pattern observed in North Pacific bowhead populations, suggests that past Arctic environmental changes may have played a role in influencing patterns of historic mixing and separation of eastern and western animals. Both stranding records and radio-carbon dating of remains have indicated that changes in sea ice distribution may have mediated bowhead whale distribution in the Canadian Arctic (Dyke *et al.* 1996, SaVelle *et al.* 2000). Within the North Pacific, Arctic-wide cooling and glaciation brought on by the “Little Ice Age” (~400-750 years ago) may have resulted in a southern shift in sea ice distribution and reduced sea level (Overpeck *et al.* 1997), potentially facilitating mixing between eastern and western whales. Sea ice expansion during the Neoglacial (~4700 to 2500 years ago) may also have limited access to parts of the Bering Sea and has been hypothesized to have altered the distribution of North Pacific pinnipeds and cetaceans (Crockford and Frederick 2007).

A second explanation for the low level of differentiation is that some limited gene flow could be occurring between the two populations. At equilibrium, the amount of

neutral genetic divergence, as measured by F_{st} , maintained between populations is dependent on the absolute number of migrants exchanged between populations, a measure which is the product of the effective size of the populations and the migration rate ($N_e m$, Wright 1931). Thus the amount of differentiation maintained between two populations is a balance between the differences generated by genetic drift and the homogenizing effects of migration; given the small size of the western population, genetic drift could be acting to counteract some degree of genetic interchange between the two populations.

A third scenario which might also explain our results involves dispersal of whales between feeding areas without genetic exchange. Since breeding in gray whales is thought to primarily occur along migratory corridors (Rice and Wolman 1971), movement between feeding regions does not necessarily imply gene flow between the populations. Given that all of the western gray whale samples were obtained on the feeding ground, low differentiation levels could potentially be generated by a small number of eastern gray whales traveling to the western gray whale feeding ground during summer months and consequently being sampled while mixed with members of the western population. If these eastern dispersers visit the western feeding ground but return to the eastern Pacific to breed, such extralimital movements would act to reduce measured levels of genetic differentiation between populations in the absence of significant gene flow.

Some support for a limited degree of dispersal and/or gene flow between populations can be derived from the results of the sex-specific comparisons. If the observed low level of differentiation were due to recent divergence, similar patterns of

differences should be observed for males and females. Contrary to this expectation, all measures of differentiation were at least twice as high for female-only versus male-only comparisons. In addition, although comparisons between males remained significant for mtDNA, the F_{st} -based comparison of microsatellite allele frequencies did not identify significant differences among males, suggesting that some degree of male-biased dispersal may be occurring between populations. Such a pattern could also provide an explanation for the large proportion of mtDNA haplotypes (11 of 22) in the western population which are represented only by a single male. Given the higher diversity and number of mtDNA haplotypes found in the eastern population, any dispersers from the east would have a relatively high probability of carrying haplotypes considered “rare” in the west (LeDuc *et al.* 2002). Eight of the eleven haplotypes carried by only a single male in the west were also found in the east; given the low proportion of sampled animals in the east, it is plausible that the other three haplotypes would also be identified among eastern animals with additional sampling.

Although the analyses summarized here are not able to discriminate between gene flow and feeding ground dispersal, a combination of genetic assignment tests and parentage analysis in the future may be useful to distinguish between these two possibilities. In addition, simulation modeling could be utilized in the future to determine the degree of gene flow or feeding-ground dispersal which could occur under non-equilibrium conditions while still allowing the two populations to maintain genetic distinctiveness.

Conclusions and conservation implications

The results presented here support past work indicating that eastern and western populations are genetically distinct, further highlighting the need for continued conservation and expanded protection of the critically endangered western gray whale population. Although highly statistically significant, the level of differentiation between the two populations is relatively low, which may reflect recent divergence of the two populations, perhaps mitigated by past environmental changes, but could also suggest that some limited degree of dispersal and/or gene flow may occur between the two populations. Discrimination between these proposed explanations is important, given that each scenario could have different effects on the recovery of the critically endangered western population. If a restricted amount of gene flow is taking place, that interchange could be important in providing “genetic rescue” for the western population, helping to maintain relatively high levels of genetic diversity in a small population which would otherwise likely suffer from inbreeding and a subsequent loss of fitness. However, if dispersal between feeding grounds without any gene flow is occurring, then any eastern dispersers are not contributing to the gene pool but could be artificially inflating our estimates of both genetic diversity and population size, which would suggest that the western population is even more vulnerable than currently thought. Given the wide range of threats, including entrapment in fishing nets as well as expanding oil and gas development, which challenge the recovery of the western gray whale population, further exploration of possible mechanisms of intermixing is needed to better understand the dynamics of this critically endangered population.

The material found in Chapter Two will be submitted for publication. I was the primary researcher. The co-authors D. Weller and A. Burdin supervised the field effort through which the genetic samples were collected. The co-authors D. Weller, R. LeDuc, and R. L. Brownell, Jr. supervised the research.

Table 2-1. Microsatellite loci used in the study. Includes the species for which primers were initially designed, size of repeats, annealing temperature (T_a), size range, and reference listing primer sequences.

Table 2-5. Analysis of molecular variance (AMOVA) and pairwise comparisons among gray whale populations from microsatellites and mtDNA control region sequences.

Significant P values (<0.05) are shown in bold. Comparisons using only females and only males did not include known relatives.

Comparison	Microsatellites			mtDNA	
		Genotype frequency		Haplotype frequency	
	F _{ST}	F _{ST} probability	Exact test probability	F _{ST}	F _{ST} probability
All individuals	0.009	≤ 0.001	≤ 0.001	0.068	≤ 0.001
No known relatives	0.005	≤ 0.001	≤ 0.001	0.045	≤ 0.001
Females	0.013	≤ 0.001	≤ 0.001	0.078	≤ 0.001
Males	0.002	0.117	0.039	0.033	≤ 0.001

Table 2-6. Results of STRUCTURE analysis using a model incorporating admixture with correlated allele frequencies. Includes the inferred number of genetic clusters (K), the estimated log likelihood value (after averaging across runs) for the data given K ($\ln P(X|K)$), and the posterior probability of K ($\Pr(K|X)$). The value of K with the highest posterior probability is shown in bold. Details about the parameters incorporated in each model are described in the text.

K	$\ln P(X K)$	$\Pr(K X)$
1	-11612.18	~0
2	-11469.22	~1
3	-11682.32	~0
4	-11808.74	~0
5	-12214.70	~0

Figure 2-1. STRUCTURE barplot for K=2 using a model based on admixture with correlated allele frequencies. Individuals are represented by vertical bars, and the different colors of the bars represent the proportion of admixture (Q), or ancestry, from a each inferred genetic cluster. Individuals are grouped according to the population in which they were sampled, and the black line denotes the boundary between animals sampled in the eastern and western Pacific.

III. CHAPTER THREE

Delineating patterns of male reproductive success in the western gray whale
(*Eschrichtius robustus*) population

ABSTRACT

Monitoring of the critically endangered western gray whale population on its primary feeding ground off Sakhalin Island, Russia, has led to the collection of genetic samples from 83% of animals photographically identified from this area. The high proportion of sampled animals provides a rare opportunity to learn more about the mating system of a baleen whale species as well as to identify factors potentially influencing this small population's recovery. Utilizing a panel of 13 microsatellite loci, paternity analysis was conducted to identify breeding males and assess the distribution of male reproductive success. Using biopsy samples from 57 mother-calf pairs and 42 candidate males, putative fathers were identified for 46 to 53% of calves sampled in the population between 1995 and 2007. Although most males were assigned paternity of only one calf, a mild skew in the distribution of reproductive success was identified, with some males siring three to four calves over the 12 seasons of the study. Eighteen putative fathers were identified, and analysis of relatedness patterns among those calves which were not assigned a father suggested that an additional 15 males may be contributing to reproduction in the population. The relatively low success rate of the paternity analysis, in comparison to expectations derived from the percentage of photographically identified animals which have been sampled, indicates that some reproductive males may not use the Sakhalin feeding area on a regular basis. While the high percentage of "missing fathers" in this small population is puzzling, these results provide evidence that many of the animals identified on the Sakhalin feeding ground interbreed, presumably while sharing a common migratory route.

INTRODUCTION

Little is known about the mating systems of most species of baleen whales. Differences in the reproductive cycles of males and females suggest that mysticetes, like the majority of mammals, are polygynous (Clutton-Brock 1989, Mesnick and Ralls 2009). In most baleen whale species, females are restricted to producing a calf every two to three years due to the energetic constraints imposed by gestation and lactation, while males have potential reproductive rates that are much higher. These differences result in a skew in the number of reproductively available females relative to reproductively active males (*i.e.*, the operational sex ratio), increasing the extent to which males must compete for females and permitting variance in male reproductive success to develop. As has been proposed for aquatically mating pinnipeds (Bartholomew 1970), however, the degree of polygyny which can be established in baleen whales is likely limited by the marine environment in which they breed, as females are highly mobile and resources are difficult to defend.

Much of the information available on mysticete mating systems has been derived from behavioral observations and the collection of physiological data. In humpback whales (*Megaptera novaeangliae*), the use of alternative mating tactics by males, including physical competition for access to females as well as “escorting” of females (Pack *et al.* 1998, Clapham 1996), has been documented and suggests a mechanism by which differential reproductive success might be generated in this species. In North Atlantic right whales (*Eubalaena glacialis*), males aggregate in large active groups and appear to compete for access to a female (Kraus and Hatch 2001). In addition, right whales, along with bowhead and gray whales, have high testes-to-body weight ratios,

indicating that sperm competition is an important strategy utilized by males (Brownell and Ralls 1986). The existence of both pre- and post-copulatory competition for fertilization in this species suggest that male reproductive success may not be evenly distributed across individuals.

While these studies have proven valuable in elucidating male mating strategies, they do not provide information on which males in a population successfully breed or how male reproductive success is allocated among individuals, which can have important implications for the maintenance of genetic diversity in small populations. The effective size of a population is determined not only by the number of animals contributing to successive generations, but also by the distribution of reproductive success among those individuals. High variance in reproductive success acts to decrease the effective size of the population (Hedrick 2005), thereby increasing the rate at which genetic diversity is lost. In addition, identifying reproductive pairs within populations can increase our understanding of the role that mate choice may play in inbreeding avoidance (*e.g.*, Archie *et al.* 2007) as well as of the relationship between offspring fitness and parental relatedness (*e.g.*, Amos *et al.* 2001).

Genetic analysis of paternity has the potential to provide detailed information on the reproductive success of individual males. In baleen whales, these analyses have thus far been limited to humpback (Clapham and Palsboll 1997, Nielsen *et al.* 2001, Cerchio *et al.* 2005) and North Atlantic right whales (Frasier *et al.* 2007). In studies of both species, the genetic results contributed valuable insight into patterns of reproduction which were not readily apparent based on previous studies. In humpback whales, the distribution of male reproductive success deviated from that predicted under random

mating, but the variation was lower than expected given the apparent skew in the operational sex ratio and the degree of male competition observed (Cerchio *et al.* 2005). In North Atlantic right whales, males demonstrated high variance in reproductive success when compared to other aquatically-mating marine mammals, although the variance was low relative to those breeding terrestrially (Frasier *et al.* 2007). These results support the idea that sperm competition creates differential reproductive success among males, but that the lack of control over resources and mates in the aquatic environment limits the degree of polygyny which could develop (Frasier *et al.* 2007). Results from this study also suggested that the low level of genetic variability in this species may be influencing reproductive success. Calves for which both parents were identified had significantly higher levels of genetic diversity, as measured by microsatellite markers, than expected under random mating, indicating that successful mating only occurs between individuals that are genetically dissimilar (Frasier 2005).

In gray whales, behavioral observations of multiple males mating with a female suggest a polygynous or promiscuous mating system (Jones and Swartz 1984). While mating behavior has been observed in all seasons, fertilization is thought to primarily occur during the southbound migration (Rice and Wolman 1971). Information from fetal growth rates suggests that females come into estrus during an approximately three-week period extending from late November to early December at the start of the southbound migration. Most females are thought to conceive during this period, although some females may ovulate approximately 40 days later when on or near the wintering grounds. Increased testes weight and the larger seminiferous tubules of males on the southbound

migration, as compared to those of northbound and summer feeding males, also support a peak in spermatogenic activity in late autumn to early winter (Rice and Wolman 1971).

As aforementioned, the high testes weight to body weight ratios found in gray whales suggest that this species utilizes sperm competition as a strategy for males to obtain successful fertilizations (Brownell and Ralls 1986), raising the possibility that, like North Atlantic right whales, some variance in male reproductive success may exist. Genetic paternity analysis would provide information valuable in assessing this possibility. Such a study would be difficult to conduct in the eastern gray whale population, given its large size and the relatively small proportion of animals which have been sampled. However, the population of gray whales found in the western North Pacific, which is both small and well-sampled, presents a valuable opportunity to conduct such an analysis. This population of whales was nearly extirpated by commercial whaling, which continued through at least 1966 (Brownell and Chun 1977, Weller *et al.* 2002). Unlike its eastern counterpart, which currently numbers approximately 20,000 to 22,000 animals (Rugh *et al.* 2008, Punt and Wade 2010), the western population has remained severely depleted and is estimated to contain approximately 130 individuals of one year or older (Cooke *et al.* 2008). Western gray whales are listed as Critically Endangered by the IUCN (Baillie *et al.* 2004). Anthropogenic threats potentially jeopardizing the population's recovery include extensive oil and gas development on the population's primary feeding area (Weller *et al.* 2002, Reeves *et al.* 2005) and mortality of whales associated with entrapment in fishing gear during their migration past Japan (Brownell *et al.* 2007).

Much of what is known about this small population of whales has been derived from long-term studies on their primary feeding ground located in the coastal waters of northeastern Sakhalin Island, Russia. Following a pilot study in the summer of 1995, a monitoring program was initiated in 1997 and continues to date. Extensive photo-identification records collected as part of this effort have shown that western gray whales exhibit a high degree of seasonal site fidelity to the Sakhalin feeding area (Weller *et al.* 1999, 2008a). This site fidelity, in combination with the population's small size, has facilitated the collection of genetic samples from a high percentage (~83%) of animals identified on the feeding ground. Analysis of these samples using both mitochondrial DNA (mtDNA) and a panel of microsatellite markers has shown that the western population is genetically distinct from the much larger eastern gray whale population (LeDuc *et al.* 2002, Chapter Two).

Given the high percentage of sampled animals and the availability of extensive sighting records for most individuals, genetic analysis of paternity in the western gray whale population will not only contribute to our understanding of mysticete mating systems but may also provide information important in assessing factors influencing the population's recovery. The low number of known reproductive females (n=24 between 1995 and 2007) has raised concern for the population's capacity for growth and recovery (Weller *et al.* 2002, 2008a). Little is known, however, about the number of breeding males in the population, or how reproductive success is distributed among these animals. Although previous studies have suggested that the western gray whale population has retained relatively high levels of genetic diversity (Chapter Two), information about

factors potentially influencing the effective size of the population may provide insight into the past and future maintenance of genetic diversity in this population.

In addition, limited information is available about the movements of western gray whales outside of their feeding range. The wintering ground(s) for this population is suspected to be off the southern coast of China, but the location has yet to be confirmed. Sightings, strandings, and entrapments suggest that gray whales migrate along both the eastern and western coasts of Japan, as well as along mainland Asia (Brownell *et al.* 2008). Although photo-identification records have identified one of the animals entrapped off the Pacific coast of Japan as an animal known to utilize the Sakhalin feeding ground (Weller *et al.* 2008b), thus far this is the only established link between a feeding area and a migratory pathway. Given that mating is thought to occur primarily while on migratory routes, the use of paternity analysis to identify pairs of interbreeding animals will provide information on which animals have utilized the same areas for migration and potentially overwintering.

Finally, questions have been raised about the isolation of this small population. Although the eastern and western populations have traditionally been considered geographically separate, in recent years gray whales have been sighted in feeding areas located off the eastern coast of Kamchatka. Some of these whales are known to have visited the Sakhalin feeding area, while others are of unknown origin (Tyurneva *et al.* 2009). These sightings have raised speculation about possible overlap among feeding regions for the eastern and western populations. In addition, although genetic studies have confirmed that eastern and western gray whale populations are distinct, the level of nuclear differentiation between the two populations is relatively low, suggesting that

some intermixing of eastern and western animals could be occurring (Chapter Two). Such intermixing could entail the use of the Sakhalin feeding area by eastern whales which then return to the eastern Pacific, or it might include some limited amount of interbreeding between the two populations. Although the lack of extensive sampling of the eastern population limits comparisons across populations, the proportion of reproduction that can be attributed to animals sampled off Sakhalin will provide some insight into the extent and nature of any interbreeding which may be occurring.

Between 1995 and 2007, 57 mother-calf pairs and 42 males of unknown age were sampled on the feeding ground off Sakhalin. These samples represent 90% of identified mother-calf pairs, and 83% (n=142) of all animals identified on the Sakhalin feeding ground during the study period. Using these samples and a suite of 13 microsatellite markers, a genetic paternity assessment was conducted for this population. The primary objectives of this work were to identify the number of males contributing to reproduction in the western population and to evaluate the distribution of reproductive success among these males. The results of the assessment not only expand our knowledge of mating systems of baleen whales, but also increase our understanding of factors potentially affecting the recovery of the western gray whale.

METHODS

Sample collection

Following a Russian-American pilot effort in 1995, a collaborative Russia-U.S. research program was established in 1997 which focuses on individual monitoring of western gray whales using photo-identification and genetic sampling (Weller *et al.*, 1999,

2002). Field studies are carried out annually during summer months on the primary feeding ground off the northeastern coast of Sakhalin Island, Russia. Surveys (n=337) of this area have led to the photographic identification of 169 whales; genetic samples for 141 (83.4%) of the identified whales have been collected through biopsy-darting (Weller *et al.* 2008).

The genetic sample set includes samples collected from 57 animals which were first identified as calves (approximately 6-8 months of age) on the feeding ground and which are linked to known and genetically sampled mothers. Animals were identified as calves based on their small body size (approximately one third that of an adult), and, in most cases, their constant affiliation with a particular adult whale (Weller *et al.* 1999). For 54 of the calves, identification of the mother was first established via behavioral observations and confirmed by genetic analysis. Three calves were already separated from their mothers when first identified; in these cases the mother was identified using genetic parentage analysis alone.

The sex of all animals was determined using molecular methods (detailed in Chapter Two). Forty-two animals were identified as males of unknown age and were included as candidate fathers in the analysis. Males first identified as calves which may have reached sexual maturity during the study period were also included as potential candidate males. Although it is not known at what age male western gray whales first reproduce, the earliest estimates of age at sexual maturity in eastern gray whales is five years (IWC, 1993). Therefore, male calves were included as potential candidates for those years in which they would have been at least five years of age and potentially capable of reproduction in the preceding season when fertilization would have occurred.

To incorporate the changing number of candidates as calves from earlier years of the study became potentially sexually mature, paternity analysis was run separately for each year of the study.

Analysis

Samples utilized in the study had been genotyped at 13 microsatellite loci for use in the previous study; the protocols used to produce this data are detailed in Chapter Two. Paternity was assessed using the likelihood-based approach as implemented in CERVUS v3.0 (Marshall *et al.* 1998, Kalinowski *et al.* 2007). The objective of this analysis was to identify the candidate father which was statistically the most likely to be the true parent of the calf. The likelihood for each candidate was calculated using information on the allele frequencies in the population, such that a candidate male which shared a rare allele at a given locus with the calf was considered to be more likely to be the true father than a candidate sharing a common allele with the calf. The number of mismatches between the genotype of the father and the genotype of the calf (after removal of the maternal contribution to the calf's genotype) was also utilized in the likelihood analysis.

Simulations were used to generate critical values allowing confidence in the assignments to be evaluated. These simulations used the allele frequency data from the population being analyzed to generate simulated genotypes for parent-offspring pairs and unrelated individuals. The simulated data were then used to calculate the likelihood of parentage for the true parent as well as for each of the unrelated candidate parents for the simulated offspring. For each candidate identified as the most likely parent (whether or not it represented the true parent), the difference in likelihood scores between that

individual and the next most likely individual, referred to as Δ , was recorded. The distribution of Δ scores where the identified parent was the true parent with the distribution of scores where the identified parent was an unrelated individual was then compared to determine a critical value, such that the identified Δ was sufficiently large to distinguish true parents from unrelated parents at a specified (e.g. 95%) level of confidence.

One of the strengths of the CERVUS analysis is that it is able to account for potential errors in the dataset. Genotyping errors, mutations, or null alleles may create mismatches between the genotypes of candidate fathers and offspring, such that the true father might be falsely excluded when such factors are not taken into account. By incorporating an estimated error rate into the simulations run by CERVUS, the potential for such false exclusions is reduced. Here we ran the CERVUS analysis utilizing two different error rates. The first analysis assumed that no errors were present in the dataset, but this differs from a strict exclusionary approach in that likelihood scores were used to differentiate between candidate parents when more than one male had genotypes which matched that of the mother-calf dyad at all loci. The second analysis utilized an error rate of 0.01, allowing candidates to be assigned as putative fathers which had genotypes mismatching that of the mother-calf dyad at up to two loci. Additional parameters used in the simulations included 1) the number of simulated genotypes = 10,000, 2) proportion of loci typed = 0.99 (the true proportion), 3) minimum number of loci typed = 12, and 4) proportion of candidate males sampled=0.50. Given that the error rate and the proportion of sampled males are not known, additional simulations to explore the effects that these parameters may have had on the results are described in the Supplementary Information.

Results were evaluated at both the strict (95%) and relaxed (80%) levels of statistical confidence. The allele frequencies utilized for the likelihood calculations and simulations incorporated only the genotypes of non-calves, to avoid skewing the allele frequency distribution by inclusion of known relatives.

The pool of candidate males changed during some years of the study, as males first identified as calves and known to be ≥ 5 years of age became incorporated in the analysis. As such, the simulations used to calculate critical values were run separately for years with different pools of candidate males, such that while the proportion of candidate males sampled (0.50) was held constant throughout the study, the number of candidates was updated to reflect the changing number of sampled males. The total number of candidate males used in the CERVUS simulation was set by multiplying the number of sampled males by two in accordance with the assumption that 50% of candidates had been sampled.

To provide insight into the reproductive success of unsampled males, the program DADSHARE (<http://www.zoo.cam.ac.uk/zoostaff/amos>, see Hoffman *et al.* 2003) was used to estimate the number of putative sires for the calves for which all sampled candidates were excluded. This program inferred paternal sibships by calculating pairwise paternal relatedness coefficients among unassigned offspring using the relatedness coefficient of Queller and Goodnight (1989). A clustering algorithm (UPGMA) was then used to produce a dendrogram linking the most closely related individuals and sorting offspring into groups compatible with having a single father (e.g. paternal half-siblings). In addition, Monte Carlo simulations were used to explore the pattern which would be produced if 1 to K fathers sired the offspring, with K representing

the total number of offspring being assigned (e.g., the pattern produced if each offspring had a different father). The average *r*-values and standard deviations generated in the simulated scenarios were compared with the observed average *r*-values presented in the dendrogram. In order to evaluate how this method compares with direct parentage assignment, DADSHARE was run both with a dataset containing only those calves which were not assigned a putative father by the paternity assessment analysis as well as with a dataset including only those calves which were assigned putative fathers in the previous analyses.

A simulation-based approach, similar to that employed in previous parentage analyses conducted for mysticetes (Cerchio *et al.* 2005, Frasier *et al.* 2007), was used to evaluate how the observed patterns of male reproductive success compared with those expected if all candidate males had an equal probability of fathering calves within a year (e.g., if mating were random). To make the results of the simulation comparable to those generated in the CERVUS analysis, simulations were based on the number of sampled candidate males included in each year of the analysis as well as the number of paternities which were assigned for those years. For each year of the analysis, candidate males were randomized, and then fathers were selected with replacement for the number of calves which were assigned paternity in that year. This process was repeated for each year of the study, and the number of calves fathered by each male was summed across years to generate the expected distribution of reproductive success for the study period under the expectation of random mating. This process was repeated 1000 times to generate the mean expected number of sampled males which were assigned paternity of zero, one, two, three, four or more calves under random mating.

To facilitate comparisons of male reproductive success with other species, the standardized variance ($SV = \text{variance}/\text{mean}$) in reproductive success was calculated as implemented in previous studies (e.g., Coltman *et al.* 1998, Frasier *et al.* 2007) and using both the results of the paternity analysis and results from the simulations based on random mating. This measure was based only on the reproductive success of males which were assigned as putative fathers of at least one calf during the study. The standardized variance in reproductive success is considered to be zero in truly monogamous species and to increase with the extent of polygyny (Boness *et al.* 1993).

Results

Genetic profiling

Summary statistics for the microsatellite loci used in the study are shown in *Table 3-1*. The total exclusionary probability of the multilocus genotypes used in the paternity analysis, as calculated by CERVUS when one parent is known, was high at 0.9999. The probability of identity (P_{ID} , Paetkau and Strobeck 1994) was estimated to be 2.83×10^{-13} , indicating that the loci utilized in the study provided high power to resolve relationships between individuals. The more conservative P_{ID-sib} (Evetts and Weir 1998) was also calculated to account for the possible presence of related individuals within the dataset. This estimate was low (1.38×10^{-5}), suggesting that the data would be able to distinguish between any full siblings included as candidates. Rechecking of ~20% of all genotypes did not identify a substantial source of error.

Paternity assignment

When no mismatches were allowed between the genotype of candidate males and that of the mother-calf dyad (hereafter referred to as the “stringent criterion”), paternities were assigned for 26 (45.6%) of the 57 calves. All paternities were assigned at the 95% confidence level. One calf had a genotype which matched that of two candidate males; for the remaining 25 calves only one possible match was identified. No putative fathers were identified for the remaining 31 calves.

Incorporating an error rate of 0.01 (later referred to as the “relaxed” criterion), the CERVUS analysis supported all of the assignments previously made and identified putative fathers for an additional four calves, such that paternity was resolved for 52.6% of calves in the study. The four additional assignments included putative fathers with one (n=2) to two (n=2) mismatches with the genotypes of the mother-calf dyads. All CERVUS assignments were supported at the 95% confidence level, with the exception of the one calf whose genotype matched that of two candidate males with no errors, which was assigned at 80% confidence. Those calves which were not assigned putative fathers by the CERVUS analysis mismatched all potential candidates at ≥ 2 loci; for the majority (79%) of these calves, mismatches for ≥ 3 loci were present with all candidates.

The success of the paternity assignment varied greatly across the 12 years of the study (*Table 3-2*). Excluding years in which only one calf was sampled, the proportion of paternities assigned per year ranged from one year in which no paternities were assigned to years (n=3 using the relaxed criterion) in which putative fathers were assigned to two thirds of sampled calves.

The paternity assignment also varied greatly across the reproductive females included in the study (*Table 3-3*). Excluding females which only had one offspring during the study, the average proportion of calves with assigned fathers per female was 0.54 (relaxed criterion) and assignment success ranged from having no calves assigned putative fathers (n=3 females) to having all calves born during the study assigned putative fathers (n=5 females).

Male reproductive success

When no errors were allowed, 17 males were assigned paternity of the 26 calves, for an average of 1.5 (± 0.72 SD) calves per male (*Table 3-4*). Average reproductive success was slightly higher when calculated from analysis incorporating error, with 18 males assigned paternity for 30 calves and an average of 1.7 (± 0.91 SD) calves per male. In both cases, the majority of males (59% and 65% of assigned males for the stringent and relaxed analyses, respectively) were assigned paternity of only one calf each, although a small number of males were assigned paternity of 3-4 calves during the 12 seasons of the study.

These estimates of reproductive success do not incorporate males which were not assigned paternity of any calves. Although the number of candidate males varied across years of the study, 57-69% of candidate males were not assigned paternity of any calves over the twelve years of the study. Inclusion of these males would reduce estimates of average reproductive success to 0.47-0.71 calves per male.

As expected, none of the 13 males of known age (*i.e.*, first identified as calves, ranging from 5 to 11 years old during the season of fertilization) were identified as

putative fathers during the study (*Table 3-5*). These males, as well as some proportion of the males of unknown age, were not sexually mature for all or part of the study. Of those males which were identified as putative fathers, all except one (only identified using the relaxed criterion) were identified prior to the 2000 season, and the majority (n=14, 77.8%) had been first identified by the end of the second season of the study (*Table 3-6*). All except two of the males were sighted at least once for six or more years of the study, with 14 males sighted for at least 8 of the 12 years of the study (*Table 3-6*). For the majority of assigned paternities (n=26 between 1999 and 2007), the putative father was identified on the feeding ground in the season prior to conception (77% of paternities) and/or the season following conception (73% of paternities).

Only one male was assigned paternity of 2 calves in any one season. Excluding this case, the average interval between successful reproductions was 2.8 years (relaxed criterion) to 3.75 years (stringent criterion). Although the maximum interval between assignments was six years, there were three males which were assigned as putative fathers early in the study and which were not assigned any additional calves for the following 8 to 11 seasons. Although some calves may have been lost before reaching the feeding ground, this finding suggested that intervals between successful mating may be even longer than illustrated with our dataset. The longest time span over which a male in the study was considered reproductively active was nine years, during which the male was assigned as the putative father of three calves.

In the seven to nine cases (stringent and relaxed criteria, respectively) in which a reproductive female had multiple calves which were assigned putative fathers, there was only one case in which the same male was assigned as the putative father of more than

one calf of the same female. Female Q had three calves during the study, and all three calves were assigned to the same male (I) under the relaxed criterion. One of these calves mismatched the assigned father at two of the 13 loci and was only assigned to the male in the relaxed analysis. One of the other two assignments for calves of this female was the case where the genotype of the calf matched that of two different putative fathers with no errors. Although male I was assigned as the most likely father, relatedness analysis (data not shown) suggests that the two putative fathers may represent a parent-offspring pair. Given that this was the only case in which more than one putative father had a genotype which matched that of a calf at all loci, the paternity analysis seemed to generally perform well at discriminating between relatives. However, it is possible that in at least this case the candidate male with the highest likelihood of being the true father shared a different relationship to the calf.

DADSHARE estimated that 15 males were likely to account for the 27 calves not assigned fathers in the CERVUS analysis. Average reproductive success among these 15 males was 1.8 calves per male. Relative to the paternity analyses, a larger proportion of these unsampled males (53%) were assigned paternity for two calves each during the study (*Graph 2-1*), suggesting these males may have greater reproductive success on average than those males which were sampled. When the DADSHARE analysis was run using only those calves which were assigned to putative fathers, 18 putative fathers were needed to account for the 30 calves, which corresponds exactly with the number of putative fathers identified in the “relaxed” CERVUS analysis. Similar to the results for the unassigned calves, however, the distribution of reproductive success among these 18 males was somewhat different than the observed pattern, with more males assigned as the

putative father of two calves during the study. Differences in reproductive success between the sampled and unsampled males may be an artifact of differences in the resolution of the two methods.

At least some of these unsampled males may be accounted for among the 28 animals which have been photographically identified on the Sakhalin feeding ground but which have yet to be genetically sampled. One of these is presumed to be a female based on its close and prolonged affiliation with a calf during the one season it was sighted, and nine are animals first identified as calves (≤ 9 years of age at the end of the study) and may not have been reproductively mature for much, if any, of the study period. This leaves at least 18 animals of unknown sex or age which have been identified on the feeding ground but are not represented in the sample set. Although some proportion of these animals may be males contributing to reproduction in the population, based on the overall sex ratio of the population (58% male, Weller *et al.* 2008a), it is unlikely that all of the missing males are included in this group of animals. However, obtaining samples from these animals could potentially increase the success of the paternity assessment.

When the observed results were compared with those generated via the simulation of random mating (*Graph 3-2, Graph 3-3*), the average number of calves per father was significantly higher in both the relaxed ($p \leq 0.014$) and the stringent ($p \leq 0.037$) analysis. These results were due to significantly fewer than expected candidate males which were assigned only one offspring in the analysis ($p \leq 0.036$, stringent criterion; $p \leq 0.039$, relaxed criterion). The average numbers of males assigned paternity of two calves were similar between the simulated and observed results, while the average number of males assigned three calves over the study period was higher in the observed than the simulated

results, although the differences were not significant. In addition, the number of males which were not assigned the paternity of any calves during the study was significantly higher than would be expected under random mating for both the stringent- and relaxed-criterion analyses ($p \leq 0.037$ and $p \leq 0.007$, respectively).

The standardized variance calculated from the results of the paternity analysis ($SV_{\text{obs}}=0.42$) was higher than that calculated from the data simulated under expectations of random mating ($SV_{\text{exp}}=0.27$). When compared to other mysticete studies, the SV_{obs} was most similar to the value calculated in the study of paternity in North Atlantic right whales ($SV_{\text{RW}}=0.35$; Frasier *et al.* 2007) and was higher than that calculated for the humpback whale population ($SV_{\text{HW}}=0.23$; Cerchio *et al.* 2005).

DISCUSSION

Paternity assessment

Approximately half (46-53%) of the calves sampled on the Sakhalin feeding ground were assigned putative fathers which had been identified and sampled in the same area. Using the stringent criterion, all assignments were supported at the 95% confidence level, and the panel of loci utilized in this study provided sufficient resolution to discriminate between all possible candidates using a simple exclusion approach in all except for one case. Even when the more relaxed criterion was applied, all except one of the assignments was supported with high confidence (95%), and only four additional paternities were assigned. Assignment success was in relatively close agreement for both criteria, and it is likely that the true patterns of paternity are encompassed within this range of estimates.

Similar paternity assignment success rates have been generated in other studies of mysticete mating systems, including those conducted for humpback whales in the Mexican Pacific (32.5 to 49.6 %, Cerchio *et al.* 2005) and for North Atlantic right whales (41.4 to 62.1%, Frasier *et al.* 2007). Although sampling in the humpback whale population was not as complete, it is notable that in both our study and the North Atlantic right whale study, a very high proportion of photographically identified individuals had been sampled. As such, the success rates of the paternity assignments were somewhat less than might be expected given the overall pattern of sampling. As discussed below, this pattern may have implications for our understanding of the population's status.

Distribution of male reproductive success

A mild skew in male reproductive success was detected over the 12 seasons covered by the study. Although most (56-59%) of the putative fathers identified were assigned paternity of only one calf each, this proportion was lower than that predicted in the simulations based on random mating. While not statistically significant, more males than expected were assigned paternity of three to four calves during the study, suggesting that some males achieved higher reproductive success than others. These results are consistent with those observed in both humpback whales and right whales, both of which demonstrated mild skews compared to random mating expectations (Frasier *et al.* 2007, Cerchio *et al.* 2005). However, in all cases the skew was slight, with most males siring only one calf during each of these studies. While the differences in reproductive success among males were relatively small over the course of the study, continuation of this pattern over the lifespan of these individual males would result in a substantially higher

reproductive advantage for some males. However, if male reproductive success varied with age, the advantage gained by individuals during the study period would level out over time.

Based on testes to body size ratios, both gray and right whales are thought to utilize sperm competition (Brownell and Ralls 1986). The standardized variance of reproductive success, a measure often used for comparisons across species, was found to be high in North Atlantic right whales relative to values found in other aquatically mating species (Frasier *et al.* 2007), including a population of humpback whales (Cerchio *et al.* 2005). These results suggested that sperm competition may result in higher variance in reproductive success when compared to tactics employed by some other marine mammals (Frasier *et al.* 2007). The standardized variance estimated for western gray whales was comparable to that found in North Atlantic right whales, providing further support for the role of sperm competition in generating variance in reproductive success among males.

A high proportion of sampled males were not assigned any offspring during the 12 seasons of the study. These findings may suggest that many of the animals of unknown age were too young to successfully compete for mating opportunities. Rice and Wolman (1971) found that 24% of the animals from their sample were sexually immature and estimated that the total proportion of immature animals in the eastern gray whale population was approximately 44-61%. If the results of the paternity analysis are combined with the results of the DADSHARE analysis, the proportion of males (53-54%) that are potentially too young to reproduce falls within the range estimated by Rice and Wolman (1971). It is important to note, however, that successful fertilization not only

necessitates that males are sexually mature but also that they are able to successfully compete for fertilization opportunities. Therefore, estimates derived from the paternity analysis are not necessarily representative of the proportion of animals which have not reached sexual maturity. In addition, this estimate assumes that the unsampled males are only those which are contributing to reproduction; if some proportion of non-breeding males has also not been sampled off Sakhalin, this percentage would be lower.

The results suggest a lack of mate fidelity among breeding pairs, with only one female with more than one calf assigned to the same male. These findings agree with expectations based on morphology and behavior. Similar results have been found in paternity analyses in humpback whales (Clapham and Palsboll 1997) and right whales (Frasier *et al.* 2007).

Identification of reproductive males

The paternity assignment identified 17 to 18 males as putative fathers, and analysis of relatedness patterns among the calves with unassigned paternities suggested that approximately 15 additional reproductive males have yet to be sampled. Twenty-four females were determined to be the mother of at least one calf in the western population between 1995 and 2007 (Weller *et al.* 2008a). Combining this information suggests that approximately 57 animals are capable of reproduction. These numbers are slightly higher than previous estimates (Weller *et al.* 2002), which indicated that the number of mature individuals was approximately 39-49 animals if the population was growing and 55 animals if the population was stable. These estimates were based on parameters (*e.g.*, percent of immature animals) derived from the eastern gray whale population and on the

western population's size in 1999. Integrating information on the number of putative fathers with the number of females known to reproduce provides a more direct assessment of the number of animals contributing to reproduction in the population, including those which may not be regularly sighted on the primary feeding ground. Although slightly higher than previous estimates of the number of mature animals, the estimate incorporating the results of the paternity analysis supports the need for continued concern over the small size of the population. In particular, the low number of reproductive females may contribute to the low population growth and recovery (Weller *et al.* 2008a).

Although one of the putative fathers was not identified until the last year of the study, all other males identified as putative fathers were identified early in the study. These animals demonstrated a high degree of seasonal site fidelity to the primary feeding area, indicating that at least this subset of reproductive males are regular visitors to the Sakhalin area. Although some of the unsampled males may be represented among those animals which have been sighted on the feeding ground but not yet sampled, it seems likely that at least some of the "missing fathers" are animals which do not utilize the Sakhalin feeding ground on a regular basis.

The majority of the putative fathers had four of the five most common mtDNA haplotypes found in the western population. Only two (one of which was identified only in the relaxed analysis) of the nine males which have haplotypes considered to be rare in the western population were identified as putative fathers. These "rare haplotype males" have been hypothesized to represent possible dispersers from the eastern population (Chapter Two), although additional analyses evaluating this hypothesis have yet to be

conducted. However, these results suggest that the majority of these “rare haplotype males” may not be currently contributing to reproduction in the population.

No males of known age were identified as putative fathers during the study; therefore, no conclusions about the minimum age at which males attain reproductive success can be derived from these results. However, the lack of assigned fathers among the known-age males suggests that the age of first reproduction in males may be later than in females. Despite similar limitations in sample size, two females of known age (seven and eleven), out of 17 possible through the 2009 season, have been identified with calves (Bradford *et al.*, submitted). In right whales, paternity analysis suggested that most males do not attain their first successful mating until they were almost twice as old as the average age of fertilization for females (~15 years in males as compared to ~8 years for females; Frasier *et al.* 2007). Although no direct evidence was provided in this study, the lack of paternities assigned to males of known age (≤ 11 yrs) suggests that a similar pattern may be true in western gray whales.

Conservation implications

Despite the high proportion of sampled individuals, the paternity analysis was only able to identify putative fathers for about half of the animals first sighted as calves on the Sakhalin feeding ground. Some of the “missing fathers” may be accounted for by the animals which have been sighted off Sakhalin but not genetically sampled. However, these results suggest that many of the males which are contributing to reproduction in the population may not be regular visitors to the Sakhalin feeding ground, raising questions about the identity and habitat use patterns of these individuals.

A potential explanation for the high proportion of unassigned paternities in the western gray whale population is that some gene flow with the eastern gray whale population may be occurring. Previous work has demonstrated that the eastern and western populations are genetically distinct (LeDuc *et al.* 2002, Chapter Two); however, the low level of nuclear differentiation identified between the two populations raised the possibility that some limited degree of interchange may occur (Chapter Two). Such interchange might be characterized by mixing of animals from the two populations on the feeding ground, or might involve some degree of interbreeding. If gene flow between eastern and western populations occurs on a regular basis, then the percentage of candidate fathers that have been genetically sampled would be greatly reduced and a lower assignment success would be expected. Running the paternity analysis with the eastern males included did not identify any additional paternities (see Supplementary Information), but given the very small percentage (<1%) of the eastern population that has been sampled, this result is not very meaningful. However, although genetic drift acts strongly to maintain distinctiveness in small populations, the degree of interbreeding needed to account for the unassigned paternities (~50% of the reproduction in the population) would be likely to dissolve differentiation between the two populations.

If we assume that mating occurs primarily while on migratory routes as has been described in eastern gray whales, two other considerations are important. First of all, if any of the males identified off Sakhalin are animals which originated from the eastern Pacific, then they have a high probability of already being sampled. Therefore, interpopulation breeding between animals of eastern origin and females sampled off Sakhalin can only be used as an explanation for the “missing fathers” if the eastern males

demonstrate lower levels of fidelity to the Sakhalin feeding ground and/or utilize other feeding areas but migrate along routes commonly used by Sakhalin animals. Secondly, interbreeding with the eastern population could occur if reproductive females which utilize the Sakhalin feeding area then return to the eastern Pacific to overwinter. Given the increased energetic demands of pregnancy and lactation, females are generally considered to be less likely candidates for dispersal than are males. In addition, of the 18 females which had multiple calves during the study period, the majority (83%, n=15) had at least one calf which was assigned a putative father among the animals sampled off Sakhalin, linking these breeding pairs to the use of common migratory routes during at least some seasons of the study.

An alternate explanation for the unassigned paternities, however, is that many of the males which are contributing to reproduction in the western population utilize other areas in the western Pacific to feed and are rarely found in the waters off Sakhalin. Similar reasoning was invoked to explain the relatively low paternity assignment success observed in North Atlantic right whales, in which only 51% of fathers were identified despite presumed high rates of sampling (69% of identified males; Fraser *et al.* 2007). The discrepancy between the number of assigned paternities and the proportion of whales which were thought to be sampled led the authors to conclude that the size of the North Atlantic right whale population is slightly larger than previously estimated. In addition, information from paternity analysis, in combination with photo-identification records suggesting that as many as one-third of the identified animals were “missing” during a given season (*i.e.*, could not be accounted for within areas known to be utilized by this

species), supported the existence of additional habitat(s) utilized by North Atlantic right whales but not yet located by researchers.

The results of the paternity analysis in the western gray whale population may suggest a similar pattern. Although it is possible to account for the “missing fathers” among animals identified but not sampled while on the Sakhalin feeding ground, it is unlikely that such a high proportion of the unsampled animals are reproductive males. However, sightings of animals identified as western gray whales have been made in other areas of the Okhotsk Sea (Weller *et al.* 2002), as well as the southwestern Bering Sea (Weller *et al.* 2003) and southeastern Kamchatka (Tyurneva *et al.* 2009). In addition, a relatively high proportion (n=39 of 78; 50%) of the whales sighted off southeastern Kamchatka have not been sighted on the Sakhalin feeding ground (Tyurneva *et al.* 2009). Although these individuals may be of eastern origin, they may also represent western gray whales which use the Sakhalin area infrequently or not at all. These observations suggest that at least some animals in the western population may range more widely during summer and may not have been identified on the Sakhalin feeding ground.

Patterns of relatedness among the unassigned calves suggest that the “missing fathers” may number approximately 15 different animals. Current population assessment models, which indicate that the population contains approximately 130 animals, assume that all western gray whales are sighted off Sakhalin, although not necessarily in all seasons (Cooke *et al.* 2008). The results of the paternity analysis suggest that this assumption may be violated, although the relatively small number of “missing fathers”, some of which may be accounted for by photographically identified but not sampled individuals, likely wouldn’t change estimates of the population’s size or trajectory

dramatically. However, these results raise questions about the proportion of animals of other classes which may also not be accounted for in current estimates. Although little is known about the sex of most animals sighted in other parts of the Okhotsk Sea and eastern Kamchatka, sightings of mother-calf pairs thus far have been largely confined to the waters of the primary feeding ground off Sakhalin, with only one sighting of a female with a calf in other parts of the range (Tyurneva *et al.* 2009). This female had previously been identified with a calf while utilizing the Sakhalin feeding ground. Thus, although females may range more widely during some seasons, they appear to exhibit particularly strong fidelity to the primary feeding ground in years when they have produced a calf. As such, the proportion of sampled to unsampled reproductive females is likely to be higher than the ratio suggested for males. Interestingly, a male bias has already been documented to exist among those western gray whales which have been sampled, such that approximately 60% of animals first identified (and sampled) as adults or subadults on the Sakhalin feeding ground are males. Results of the paternity analysis suggest that this male bias could be more pronounced than previously estimated.

Conclusions

Much of our understanding of the role that males play in the mating system of baleen whales is based on general patterns derived from behavioral and physiological data as well as predictions based on known differences in the reproductive cycles of males and females. While genetic analyses can provide valuable information on the distribution of reproductive success among males, in many species such studies are limited by the difficulty of collecting a sample set that is representative of population

patterns. Due in large part to its small size and the high degree of site fidelity demonstrated by individuals, the western gray whale population is one of the most thoroughly sampled of all mysticete populations, providing a rare opportunity to learn more about the mating system of baleen whales. The findings presented here indicate that the distribution of reproductive success in this small population is similar to that described in North Atlantic right whales. Such comparisons suggest that sperm competition may create differential reproductive success among males, but that the degree of skew is mild in comparison to terrestrially mating mammals. Longer-term studies are needed, however, to determine how differential reproductive success over the relatively short time span of this study compares with patterns produced over the lifespan of individuals.

The lower-than-expected success rate in the paternity assignment for western gray whales raises many questions and suggests that the structure of this population may be more complicated than previously thought. In particular, the results presented here suggest that some animals which are part of the western population may not routinely visit the Sakhalin feeding area. Although this group of “missing fathers” may be small in number, they play a significant role in the reproduction of the population. As such, increasing our understanding of the habitat use and behavior of these animals is important. Genetic sampling of animals identified in other areas of the western Pacific, particularly those which have been sighted off Kamchatka but have not been identified as animals utilizing the Sakhalin feeding area, is one avenue that may elucidate habitat use of animals outside of the primary feeding area. Genetic analysis could be used to determine if these animals are any of the “missing fathers”, and genetic assignment tests

could be used to better understand if these animals originated from the eastern or western populations.

Although the relatively high proportion of calves which could not be assigned fathers is puzzling, assignment of putative fathers for approximately 50% of sampled calves provides strong evidence for intrapopulation breeding among animals demonstrating fidelity to the western feeding ground. Most females had at least one calf which was assigned a putative father from among the animals sampled off Sakhalin, suggesting the use of common migratory routes among these animals and the putative fathers which were identified. In the future, combining the results of the paternity analysis with genetic assignment tests may provide additional information on the extent and nature of any dispersal which may be occurring between the eastern and western populations.

The material found in Chapter Three will be submitted for publication. I was the primary researcher. The co-authors D. Weller and A. Burdin supervised the field effort through which the genetic samples were collected. The co-authors D. Weller, R. LeDuc, and R. L. Brownell, Jr. supervised the research.

Table 3-1. Diversity of the microsatellite loci utilized in the parentage analysis as calculated in CERVUS. The number of alleles (k), observed (H_{obs}) and expected (H_{exp}) heterozygosities, and polymorphic information content for each locus are shown. No loci were found to be out of Hardy-Weinberg equilibrium. The probability for non-exclusion of a parent pair, the probability of identity (assuming Hardy-Weinberg equilibrium), and the probability of identity assuming full siblings are represented in the data area are also shown.

SUPPLEMENTAL INFORMATION

A. Additional CERVUS simulations

A series of simulations were run in the program CERVUS to evaluate the effect of incorporating different values for some of the parameters which are required as input into the analysis. For all of the following analyses, only males of known age (n=42) were included in the paternity assessment; animals first identified as calves which may have matured over the study period were not incorporated. Unless otherwise noted, the parameters incorporated in the simulation were consistent with those used in the above analyses and incorporated an error rate of 0.01.

1) Proportion of candidate males sampled: Since the proportion of candidate males sampled was unknown for this study, the simulations employed by CERVUS were used to explore the effect of varying this parameter on the paternity results. The proportion of sampled males was varied between 0.20 (considered to be much lower than expected given the photo-identification results), 0.50 (as used in the analysis above), and 0.80 (consistent with the results of photo-identification studies). The total number of candidates was adjusted accordingly, such that when the simulation was based on 50% of candidate males being sampled, the number of candidate males was assumed to be 84.

Results: Results are shown in *Table S3-1*. Varying the proportion of candidate males sampled in the study did not change the number of assigned paternities or the identity of assigned fathers. As compared to the assumption used in the analysis (e.g. the proportion

of candidate parents sampled is 0.50), reducing the proportion sampled (e.g. $p=0.20$) acted to increase the critical delta value, making the paternity assessment more stringent. As such, one of the assignments previously made at the 95% confidence level was only supported at the 80% confidence level. Assuming the proportion of candidate males was high (0.80) had the reverse effect, reducing the critical delta value and thus the stringency of the test. As such, the assignment previously made at 80% confidence in the original (e.g., $p=0.50$) assessment was supported at 95% confidence using these parameters. Of note, the expected and observed results were very similar when the simulations assumed that the proportion of candidate males sampled was 50%, but were quite disparate for the other simulations.

2) *Possible effects of increased error rates:* Simulations were conducted in CERVUS to examine the effect that potential errors in the genotype data might have on the paternity assignment success rate. Error rates were allowed to vary between 0.00, 0.01, and 0.10.

Results: Results are shown in *Table S3-2*. As expected, when the error rate was high (10%) the number of assigned paternities at the 80% confidence level increased to 61% ($n=35$). However, allowing for an increased error rate also raised the critical value of delta, resulting in fewer assigned paternities at the 95% confidence level. Allowing the error rate to increase to 10% also allowed for up to 4 mismatches between the mother-calf dyad and the putative father. Thus even if a significant source of genotyping error is present in the data, the number of calves for which paternity could not be assigned is still

larger than would be expected given that ~80% of photographically identified animals have been sampled.

3) Possible effects of relatedness: Given the small size of the western gray whale population, it is likely that some proportion of the animals included in the study may be related to other included individuals. The presence of such relatives might provide a high rate of false positive assignments in the study, such that a male might be assigned as the true father which shares a different relationship with the calf. However, pending relatedness analysis, the proportion of related animals in the population is currently unknown. To further explore potential biases caused by incorporating related individuals, simulations were run in CERVUS which allowed some proportion of the animals to be related. Based on the results presented below, and the fact that baleen whales are not expected to be monogamous, the presence of full siblings, which are the most likely to be confused with parent-offspring relationships, is unlikely. As such, the two scenarios explored were: 1.) some proportion (ranging from 0.20 to 0.50) of candidate males are related at the level of half siblings ($r=0.25$) with other candidate males; 2.) some proportion (ranging from 0.20 to 0.50) of candidate males are related to the mother of the calf; 3.) some proportion (ranging from 0.20 to 0.50) of candidate males are half siblings ($r=0.25$) with the calves being analyzed in the study.

Results: Assuming that some proportion of the candidate males are related either to each other or to the calves being analyzed acts to increase the critical delta values considerably (see *Table S3-3*) over those in the standard analysis. As would be expected, the minimum

number of paternities (n=24 calves with assigned fathers) were assigned when assuming the highest proportion of animals were related; however, this minimum value is very similar to that generated by the analysis with stringent criteria (n=26), suggesting that even if relatives are included the analyses presented above are within the range of expected results. The type of relationship presumed (i.e. whether the candidate males were related to each other or were related to the offspring) did not make a large difference in the number of assigned paternities and only made a slight difference in the number of paternities expected to be assigned. In all cases the identity of the assigned father remained the same.

Assuming a high proportion of related individuals, regardless of the type of relationship, reduced confidence in the assignments, such that in two cases father-offspring assignments were no longer supported. Of the four father-offspring assignments that included mismatches between the genotypes of the calf and the assigned male, one was no longer significant and two others were supported at the 80% confidence level. Assuming only 20% of individuals were related also reduced confidence in all except one of the father-offspring assignments that included mismatches.

The stringency of the analysis did not change appreciably when simulations were run assuming that some proportion of the candidate males were related to the mothers of the calves. Further evidence that the assigned fathers were not related to the mother of the calf being assigned can be derived from comparing the mtDNA haplotypes of the mother-calf dyad to that of the assigned father. Only 8 of the assigned paternities shared mtDNA haplotypes with the mother-calf dyad to which they were assigned, supporting that

approximately two-thirds of the assigned fathers could be definitively ruled out as sharing a maternal half-sibling relationship with the calf or with the mother.

B. Paternity analysis incorporating males sampled in the eastern North Pacific:

To further evaluate the ability of our data to resolve father-offspring relationships, the paternity analysis was rerun after incorporation of samples collected from gray whales on feeding grounds or migratory routes in the eastern North Pacific (for details see Chapter Two). Those eastern animals determined via molecular methods to be males (n=87) were included with the candidates from the western population in the pool of candidate males. Because differences in the sampling strategies between the two populations made estimation of input parameters (e.g. proportion of candidate males sampled) complicated, a simple exclusionary approach was utilized for this analysis, such that no mismatches were allowed between the genotype of the calf and the putative father.

Results: The inclusion of males sampled as part of the eastern population into the paternity analysis did not result in any additional paternity assignments being identified.

C. Paternity analysis for calves with unknown mothers:

An additional four animals were first identified as calves on the study area but had already separated from their mother when they were first identified and could not be genetically linked to any sampled females. As well, one calf was behaviorally linked to

an identified female from which no genetic sample was obtained, and two calves were linked behaviorally to adult females but the affiliation was not supported by genetic analysis. Confidence in parentage assignments is greatly reduced when one known parent is not included, so these seven animals were not included in the primary parentage analysis but were run separately to evaluate the possibility of identifying additional reproductive males contributing to the population.

Results: No fathers were assigned to the calves without identified mothers.

Table S3-1. Comparison of the observed and expected number of paternities assigned when the proportion of candidate males assumed to have been sampled is allowed to vary from 0.20 to 0.80.

Proportion of candidate males sampled	Critical Delta*	Number of paternities assigned	
		Observed (Expected)	
		95%	80%
0.2	3.77 (0.50)	28 (12)	30 (14)
0.5	1.00 (0.00)	29 (29)	30 (30)
0.8	0.00 (0.00)	30 (47)	30 (47)

* Denotes critical delta value at the 80% confidence level

Table S3-2. Comparison of the observed and expected number of paternities assigned when the error rate is allowed to vary from 0 – 0.10.

Proportion of candidate males sampled	Number of paternities assigned		
	Critical	Observed (Expected)	
	Delta*	95%	80%
0.00	0.00 (0.00)	26 (29)	26 (29)
0.01	1.00 (0.00)	29 (29)	30 (30)
0.10	3.91 (1.66)	27 (22)	35 (31)

* Denotes critical delta value at the 80% confidence level

Table S3-3. Comparison of the observed and expected number of paternities assigned when related individuals are included in the analysis. The proportion related refers to the average proportion of all candidate parents which are related. In all cases except that were no relatives are incorporated into the analysis, all relationships refer to that of half-siblings (e.g., $r=0.25$).

Candidate		Number of		
		paternities assigned		
male related	Proportion	Critical	Observed (Expected)	
to:	related:	Delta*	95%	80%
Calf:	0.20	6.48 (1.79)	26 (25)	28 (34)
	0.50	8.17 (3.70)	24 (18)	28 (32)
True father:	0.20	5.54 (1.06)	26 (27)	29 (35)
	0.50	7.77 (2.85)	24 (20)	28 (34)
True mother:	0.20	1.06 (0.00)	29 (30)	30 (31)
	0.50	1.13 (0.00)	29 (30)	30 (31)
No relatives:	0.00	1.00 (0.00)	29 (29)	30 (30)

* Denotes critical delta value at the 80% confidence level

IV. CHAPTER FOUR

Exploring patterns of genetic heterogeneity among gray whales (*Eschrichtius robustus*)
sampled on a feeding ground in the western North Pacific

ABSTRACT

Much of what is known about western gray whales is derived from studies based on the population's feeding ground off Sakhalin Island, Russia. Although genetic studies have supported the differentiation of this critically endangered population from the much larger eastern North Pacific population, previous analyses have suggested that some degree of male-biased dispersal may occur, raising the possibility that some of the animals identified on the feeding ground may be of eastern origin. In this chapter, a suite of different genetic analyses were used to assess whether genetic heterogeneity exists among animals sampled on the Sakhalin feeding ground and to explore potential processes creating such heterogeneity. Patterns of substructure were identified, with two genetic clusters detected within the feeding ground samples. The similarity of one of the clusters to the eastern population suggests that dispersal influenced the clustering pattern. Both the results of a genetic assignment test, designed to identify putative first-generation migrants between populations, and the significant differentiation detected between males and females (as well as between males and animals first identified as calves), suggest that such dispersal is largely driven by, although not exclusive to, males. However, when relatedness analysis was used to identify putative mother/offspring relationships between animals first identified as non-calves, the results indicated that, as has been illustrated by field observations, the fidelity demonstrated by some females and their offspring has been important in shaping the structure of the population. Although further studies are needed to elucidate the extent and nature of possible dispersal of eastern animals onto the western feeding ground, these results suggest that not all animals

identified on the western feeding ground may be western gray whales, which has potential consequences for assessment of this small population's status.

INTRODUCTION

The population of gray whales found in the western North Pacific was greatly depleted by commercial whaling, which continued through at least 1966 (Brownell and Chun 1977, Kato and Kasuya 2002). Today the population survives as a small remnant and is considered one of the most critically endangered baleen whale populations (Clapham *et al.* 1999, Baillie *et al.* 2004). The continued survival of western gray whales is threatened by a wide range of potential anthropogenic threats, including but not limited to disturbance due to oil and gas development on its feeding ground (Weller *et al.* 2002, Reeves *et al.* 2005, IISG 2006) and mortality due to incidental entrapment in nets while migrating past Japan (Brownell *et al.* 2007, Kato *et al.* 2007).

Concern for this small population led to the initiation of a joint Russia-U.S. research program in 1995, which has focused on studying these animals on their primary feeding ground located in the coastal waters of northeastern Sakhalin Island, Russia (Weller *et al.* 1999, 2008). Monitoring of the population has incorporated both boat-based photo-identification surveys and genetic sampling. Information from photo-identification surveys has revealed that most of the identified animals demonstrate high levels of seasonal site fidelity and annual return to this feeding ground (Weller *et al.* 1999, 2008). The population is estimated to contain approximately 130 individuals of age one or older, of which only 23 are known to be reproductive females (Cooke *et al.* 2008, Weller *et al.* 2008).

Genetic differentiation of the small western population from the much larger population of gray whales found in the eastern North Pacific was initially described on the basis of mitochondrial DNA (mtDNA) haplotype frequencies (LeDuc *et al.* 2002). Subsequent studies utilizing microsatellites provided additional support for recognition of the two populations as distinct units, with small but statistically significant differences in microsatellite allele frequencies identified between the two populations (Chapter Two). These studies also revealed that, although the mtDNA haplotype diversity found in the western population is markedly smaller than that found in the eastern population ($h=0.77$ versus $h=0.95$; LeDuc *et al.* 2002, Chapter Two), the western population has maintained a relatively high number of mtDNA haplotypes ($n=22$) given its small size. The amount of nuclear genetic diversity found in the western population is comparable to that found in the eastern population, indicating that significant amounts of genetic diversity have yet to be lost (Chapter Two).

Although the level of genetic differentiation between the two populations using microsatellites was highly significant statistically, the degree of differentiation was relatively low ($F_{st} = 0.009$, Chapter Two). Bayesian clustering analysis using the microsatellite data provided support for the presence of two populations within the dataset, but many of the individuals in both populations showed low or equivocal assignment indices to their source population. While the low level of observed divergence might be representative of relatively recent separation between the two populations, sex-specific comparisons indicated substantially higher levels of differentiation between females of the two populations than between males, for which, in the case of the microsatellite comparisons, comparisons were not statistically significant

(Chapter Two). Since relatively recent separation between the two populations should affect males and females in a similar fashion, these comparisons suggested that the low level of observed differentiation was more likely due to the occurrence of some degree of male-biased dispersal between the two populations.

Given that current records of western gray whales outside of their feeding range are limited, much of our understanding of the status of this population has been derived from monitoring on the Sakhalin feeding ground. Many of the analyses that have been conducted, including estimates of abundance and measures of genetic diversity, have assumed that all of the animals sampled on the western feeding ground represent western gray whales. If, as suggested by the sex-specific analyses reported in Chapter Two, some of the animals identified on the western feeding ground are dispersers from the eastern population, these assessments may need to be re-evaluated.

If such dispersal is occurring, a signal of genetic heterogeneity could be created within the western sample set. However, studies of other baleen whale populations have shown that intra-population processes can also generate sub-structuring within populations, particularly those that are out of genetic equilibrium due to recovery from whaling. For example, genetic heterogeneity has been found in the Bering-Chukchi-Beaufort Seas (BCB) stock of bowhead whales (*Balaena mysticetus*, Givens *et al.* 2007, Jorde *et al.* 2007; LeDuc *et al.* 2007). Although much debate has centered around the source(s) of this heterogeneity, mtDNA differentiation between age cohorts has been identified (LeDuc *et al.* 2007), and simulation-based studies have verified that detectable differences could be generated between age cohorts given the stock's history and the long

life span characteristic of the species (Ripley *et al.* 2006, Archer *et al.* 2007, Martien *et al.* 2007).

Genetic heterogeneity within a population can also arise through unequal reproductive success among individuals. Differential reproductive success among matriline has been demonstrated in humpback whales (*Megaptera novaeagliae*) feeding in the Gulf of Maine and was shown to have the potential to substantially affect the frequency and distribution of maternal lineages in this population over time (Rosenbaum *et al.* 2002). In addition, high reproductive success of a relatively small number of females over time would create cohorts of maternal half-siblings in the population, introducing relatedness structure into the population.

Examination of the mtDNA haplotype distribution found in the western gray whale population provides some indication that either or both of these two mechanisms may be influencing the structure of the population. Unlike in the eastern gray whale population, in which haplotypes are relatively evenly distributed among individuals, the distribution of haplotypes in the western population is highly skewed, with two haplotypes found in very high frequencies (36% and 31% of all sampled animals), six in moderate frequencies (2 - 5% of sampled animals), and 14 in only one to two individuals (LeDuc *et al.* 2002, Chapter Two). The high frequencies of the two dominant haplotypes suggest that females in these matriline may have enjoyed relatively high reproductive success over the past several decades. Among those haplotypes found in only one or two individuals, eleven are found in only a single male. Although two of these males were first identified as calves (either without an identified mother or with a mother who was not sampled) during the field study, the remaining nine were identified as non-calves.

These nine males (referred to as the “rare haplotype” males) have been hypothesized to represent possible dispersers from the eastern population (LeDuc *et al.* 2002, Chapter Two). Since whaling on this population continued through at least 1966 (Brownell and Chun 1977), an alternative explanation is that some of these males might represent animals which survived extirpation. Given that males cannot pass down their mtDNA, the haplotypes found in these animals could represent remnant haplotypes which were present (although likely not common) in the population prior to the end of exploitation and which will be lost when these males die.

Although these findings suggest the potential for both intra- and inter-population processes to be creating genetic heterogeneity within the western gray whale population, additional analysis may be able to better assess the influence of these factors on the genetic structure of the population. To evaluate whether a signature of genetic heterogeneity can be identified within the samples collected on the western feeding ground, Bayesian clustering analysis, incorporating a model designed to detect subtle patterns of structure, is used here to identify the number of genetic clusters found among the gray whale data. The sample set is also stratified according to various criteria and analyzed to determine whether differences between these strata can be detected. Finally, relatedness analysis and a genetic assignment test are used to better assess whether differential reproductive success of females and/or putative dispersal between populations, respectively, may be factors influencing the genetic structure of the population.

METHODS

Details on sample collection are included in Chapter Two. Most of the analyses described below utilized only samples collected in the western North Pacific ($n=142$), although samples ($n=136$) collected in the eastern North Pacific were included for comparative purposes for some analyses. When appropriate, samples collected from animals which were first identified as calves ($n=64$) on the western feeding ground were excluded from analysis. The analyses described below were conducted using information on the sex, mtDNA sequence, and microsatellite genotype ($n=13$ loci) generated from each sample as described in Chapter Two.

Clustering analysis

A Bayesian model-based clustering approach (STRUCTURE v2.3.2, Pritchard *et al.* 2000, Falush *et al.* 2003) was used with the microsatellite data to evaluate how many genetic clusters were present in the eastern and western gray whale sample sets. Unlike the approach taken in Chapter Two, information on the location in which individuals were sampled (eastern Pacific versus western Pacific) was incorporated into the model using the LOCPRIOR option and assuming admixture with correlated allele frequencies. Like the USE POPINFO option in STRUCTURE, the LOCPRIOR option makes use of information on the location in which individuals were sampled. However, unlike the former option, which assumes that the information on sampling location is usually correct and that population structure is relatively strong, the LOCPRIOR option was designed to be most useful in scenarios where only weak structure has been observed (Hubisz *et al.* 2009). Although information on sampling locations is assumed to be informative, this

option allows such *a priori* information to be ignored for individuals whose ancestry appears uncorrelated. As in previous analyses, five independent runs of $K=1-5$ were performed with a burn-in period of 50,000 iterations followed by 100,000 Markov-chain Monte Carlo repetitions. After averaging across runs, the number of clusters (K) most compatible with the data was identified as the value of K with the highest log probability ($\text{Ln } P(X|K)$).

To further investigate sub-structuring within the western population, the STRUCTURE analysis was rerun using only those samples collected from animals in the western Pacific. A model of admixture with correlated allele frequencies was used; additional input parameters for the analysis were identical to those outlined in Chapter Two.

Genetic differentiation

The sample sets were stratified using two approaches to evaluate factors potentially contributing to genetic heterogeneity among animals sampled on the primary western feeding ground. First, samples collected on the western feeding ground were stratified by their status as having been first identified as a calf or non-calf. Animals initially identified as non-calves were then further stratified by sex. The eastern sample set was also stratified by sex. For both the mtDNA and microsatellite data, frequency-based (F_{ST}) estimates of differentiation (Weir and Cockerham 1984) among these five strata were generated using ARLEQUIN v3.0.1 (Excoffier *et al.* 2005). Significance was assessed using 20,000 permutations, and the false discovery rate procedure of Benjamini & Hochberg (1995) was used to correct for multiple comparisons.

In addition, the results of the STRUCTURE analysis, when run utilizing only those animals sampled on the western feeding ground and assuming $K=2$, were used to assign individuals into strata based on Q values. Using the same methods as stated above, these clusters were compared both to each other and to the eastern sample set. In addition, a Markov-chain approximation of an exact test, as implemented in GENEPOP v3.4 (Raymond and Rousset 1995) was used to test for departures from Hardy-Weinberg expectations and for linkage disequilibrium between all pairs of loci within each cluster.

Identification of putative mother/offspring pairs

Relatedness analysis was conducted to identify individuals that shared a potential mother/offspring relationship with another animal sampled in the population. Given that parent-offspring relationships for those animals first identified as calves were presented in Chapter Three, only sampled animals which were first identified as non-calves were assessed here. For these animals ($n=78$), putative mother/offspring pairs were identified as those pairs of individuals which shared at least one allele at each microsatellite locus and had the same mtDNA haplotype. Because determining the directionality (*i.e.*, which animal was the putative mother and which the possible offspring) was complicated due to the lack of information or proxy for age, animals were not identified as either the mother or the offspring but were simply labeled as pairs.

Note that this analysis differs in several ways from the paternity analysis presented in Chapter Three. First, in the paternity analysis, the maternal contribution to the calf's genotype is removed prior to attempting to identify a putative father, requiring in most cases (unless the genotype of the calf and the mother match at both alleles for a

given locus) that the putative father's genotype have one specific allele at each locus in order to match the genotype of the calf. In identifying putative mother/offspring relationships among animals first identified as non-calves, however, no parental contribution can be removed from the animal's genotype; thus for loci that are heterozygous, putative matches can be made at either of the two alleles, making the matching criteria less stringent than used in the paternity analysis. Secondly, the criterion used for assessing confidence in assignments in the paternity analysis was based on the difference between the most likely candidate parent and the second- most- likely candidate parent (Δ). Use of this criterion was possible because the directionality of the relationship was known and only one animal could represent the true father. However, in the identification of mother/offspring pairs among non-calves, directionality of the relationship could not be reliably determined; if successive offspring of the same female were included in the sample set, that female would share a mother/offspring relationship with more than one of the other sampled animals. Therefore, comparing likelihood scores between possible candidates was not a viable approach, and the criterion used to assess confidence in the paternity analysis could not be implemented here. Given these differences, the identification of putative mother/offspring pairs among animals first identified as non-calves should be considered less stringent than the method used to identify putative fathers for calves with known mothers. This lower level of stringency may have been counter-balanced to a small extent by the requirement that mother/offspring pairs share the same mtDNA haplotype and that the genotypes of putative mother/offspring pairs had at least one matching allele at all loci. The latter

criterion may have resulted in the elimination of some true mother/offspring pairs due to genotyping errors or null alleles.

Assignment test

The “detection of first-generation migrants” function, as implemented in GENECLASS 2.0 (Piry *et al.* 2004, Paetkau *et al.* 2004), was used with the microsatellite data to identify putative dispersers between the eastern and western populations. Putative dispersers are defined as animals born in a population other than that in which they were sampled; therefore, animals first identified as calves on the western feeding ground were excluded from this analysis. The test statistic $L_{\text{home}}/L_{\text{max}}$, which represents the ratio of the likelihood of an individual’s genotype in its source population (L_{home}) to the highest likelihood of that individual’s genotype in either of the two possible source populations (L_{max}), was computed using the Bayesian criterion of Rannala and Mountain (1997). This test statistic is the most powerful of the options provided in GENECLASS and is considered appropriate in scenarios where all source populations are thought to be sampled (Piry *et al.* 2004, Paetkau *et al.* 2004). The probability that each individual was not a first- generation migrant was then computed using the re-sampling algorithm of Paetkau *et al.* (2004) to create 10,000 simulated individuals. For the “conservative” analysis, the type- I error rate (denoting the false classification of a resident as a disperser) was set to 0.01, which is thought to represent the appropriate balance between stringency and power (Paetkau *et al.* 2004). The results were also evaluated using a more relaxed error rate of 0.05.

RESULTS

Clustering analysis

Using a model based on admixture with correlated allele frequencies and which incorporated information on the sampling location of individuals (via the LOCPRIOR option described in Hubisz *et al.* 2009), the highest likelihood was observed for K=3 clusters being represented in the combined eastern and western gray whale sample sets (*Table 4-1*). However, when choosing K, the authors of the STRUCTURE manual recommend that users choose the smallest value of K which captures the major structure in the data, and they mention that the value of K often “more or less plateaus” when the true K is reached (Evanno *et al.* 2005, Pritchard *et al.* 2010). Inspection of the graphical representation of the likelihood values (*Graph 4-1*) suggests the majority of structure was captured using K=2 clusters, with a plateau in likelihood values after K=2 is reached. To further evaluate the true number of clusters contained in the data, ΔK was calculated according to Evanno *et al.* (2005). Although this measure, which represents the second-order rate of change in the likelihood, cannot be used to evaluate the probability that the data contain only one cluster, it has been shown to be more accurate at detecting the uppermost hierarchical level of structure when the true K is greater than one (Evanno *et al.* 2005). A clear peak in ΔK was observed at K=2, confirming that the most likely number of clusters in the dataset was considered to be two.

These results closely mirrored those presented in Chapter Two, which did not include information on sampling locations but also supported the presence of two clusters within the dataset. However, when sampling location information was not utilized, average Q_{source} values, denoting the proportion of an individual’s genotype which could

be attributed to its source cluster, were relatively low for individuals in both populations (mean $Q_{\text{east}} = 0.69$; mean $Q_{\text{west}} = 0.60$), and only 80% and 65% of the individuals sampled in the east and west, respectively, were assigned to their source population. Within the eastern sample set, the incorporation of information on sampling location increased the average Q_{source} value (mean $Q_{\text{east}} = 0.98 \pm 0.047\text{SD}$). All of the animals sampled as part of the eastern population were assigned to that region, with 97% of individuals having $Q \geq 0.90$ and only one animal with $Q \leq 0.75$ (*Figure 4-2*). In contrast, the average Q_{source} value decreased for animals sampled in the western Pacific, and Q values varied greatly among individuals (mean $Q_{\text{west}} = 0.53 \pm 0.367\text{SD}$). Only 51% ($n=73$) of animals sampled in the west were assigned to their source cluster, with only 42 individuals (30%) with $Q \geq 0.90$ (*Figure 4-2*). There were 31 animals (28% of sampled individuals) which were sampled in the western Pacific but had $Q \geq 0.90$ to the eastern cluster.

Although examination of the results indicated that the majority of structure in the combined eastern and western dataset was captured by two clusters, the assignment of individuals when $K=3$ clusters were defined was examined to evaluate the potential for additional sub-structuring within the western sample set. Under this scenario, the third cluster that was created consisted of a small number ($n=20$) of animals sampled in the western Pacific, most of which ($n=12$, 60%) demonstrated low assignment probabilities ($Q \leq 0.75$) to this cluster. A high proportion ($n=62$, 44%) of western animals continued to be assigned to the eastern group, suggesting that inter- versus intra-population processes were largely responsible for driving the clustering pattern.

When only those samples collected from animals identified on the western feeding ground were utilized in the STRUCTURE analysis, the highest probability was

observed for K=3 clusters (*Table 4-2*). However, similar to the results above, calculation of ΔK indicated that the majority of structure in the data was captured at K=2. Average Q values were relatively high for both clusters ($Q_{\text{cluster1}} = 0.85 \pm 0.125\text{SD}$, $Q_{\text{cluster2}} = 0.84 \pm 0.117\text{SD}$; *Figure 4-2*). Based on their Q scores, 59 individuals were assigned to western cluster 1, while 83 were assigned to western cluster 2. All except one of the individuals which were assigned to the eastern population in the above analysis were assigned to western cluster 2. However, this cluster also contained an additional 15 animals which had been assigned to the western cluster in the previous analysis.

Animals first identified as calves were assigned into both clusters (n=31 into western cluster 1, n = 33 into western cluster 2). The majority (n=42 of 57; 74%) of calves grouped in the same cluster as their mother. For the nine cases in which a calf with an assigned father was grouped in a cluster other than that shared with its mother, the calf's cluster was shared with the assigned father. Animals identified as reproductive females and putative fathers (Chapter Three) were apportioned relatively evenly among the two clusters.

All loci in both clusters were found to be in Hardy-Weinberg equilibrium. However, three pairs of loci were in linkage disequilibrium in western cluster 1, while one loci pair was in linkage disequilibrium in the second cluster.

Genetic differentiation

Estimates of genetic differentiation after stratification by sex and by status of being first identified as a calf or non-calf (western samples only) are shown in *Table 4-3*. As mentioned in Chapter Two, all between-population comparisons were significant

except for comparisons between eastern males and western males, where there was no significant differentiation in either microsatellite allele or mtDNA haplotype frequencies after correction for multiple comparisons. Although no within-population comparisons were statistically significant for animals sampled in the eastern Pacific, within the western sample set significant differences in microsatellite allele frequencies, but not mtDNA haplotype frequencies, were identified between males and females and between males and animals first identified as calves between 1995 and 2007.

In addition, animals sampled in the western North Pacific were assigned to clusters using the results of the STRUCTURE analysis, and these strata were compared to each other and to the samples from the eastern North Pacific. Significant differences in both mtDNA haplotype and microsatellite allele frequencies were found in all comparisons (*Table 4-4*). However, the level of differentiation identified between western cluster 2 and the eastern sample set was markedly lower than that identified between western cluster 1 and the eastern samples.

Assignment test

Using the most stringent criteria in GENECLASS ($\alpha \leq 0.01$), six individuals were identified as being probable first-generation migrants (*Table 4-5*). Of those individuals, two were sampled as part of the eastern population and four were sampled as part of the western population. Under the more relaxed criterion ($\alpha \leq 0.05$), an additional 8 putative migrants were identified, including three more animals originally sampled in the eastern Pacific and five additional animals sampled as part of the western population. When the self-assignment probabilities of putative dispersers were examined in more detail, the

animals sampled in the west but assigned to the east had markedly higher assignment probabilities for the eastern population. However, the animals sampled in the east but assigned to the west had more similar probabilities of originating from either of the two source populations, suggesting the genotypes of these animals contained alleles common to both populations.

Four of the five animals which were sampled in the eastern Pacific but were assigned as putative dispersers from the western population were females. With one exception, samples from these animals were collected from animals which stranded along the migratory route. Sample #4159, however, was taken from an animal killed as part of the aboriginal harvest off Chukotka, Russia.

A male bias was present among the putative dispersers sampled in the west, with eight of the nine animals being males. Five of the nine putative dispersers had one of the 12 haplotypes which have been identified in males but not females sampled in the west. Three of those putative dispersers belong to the subset of animals (n=11) labeled as “rare haplotype males” because they are the only animals which carry their haplotype in the western population (*Table 4-5*).

All of the putative dispersers sampled in the western population have demonstrated site fidelity to the western feeding ground, with the majority (n=6) being sighted for at least two-thirds of all seasons subsequent to their initial identification and all being sighted in at least 50% of such seasons (*Table 4-6*). All putative dispersers were identified on the Sakhalin feeding ground for at least three seasons of the field study, with two animals sighted over nine seasons.

To evaluate the role of the putative dispersers in generating genetic heterogeneity within the western population, these animals (n=14) were removed from the dataset and the analysis of genetic differentiation was repeated. In contrast to the previous results, no statistically significant differences were found when males and females of the western population were compared (*Table 4-7*). In addition, after putative dispersers were removed, significant differences in microsatellite allele frequencies were found between eastern and western males (*Table 4-7*).

Identification of maternal-offspring relationships

Among those animals (n=78) which were not first identified as calves, there were 42 animals which shared a putative mother/offspring relationship with at least one other animal. The 36 individuals for which no putative mother/offspring relationships were identified among the “non-calf” sample set included 12 females (33% of all sampled female non-calves) and 24 males (57% of all sampled male non-calves). The majority of animals identified as either mothers (78%, 18 of 23 sampled) or as fathers (67%, 12 of 18 sampled) in the analysis of paternity in animals first identified as calves (Chapter Three) also shared a putative mother/offspring relationship with at least one other non-calf animal. When combined with information about known mother-calf pairs and with the results of the paternity analysis, 75% (n=107) of animals sampled on the western feeding ground share a putative parent-offspring relationship with at least one other sampled animal.

Forty-two percent ($n = 33$) of animals sampled as non-calves and 56% ($n = 80$) of all sampled animals could be traced back through matriline to a minimum of five reproductive females. Four of these females shared possible mother/offspring relationships with between four and seven non-calf offspring within the sample set, while one of the reproductive females could potentially account for up to 14 non-calf individuals over two generations. Two additional females were designated as putative mothers of only one other sampled non-calf. All of the five matriline demonstrating high reproductive success had one of the two most common haplotypes (A and B) found in the western North Pacific. The majority ($n=16$, 70%) of the 23 sampled females identified as reproductive during 1995 through 2007 (Weller *et al.* 2008) also shared one of these two common haplotypes; with one exception, these females were included in the matriline described above.

Cluster composition

Integrating the results from the assignment test and the relatedness analysis with those of the Bayesian clustering approach revealed some patterns worthy of mention. First, all of the animals ($n=9$) identified as putative dispersers were grouped with western cluster 2, as were all of the rare haplotype males. All but one of the animals which were grouped in cluster 1 were identified as members of a putative mother/offspring pair, while only half ($n=42$, 50%) of the animals which were grouped in cluster 2 shared this distinction.

In addition, the majority (88%, $n=23$ of 26 total) of animals which were first identified (as non-calves) during the later years of the study (1999 – 2007) were grouped

with cluster 2. Only six of these animals shared a putative mother/offspring relationship with another sampled animal. This subset of animals, which was comprised of 15 males and 11 females, included five of the putative dispersers as well as six of the rare haplotype males.

DISCUSSION

Both the clustering analysis and comparisons of various strata indicate that some degree of genetic heterogeneity exists among the animals sampled on the Sakhalin feeding ground. The patterns identified suggest that the structure of this group of animals is complex and is likely mediated by both intra- and inter-population processes. Although many questions remain about the extent to which these processes are influencing measures of genetic diversity and differentiation within and between gray whale populations, some insight into the factors most likely to be shaping the structure of this group of animals can be derived from the above analyses.

Within-population processes

Genetic differentiation between age cohorts was demonstrated in the BCB stock of bowhead whales (LeDuc *et al.* 2007); simulation-based analysis showed that these differences were generated as a result of comparisons of older males, which had retained mtDNA diversity characteristic of pre-exploitation levels, with younger animals carrying levels of diversity representative of current, post-exploitation and recovery levels (Ripley *et al.* 2006, Archer *et al.* 2007, Martien *et al.* 2007). This work illustrated that non-equilibrium dynamics, particularly in such a long-lived species, could produce patterns

often interpreted as stock structure. Although the expected life span of gray whales is much shorter than that found in bowhead whales, given the relatively recent end of commercial whaling in the western population it is possible that similar mechanisms may be influencing the population's genetic diversity. The high number of mtDNA haplotypes found only in a single male in the western population provides some support for this hypothesis. However, although the lack of known age of many of the animals in the western population limits the conclusions that can be drawn, the results of the sex- and age-specific comparisons are somewhat inconsistent with this explanation. Given the matrilineal inheritance pattern of mtDNA, differences between age cohorts should be most apparent in the mtDNA comparisons of males and younger animals. However, age- and sex-related differences among animals sampled on the western feeding ground were only observed in the microsatellite comparisons.

The lack of mtDNA differentiation detected when non-calf males and younger animals were compared may be related to the history of exploitation in the western gray whale population. Relative to the BCB bowhead whale population, in which exploitation was intense but occurred over only a few decades, the decline of the western gray whale population was more extended, with a peak in catches occurring between 1911 and 1919 that was followed by several decades of continued takes. The more prolonged period of exploitation in the western gray whale population would likely have resulted in a steady decrease in the population's diversity over time but may not have created sharp differences between age cohorts.

Differences in reproductive success among females have been shown to influence population structure in humpback whales (Rosenbaum *et al.* 2002). The relatedness

analysis provided some support for differential reproductive success among matriline found in the western population, indicating that when animals first identified as calves were included, 56% (n=80) of animals sampled in the population could be traced back to as few as five females, all of which shared one of the two most common haplotypes found in the western population. Relative to other females sampled in the population, females of these five matriline appear to have enjoyed high reproductive success over the past several decades.

Although the majority (70%) of reproductive females identified during the field study also carried one of the two most common haplotypes, six of the other seven females which produced calves during that time had haplotypes which were either not found in any other animals first identified as non-calves, or which were found in only one other sampled non-calf. If these females, or their mothers, have been exhibiting site fidelity to the Sakhalin feeding ground prior to 1995, then these results indicate that females in these matriline have experienced low reproductive success and/or high offspring mortality over the last couple of decades, and suggest that, in some cases, even those haplotypes which are found among females could be in danger of disappearing from the western population. Of note, however, these measures of reproductive success assume that all females demonstrate similar levels of fidelity to the western feeding ground over this time period.

Of the two groups identified in the clustering analysis, one was comprised almost exclusively of animals which were part of the five identified matriline, suggesting that the high reproductive success of these females may have played a role in generating the pattern of clustering. The other cluster contained all except one of the animals for which

no putative mother/offspring relationships could be identified among the sampled animals. The genetic similarity of this cluster to animals sampled in the east is difficult to explain; although significant differences between the two western clusters might be derived from relatedness structure within the population, both clusters should still be more closely related to each other than they are to the eastern population in the absence of intermixing between the two populations.

Inter-population processes

Previous work has indicated that some degree of male-biased dispersal may exist between eastern and western gray whale populations and could provide an explanation for the relatively low levels of nuclear divergence observed between populations (Chapter Two). The results of the genetic assignment test support this hypothesis, suggesting that some level of dispersal between the two populations is likely occurring and that it is primarily, although not exclusively, driven by males.

It is important to note that simulation-based studies have shown that the accuracy of assignment-based approaches is correlated with the degree of divergence between source populations (Berry *et al.* 2004, Paetkau *et al.* 2004, Latch *et al.* 2006, Waples and Gaggioti 2006). Although limited, some evidence exists that such tests may provide valid results even when differentiation is moderate, particularly when populations are in genetic disequilibrium (Hall *et al.* 2009). In light of these findings, the assignment test results presented here should be considered preliminary until simulation-based testing can be used to evaluate how well this approach works under the level of divergence observed and the sampling protocol used in this specific study. However, the results of the

assignment test were generally concordant with those generated using the other approaches. At the individual level, none of the possible male dispersers shared a putative mother/offspring relationship with any other non-calf animal, and five of them carried haplotypes which have not been identified in females in the western Pacific and which, with one exception (the animal carrying a haplotype that is unique in both populations), are more common among eastern animals. At the population level, the differentiation observed between males and females in the west, the differentiation between the two western clusters (one of which contained all of the potential dispersers), and the lack of significant differences found when males of the two populations were compared all indicate that dispersal, rather than recent divergence, is driving the low level of differentiation found between the two populations.

If dispersal of eastern gray whales onto the western feeding ground is occurring, it may be a response to relatively recent changes in prey availability on traditionally used eastern feeding areas coupled with the increasing size of the population. In the 1980s, the Chirikov Basin, in the northern Bering Sea, was considered one of the primary foraging areas for eastern gray whales, based on both high densities of gray whales (Braham 1984, Kim and Oliver 1989, Highsmith and Coyle 1990) and their amphipod prey (Grebmeier *et al.* 1989, Highsmith and Coyle 1990). By 2002, however, sighting rates of gray whales in this area had decreased considerably (Moore *et al.* 2003). During this same time period, amphipod biomass in the Chirikov Basin declined by nearly 50% (Coyle *et al.* 2007), likely as a response to foraging whales (Highsmith *et al.* 2006) and/or ecosystem changes (Grebmeier *et al.* 2006). The downturn in amphipod biomass during a time when the gray whale population would have been increasing suggests that gray

whales simply expanded their foraging range (Moore *et al.* 2003). Although other causes couldn't be ruled out, these declines in amphipod biomass have also been implicated as a possible cause of the 1999-2000 gray whale mortality event, in which the number of stranded gray whales, many of which were emaciated, increased by an order of magnitude over previous levels (Gulland *et al.* 2005). Beginning in 1999, gray whales have also been sighted foraging year-round off Kodiak Island, Alaska (Moore *et al.* 2007), an area traditionally considered part of the migratory route. The primary prey of whales feeding in this area is cumaceans, which are not considered a typical prey species for gray whales (Nerini 1984, Darling 1998, Dunham and Duffus 2002).

This evidence suggests that gray whales are capable of expanding their foraging range in response to declines in prey abundance, and that conditions favoring such an expansion may have been present within at least the past decade. Given these observations, it seems plausible that some eastern gray whales, rather than feeding in more southern or more northern areas, may instead have traveled farther west. In recent years, sightings of gray whales off the eastern coast of Kamchatka have raised questions about potential mixing of eastern and western gray whales in this area, with some of the identified animals known to utilize the western feeding ground off Sakhalin but others being of unknown origin (Tyurneva *et al.* 2009). Increased monitoring, via both photo-identification and genetic studies, of whales utilizing this area might provide additional insight into the possibility of mixing of eastern and western gray whales off Sakhalin.

Such dispersal, if occurring, seems to be resulting in long-term fidelity to the Sakhalin feeding area, rather than occasional use of the area by eastern whales. All of the putative dispersers, as well as the majority of whales within the cluster showing similarity

to eastern animals, have demonstrated site fidelity to the Sakhalin feeding area. In general, our understanding of long-term patterns of feeding ground fidelity in gray whales is limited. Within the eastern gray whale population, a subset of individuals, generally referred to as the Pacific Coast Feeding Aggregation, terminate their northward migration in lower latitudes and feed along the coasts of California, Oregon, Washington, British Columbia, and Alaska (Darling 1984, Calambokidis *et al.* 2002). Within this region, many whales return on an annual basis, although they may utilize different areas within the broader region within seasons or between years (Calambokidis *et al.* 2002, 2004). Recruitment into this aggregation is not well understood. Initial genetic studies have not found support for these animals being a maternal isolate (Steeves *et al.* 2001, Ramakrishnan *et al.* 2001), although studies utilizing more samples are currently underway and may provide additional insight. Sighting patterns of individual whales have also suggested that fidelity to the area may be mediated by foraging success or failure (Calambokidis *et al.* 2004). Additional sampling of gray whales utilizing other feeding areas would be valuable in increasing our understanding of how the fidelity observed on the Sakhalin feeding ground and within the PCFA compares with that on other feeding areas.

Although the results presented here suggest that some dispersal of eastern animals onto the western feeding ground may be occurring, determining whether such dispersal can be characterized as feeding ground mixing only, or whether it entails gene flow between populations, is not clear. While approximately half ($n = 18$ of 42) of the males first identified as non-calves were assigned as putative fathers (Chapter Three), only one of the eight males designated as possible dispersers was identified as a putative father,

and the only female has never been sighted with a calf. Although these individuals could potentially be animals that are too young to reproduce, these results suggest that most, although potentially not all, of the putative dispersal events have yet to result in genetic exchange between the two populations. The maintenance of genetic differentiation between the two populations (Chapter Two) also indicates that significant gene flow is unlikely. Future work using simulation-based approaches will be valuable in assessing how much confidence can be placed on the assignment test results and may also allow exploration of the extent of gene flow which could occur between the populations while still allowing genetic differentiation to persist.

Summary

Complex patterns of structuring, driven by both intra- and inter-population processes, exist among animals sampled on the Sakhalin feeding ground. The sex-specific analyses presented in the second chapter, which demonstrated markedly lower levels of differentiation between males of the two populations when compared to females, suggested that the low level of nuclear differentiation between the two populations was likely derived from some degree of male-biased dispersal between the eastern and western populations. The results presented here are largely congruent with that hypothesis, suggesting that heterogeneity exists between males and females utilizing the Sakhalin feeding ground. Furthermore, the results of the genetic assignment test indicate that any dispersal between populations is largely mediated by, although not necessarily exclusive to, males.

As discussed in Chapter Two, increasing our understanding of the extent and nature of any dispersal that may be occurring between the two gray whale populations has important consequences for evaluating the status of the western gray whale population. If dispersal is characterized not only by mixing on the feeding ground but also by interbreeding of migrants with western animals, it has likely been important in providing “genetic rescue” to the western population by contributing valuable genetic diversity and reducing the incidence of breeding among close relatives. On the other hand, if putative eastern dispersers demonstrate fidelity to the western feeding ground during summer months but return to the eastern Pacific to overwinter, current estimates of the population’s abundance and of the genetic diversity it has maintained may be artificially inflated by the assumption that all animals identified off Sakhalin are western gray whales. Furthermore, these eastern interlopers might be increasing competition for food resources on the western feeding ground.

The eastern North Pacific gray whale has been heralded as a “sentinel of ecosystem change” based on several indications that the population is responding to alterations in its habitat over the past several decades (reviewed in Moore 2008). Although its value in this regard is based on the population’s seasonal dependence on Arctic waters for feeding, the link between eastern gray whales and their environment is likely to have intensified with the population’s recovery and the subsequent increase in competition for prey resources. If dispersal of eastern whales onto the western feeding ground is occurring, as suggested here, it may indicate that changes in the structure of gray whale populations could occur or be occurring both as a result of the eastern population’s recovery and the changing Arctic environment. Additional efforts to

understand the extent and nature of connectivity between gray whale populations may provide insight into the potential for population recovery and habitat alteration to affect the structure of other, less well-studied populations of baleen whales.

Although the results presented here suggest that some dispersal of eastern animals onto the western feeding ground may be occurring, a strong signature of internal recruitment into the population was identified, such that 63% of sampled animals shared a putative mother/offspring relationship with at least one other sampled animal. In fact, over half (58%) of sampled animals could be traced back to as few as five females, indicating that the reproductive success of these females and their offspring has played an important role in shaping the genetic structure of the western population. This pattern is an extension of our understanding based on monitoring of the population between 1995 and 2007, during which time strong fidelity of reproductive females to the Sakhalin feeding area has been documented, with some females observed returning with four to five calves during this time (Weller *et al.* 2009). Evaluation of the numerous threats potentially facing this population, including but not limited to disturbance related to oil and gas development on their feeding ground as well as mortality resulting from incidental net entrapment on their migratory route should take into account the possible consequences of disruption of the fidelity of these matrilineal groups to the Sakhalin feeding ground.

Some or all of the material found in Chapter Four will be submitted for publication. I was the primary researcher. The co-authors D. Weller and A. Burdin supervised the field

effort through which the genetic samples were collected. The co-authors D. Weller, R. LeDuc, and R. L. Brownell, Jr. supervised the research.

Table 4-1. Results of STRUCTURE analysis utilizing samples collected from both the eastern and western North Pacific. The inferred number of genetic clusters (K), the estimated log likelihood value (after averaging across runs) for the data given K ($\ln P(X|K)$), the posterior probability of K ($\Pr(K|X)$), and the second order rate of change in the likelihood (ΔK) are shown. Note that ΔK cannot be calculated for the smallest or the largest K being tested. The parameters incorporated in the model are described in the text.

Ln			
K	P(X K)	Pr (K X)	ΔK
1	-11612.42	≤ 0.001	NA
2	-11398.74	≤ 0.001	14.3
3	-11365.8	0.983	1.1
4	-11369.88	0.016	1.7
5	-11458.62	≤ 0.001	NA

Graph 4-1. Graphical representation of STRUCTURE results utilizing samples collected from both the eastern and western North Pacific. The log-likelihood values ($\text{Ln}P(X|K)$) shown are based on averages across 5 runs. Error bars denote standard deviations. The parameters incorporated in the model are described in the text.

Figure 4-1. STRUCTURE barplot for samples collected in both the eastern and western North Pacific. The plot for $K=2$ using a model based on admixture with correlated allele frequencies and incorporating information on the sampling location of individuals (Hubisz *et al.* 2009) is shown. Individuals are represented by vertical bars, and the different colors of the bars represent the proportion of admixture, or ancestry, from a certain inferred genetic cluster. The Y-axis represents Q , the proportion of admixture. Individuals are grouped according to the population in which they were sampled, and the black line denotes the boundary between animals sampled in the eastern and western Pacific.

Table 4-2. Results of STRUCTURE analysis using only the samples collected in the western North Pacific. The inferred number of genetic clusters (K), the estimated log likelihood values (after averaging across runs) for the data given K ($\text{Ln } P(X|K)$), the posterior probabilities of K ($\text{Pr } (K|X)$), and the second order rate of change in the likelihood (ΔK) are shown. Note that ΔK cannot be calculated for the smallest or the largest K being tested.

Ln			
K	P(X K)	Pr (K X)	ΔK
1	-5700.86	≤ 0.001	NA
2	-5565.66	≤ 0.001	7.1
3	-5532.32	1	1.4
4	-5728.7	≤ 0.001	0.8
5	-5681.9	≤ 0.001	NA

Figure 4-2. STRUCTURE barplot for samples collected in the western North Pacific. The results for $K=2$ clusters are shown. Individuals are represented by vertical bars, and the different colors of the bars represent the proportion of admixture, or ancestry, from a certain inferred genetic cluster. The Y-axis represents Q , the proportion of admixture. Individuals are grouped by the cluster to which they were assigned, and the black line denotes the boundary between animals in the two clusters.

Table 4-3. Estimates of genetic differentiation after stratification by sex and by status as calf or non-calf when first identified (western samples only). F_{st} values for mtDNA haplotype frequency comparisons are shown above the diagonal and for microsatellite allele frequencies below the diagonal. Significant values are displayed in bold.

		East		West		
		Females	Males	Females	Males	Calves
East	Females	*	≤ 0.001	0.078	0.043	0.099
	Males	≤ 0.001	*	0.058	0.033	0.075

V. CHAPTER FIVE

Possible movements of two gray whales (*Eschrichtius robustus*) between the eastern and western North Pacific inferred using genetic tags

ABSTRACT

Genetic tagging approaches that utilize microsatellite genotypes to provide a genetic profile useful in identifying individuals have proven valuable in detecting movement patterns of individuals. In the course of a study designed to evaluate the population structure of gray whales (*Eschrichtius robustus*) in the North Pacific, two individuals were identified in the western North Pacific which had identical microsatellite genotypes (n=13 loci), mtDNA haplotypes, and sexes as those obtained from two biopsy samples collected off central California. While previous studies have supported genetic differentiation between the eastern and western populations of gray whales, the relatively low level of genetic differences observed at nuclear markers suggests that some dispersal between the two populations could be occurring. The finding of two whales apparently sampled on both sides of the North Pacific, although subject to numerous caveats, provides support for that possibility. In addition, if the genetic matches represent true dispersal events between the eastern and western Pacific, our understanding of the reproductive history of the animals sampled in the west indicates that such dispersal may result in a limited amount of gene flow between populations. Given sampling limitations, these findings cannot be used to evaluate the magnitude of such dispersal, but they highlight the need for additional genetic, photo-identification, and satellite tagging studies to assess this question. The results also demonstrate how the combination of genetic information with long-term field studies can be valuable in elucidating factors affecting population structure in cetaceans.

INTRODUCTION

Like most baleen whales, gray whales (*Eschrichtius robustus*) exhibit seasonal movements between high- latitude summer feeding grounds and low- latitude wintering areas. The current distribution of this species is limited to the eastern and western margins of the North Pacific (Rice and Wolman 1971), where two populations have been identified. Animals from the eastern North Pacific population spend their summers feeding in the waters of the Bering, Beaufort, and Chukchi Seas, with some animals demonstrating fidelity to more southern feeding areas ranging from Southeast Alaska to northern California (Darling 1984, Calambokidis *et al.* 2002). Although some gray whales may overwinter at high latitudes (Stafford *et al.* 2007), most animals from this population migrate south to the lagoons and coastal waters off Baja Mexico to spend their winter months. Although this stock of whales was greatly depleted by commercial whaling, the population was removed from the Endangered Species list in 1994 and currently numbers ~20,000 – 22,000 animals (Rugh *et al.* 2008, Punt and Wade 2010).

In contrast, the population of whales in the western North Pacific has been estimated to contain only about 130 animals of age one or older (Cooke *et al.* 2008) and is currently listed as Critically Endangered by the IUCN (Weller *et al.* 2002, Baillie *et al.* 2004). The primary feeding ground for this population is located in the coastal waters of northeastern Sakhalin Island, Russia (Weller *et al.* 1999, 2002), although use of areas farther offshore off Sakhalin as well as off the southern and eastern coasts of Kamchatka have also been documented (Yakovlev *et al.* 2007, Tyurneva *et al.* 2009). The location of the wintering ground(s) for this population is unknown, but information from sightings,

strandings, and catches suggests that at least some animals may winter in the coastal waters of southern China (Zhu 1998, Kato and Kasuya 2002, Weller *et al.* 2002).

Genetic studies utilizing both mtDNA and microsatellites have established that the two populations are genetically differentiated (LeDuc *et al.* 2002, Chapter Two). However, the level of nuclear differentiation found between the two populations is relatively low, suggesting that some amount of dispersal between them may exist. The results of sex-specific analysis, as well as of genetic assignment tests, have suggested that any such dispersal is likely to be male-biased (Chapter Two and Chapter Four).

As part of the above studies, the mtDNA haplotype, sex, and the genotypes for 13 microsatellite loci were generated from 142 samples collected on the western feeding ground located off Sakhalin Island, Russia. With one exception, these samples are linked to individuals photographically identified on the study area, and they represent 83% of all animals (n=169) photographed in the area. Photographic records documenting the use patterns of these animals within the study area also exist (Weller *et al.* 1999, 2002, 2008). For comparative purposes, 136 samples collected from animals in the eastern Pacific were also analyzed. Given the size of the eastern population, however, these samples represent less than 1% of the population, and with only a few exceptions these samples are not linked to any photographic records.

Traditionally, cetacean studies have relied on the use of natural markings to identify individuals and document movements between areas (e.g. Hammond *et al.* 1990a). In the past decade or so, however, numerous microsatellite loci have been developed for use with cetaceans (e.g., Valsecchi and Amos 1996, Berube *et al.* 2000, 2005), supplying an alternative method for discriminating between individuals. When a

sufficient number of loci are utilized, microsatellite genotypes can provide a “genetic tag” which allows animals to be tracked through space and time (Palsboll 1999). In cetaceans, this approach was first used in a study of humpback whales (*Megaptera novaeangliae*) in the North Atlantic (Palsboll *et al.* 1997), where genetic tags were used to document movements of whales between feeding areas and mixing of animals on winter breeding grounds, as well as to estimate abundance. Genetic tagging studies are now widely used to estimate population size, often utilizing noninvasive sampling strategies (e.g., Eggert *et al.* 2003). This approach has also provided information on the movements of individual animals, including the seasonal migration of a humpback whale between the Norwegian Sea and the eastern Caribbean (Berube *et al.* 2004) as well as the surprising movement of a male humpback whale between two wintering regions in different ocean basins (Pomilla and Rosenbaum 2005).

Given that questions have been raised about the potential for movements of gray whales between the eastern and western North Pacific, genetic tagging could provide a method to evaluate contemporary dispersal between areas. Based on the size of the eastern population, much more extensive sampling of this population would be needed to make such an approach viable for making inferences about the extent and nature of any such dispersal. Despite the limitations of the currently available dataset, however, two pairs of individuals with matching genotypes, haplotypes, and sexes were identified in our study. In both cases, one animal of each pair was sampled in the eastern Pacific and, the other in the western Pacific. Each pair may represent a single whale. Although additional studies are needed before any conclusions can be drawn, the possible significance of these finding is discussed below.

METHODS

One hundred forty-two western gray whale samples were collected between 1995 and 2007 via biopsy darting of free-ranging whales on the population's feeding ground off Sakhalin Island, Russia. All except for one of the western gray whale samples are linked to a photographically identified animal, and this sample set represents 83% of all animals (n=169) identified on the western feeding ground through 2007. One hundred thirty-seven eastern gray whale samples obtained from the archive at the Southwest Fisheries Science Center were used for comparison to the western population. These samples were taken primarily from stranded animals, with some samples obtained from directed subsistence takes, fisheries bycatch, and biopsies of free ranging whales. Collection locations ranged from southern California north to the Chukotka Peninsula in Russia (*Table 5-1*).

The sex, mtDNA haplotypes, and microsatellite genotypes were determined for these samples as part of an earlier study examining genetic differentiation between eastern and western populations (Chapter Two). The microsatellite loci utilized in the study are shown in *Table 1-1* (Chapter Two); the diversity of the loci in each population is shown in *Table 5-2*. The EXCEL add-in MS_TOOLKIT (Park 2001) was used to identify samples with genotypes that matched at all 13 loci. The mtDNA haplotype and sex of animals with identical genotypes were used to confirm all identified matches.

The program GENEAP (Wilberg and Dreher 2004) was used to calculate the probability of identity using the microsatellite genotypes. The probability of identity (PID) is defined as the probability that two individuals drawn randomly from the dataset will have the same genotype at multiple loci. This statistic was initially calculated under

the assumption of Hardy-Weinberg equilibrium (PID_{HW} , Paetkau and Strobeck 1994).

However, such estimates may be biased in the presence of population structure.

Calculations assuming the presence of full siblings within the dataset (PID_{SIB}) are considered more conservative (Waits *et al.* 2001) and were calculated using the formula of Evett and Weir (1998). PID values were calculated using the combined dataset and also utilizing the data for each population separately.

The match probability (*e.g.*, individual probability of identity) is defined as the probability that given the genotype of one individual, a second individual will have the same genotype. The match probability was calculated for all identified pairs of duplicate genotypes both under the assumption of Hardy-Weinberg equilibrium and assuming that the two individuals were full siblings (Woods *et al.* 2009).

RESULTS

Two pairs of animals with identical genotypes, mtDNA haplotypes, and sexes were identified. In both cases, one animal of the pair was sampled as part of the eastern population and the other as part of the western population. The average probability of identity utilizing the combined dataset and assuming Hardy Weinberg equilibrium was calculated as 8.65×10^{-14} , while PID_{sib} was calculated as 1.04×10^{-5} . When the average probability of identity was calculated for each population separately, the PID_{sib} was 6.72×10^{-6} for the eastern population and 1.48×10^{-5} for the western population. PID_{HW} was 1.25×10^{-14} and 4.13×10^{-13} for the eastern and western populations, respectively. Match probabilities (P_{HW} and P_{SIB}) for both pairs, as well as the mtDNA haplotype and sex of the matching animals, are shown in *Table 5-3*. The two pairs of matching genotypes were

heterozygous for 10 of the 13 loci utilized. All other samples utilized in the study had genotypes which mismatched at 5 (n=1 pair), 6 or more loci.

Interestingly, both of the biopsies from the eastern population were collected during the same expedition. Sample #3947 was collected on 20 March 1995, and sample #3950 on 23 March 1995. Both samples were taken from whales in the Santa Barbara Channel off central California. Although some video was taken during this sampling trip, it proved to be of too poor resolution to be useful in photographic comparisons.

Sample #12186 was collected from an animal on the Sakhalin feeding ground on 14 August 1998. Photo-identification records link this whale to an animal which was first identified in that area on 19 August 1995. This male was sighted off Sakhalin during ten of the 12 seasons covered by the study. Sample #50728 was collected from a whale on the Sakhalin feeding ground on 27 August 2004. Photo-identification was used to link this animal to a whale first identified in that area in 1999. This female was then sighted off Sakhalin in all subsequent years of the study. Extensive photo and video documentation exists for both of these animals.

DNA was extracted from the two samples collected in the eastern Pacific in June 1995, prior to the arrival of any tissue samples collected from the western Pacific. Sample #12186 was cleared in 1999 and was first extracted in April. The initial microsatellite amplification of #3947, 3950, and 12186 were conducted as part of the same batch. However, when the genetic match between #12186 and #3950 was first identified, both of these samples were re-extracted and re-amplified; no genotyping errors were identified. Sample #50728 was cleared in October 2005 and was extracted in November 2005; no samples collected in the eastern Pacific were included in this batch of

extractions. All four samples were re-extracted in October of 2008. The mtDNA haplotypes from the new extractions were sequenced, and microsatellite genotypes were generated from all four of the new extractions as part of the same run to control for possible errors in calibration across runs. No errors were identified.

DISCUSSION

Before considering the implications of these results for our understanding of gray whale population structure, possible explanations should be addressed. Precautions were taken to ensure that the matching genotypes were not an artifact of lab error. Given that the initial archiving and extraction of tissue samples were conducted as part of three separate batches in three different years, the probability that a mixup at the level of the tissue is extremely low. For all samples, genotypes were replicated after re-extraction of DNA from the tissue; no errors were identified, suggesting that genotyping errors were also unlikely.

The power of the microsatellite panel used to discriminate between individuals was high ($PID_{HW} = 8.65 \times 10^{-14}$; $PID_{SIB} = 1.04 \times 10^{-5}$) and comparable to that used in other studies utilizing genetic tagging to infer movements of individuals between areas (*e.g.*, $PID_{ave} = 1.51 \times 10^{-7}$, Palsboll *et al.* 1997; $PID_{sib} = 2.8-3.11 \times 10^{-5}$, Pomilla and Rosenbaum 2005). The more conservative estimates of the match probabilities (P_{sib}) calculated from the gray whale microsatellite data suggest that the probability of finding two animals with these identical genotypes is 1/50,000 (for the match between females) and 1/100,000 (for the match between males); and the less conservative measures (P_{HW}) suggest that the probability is almost infinitesimally small. It is likely that the true

probability lies somewhere between these two estimates, given that there is evidence for population structure in our data but it is unlikely that many full siblings were represented, based on studies of paternity in western gray whales (Chapter Three).

Based on these considerations, the probability that the two sets of matching genotypes identified here are an artifact of laboratory errors or a lack of resolution in the markers used is vanishingly small. However, even if all 130 of the animals in the western Pacific were to have visited the eastern Pacific during the study period, it is highly unlikely that one of the western animals would have been sampled given the size of the eastern population and the relatively low proportion of animals in the eastern Pacific which have been sampled. The probability of sampling one of ~130 western animals among an estimated 20,000 eastern gray whales is approximately 1/150 ($p = 0.006$); assuming the two events are independent, the probability of capturing two western animals is approximately 1/22500 ($p = 4.17 \times 10^{-5}$). These probabilities would be even lower if only a small number of the animals identified in the western Pacific travel to the eastern Pacific. Only 115 eastern samples were collected during the period of time (*i.e.*, in 1995 or later) in which an animal identified on the western feeding ground could have feasibly been sampled (*Table 5-1*). Only 19 of these samples were collected from live animals, meaning that almost all of the animals sampled in the east were not present during the entire study period.

Given the low probability of sampling a western animal in the eastern Pacific, these calculations indicate that if the matching genotypes do represent animals which have travelled between the two areas, some source of capture heterogeneity may exist which acts to increase the probability of sampling an animal sighted in the western

Pacific relative to those which remain in the eastern Pacific. Mark-recapture studies based on photo-identification have identified several sources of capture heterogeneity among cetaceans (Hammond *et al.* 1990b). While some of these are specific to photo-identification methods (*e.g.*, variation in the distinctiveness of marking patterns), others, including differences in behavior between individuals, could potentially increase the probability of sampling a western animal relative to that of sampling an eastern animal. It is plausible that, given the long-term field study conducted on the western feeding ground, western whales may have become more accustomed to being monitored by small boats and thus may be more easily approached for sampling than eastern whales are. However, both of the animals sampled in the eastern Pacific were sampled prior to the start of field efforts in the western Pacific, suggesting that the source of any capture heterogeneity between eastern and western animals may be more subtle.

However, if the genotype matches do represent true dispersal events, the tightly linked timing of the two sampling events in the eastern Pacific raises questions about the independence of the two events. If these putative movements represent some colonization of the western feeding ground by eastern animals, perhaps such events occur as one animal follows another into a new area. Another possibility is that some segregation takes place on the migratory route relative to the feeding location. Southbound migration timing has been correlated with feeding ground origin in North Atlantic humpback whales (Stevick *et al.* 2004), which utilize two different feeding areas but a common breeding area in the West Indies. Animals which fed in the Gulf of Maine and eastern Canada had earlier mean sighting dates in the West Indies than did animals known to feed in Greenland, Iceland, and Norway, suggesting that the migration from feeding area

to breeding area might be segregated. Although stratification of the gray whale migration relative to age, sex, and reproductive status is known to occur (Rice and Wolman 1971), no additional mechanisms for segregation have been identified.

Although previous studies have confirmed that the eastern and western gray whale populations are genetically distinct, the relatively low level of differentiation observed at nuclear markers has suggested that some degree of dispersal of eastern animals onto the western feeding ground may occur (Chapter Two and Chapter Four). Although rare, “extralimital” movements have been observed in other baleen whale species. In a study similar to that reported here, Pomilla and Rosenbaum (2005) used genetic tagging to document the transoceanic movement of a male humpback whale from wintering grounds off the northeastern coast of Madagascar in the southwestern Indian Ocean to wintering grounds off the coast of Gabon in the eastern South Atlantic Ocean. Although the movement of this whale was initially detected using genetic evidence, the match was later confirmed via photo-identification, further validating the utility of genetic studies to track individuals. Photo-identification studies have also documented movements of humpback whales in the North Pacific between different breeding regions and between western Pacific breeding regions and eastern North Pacific wintering regions (Darling *et al.* 1997, Salden *et al.* 1999, Calambokidis *et al.* 2001, 2008). In addition, movement of a North Atlantic right whale (*Eubalaena glacialis*) from the western North Atlantic to northern Norway and back has been documented using photoidentification (Jacobsen *et al.* 2004).

Previous studies of gray whale population structure (LeDuc *et al.* 2002, Chapter Two) have noted that the western gray whale population contains a relatively high

number of mtDNA haplotypes ($n=22$) and that many of those haplotypes ($n=11$) have thus far been found in only a single male. These males were hypothesized to represent good candidates for dispersal from the eastern Pacific to the western feeding ground (LeDuc *et al.* 2002, Chapter Two). However, the male which was apparently sampled in both the east and the west carried a haplotype (B) which is common in both populations, providing no additional information on the likelihood of this animal being a migrant. The haplotype (35) carried by the female samples has been identified in only one other sample collected in the eastern Pacific and six samples obtained from whales in the western Pacific. However, these six samples include three of the western female's offspring, as well as one other female and her two offspring. Given the low sampling coverage in the eastern Pacific, it is likely that this haplotype would be found in additional animals on that side of the ocean basin with more complete sampling.

In addition to the temporal proximity of the two sampling events in the eastern Pacific, a couple of other aspects of the timing in which the samples were collected should be addressed. First of all, the sample from the male animal off Santa Barbara was obtained approximately five months prior to the first sighting of the whale associated with sample 12186 on the Sakhalin feeding ground, suggesting a maximum travel time of 150 days. Assuming that a whale moving between these two areas would likely have traveled along the Aleutian Islands and then down the eastern coast of Kamchatka, the distance between the two sampling locations is approximately 10000 km, which would entail a travel speed of $\sim 70\text{km/day}$. Speeds of approximately 150km/day are considered representative of travel rates for southbound migrating gray whales (Rugh *et al.* 2001),

suggesting that a gray whale would be capable of traveling between these two areas in the given time.

Secondly, the eastern gray whale samples were collected off central California in March, indicating that the samples were collected from whales which were likely migrating north after having spent the winter off Baja Mexico. The samples collected in the western Pacific were obtained from whales which were utilizing the Sakhalin feeding area and which have demonstrated high levels of fidelity to that region. Therefore, the putative movements of these whales could provide evidence of feeding ground exchange, such that these individuals feed in the western Pacific but continue to return to the eastern Pacific during winter months. Alternatively, they could represent more permanent dispersal into the western Pacific, such that subsequent to “discovering” the Sakhalin feeding area the animals then utilized wintering areas in the western Pacific.

Integrating additional genetic evidence with that obtained from photo-identification of the western animals may provide some insight into the nature of these putative movements. Paternity analysis of sampled calves born into the population between 1995 and 2007 indicated that the male associated with sample #12186 was the putative father of a calf born in 2007 (Chapter Three). The female associated with sample #50728 is identified (both behaviorally and genetically) as the mother of three calves born during the same time period; although two of her calves were not assigned a putative father among the sampled western animals, her 2007 calf was assigned a putative father which has been sighted regularly on the Sakhalin feeding ground. This evidence suggests that both of the whales sampled as part of the western population interbred at least one time with other animals considered to be western gray whales. Given that

mating in gray whales is thought to primarily occur while on migratory routes (Rice and Wolman 1971), these results suggest that the whales would have used migratory routes in the western Pacific at least on some occasions.

SUMMARY AND FUTURE STUDIES

If these genetic matches do indeed represent movements of animals between the eastern and the western Pacific, such dispersal raises questions about the degree and nature of the connectivity of these two populations. Previous work has shown that the eastern and western populations are genetically distinct, although the relatively low level of nuclear differentiation suggested that some dispersal may occur between the two areas (Chapter Two). The putative dispersal events described here provide further support for that possibility. However, the conclusions that can be drawn from these events are limited by the lack of photographic documentation of the animals sampled in the east, as well of the paucity of genetic samples analyzed from that area.

Some resolution to the questions raised here may come with future studies integrating photo-identification comparisons and satellite tagging with the genetic data. Extensive photo-identification records exist for the western gray whale population, documenting individual use patterns of the Sakhalin feeding area over 12 summer feeding seasons (Weller *et al.* 1999, 2008). However, the Sakhalin photo-identification catalogues have not been compared with those existing for the animals in the eastern Pacific. Photo-identification studies have been conducted over many years in the calving lagoons of Baja Mexico, and additional studies have been conducted in various regions of the eastern population's feeding range. Comparison of photo-identification records between

the eastern and western Pacific would provide some insight into the frequency and nature of any movements between the two areas.

In addition, satellite tagging studies for western Pacific gray whales are scheduled to begin in the summer of 2010. The objective of these studies is to learn more about the location of the primary wintering area for the western population, which has yet to be confirmed. However, such studies may also provide more direct evidence of movements between populations or perhaps indicate that few, if any, whales move between areas.

Some or all of the material found in Chapter Five will be submitted for publication. I was the primary researcher. The co-authors D. Weller and A. Burdin supervised the field effort through which the genetic samples were collected. The co-authors D. Weller, R. LeDuc, and R. L. Brownell, Jr. supervised the research.

Table 5-1. List of genetic samples used in this study which were collected from gray whales in the eastern North Pacific. The year of sample collection and source of tissue are shown.

Year	Biopsy	Fishery	Harvest	Strand	Total

VI. CONCLUSIONS

The work presented here used a suite of different genetic approaches to characterize the population structure of gray whales in the North Pacific. The results highlight the complexity of elucidating patterns of movements in animals which are capable of traveling long distances, are sensitive to environmental changes, and whose life history dictates that they utilize different areas for feeding and breeding. While the information presented here contributes to our understanding of gray whale population structure, many additional questions were raised about the extent and nature of connectivity between the two populations.

Summary

Although some dispersal of eastern animals onto the western feeding ground may be occurring, the maintenance of genetic differentiation between the eastern and western populations supports their continued recognition as separate populations. Both field-based and genetic studies indicate that recruitment into this small population is driven in large part by the fidelity of females and their offspring to the primary feeding ground. In addition, the results of the paternity analysis indicate that interbreeding among individuals known to utilize the Sakhalin feeding ground occurs, presumably while these animals are travelling along common migratory routes.

Whether any dispersal which occurs between populations is representative of feeding ground mixing only, or if it entails gene flow between populations, is not clear. At the population level, the maintenance of genetic differences between eastern and western populations suggests that any gene flow that is occurring is likely to be minimal. However, genetic drift could be acting to counterbalance some restricted degree of

genetic interchange between populations, and the balance between these two forces in this small population is not well understood. Based on the individual-level analyses, only one of the nine animals designated as a putative disperser was identified as potentially contributing to reproduction in the population, indicating that most, although potentially not all, of the putative dispersal events did not result in genetic exchange during the study period. However, the results of the paternity analysis indicated that both of the two western animals which shared identical genetic profiles to animals sampled in the eastern North Pacific had interbred with other animals on the western feeding ground, suggesting that, if these genetic matches represent real movements of individuals, some gene flow may be occurring. While these results are intriguing, the caveats associated with both findings suggest additional studies are needed before any conclusions can be drawn.

Discriminating between gene flow and feeding ground mixing has important consequences for our understanding of the status of the western gray whale population. As aforementioned, if dispersal of eastern animals onto the western feeding ground is resulting in gene flow, then these dispersers may be acting to “genetically rescue” the remnant western population by providing an additional source of genetic diversity. Mixing on the feeding grounds without gene flow, however, could be artificially inflating our estimates of both genetic diversity and population size, which would suggest that the western population is more vulnerable than currently thought.

Finally, a number of different observations suggest that the habitat use patterns of gray whales in the eastern Pacific have recently shifted as a result of some combination of the population’s growth and recent environmental changes. If dispersal of eastern whales onto the western feeding ground is occurring, as suggested here, it may indicate

that changes in the structure of gray whale populations could also result from these conditions. Additional efforts to understand the extent and nature of connectivity between gray whale populations may provide insight into the potential for population recovery and habitat alteration to affect the structure of other, less well-studied populations of baleen whales.

Future Studies

Although continuing to collect biopsies from unsampled animals, particularly calves, on the western feeding ground would be valuable in further evaluating the patterns described here, expanding sampling efforts to include other areas in the western Pacific would contribute to our understanding of the size of the population in the western Pacific and the potential for intermixing with eastern animals. In particular, the collection of genetic samples from animals of unknown origin which utilize the waters of southeastern Kamchatka during summer months could provide information on the relationship of these animals to those sampled off Sakhalin. In addition, genetic analysis of any animals sighted, stranded, or entrapped in areas used as migratory corridors or wintering areas would be helpful in elucidating movements of individuals outside of the primary feeding ground. Analysis of historic gray whale samples, such as bones or baleen, collected in the western Pacific would be useful in evaluating how much genetic diversity has been lost in this population and has the potential to provide insight into which animals are more likely to represent “true” western gray whales.

Future work using simulation-based modeling would provide valuable context for interpreting the patterns identified using the genetic data. This approach could be used to

assess how much confidence can be placed into the assignment test results as well as to explore the extent of gene flow and/or intermixing which could occur between populations while still allowing genetic differentiation be detected.

Integrating the genetic data with information gained via other approaches might also provide resolution to the questions raised here. Although not a trivial undertaking, comparison of photo-identification records between the eastern and western Pacific would provide some insight into the frequency and nature of any movements between the two areas. In addition, satellite tagging of western gray whales, which is scheduled to begin in the summer of 2010, may provide valuable information about the location of migratory routes and wintering ground(s) in the western Pacific and the identity of whales which utilize these areas.

VII. APPENDIX

Why **not** Y? Lack of variability in the Y chromosome of gray whales (*Eschrichtius robustus*)

INTRODUCTION

Comparison of variation and population structure at Y chromosome loci with that found in maternally-inherited mitochondrial DNA (mtDNA) and biparentally-inherited microsatellite markers can provide valuable information on sex-specific population parameters and insight into reproductive strategies and dispersal (*e.g.*, Vila *et al.* 2003, Eriksson *et al.* 2006, Douadi *et al.* 2007). While mtDNA and microsatellites are often used to study cetaceans, knowledge of intraspecific Y chromosome variability has been limited to fin whales, which demonstrated relatively high levels of polymorphism at Y loci when compared with that observed in many other mammal species (Hatch 2004, Hatch *et al.* 2006). The intent of this work was to expand our understanding of Y chromosome diversity in cetaceans by assessing variability in the gray whale. Although previous work utilizing mtDNA and nuclear microsatellites has indicated that eastern and western gray whale populations are genetically distinct (LeDuc *et al.* 2002, Chapter II), several questions remain about the role that male dispersal may have played in both historic and current differentiation between populations. The use of Y markers could potentially address these questions.

METHODS

Seventeen Y-chromosome markers designed for use in other studies (Hatch 2004, Hellborg and Ellegren 2003, Hatch *et al.* 2006) were selected based on their successful amplification in other cetacean species (*Table A-1*). These markers included three anonymous regions designed from the Y chromosome of fin whales (Hatch 2004) and shown to amplify in a range of other mysticete species, including gray whales (Hatch *et*

al. 2006). The remaining 14 primer sets were designed from regions known to be conserved across mammals (Y Chromosome Conserved Anchored Tagged Sequences, YCATS) and amplified introns (Hellborg and Ellegren 2003). Although a total of 48 YCATS have been screened on mammals, the fourteen markers chosen here had been shown to successfully amplify in Risso's dolphins (Hellborg and Ellegren 2003).

To determine if these markers produced successful and male-specific amplification in gray whales, a PCR was conducted for each primer set using two samples collected from male gray whales and one sample collected from a female gray whale, which acted as a positive control. PCR conditions followed those described in the original studies (Hatch 2004, Hellborg and Ellegren 2003). Following PCR, products were visualized on a gel to determine if amplification was successful and male-specific. Those products which produced a single male-specific band on the gel were then sequenced using the marker-specific primers and following the sequencing protocol described in Chapter II.

The second step of the screening process was to determine if these markers amplified regions on the Y chromosome which were variable in gray whales. Samples collected from twenty male gray whales (n=10 from the eastern population and n=10 from the western population) were used to evaluate variability. These samples were chosen to maximize the chance of finding polymorphism by selecting samples which were known to have different mtDNA haplotypes and divergent genotypes. Amplification and sequencing for these markers followed the procedure described above; a female control was included in all amplifications.

RESULTS

Although eleven of the 17 Y-chromosome markers produced a product, only five of these markers produced a single, male-specific band when visualized on the gel (*Table A-1*). Sequencing of these five products, which totaled ~2.0 kb in length, revealed no variability among the twenty male gray whale samples selected for the screening. In addition, close inspection of the sequences for SMCY7 and UTY11 revealed that each sequence contained one site for which the base call was ambiguous. Given the lack of amplification in the female control, this finding suggested that amplification of Y-specific repetitive regions, known to be common on the Y chromosome (Skaletsky *et al.* 2003) may have been an issue. Although this problem might have been addressed by redesigning the primers used in the study, the lack of variation found in these regions indicated that such efforts would not be worthwhile.

DISCUSSION

In contrast to the relatively high levels of diversity observed in gray whales using mtDNA and microsatellite markers, analysis of ~2.0 kb of anonymous and intron sequences revealed no variation in the Y chromosome of gray whales. Although low polymorphism has been found on the Y chromosome of many mammal species (*e.g.*, Hellborg and Ellegren 2004), this lack of variation is inconsistent with that observed in fin whales. This raises questions about how other factors, such as life history traits and demography, may influence levels of Y chromosome diversity in cetaceans. These results also suggest that technical challenges, such as amplification of replicated regions, may continue to plague the amplification of Y chromosome regions in some species, although

new molecular techniques (reviewed in Greminger *et al.* 2009) may provide strategies to circumvent these issues in the future.

Table A-1. Y-chromosome loci screened in gray whales. The locus name and expected size were taken from the original studies. The results of the marker screening on gray whales are characterized by successful amplification, the presence of a single band, the presence of a male-specific band, and the length of the sequence (in basepairs) when amplified using DNA derived from gray whales.

Update on the use of a simulation-based approach to evaluate plausible levels of recruitment into the Pacific Coast Feeding Group of gray whales

Lang, A.R., and Martien, K. K.

Protected Resources Division, Southwest Fisheries Science Center, La Jolla, CA 92037

ABSTRACT

Previous genetic comparisons of the Pacific Coast Feeding Group (PCFG) of gray whales with whales feeding north of the Aleutians have shown significant levels of mitochondrial differentiation. The magnitude of the differentiation, along with the relatively high levels of genetic diversity identified within the PCFG, have raised questions about how much immigration into the group could occur before the signal of mtDNA differentiation is erased. Here we use a simulation-based approach to evaluate the range of plausible levels of immigration into the PCFG that could be occurring. The simulations incorporate annual immigration ranging from between 0 and 16 animals per year (once the larger ENP population reaches K), and simulations both with and without a pulse of +20 immigrants over two years are included. Results suggest that under the scenarios tested, current immigration into the PCFG of one migrant per year or less would produce levels of genetic diversity and differentiation that are inconsistent with the empirical data. The simulations were less informative with regard to placing an upper limit on the number of animals per year which could be immigrating into the PCFG, although comparison of F_{ST} and χ^2 (per degree of freedom) values between the simulated and empirical data suggests that immigration higher than 8 animals per year is unlikely. Comparisons between the observed and simulated values for the number of haplotypes, F_{ST} , and χ^2 (per df), which were the most informative measures, suggest that immigration of approximately 4 animals per year is most plausible.

INTRODUCTION

Genetic comparisons of samples collected from gray whales considered to be part of the Pacific Coast Feeding Group (PCFG) with those from animals that feed north of the Aleutians have revealed small but significant levels of mtDNA differentiation but no nuclear differentiation (Lang *et al.* 2011). In addition, a relatively large number of mtDNA haplotypes were identified within the PCFG ($n=23$ haplotypes, Lang *et al.* 2011), which is estimated to contain ~200 animals (IWC 2011). Analysis of photo-identification data indicates that on average, 10 animals per year were recruited¹ into the PCFG between 2004 and 2008, with larger numbers of recruits identified between 2000 and 2002 (IWC 2011). These recruits could be internal (i.e., calves born to PCFG mothers) or external (animals that previously fed north of the Aleutians and subsequently immigrated into the PCFG). An average of three calves per year were identified in the PCFG between 1998 and 2008 (Calambokidis *et al.* 2010), and it is presumed that at least half of the calves born each year may not have been identified as such (IWC 2011). Based on those assumptions, an estimated four animals per year may have recruited into the PCFG from northern feeding area(s) between 2004 and 2008, and a pulse of higher immigration may have occurred between 1999 and 2002, potentially in response to the increase in gray whale mortality that occurred in 1999 and 2000.

The results of these genetic and photo-id studies of the PCFG have raised questions about how much external recruitment into the PCFG could occur while still maintaining the observed level of mtDNA differentiation between the PCFG and animals feeding north of the Aleutians. The use of a simulation-based approach has the potential to provide information relevant to this question. As part of a previous IWC exercise (the Testing of Spatial Structure Methods, or TOSSM, project), simulated genetic datasets representing different population structure archetypes were created for performance testing of different analytical methods (Martien *et al.* 2009). The demographic parameters underlying the dataset generation model were based on the vital rates of

¹ Here a 'recruit' is defined as an individual first photographed in the PCFG seasonal range (within the area spanning 41-52°N and between June 1 and November 30) in a given year and resighted within the seasonal PCFG range in at least one subsequent year.

eastern gray whales (Martien *et al.* 2004, Martien 2006). In discussions with the IWC Stock Definition subcommittee, it was agreed that the TOSSM dataset generation model could be useful in creating simulated datasets that would allow the plausibility of different hypotheses (e.g., different immigration rates into the PCFG) to be evaluated.

METHODS

Rmetasim

Simulated datasets were produced using the *rmetasim* package (version 1.1.05, Strand 2002) as run in the R statistical environment (R 2.14.1). *Rmetasim* performs individual-based population genetic simulations utilizing stage-based matrix population models. The transition probabilities in the matrices are used to randomly assign births, stage transitions, and deaths of individuals over time. Density dependent growth is implemented by the linear interpolation between matrices representing survival and reproduction rates at carrying capacity (K) and at zero population density (ZPD). A pre-birth pulse model is used, such that at the end of each simulation year, the youngest animals in the population are one year old.

Stage-based matrices

As previously mentioned, vital rate estimates for eastern Pacific gray whales (as described in Martien *et al.* 2004, Martien 2006) were used to parameterize stage-based matrices for the TOSSM exercise. Since the construction of these matrices, additional information has become available on the life history of gray whales. This new information was utilized to update the stage-based matrices from TOSSM, and when possible the vital rates used in constructing the new matrices were chosen to be the same as those utilized in the IWC's Implementation Review of gray whales. The following changes were made:

- 1) Adult survival rate was increased to the median estimate from Punt & Wade 2010 ($S_A=0.982$)
- 2) A separate term for calf survival rate (set to $S_c=0.732$, the median estimate in Punt & Wade 2010) was utilized. In the previous matrices, calf survival was the same as juvenile survival.
- 3) The median estimate from Punt & Wade 2010 was utilized for the rate of increase at ZPD ($\lambda=1.063$)
- 4) The age of first reproduction (AFR) was increased to 7 years at ZPD based on the Bradford *et al.* 2010 review.
- 5) A third juvenile stage was added to provide better control of AFR.

In addition, three identical adult stages for each sex were included in the new matrices. In contrast, the matrices used in the TOSSM project included a single adult male stage and separate fertile and lactating stages for adult females. This change was implemented for two reasons. First, it allowed for better control of generation time and greatly reduced the proportion of individuals in the simulations that lived to unrealistic ages under the increased adult survival rate. Secondly, it reduced the number of multiple births by the same female in a given year. In *rmetasim*, the fertility term represents the mean number of calves produced per female based on a Poisson distribution (Strand 2002). This results in some females producing more than one calf per year. Eliminating the separate fertile and lactating stages allowed us to reduce the fertility term (since it was applied to all adult females, not just a subset in the lactating stage), thereby reducing the number of multiple births (Table 1). However, this change also eliminated the minimum two-year calving interval that had been enforced in the TOSSM matrices. As such, under the new matrices some females in the simulation will give birth in consecutive years (Table 2).

Given the number of changes implemented in the new matrices, we ran the simulations using both the updated nine-stage matrices as well as the original five-stage matrices (as described in Martien 2006) utilized in the TOSSM exercise. The vital rates used to construct the original matrices and those utilized in the updated 9-stage matrices are detailed in Table 3. The parameter for juvenile survival rate was not derived from the literature but was calculated from the matrices to produce the desired value of lambda. The

Maximum Sustainable Yield Rate (MSYR) calculated from the 9-stage matrices is ~3.3%, while MSYR for the 5-stage TOSSM matrices is ~3.6%.

These vital rates were used to construct stage-based matrices representing the demography of the population near carrying capacity (K) and near zero population density (ZPD). Transition probabilities were calculated according to Caswell (2001) and the resulting matrices are shown in Table 4.

Population Trajectories

Dataset generation followed the steps outlined in Martien 2006, with the exception that coalescent datasets were generated using FastSimcoal (Excoffier and Foll, 2011) rather than SimCoal 2.1.2 (Laval and Excoffier 2004) to establish the effective size (N_e). In all scenarios, a single population was simulated in *rmetasim* for 4000 years to provide datasets representing the equilibrium population. This time period was shown to be sufficient for reaching equilibrium in a similar exercise for bowhead whales (Archer *et al.* 2010), that have a markedly longer generation time.

The mutation parameter incorporated in the simulations was adjusted to produce genetic diversity levels (as measured by the number of haplotypes and the haplotypic diversity) that are similar to the values observed for the “North” strata in the Lang *et al.* 2011 study. A range of mutation parameters were explored before setting the mutation parameter to 3.8×10^{-3} per generation, which produced measures of genetic diversity that were the most consistent with the observed data.

Carrying capacity (K) for the larger ENP population of gray whales was set to 20,000 animals, similar to the most recent abundance estimate (19,126 animals in 2006/2007; Laake *et al.* 2009). Carrying capacity for the PCFG was set to 200 in accordance with the estimated abundance of 194 animals in 2008 (Annex F, IWC 2011).

For all population trajectories, depletion due to commercial whaling was simulated as having occurred between 1846 and 1930. Attempts were made to utilize the catch history (Annex E, IWC 2011) with a multiplier to produce the desired level of depletion in 1930 (10% of K). However, when this modification was incorporated it resulted in a high number of simulation runs that failed due to the simulated population(s) going extinct. As such, the depletion per year was set to a constant proportion of K, such that the population was depleted by 7.1% of K in each year for the duration of the simulated whaling period. This level of depletion allowed the population to reach the desired level (0.10 of K, or ~2000 animals) by 1930. Examples of the population trajectories produced are shown in Figure 5.

Given that little is known about the origin of the PCFG, two different population histories were simulated. The first scenario (“post-whaling split”) assumes that the PCFG split from the larger ENP population following depletion. After reaching equilibrium a single population was projected forward through the 1846-1930 whaling period with depletion occurring as described above. In 1930, 20 animals (10% of K_{PCFG}) were split from the larger population to represent the PCFG. The two populations were then allowed to increase until reaching K. *Rmetasim* employs a “hard ceiling” to restrict population growth to K, such that individuals are killed off randomly after reaching levels >10% higher than K.

The second scenario (“pre-whaling split”) assumes that the PCFG split from the larger ENP gray whale population prior to the depletion of gray whales due to commercial whaling. In this scenario, the equilibrium population was split into two feeding groups to represent the northern feeding ground ($K_{ENP}=20,000$) and the PCFG ($K_{PCFG} = 200$). The split was presumed to occur at the start of the Little Ice Age (considered here to be at 1540), a period in which it seems plausible that ice conditions would have been favorable for gray whales to begin using more southern feeding grounds. Both populations were projected forward until 1846, when the depletion due to commercial whaling was simulated as described above. After reaching 1930, the simulated depletion ceased and the two populations were allowed to grow until reaching K.

Immigration rates ranging from 0 to 0.0008 were simulated. These migration rates correspond to the immigration of between 0 and 16 animals per year into the PCFG from the larger ENP population once it has reached K (Figure 6). In addition, each population history and migration rate combination was also simulated with a migration “pulse” of 20 individuals over two years. This pulse is reflected in the abundance of the PCFG in 2000 and in 2001. Examples of abundance trajectories for the PCFG under the different immigration scenarios are shown in Figure 7.

Additional simulations were performed in which the value of K_{PCFG} was increased from 200 to between 500 and 5000. These simulations incorporated a post-whaling split of the PCFG from the larger ENP, with the pulse migration of +20 animals over two years but no annual immigration into the PCFG. As in the “post-whaling split” scenarios described above, the split of the PCFG from the larger ENP was modeled such that the number of animals colonizing the PCFG in 1930 was 10% of K.

A final set of simulations were performed that incorporated a more recent split (between 1940 and 1990) of the PCFG from the larger ENP population. The number of animals splitting off to form the PCFG in a given year was derived by taking an average (over ten replicates) of the simulated abundance of the PCFG in each year when the abundance trajectories were modeled under the scenario of a post-whaling split of the PCFG in 1930 with no annual immigration.

A list of scenarios that have been simulated to date is included in Table 7. Of note, the simulations incorporating a pre-whaling split of the PCFG from the larger ENP are in progress and have not yet been completed.

Sampling and Genetic Analyses:

To generate the simulated dataset, the number of simulated animals sampled per year was set to match the number of animals sampled per year and per stratum in the Lang *et al.* (2011) study (Table 8). In the empirical study, some animals were sampled multiple times, and only one sample per individual was retained for the data analysis. For the simulated sampling, the year of sampling for such individuals was assigned as the first year that the animal was sampled. A total of 103 samples were collected from simulated ENP individuals and 71 samples were collected from simulated PCFG individuals.

These sampled individuals were used to generate summary statistics for each group. Genetic diversity was characterized by the number of mtDNA haplotypes, the mtDNA haplotype diversity, and the mtDNA nucleotide diversity. Differentiation between the two simulated groups was measured using F_{ST} , χ^2 (per degree of freedom), and ϕ_{ST} . The summary statistics generated from the simulated datasets were then compared to the observed summary statistics generated for the PCFG and the North strata in Lang *et al.* 2011.

To further evaluate how well the shape of the haplotype frequency distribution for the simulated ENP population matched the shape of the distribution for the North stratum in the empirical data, a χ^2 test was used to compare the two haplotype frequency distributions, and the number of significant tests ($p < 0.05$) was calculated. In addition, the frequency of the most common haplotype in each replicate simulation was calculated and compared to the frequency of the most common haplotype in the empirical data for the North stratum. Given that the mtDNA summary statistics produced for the simulated ENP population under all scenarios was similar, these tests were only conducted using the data for the simulated ENP population produced under the model with a post-whaling split with pulse migration but no annual immigration.

In addition to showing the proportion of simulations that had higher and lower values for each statistic than the values generated from the empirical data, we used interpolation to calculate the “crossover point” at which the 50% probability (median) was reached (i.e. the point at which the proportion of simulated runs had values higher than the observed reached 50%). For the number of haplotypes, the crossover point was

calculated as the point at which the lines representing the proportion greater than and the proportion less than crossed (as for the other statistics), but because some simulation replicates had values equal to (rather than less than or greater than) the observed value, this point was slightly lower than the 50% probability.

RESULTS

Although the goal is to produce 500 replicates of each scenario, currently only 100 replicates of each scenario are complete and are utilized in the results shown here.

Comparison of simulated and observed data for ENP

Table 9 includes a summary of the number of haplotypes, haplotypic diversity and nucleotide diversity for the simulated ENP population for the model incorporating the 9-stage matrices with a post-whaling split and pulse immigration. Results were similar under all scenarios tested (data not shown). Overall, median values for both the haplotypic diversity and the number of haplotypes were similar among the simulated and empirical datasets. The haplotypic diversity values generated in the simulated data were slightly lower than that in the observed data, with median values for the simulated data ranging from 0.948 to 0.950 (as compared to the observed haplotypic diversity of 0.952) and with 52-64% of replicates under the different immigration scenarios having lower haplotypic diversity than found in the empirical data. In contrast, the median number of haplotypes generated in the simulated datasets (33 to 34 haplotypes) was slightly higher than that found in the observed data (32 haplotypes). Between 62 and 75% of replicates for the different immigration scenarios generated values higher than the number identified in the empirical dataset. Although the nucleotide diversity calculated from the empirical data fell within the 90% range of the simulated values, nucleotide diversity in the simulated data was higher than that found in the observed data.

To evaluate whether the shape of our simulated haplotype distributions matched the shape of the observed distribution, we used a χ^2 test to compare the observed (North stratum) versus the simulated haplotype frequency distributions for the ENP population. The χ^2 test evaluates whether the haplotype distributions representing the empirical and simulated data could have been generated by random sampling of a single population. The χ^2 test is particularly sensitive to the frequencies of the most common haplotypes, as those haplotypes are the most likely to be represented in the random draws that represent immigration events. In our comparison, 12% of tests showed significant ($p < 0.05$) differences (Figure 10), suggesting that the shape of the observed and simulated distributions were similar in most cases. We also compared the frequency of the most common haplotype in the empirical data with the frequency of the most common haplotype in the simulations. We found that the frequency of the most common haplotype was higher than that found in the empirical data for 47% of the simulation replicates. This finding is consistent with the expectation that if two samples are drawn from the same distribution, the frequency of most common haplotype would be expected to be greater in one sample than the other 50% of the time.

Comparison of simulated and observed data for the PCFG

Figure 11 shows a graphical representation of the proportion of simulated values for each statistic that are lower (shown in black) or higher (shown in gray) than the observed value generated from the empirical data for one of the scenarios tested (post-whaling split with pulse immigration, nine-stage matrices). Summaries of the number of mtDNA haplotypes (Table 12), mtDNA haplotype diversity (Table 13), mtDNA nucleotide diversity (Table 14), F_{ST} (Table 15), ϕ_{ST} (Table 16), and χ^2/df (Table 17) produced by the simulations under all completed scenarios are shown below.

With regard to comparisons between the observed and simulated data, the statistics based on haplotype frequencies (haplotypic diversity, F_{ST} , and χ^2/df) and haplotype numbers were the most informative. For all four of these statistics, scenarios based on annual immigration of one animal or less per year (at K) produced values that were inconsistent with the empirical data. The comparisons were less informative with regard to the highest level of immigration that could be occurring, although comparison of F_{ST} and χ^2/df values suggested that levels of immigration including > 8 animals/year (along with the pulse immigration) would produce values inconsistent with those produced by the empirical data.

Similar to the pattern seen in comparison of the observed and simulated data for the larger ENP population, the nucleotide diversity identified among the simulated datasets was higher than that seen in the empirical data. In the ϕ_{ST} comparisons, the value generated in the empirical comparison was more consistent with the lower range of values for annual immigration and indicated that more than 8 immigrants per year into the PCFG would produce values of ϕ_{ST} lower than that observed. Caution should be applied when interpreting this pattern, however, given the lower nucleotide diversities identified in the observed data when compared to the simulated datasets.

Table 18 shows the results of simulations evaluating scenarios in which the PCFG splits from the larger ENP population between 1940 and 1990. The results shown suggest that for no annual immigration into the PCFG to be plausible, the PCFG would have had to split from the larger population after 1950.

Table 19 shows the results of simulations evaluating scenarios in which the carrying capacity for the PCFG was set to between 500 and 5000. The results indicate that the carrying capacity for the PCFG would need to be higher than 500 animals for the simulated results to be consistent with the empirical data under a scenario of no annual immigration. Examples of the abundance trajectory of the PCFG for the K values tested are shown in Table 20. For all K values simulated, the abundance of the PCFG was close to carrying capacity by 2010 (Table 21).

DISCUSSION:

Comparison of the simulated and empirical datasets for the larger ENP population suggests that the simulations represent the empirical data reasonably well with regard to the number of haplotypes and their distribution. Although the simulations predict that we would find slightly higher number of haplotypes and a slightly lower haplotypic diversity than is present in the empirical data, the differences are small and the χ^2 test suggests that the two samples would be interpreted as being drawn from the same population in the majority (88%) of cases. The results of these comparisons suggest that similar frequency-based comparisons of the simulated and empirical data representing the PCFG should be informative.

The level of nucleotide diversity in the simulated data representing the larger ENP population is higher than that found in the empirical data, indicating that there are some aspects of the population's history that are not being captured by the simulations. It is likely that the gray whales in the North Pacific have experienced numerous fluctuations in abundance due to changing ice conditions in the past, and historic K may have been substantially larger than we have simulated here (e.g., Alter *et al.* 2007). Our simulations incorporate only a simplified version of the recent history of gray whales, and our results suggest that the statistics relying on nucleotide differences (e.g., nucleotide diversity and ϕ_{ST}) may be more sensitive to violations of our assumptions about past (pre-commercial whaling) population size and equilibrium. As such, the results derived from the comparisons of nucleotide diversity and ϕ_{ST} warrant further investigation and should be interpreted with caution.

The comparison of frequency-based statistics between the simulated and empirical datasets representing the PCFG suggests that annual immigration into the PCFG is likely to be higher than 1 immigrant per year under the scenarios tested. The simulations were less informative with regard to the upper bound on annual immigration that could be occurring. Although the F_{ST} and χ^2/df comparisons indicated that immigration of >8 animals/year would be inconsistent with the empirical data, the proportion of simulations with higher than the observed values for the number of haplotypes and the haplotypic diversity never exceeded 84% and 63%, respectively. For all four statistics, the proportion of simulations with higher (for the number of haplotypes and haplotypic diversity) or lower (for F_{ST} and χ^2/df) values than the observed appears to level off at the higher (8 -10 or more per year) levels of immigration. This pattern is particularly evident in the comparisons utilizing haplotypic diversity, where the proportion of simulations with higher or lower values than the observed levels off at ~50% for immigration of 8 or more animals per year. Haplotypic diversity is calculated based on the sum of squared allele frequencies. Given that relationship, as the number of haplotypes in a population increases, the addition of another haplotype, particularly one found in low frequencies as would be expected to be brought in by an immigrant, has little impact on diversity. As such, this statistic, and to a lesser extent the others, appear to have limited power to differentiate between the higher levels of immigration.

Although these statistics were limited in their ability to distinguish an absolute upper bound on how much immigration could be occurring, the calculation of the number of immigrants per year which corresponds to the “crossing point” provides some information on what the most plausible values of immigration could be (Table 22). The estimated number of migrants ranged from ~2 to 8 for the scenarios with pulse immigration under the updated matrices. For the reasons discussed above, the calculations based on ϕ_{ST} and haplotypic diversity may not provide the best estimates. Comparisons between the observed and simulated values for the number of haplotypes, F_{ST} , and χ^2/df , suggest that immigration of approximately 4 animals per year is most plausible. If the current abundance of the PCFG is approximately 200 animals, this represents immigration of ~ 2% per year. Of note, this estimate does not include the +20 animals which were simulated to immigrate into the PCFG in 2000 and 2001.

Although the simulation results could be sensitive to other parameters incorporated in the models, a limited evaluation of the effects of increased carrying capacity for the PCFG or a more recent founding time was conducted. These simulations suggested that to obtain the empirical results presented in Lang *et al.* 2011 under a scenario of no annual immigration, the abundance of the PCFG would have to be larger (>500 animals) than currently estimated. Gray whales have been observed feeding off of Kodiak Island, Alaska since at least 1999, with ~350-400 individuals counted during a single day in July 2000 (Moore *et al.* 2007). Approximately 20% of the animals photographically identified in this area between 2002 and 2005 are known to be animals that have also been photographed in the Pacific Northwest from northern California to southeast Alaska (Gosho *et al.* 2011). However, the median “crossing point” calculated from these comparisons suggest that values of K between 2000 (based on F_{ST}) and 3000 (based on the number of haplotypes) animals produce values that are most consistent with the empirical data, indicating that additional explanation may be needed.

The simulations exploring more recent founding times suggest that under a scenario with no annual immigration, the PCFG would have to have been founded after 1950, and more plausibly between the mid-1960s to mid-1970s, to produce simulated results that are consistent with the empirical data. Small numbers of gray whales have been sighted within the seasonal range of the PCFG since at least 1926 (Howell & Huey 1930, Gilmore 1960, Pike and MacAskie 1969, additional references in Rice & Wolman 1971), but photo-identification studies did not start until the 1970s, when the repeated return of individuals to the area was first documented (Hatler & Darling 1974, Darling 1984). Our simulations model an instantaneous colonization of the PCFG, such that for the scenarios modeling colonization in 1960 or later at least 60 whales become part of the PCFG in a given year. This aspect of our simulations is clearly an oversimplification. Given both the limited information available on use of the PCFG seasonal range prior to the 1970s and the limitations of our model, it is difficult to evaluate how the simulation results fit in with past records.

The simulations incorporating a pre-whaling split of the PCFG from the larger ENP population are in progress and are expected to be completed by the 2012 SC meeting. Future work will also include integrating the genetic data representing ENP gray whales in LeDuc *et al.* 2002 and Lang 2010 with the data represented in Lang *et al.* 2011 to ensure that the diversity values utilized here are as representative as possible of the larger ENP population. Simulations will also be performed to explore the effect of incorporating lower MSYR rates for the PCFG into the life history matrices underlying the models.

Table 9. Summary of the haplotypic diversity, number of mtDNA haplotypes, and nucleotide diversity generated in the simulated ENP population. Only the results from the post-whaling split with immigration pulse models are shown as results were similar under all other models.

Haplotypic diversity:

ENP: $H_{obs} = 0.952$

Matrices	Scenario	Immigration (Inds/Yr at K)	With pulse?	Median_ENP	Min_ENP	Max_ENP	Prop < than ENP	Prop > than ENP
9-stage	Post-whaling split	0	Y	0.948	0.883	0.973	61	39
9-stage	Post-whaling split	1	Y	0.951	0.869	0.973	52	48
9-stage	Post-whaling split	2	Y	0.950	0.878	0.974	56	44
9-stage	Post-whaling split	4	Y	0.950	0.874	0.974	57	43
9-stage	Post-whaling split	6	Y	0.950	0.890	0.972	56	44
9-stage	Post-whaling split	8	Y	0.948	0.869	0.973	64	36
9-stage	Post-whaling split	10	Y	0.949	0.878	0.977	62	38
9-stage	Post-whaling split	12	Y	0.950	0.786	0.971	54	46
9-stage	Post-whaling split	14	Y	0.948	0.862	0.973	61	39
9-stage	Post-whaling split	16	Y	0.950	0.877	0.977	52	48

Number of haplotypes:

ENP: $Nb_haps_{obs} = 32$

9-stage	Post-whaling split	0	Y	33	25	47	36	52
9-stage	Post-whaling split	1	Y	33	24	44	33	57
9-stage	Post-whaling split	2	Y	33	23	46	40	54
9-stage	Post-whaling split	4	Y	33	22	44	37	54
9-stage	Post-whaling split	6	Y	34	24	42	25	62
9-stage	Post-whaling split	8	Y	33	22	45	38	55
9-stage	Post-whaling split	10	Y	33	20	45	38	54
9-stage	Post-whaling split	12	Y	33	20	43	37	57
9-stage	Post-whaling split	14	Y	33	23	44	38	52
9-stage	Post-whaling split	16	Y	33	25	45	31	56

Nucleotide diversity:

ENP: $\Pi_{obs} = 0.0142$

9-stage	Post-whaling split	0	Y	0.026	0.012	0.065	7	93
9-stage	Post-whaling split	1	Y	0.025	0.011	0.060	10	90
9-stage	Post-whaling split	2	Y	0.024	0.012	0.056	9	91
9-stage	Post-whaling split	4	Y	0.025	0.011	0.059	9	91
9-stage	Post-whaling split	6	Y	0.025	0.011	0.060	10	90

9-stage	Post-whaling split	12	Y	0.025	0.010	0.057	9	91
9-stage	Post-whaling split	14	Y	0.025	0.011	0.071	7	93
9-stage	Post-whaling split	16	Y	0.025	0.011	0.066	9	91

Figure 10. Histogram showing the distribution of p-values for a χ^2 test comparing the observed to the simulated haplotype distributions for the larger ENP population.

Figure 11. Graphical representation of the proportion of simulated values that are lower (shown in black) or higher (shown in gray) than the observed value generated from the empirical data. Simulated values are derived from the model incorporating a post-whaling split with pulse migration under the nine-stage matrices.

a.) Number of haplotypes:

b.) Haplotypic diversity:

c.) Nucleotide diversity:

d.) F_{ST} :e.) Φ_{ST} :f.) χ^2/df :

Table 12. Summary of number of mtDNA haplotypes in the simulated data for the PCFG. Scenarios highlighted in bold type produced results which were not consistent with those based on the empirical data.

PCFG: Nb_haps_{obs}=23

Matrices	Scenario	Immigrants/yr (at K)	With pulse?	Median_PCFG	Min_PCFG	Max_PCFG	Prop < PCFG	Prop > than obs

ABSTRACT

Monitoring of the critically endangered western gray whale population on its primary feeding ground off Sakhalin Island, Russia, has led to the collection of genetic samples from 83% of animals photographically identified from this area. The high proportion of sampled animals provides a rare opportunity to learn more about the mating system of a baleen whale species as well as to identify factors potentially influencing this small population's recovery. Utilizing a panel of 13 microsatellite loci, paternity analysis was conducted to identify breeding males and assess the distribution of male reproductive success. Using biopsy samples from 57 mother-calf pairs and 42 candidate males, putative fathers were identified for 46 to 53% of calves sampled in the population between 1995 and 2007. Although most males were assigned paternity of only one calf, a mild skew in the distribution of reproductive success was identified, with some males siring three to four calves over the 12 seasons of the study. Eighteen putative fathers were identified, and analysis of relatedness patterns among those calves which were not assigned a father suggested that an additional 15 males may be contributing to reproduction in the population. The relatively low success rate of the paternity analysis, in comparison to expectations derived from the percentage of photographically identified animals which have been sampled, indicates that some reproductive males may not use the Sakhalin feeding area on a regular basis. While the high percentage of "missing fathers" in this small population is puzzling, these results provide evidence that many of the animals identified on the Sakhalin feeding ground interbreed, presumably while sharing a common migratory route.

INTRODUCTION

Little is known about the mating systems of most species of baleen whales. Differences in the reproductive cycles of males and females suggest that mysticetes, like the majority of mammals, are polygynous (Clutton-Brock 1989, Mesnick and Ralls 2009). In most baleen whale species, females are restricted to producing a calf every two to three years due to the energetic constraints imposed by gestation and lactation, while males have potential reproductive rates that are much higher. These differences result in a skew in the number of reproductively available females relative to reproductively active males (*i.e.*, the operational sex ratio), increasing the extent to which males must compete for females and permitting variance in male reproductive success to develop. As has been proposed for aquatically mating pinnipeds (Bartholomew 1970), however, the degree of polygyny which can be established in baleen whales is likely

limited by the marine environment in which they breed, as females are highly mobile and resources are difficult to defend.

Much of the information available on mysticete mating systems has been derived from behavioral observations and the collection of physiological data. In humpback whales (*Megaptera novaeangliae*), the use of alternative mating tactics by males, including physical competition for access to females as well as “escorting” of females (Pack *et al.* 1998, Clapham 1996), has been documented and suggests a mechanism by which differential reproductive success might be generated in this species. In North Atlantic right whales (*Eubalaena glacialis*), males aggregate in large active groups and appear to compete for access to a female (Kraus and Hatch 2001). In addition, right whales, along with bowhead and gray whales, have high testes-to-body weight ratios, indicating that sperm competition is an important strategy utilized by males (Brownell and Ralls 1986). The existence of both pre- and post-copulatory competition for fertilization in this species suggest that male reproductive success may not be evenly distributed across individuals.

While these studies have proven valuable in elucidating male mating strategies, they do not provide information on which males in a population successfully breed or how male reproductive success is allocated among individuals, which can have important implications for the maintenance of genetic diversity in small populations. The effective size of a population is determined not only by the number of animals contributing to successive generations, but also by the distribution of reproductive success among those individuals. High variance in reproductive success acts to decrease the effective size of the population (Hedrick 2005), thereby increasing the rate at which genetic diversity is lost. In addition, identifying reproductive pairs within populations can increase our understanding of the role that mate choice may play in inbreeding avoidance (*e.g.*, Archie *et al.* 2007) as well as of the relationship between offspring fitness and parental relatedness (*e.g.*, Amos *et al.* 2001).

Genetic analysis of paternity has the potential to provide detailed information on the reproductive success of individual males. In baleen whales, these analyses have thus far been limited to humpback (Clapham and Palsboll 1997, Nielsen *et al.* 2001, Cerchio *et al.* 2005) and North Atlantic right whales (Frasier *et al.* 2007). In studies of both species, the genetic results contributed valuable insight into patterns of reproduction which were not readily apparent based on previous studies. In humpback whales, the distribution of male reproductive success deviated from that predicted under random mating, but the variation was lower than expected given the apparent skew in the operational sex ratio and the degree of male competition observed (Cerchio *et al.* 2005). In North Atlantic right whales, males demonstrated high variance in reproductive success when compared to other aquatically-mating marine mammals, although the variance was low relative to those breeding terrestrially (Frasier *et al.* 2007). These results support the idea that sperm competition creates differential reproductive success among males, but that the lack of control over resources and mates in the aquatic environment limits the degree of polygyny which could develop (Frasier *et al.* 2007). Results from this study also suggested that the low level of genetic variability in this species may be influencing reproductive success. Calves for which both parents were identified had significantly higher levels of genetic diversity than expected under random mating, indicating that successful mating only occurs between individuals that are genetically dissimilar (Frasier 2005).

In gray whales, behavioral observations of multiple males mating with a female suggest a polygynous or promiscuous mating system (Jones and Swartz 1984). While mating behavior has been observed in all seasons, fertilization is thought to primarily occur during the southbound migration (Rice and Wolman 1971). Information from fetal growth rates suggests that females come into estrus during an approximately three-week period extending from late November to early December at the start of the southbound migration. Most females are thought to conceive during this period, although some females may ovulate approximately 40 days later when on or near the wintering grounds. Increased testes weight and the larger seminiferous tubules of males on the southbound migration, as compared to those of northbound and summer feeding males, also support a peak in spermatogenic activity in late autumn to early winter (Rice and Wolman 1971).

As aforementioned, the high testes weight to body weight ratios found in gray whales suggest that this species utilizes sperm competition as a strategy for males to obtain successful fertilizations (Brownell and Ralls 1986), raising the possibility that, like North Atlantic right whales, some variance in male

reproductive success may exist. Genetic paternity analysis would provide information valuable in assessing this possibility. Such a study would be difficult to conduct in the eastern gray whale population, given its large size and the relatively small proportion of animals which have been sampled. However, the population of gray whales found in the western North Pacific, which is both small and well-sampled, presents a valuable opportunity to conduct such an analysis. This population of whales was nearly extirpated by commercial whaling, which continued through at least 1966 (Brownell and Chun 1977, Weller *et al.* 2002). Unlike its eastern counterpart, which currently numbers approximately 22,000 animals (Punt and Wade 2010), the western population has remained severely depleted and is estimated to contain approximately 130 individuals of one year or older (Cooke *et al.* 2008). Western gray whales are listed as Critically Endangered by the IUCN (Baillie *et al.* 2004). Anthropogenic threats potentially jeopardizing the population's recovery include extensive oil and gas development on the population's primary feeding area (Weller *et al.* 2002, Reeves *et al.* 2005) and mortality of whales associated with entrapment in fishing gear during their migration past Japan (Brownell *et al.* 2007).

Much of what is known about this small population of whales has been derived from long-term studies on their primary feeding ground located in the coastal waters of northeastern Sakhalin Island, Russia. Following a pilot study in the summer of 1995, a monitoring program was initiated in 1997 and continues to date. Extensive photo-identification records collected as part of this effort have shown that western gray whales exhibit a high degree of seasonal site fidelity to the Sakhalin feeding area (Weller *et al.* 1999, 2008a). This site fidelity, in combination with the population's small size, has facilitated the collection of genetic samples from a high percentage (~83%) of animals identified on the feeding ground. Analysis of these samples using both mitochondrial DNA (mtDNA) and a panel of microsatellite markers has shown that the western population is genetically distinct from the much larger eastern gray whale population (LeDuc *et al.* 2002, Lang *et al.* 2010).

Given the high percentage of sampled animals and the availability of extensive sighting records for most individuals, genetic analysis of paternity in the western gray whale population will not only contribute to our understanding of mysticete mating systems but may also provide information important in assessing factors influencing the population's recovery. The low number of known reproductive females (n=24 between 1995 and 2007) has raised concern for the population's capacity for growth and recovery (Weller *et al.* 2002, 2008a). Little has been known, however, about the number of males which are breeding in the population, or how reproductive success is distributed among these animals. Although previous studies have suggested that the western gray whale population has retained relatively high levels of genetic diversity (Lang *et al.* 2010), information about factors potentially influencing the effective size of the population may provide insight into the past and future maintenance of genetic diversity in this population.

In addition, limited information is available about the movements of western gray whales outside of their feeding range. The wintering ground(s) for this population is suspected to be off the southern coast of China, but the location has yet to be confirmed. Sightings, strandings, and entrapments suggest that gray whales migrate along both the eastern and western coasts of Japan, as well as along mainland Asia (Brownell *et al.* 2008). Although photo-identification records have identified one of the animals entrapped off the Pacific coast of Japan as an animal known to utilize the Sakhalin feeding ground (Weller *et al.* 2008b), thus far this is the only established link between a feeding area and a migratory pathway. Given that mating is thought to occur primarily while on migratory routes, the use of paternity analysis to identify pairs of interbreeding animals will provide information on which animals have utilized the same areas for migration and potentially overwintering.

Finally, questions have been raised about the isolation of this small population. Although the eastern and western populations have traditionally been considered geographically separate, in recent years gray whales have been sighted in feeding areas located off the eastern coast of Kamchatka. Some of these whales are known to have visited the Sakhalin feeding area, while others are of unknown origin (Tyurneva *et al.* 2009). These sightings have raised speculation about possible overlap among feeding regions for the eastern and western populations. In addition, although genetic studies have confirmed that eastern and western gray whale populations are distinct, the level of nuclear differentiation between the two populations is relatively low, suggesting that some intermixing of eastern and western animals could be occurring (Lang *et al.* 2010). Such intermixing could entail the use of the Sakhalin feeding area by eastern

whales which then return to the eastern Pacific, or it might include some limited amount of interbreeding between the two populations. Although the lack of extensive sampling of the eastern population limits comparisons across populations, the proportion of reproduction that can be attributed to animals sampled off Sakhalin will provide some insight into the extent and nature of any interbreeding which may be occurring.

Between 1995 and 2007, 57 mother-calf pairs and 42 males of unknown age were sampled on the feeding ground off Sakhalin. These samples represent 90% of identified mother-calf pairs, and 83% (n=142) of all animals identified on the Sakhalin feeding ground during the study period. Using these samples and a suite of 13 microsatellite markers, a genetic paternity assessment was conducted for this population. The primary objectives of this work were to identify the number of males contributing to reproduction in the western population and to evaluate the distribution of reproductive success among these males. The results of the assessment not only expand our knowledge of mating systems of baleen whales, but also increase our understanding of factors potentially affecting the recovery of the western gray whale.

METHODS

Sample collection

Following a Russian-American pilot effort in 1995, a collaborative Russia-U.S. research program was established in 1997 which focuses on individual monitoring of western gray whales using photo-identification and genetic sampling (Weller *et al.*, 1999, 2002). Field studies are carried out annually during summer months on the primary feeding ground off the northeastern coast of Sakhalin Island, Russia. Surveys (n=337) of this area have led to the photographic identification of 169 whales; genetic samples for 141 (83.4%) of the identified whales have been collected through biopsy-darting (Weller *et al.* 2008).

The genetic sample set includes samples collected from 57 animals which were first identified as calves (approximately 6-8 months of age) on the feeding ground and which are linked to known and genetically sampled mothers. Animals were identified as calves based on their small body size (approximately one third that of an adult), and, in most cases, their constant affiliation with a particular adult whale (Weller *et al.* 1999). For 54 of the calves, identification of the mother was first established via behavioral observations and confirmed by genetic analysis. Three calves were already separated from their mothers when first identified; in these cases the mother was identified using genetic parentage analysis alone.

The sex of all animals was determined using molecular methods (detailed in Lang *et al.* 2010). Forty-two animals were identified as males of unknown age and were included as candidate fathers in the analysis. Males first identified as calves which may have reached sexual maturity during the study period were also included as potential candidate males. Although it is not known at what age male western gray whales first reproduce, the earliest estimates of age at sexual maturity in eastern gray whales is five years (IWC, 1993). Therefore, male calves were included as potential candidates for those years in which they would have been at least five years of age and potentially capable of reproduction in the preceding season when fertilization would have occurred. To incorporate the changing number of candidates as calves from earlier years of the study became potentially sexually mature, paternity analysis was run separately for each year of the study.

Analysis

Samples utilized in the study had been genotyped at 13 microsatellite loci for use in the previous study; the protocols used to produce this data are detailed in Lang *et al.* 2010. Paternity was assessed using the likelihood-based approach as implemented in CERVUS v3.0 (Marshall *et al.* 1998, Kalinowski *et al.* 2007). The objective of this analysis was to identify the candidate father which was statistically the most likely to be the true parent of the calf. The likelihood for each candidate was calculated using information on the allele frequencies in the population, such that a candidate male which shared a rare allele at a given locus with the calf was considered to be more likely to be the true father than a candidate sharing a common allele with the calf. The number of mismatches between the genotype of the father and the genotype of the calf (after removal of the maternal contribution to the calf's genotype) was also utilized in the likelihood analysis.

Simulations were used to generate critical values allowing confidence in the assignments to be evaluated. These simulations used the allele frequency data from the population being analyzed to generate simulated genotypes for parent-offspring pairs and unrelated individuals. The simulated data were then used to calculate the likelihood of parentage for the true parent as well as for each of the unrelated candidate parents for the simulated offspring. For each candidate identified as the most likely parent (whether or not it represented the true parent), the difference in likelihood scores between that individual and the next most likely individual, referred to as Δ , was recorded. The distribution of Δ scores where the identified parent was the true parent with the distribution of scores where the identified parent was an unrelated individual was then compared to determine a critical value, such that the identified Δ was sufficiently large to distinguish true parents from unrelated parents at a specified (e.g. 95%) level of confidence.

One of the strengths of the CERVUS analysis is that it is able to account for potential errors in the dataset. Genotyping errors, mutations, or null alleles may create mismatches between the genotypes of candidate fathers and offspring, such that the true father might be falsely excluded when such factors are not taken into account. By incorporating an estimated error rate into the simulations run by CERVUS, the potential for such false exclusions is reduced. Here we ran the CERVUS analysis utilizing two different error rates. The first analysis assumed that no errors were present in the dataset, but this differs from a strict exclusionary approach in that likelihood scores were used to differentiate between candidate parents when more than one male had genotypes which matched that of the mother-calf dyad at all loci. The second analysis utilized an error rate of 0.01, allowing candidates to be assigned as putative fathers which had genotypes mismatching that of the mother-calf dyad at up to two loci. Additional parameters used in the simulations included 1) the number of simulated genotypes = 10,000, 2) proportion of loci typed = 0.99 (the true proportion), 3) minimum number of loci typed = 12, and 4) proportion of candidate males sampled=0.50. Given that the error rate and the proportion of sampled males are not known, additional simulations to explore the effects that these parameters may have had on the results are described in the Supplementary Information. Results were evaluated at both the strict (95%) and relaxed (80%) levels of statistical confidence. The allele frequencies utilized for the likelihood calculations and simulations incorporated only the genotypes of non-calves, to avoid skewing the allele frequency distribution by inclusion of known relatives.

The pool of candidate males changed during some years of the study, as males first identified as calves and known to be ≥ 5 years of age became incorporated in the analysis. As such, the simulations used to calculate critical values were run separately for years with different pools of candidate males, such that while the proportion of candidate males sampled (0.50) was held constant throughout the study, the number of candidates was updated to reflect the changing number of sampled males. The total number of candidate males used in the CERVUS simulation was set by multiplying the number of sampled males by two in accordance with the assumption that 50% of candidates had been sampled.

To provide insight into the reproductive success of unsampled males, the program DADSHARE (www.zoo.cam.ac.uk/zoostaff/amos, see Hoffman *et al.* 2003) was used to estimate the number of putative sires for the calves for which all sampled candidates were excluded. This program inferred paternal sibships by calculating pairwise paternal relatedness coefficients among unassigned offspring using the relatedness coefficient of Queller and Goodnight (1989). A clustering algorithm (UPGMA) was then used to produce a dendrogram linking the most closely related individuals and sorting offspring into groups compatible with having a single father (e.g. paternal half-siblings). In addition, Monte Carlo simulations were used to explore the pattern which would be produced if 1 to K fathers sired the offspring, with K representing the total number of offspring being assigned (e.g., the pattern produced if each offspring had a different father). The average r-values and standard deviations generated in the simulated scenarios were compared with the observed average r-values presented in the dendrogram. In order to evaluate how this method compares with direct parentage assignment, DADSHARE was run both with a dataset containing only those calves which were not assigned a putative father by the paternity assessment analysis as well as with a dataset including only those calves which were assigned putative fathers in the previous analyses.

A simulation-based approach, similar to that employed in previous parentage analyses conducted for mysticetes (Cerchio *et al.* 2005, Frasier *et al.* 2007), was used to evaluate how the observed patterns of

male reproductive success compared with those expected if all candidate males had an equal probability of fathering calves within a year (e.g., if mating were random). To make the results of the simulation comparable to those generated in the CERVUS analysis, simulations were based on the number of sampled candidate males included in each year of the analysis as well as the number of paternities which were assigned for those years. For each year of the analysis, candidate males were randomized, and then fathers were selected with replacement for the number of calves which were assigned paternity in that year. This process was repeated for each year of the study, and the number of calves fathered by each male was summed across years to generate the expected distribution of reproductive success for the study period under the expectation of random mating. This process was repeated 1000 times to generate the mean expected number of sampled males which were assigned paternity of zero, one, two, three, four or more calves under random mating.

To facilitate comparisons of male reproductive success with other species, the standardized variance (SV = variance/mean) in reproductive success was calculated as implemented in previous studies (e.g., Coltman *et al.* 1998, Frasier *et al.* 2007) and using both the results of the paternity analysis and results from the simulations based on random mating. This measure was based only on the reproductive success of males which were assigned as putative fathers of at least one calf during the study. The standardized variance in reproductive success is considered to be zero in truly monogamous species and to increase with the extent of polygyny (Boness *et al.* 1993).

Results

Genetic profiling

Summary statistics for the microsatellite loci used in the study are shown in *Table 1*. The total exclusionary probability of the multilocus genotypes used in the paternity analysis, as calculated by CERVUS when one parent is known, was high at 0.9999. The probability of identity (P_{ID} , Paetkau and Strobeck 1994) was estimated to be 2.83×10^{-13} , indicating that the loci utilized in the study provided high power to resolve relationships between individuals. The more conservative P_{ID-sib} (Evetts and Weir 1998) was also calculated to account for the possible presence of related individuals within the dataset. This estimate was low (1.38×10^{-5}), suggesting that the data would be able to distinguish between any full siblings included as candidates. Rechecking of ~20% of all genotypes did not identify a substantial source of error.

Paternity assignment

When no mismatches were allowed between the genotype of candidate males and that of the mother-calf dyad (hereafter referred to as the “stringent criterion”), paternities were assigned for 26 (45.6%) of the 57 calves. All paternities were assigned at the 95% confidence level. One calf had a genotype which matched that of two candidate males; for the remaining 25 calves only one possible match was identified. No putative fathers were identified for the remaining 31 calves.

Incorporating an error rate of 0.01 (later referred to as the “relaxed” criterion), the CERVUS analysis supported all of the assignments previously made and identified putative fathers for an additional four calves, such that paternity was resolved for 52.6% of calves in the study. The four additional assignments included putative fathers with one ($n=2$) to two ($n=2$) mismatches with the genotypes of the mother-calf dyads. All CERVUS assignments were supported at the 95% confidence level, with the exception of the one calf whose genotype matched that of two candidate males with no errors, which was assigned at 80% confidence. Those calves which were not assigned putative fathers by the CERVUS analysis mismatched all potential candidates at ≥ 2 loci; for the majority (79%) of these calves, mismatches for ≥ 3 loci were present with all candidates.

The success of the paternity assignment varied greatly across the 12 years of the study (*Table 2*). Excluding years in which only one calf was sampled, the proportion of paternities assigned per year ranged from one year in which no paternities were assigned to years ($n=3$ using the relaxed criterion) in which putative fathers were assigned to two thirds of sampled calves.

The paternity assignment also varied greatly across the reproductive females included in the study (*Table 3*). Excluding females which only had one offspring during the study, the average proportion of calves with assigned fathers per female was 0.54 (relaxed criterion) and assignment success ranged from having no calves assigned putative fathers ($n=3$ females) to having all calves born during the study assigned putative fathers ($n=5$ females).

Male reproductive success

When no errors were allowed, 17 males were assigned paternity of the 26 calves, for an average of 1.5 (± 0.72 SD) calves per male (*Table 4*). Average reproductive success was slightly higher when calculated from analysis incorporating error, with 18 males assigned paternity for 30 calves and an average of 1.7 (± 0.91 SD) calves per male. In both cases, the majority of males (59% and 65% of assigned males for the stringent and relaxed analyses, respectively) were assigned paternity of only one calf each, although a small number of males were assigned paternity of 3-4 calves during the 12 seasons of the study.

These estimates of reproductive success do not incorporate males which were not assigned paternity of any calves. Although the number of candidate males varied across years of the study, 57-69% of candidate males were not assigned paternity of any calves over the twelve years of the study. Inclusion of these males would reduce estimates of average reproductive success to 0.47-0.71 calves per male.

As expected, none of the 13 males of known age (*i.e.*, first identified as calves, ranging from 5 to 11 years old during the season of fertilization) were identified as putative fathers during the study (*Table 5*). These males, as well as some proportion of the males of unknown age, were not sexually mature for all or part of the study. Of those males which were identified as putative fathers, all except one (only identified using the relaxed criterion) were identified prior to the 2000 season, and the majority ($n=14$, 77.8%) had been first identified by the end of the second season of the study (*Table 6*). All except two of the males were sighted at least once for six or more years of the study, with 14 males sighted for at least 8 of the 12 years of the study (*Table 6*). For the majority of assigned paternities ($n=26$ between 1999 and 2007), the putative father was identified on the feeding ground in the season prior to conception (77% of paternities) and/or the season following conception (73% of paternities).

Only one male was assigned paternity of 2 calves in any one season. Excluding this case, the average interval between successful reproductions was 2.8 years (relaxed criterion) to 3.75 years (stringent criterion). Although the maximum interval between assignments was six years, there were three males which were assigned as putative fathers early in the study and which were not assigned any additional calves for the following 8 to 11 seasons. Although some calves may have been lost before reaching the feeding ground, this finding suggested that intervals between successful mating may be even longer than illustrated with our dataset. The longest time span over which a male in the study was considered reproductively active was nine years, during which the male was assigned as the putative father of three calves.

In the seven to nine cases (stringent and relaxed criteria, respectively) in which a reproductive female had more than one calf assigned to a putative father, there was only one case in which the same father was assigned more than one calf of the same female. Female Q had three calves during the study, and all three calves were assigned to the same male (I) under the relaxed criterion. One of these calves mismatched the assigned father at two of the 13 loci and was only assigned to the male in the relaxed analysis. One of the other two assignments for calves of this female was the case where the genotype of the calf matched that of two different putative fathers with no errors. Although male I was assigned as the most likely father, relatedness analysis (data not shown) suggests that the two putative fathers may represent a parent-offspring pair. Given that this was the only case in which more than one putative father had a genotype which matched that of a calf at all loci, the paternity analysis seemed to generally perform well at discriminating between relatives. However, it is possible that in at least this case the candidate male with the highest likelihood of being the true father shared a different relationship to the calf.

DADSHARE estimated that 15 males were likely to account for the 27 calves not assigned fathers in the CERVUS analysis. Average reproductive success among these 15 males was 1.8 calves per male. Relative

to the paternity analyses, a larger proportion of these unsampled males (53%) were assigned paternity for two calves each during the study (*Graph 1*), suggesting these males may have greater reproductive success on average than those males which were sampled. When the DADSHARE analysis was run using only those calves which were assigned to putative fathers, 18 putative fathers were needed to account for the 30 calves, which corresponds exactly with the number of putative fathers identified in the “relaxed” CERVUS analysis. Similar to the results for the unassigned calves, however, the distribution of reproductive success among these 18 males was somewhat different than the observed pattern, with more males assigned as the putative father of two calves during the study. Differences in reproductive success between the sampled and unsampled males may be an artifact of differences in the resolution of the two methods.

At least some of these unsampled males may be accounted for among the 28 animals which have been photographically identified on the Sakhalin feeding ground but which have yet to be genetically sampled. One of these is presumed to be a female based on its close and prolonged affiliation with a calf during the one season it was sighted, and nine are animals first identified as calves (≤ 9 years of age at the end of the study) and may not have been reproductively mature for much, if any, of the study period. This leaves at least 18 animals of unknown sex or age which have been identified on the feeding ground but are not represented in the sample set. Although some proportion of these animals may be males contributing to reproduction in the population, based on the overall sex ratio of the population (58% male, Weller *et al.* 2008a), it is unlikely that all of the missing males are included in this group of animals. However, obtaining samples from these animals could potentially increase the success of the paternity assessment.

When the observed results were compared with those generated via the simulation of random mating (*Graph 2*, *Graph 3*), the average number of calves per father was significantly higher in both the relaxed ($p \leq 0.014$) and the stringent ($p \leq 0.037$) analysis. These results were due to significantly fewer than expected candidate males which were assigned only one offspring in the analysis ($p \leq 0.036$, stringent criterion; $p \leq 0.039$, relaxed criterion). The average numbers of males assigned paternity of two calves were similar between the simulated and observed results, while the average number of males assigned three calves over the study period was higher in the observed than the simulated results, although the differences were not significant. In addition, the number of males which were not assigned the paternity of any calves during the study was significantly higher than would be expected under random mating for both the stringent- and relaxed- criterion analyses ($p \leq 0.037$ and $p \leq 0.007$, respectively).

The standardized variance calculated from the results of the paternity analysis ($SV_{obs}=0.42$) was higher than that calculated from the data simulated under expectations of random mating ($SV_{exp}=0.27$). When compared to other mysticete studies, the SV_{obs} was most similar to the value calculated in the study of paternity in North Atlantic right whales ($SV_{RW}=0.35$; Frasier *et al.* 2007) and was higher than that calculated for the humpback whale population ($SV_{HW}=0.23$; Cerchio *et al.* 2005).

DISCUSSION

Paternity assessment

Approximately half (46-53%) of the calves sampled on the Sakhalin feeding ground were assigned putative fathers which had been identified and sampled in the same area. Using the stringent criterion, all assignments were supported at the 95% confidence level, and the panel of loci utilized in this study provided sufficient resolution to discriminate between all possible candidates using a simple exclusion approach in all except for one case. Even when the more relaxed criterion was applied, all except one of the assignments was supported with high confidence (95%), and only four additional paternities were assigned. Assignment success was in relatively close agreement for both criteria, and it is likely that the true patterns of paternity are encompassed within this range of estimates.

Similar paternity assignment success rates have been generated in other studies of mysticete mating systems, including those conducted for humpback whales in the Mexican Pacific (32.5 to 49.6 %, Cerchio *et al.* 2005) and for North Atlantic right whales (41.4 to 62.1%, Frasier *et al.* 2007). Although sampling in the humpback whale population was not as complete, it is notable that in both our study and the North

Atlantic right whale study, in which an estimated 74% of animals which were considered alive had been sampled, a very high proportion of photographically identified individuals had been sampled. As such, the success rates of the paternity assignments were somewhat less than might be expected given the overall pattern of sampling. As discussed below, this pattern may have implications for our understanding of the population's status.

Distribution of male reproductive success

A mild skew in male reproductive success was detected over the 12 seasons covered by the study. Although most (56-59%) of the putative fathers identified were assigned paternity of only one calf each, this proportion was lower than that predicted in the simulations based on random mating. While not statistically significant, more males than expected were assigned paternity of three to four calves during the study, suggesting that some males achieved higher reproductive success than others. These results are consistent with those observed in both humpback whales and right whales, both of which demonstrated mild skews compared to random mating expectations (Frasier *et al.* 2007, Cerchio *et al.* 2005). However, in all cases the skew was slight, with most males siring only one calf during each of these studies. While the differences in reproductive success among males were relatively small over the course of the study, continuation of this pattern over the lifespan of these individual males would result in a substantially higher reproductive advantage for some males. However, if male reproductive success varied with age, the advantage gained by individuals during the study period would level out over time.

Based on testes to body size ratios, both gray and right whales are thought to utilize sperm competition (Brownell and Ralls 1986). The standardized variance of reproductive success, a measure often used for comparisons across species, was found to be high in North Atlantic right whales relative to values found in other aquatically mating species (Frasier *et al.* 2007), including a population of humpback whales (Cerchio *et al.* 2005). These results suggested that sperm competition may result in higher variance in reproductive success when compared to tactics employed by some other marine mammals (Frasier *et al.* 2007). The standardized variance estimated for western gray whales was comparable to that found in North Atlantic right whales, providing further support for the role of sperm competition in generating variance in reproductive success among males.

A high proportion of sampled males were not assigned any offspring during the 12 seasons of the study. These findings may suggest that many of the animals of unknown age were too young to successfully compete for mating opportunities. Rice and Wolman (1971) found that 24% of the animals from their sample were sexually immature and estimated that the total proportion of immature animals in the eastern gray whale population was approximately 44-61%. If the results of the paternity analysis are combined with the results of the DADSHARE analysis, the proportion of males (53-54%) that are potentially too young to reproduce falls within the range estimated by Rice and Wolman (1971). It is important to note, however, that successful fertilization not only necessitates that males are sexually mature but also that they are able to successfully compete for fertilization opportunities. Therefore, estimates derived from the paternity analysis are not necessarily representative of the proportion of animals which have not reached sexual maturity. In addition, this estimate assumes that the unsampled males are only those which are contributing to reproduction; if some proportion of non-breeding males has also not been sampled off Sakhalin, this percentage would be lower.

The results suggest a lack of mate fidelity among breeding pairs, with only one female with more than one calf assigned to the same male. These findings agree with expectations based on morphology and behavior. Similar results have been found in paternity analyses in humpback whales (Clapham and Palsboll 1997) and right whales (Frasier *et al.* 2007).

Identification of reproductive males

The paternity assignment identified 17 to 18 males as putative fathers, and analysis of relatedness patterns among the calves with unassigned paternities suggested that approximately 15 additional reproductive males have yet to be sampled. Twenty-four females were determined to be the mother of at least one calf in the western population between 1995 and 2007 (Weller *et al.* 2008a). Combining this information suggests

that approximately 57 animals are capable of reproduction. These numbers are slightly higher than previous estimates (Weller *et al.* 2002), which indicated that the number of mature individuals was approximately 39-49 animals if the population was growing and 55 animals if the population was stable. These estimates were based on parameters (*e.g.*, percent of immature animals) derived from the eastern gray whale population and on the western population's size in 1999. Integrating information on the number of putative fathers with the number of females known to reproduce provides a more direct assessment of the number of animals contributing to reproduction in the population, including those which may not be regularly sighted on the primary feeding ground. Although slightly higher than previous estimates of the number of mature animals, the estimate incorporating the results of the paternity analysis supports the need for continued concern over the small size of the population. In particular, the low number of reproductive females may limit the population's growth and recovery (Weller *et al.* 2008a).

Although one of the putative fathers was not identified until the last year of the study, all other males identified as putative fathers were identified early in the study. These animals demonstrated a high degree of seasonal site fidelity to the primary feeding area, indicating that at least this subset of reproductive males are regular visitors to the Sakhalin area. Although some of the unsampled males may be represented among those animals which have been sighted on the feeding ground but not yet sampled, it seems likely that at least some of the "missing fathers" are animals which do not utilize the Sakhalin feeding ground on a regular basis.

The majority of the putative fathers had four of the five most common haplotypes found in the western population. Only two (one of which was identified only in the relaxed analysis) of the nine males which have haplotypes considered to be rare in the western population were identified as putative fathers. These "rare haplotype males" have been hypothesized to represent possible dispersers from the eastern population (Lang *et al.* 2010), although additional analyses evaluating this hypothesis have yet to be conducted. However, these results suggest that the majority of these "rare haplotype males" may not be currently contributing to reproduction in the population.

No males of known age were identified as putative fathers during the study; therefore, no conclusions about the minimum age at which males attain reproductive success can be derived from these results. Based on whales taken off central California under special permits between 1959 and 1969, the age of sexual maturity for both males and females was estimated to range between six and 12 years of age, with a median of nine years (Rice and Wolman 1971, Rice 1990). However, age at sexual maturity is not necessarily representative of age of first reproduction, particularly for males which may need to compete for successful fertilization. The lack of assigned fathers among the known-age males suggests that the age of first reproduction in males may be later than in females. Despite similar limitations in sample size, two females of known age (seven and eleven), out of 17 possible through the 2009 season, have been identified with calves (Bradford *et al.*, submitted). In right whales, paternity analysis suggested that most males do not attain their first successful mating until they were almost twice as old as the average age of fertilization for females (~15 years in males as compared to ~8 years for females; Frasier *et al.* 2007). Although no direct evidence was provided in this study, the lack of paternities assigned to males of known age (≤ 11 yrs) suggests that a similar pattern may be true in western gray whales.

Conservation implications

Despite the high proportion of sampled individuals, the paternity analysis was only able to identify putative fathers for about half of the animals first sighted as calves on the Sakhalin feeding ground. Some of the "missing fathers" may be accounted for by the animals which have been sighted off Sakhalin but not genetically sampled. However, these results suggest that many of the males which are contributing to reproduction in the population may not be regular visitors to the Sakhalin feeding ground, raising questions about the identity and habitat use patterns of these individuals.

A potential explanation for the high proportion of unassigned paternities in the western gray whale population is that some gene flow with the eastern gray whale population may be occurring. Previous work has demonstrated that the eastern and western populations are genetically distinct (LeDuc *et al.* 2002, Lang *et al.* 2010); however, the low level of nuclear differentiation identified between the two populations raised

the possibility that some limited degree of interchange may occur (Lang *et al.* 2010). Such interchange might be characterized by mixing of animals from the two populations on the feeding ground, or might involve some degree of interbreeding. If gene flow between eastern and western populations occurs on a regular basis, then the percentage of candidate fathers that have been genetically sampled would be greatly reduced and a lower assignment success would be expected. Running the paternity analysis with the eastern males included did not identify any additional paternities (see Supplementary Information), but given the very small percentage (<1%) of the eastern population that has been sampled, this result is not very meaningful. However, although genetic drift acts strongly to maintain distinctiveness in small populations, the degree of interbreeding needed to account for the unassigned paternities (~50% of the reproduction in the population) would be likely to dissolve differentiation between the two populations.

If we assume that mating occurs primarily while on migratory routes as has been described in eastern gray whales, two other considerations are important. First of all, if any of the males identified off Sakhalin are animals which originated from the eastern Pacific, then they have a high probability of already being sampled. Therefore, interpopulation breeding between animals of eastern origin and females sampled off Sakhalin can only be used as an explanation for the “missing fathers” if the eastern males demonstrate lower levels of fidelity to the Sakhalin feeding ground and/or utilize other feeding areas but migrate along routes commonly used by Sakhalin animals. Secondly, interbreeding with the eastern population could occur if reproductive females which utilize the Sakhalin feeding area then return to the eastern Pacific to overwinter. Given the increased energetic demands of pregnancy and lactation, females are generally considered to be less likely candidates for dispersal than are males. In addition, of the 18 females which had multiple calves during the study period, the majority (83%, $n=15$) had at least one calf which was assigned a putative father among the animals sampled off Sakhalin, linking these breeding pairs to the use of common migratory routes during at least some seasons of the study.

An alternate explanation for the unassigned paternities, however, is that many of the males which are contributing to reproduction in the western population utilize other areas in the western Pacific to feed and are rarely found in the waters off Sakhalin. Similar reasoning was invoked to explain the relatively low paternity assignment success observed in North Atlantic right whales, in which only 51% of fathers were identified despite presumed high rates of sampling (69% of identified males; Fraser *et al.* 2007). The discrepancy between the number of assigned paternities and the proportion of whales which were thought to be sampled led the authors to conclude that the size of the North Atlantic right whale population is slightly larger than previously estimated. In addition, information from paternity analysis, in combination with photo-identification records suggesting that as many as one-third of the identified animals were “missing” during a given season (*i.e.*, could not be accounted for within areas known to be utilized by this species), supported the existence of additional habitat(s) utilized by North Atlantic right whales but not yet located by researchers.

The results of the paternity analysis in the western gray whale population may suggest a similar pattern. Although it is possible to account for the “missing fathers” among animals identified but not sampled while on the Sakhalin feeding ground, it is unlikely that such a high proportion of the unsampled animals are reproductive males. However, sightings of animals identified as western gray whales have been made in other areas of the Okhotsk Sea (Weller *et al.* 2002), as well as the southwestern Bering Sea (Weller *et al.* 2003) and southeastern Kamchatka (Tyurneva *et al.* 2009). In addition, a relatively high proportion ($n=39$ of 78; 50%) of the whales sighted off southeastern Kamchatka have not been sighted on the Sakhalin feeding ground (Tyurneva *et al.* 2009). Although these individuals may be of eastern origin, they may also represent western gray whales which use the Sakhalin area infrequently or not at all. These observations suggest that at least some animals in the western population may range more widely during summer and may not have been identified on the Sakhalin feeding ground.

Patterns of relatedness among the unassigned calves suggest that the “missing fathers” may number approximately 15 different animals. Current population assessment models, which indicate that the population contains approximately 130 animals, assume that all western gray whales are sighted off Sakhalin, although not necessarily in all seasons (Cooke *et al.* 2008). The results of the paternity analysis suggest that this assumption may be violated, although the relatively small number of “missing fathers”, some of which may be accounted for by photographically identified but not sampled individuals, likely

wouldn't change estimates of the population's size or trajectory dramatically. However, these results raise questions about the proportion of animals of other classes which may also not be accounted for in current estimates. Although little is known about the sex of most animals sighted in other parts of the Okhotsk Sea and eastern Kamchatka, sightings of mother-calf pairs between 1995 and 2008 have been largely confined to the waters of the primary feeding ground off Sakhalin, with only one sighting of a female with a calf in other parts of the range (Tyurneva *et al.* 2009). This female had previously been identified with a calf while utilizing the Sakhalin feeding ground. Thus, although females may range more widely during some seasons, they appear to exhibit particularly strong fidelity to the primary feeding ground in years when they have produced a calf. As such, the proportion of sampled to unsampled reproductive females is likely to be higher than the ratio suggested for males. Interestingly, a male bias has already been documented to exist among those western gray whales which have been sampled, such that approximately 60% of animals first identified (and sampled) as adults or subadults on the Sakhalin feeding ground are males. Results of the paternity analysis suggest that this male bias could be more pronounced than previously estimated.

Conclusions

Much of our understanding of the role that males play in the mating system of baleen whales is based on general patterns derived from behavioral and physiological data as well as predictions based on known differences in the reproductive cycles of males and females. While genetic analyses can provide valuable information on the distribution of reproductive success among males, in many species such studies are limited by the difficulty of collecting a sample set that is representative of population patterns. Due in large part to its small size and the high degree of site fidelity demonstrated by individuals, the western gray whale population is one of the most thoroughly sampled of all mysticete populations, providing a rare opportunity to learn more about the mating system of baleen whales. The findings presented here indicate that the distribution of reproductive success in this small population is similar to that described in North Atlantic right whales. Such comparisons suggest that sperm competition may create differential reproductive success among males, but that the degree of skew is mild in comparison to terrestrially mating mammals. Longer-term studies are needed, however, to determine how differential reproductive success over the relatively short time span of this study compares with patterns produced over the lifespan of individuals.

The lower-than-expected success rate in the paternity assignment for western gray whales raises many questions and suggests that the structure of this population may be more complicated than previously thought. In particular, the results presented here suggest that some animals which are part of the western population may not routinely visit the Sakhalin feeding area. Although this group of "missing fathers" may be small in number, they play a significant role in the reproduction of the population. As such, increasing our understanding of the habitat use and behavior of these animals is important. Genetic sampling of animals identified in other areas of the western Pacific, particularly those which have been sighted off Kamchatka but have not been identified as animals utilizing the Sakhalin feeding area, is one avenue that may elucidate habitat use of animals outside of the primary feeding area. Genetic analysis could be used to determine if these animals are any of the "missing fathers", and genetic assignment tests could be used to better understand if these animals originated from the eastern or western populations.

Although the relatively high proportion of calves which could not be assigned fathers is puzzling, assignment of putative fathers for approximately 50% of sampled calves provides strong evidence for intrapopulation breeding among animals demonstrating fidelity to the western feeding ground. Most females had at least one calf which was assigned a putative father from among the animals sampled off Sakhalin, suggesting the use of common migratory routes among these animals and the putative fathers which were identified. In the future, combining the results of the paternity analysis with genetic assignment tests may provide additional information on the extent and nature of any dispersal which may be occurring between the eastern and western populations.

ACKNOWLEDGEMENTS:

Much appreciation goes to the many participants of the western gray whale research team, especially A. Bradford, Y. Ivashchenko, H.W. Kim, S. Reeve, M. Sidorenko, and G. Tsidulko. Support and funding for

western gray whales studies have been provided by (in alphabetical order): Alaska SeaLife Center, Animal Welfare Institute, Exxon Neftegas Limited, the International Fund for Animal Welfare, the International Whaling Commission, the Marine Mammal Commission, the Marine Mammal Research Program at Texas A&M University at Galveston, the National Fish and Wildlife Foundation, the National Marine Fisheries Service, the NOAA Dr. Nancy Foster Scholarship Program, Ocean Park Conservation Foundation Hong Kong, Sakhalin Energy Investment Company, the U.S. Environmental Protection Agency, and the Washington Cooperative Fish and Wildlife Research Unit. This project was conducted as part of the Marine Mammal Project under Area V: Protection of Nature and the Organization of Reserves within the U.S.-Russia Agreement on Cooperation in the Field of Environmental Protection.

ABSTRACT

Within the North Pacific, gray whales (*Eschrichtius robustus*) are recognized as distinct eastern and western populations. Although both populations were severely reduced by whaling, the eastern population is generally considered to have recovered while the western population has remained highly depleted. Previous studies have documented genetic differentiation between the two populations on the basis of mtDNA haplotype frequencies. Since mtDNA represents only maternal inheritance patterns, the present study used bi-parentally inherited microsatellite markers (n=13) to measure differentiation between populations as well as to compare levels of nuclear genetic diversity retained in each. Mean levels of genetic diversity, as measured by the microsatellites, were similar between the eastern and western populations, indicating that the western population has retained relatively high levels of nuclear genetic diversity despite its small size. Comparison of microsatellite allele frequencies confirmed that eastern and western populations are genetically distinct. Although highly statistically significant, the level of differentiation between the two populations is relatively low, and sex-specific analyses suggest that some amount of male-biased dispersal may occur between populations. While these results suggest some movements between the eastern and western populations may take place, the maintenance of genetic differences between the two populations supports their recognition as separate eastern and western populations. Future efforts should focus on elucidating the nature and extent of any dispersal which is occurring in order to better understand factors potentially influencing the recovery of the small western population.

INTRODUCTION

Although gray whales (*Eschrichtius robustus*) once inhabited the North Atlantic Ocean (Mead and Mitchell 1984), the current distribution of the species is limited to the eastern and western margins of the North Pacific (Rice and Wolman 1971). Within this region, gray whales are recognized as having distinct eastern and western populations. Eastern gray whales winter in the lagoons and adjacent waters of Baja California, Mexico and then migrate north along the west coast of North America to feed in the Bering and Chukchi Seas during summer (Rice and Wolman 1971), with a small number of animals remaining in more southern waters between northern California and southeastern Alaska during summer months (Darling 1984, Calambokidis *et al.* 2002). For western gray whales, the primary feeding ground is in the coastal waters off northeastern Sakhalin Island, Russia (Weller *et al.* 1999, 2002). The location of the wintering ground(s) for

this population remains unknown, but limited information from sightings, strandings, and catches shows that some animals winter in the coastal waters of southern China (Wang 1984, Henderson 1990, Zhu 1998).

Both gray whale populations were greatly reduced by intensive commercial whaling during parts of the 19th and 20th centuries, but the two populations have exhibited different trajectories in abundance following exploitation. Commercial whaling for eastern gray whales ceased in 1936 (Brownell and Swartz 2006), and the population's size has increased since that time (Rugh *et al.* 2005). Eastern gray whales were removed from the U.S. List of Endangered and Threatened Wildlife and Plants in 1994, and recent abundance estimates indicate that the population contains approximately 22,000 animals (Punt and Wade 2010). In the western population, however, hunting continued through at least 1966 (Brownell and Chun 1977). This population was reduced to a much smaller size than the eastern populations and was considered by some to be extinct as recently as the 1970s (Bowen 1974). Today western gray whales exist only as a small remnant population. Recent population assessment utilizing a Bayesian individually-based stage-structure model and photo-identification data collected between 1994 and 2007 projected a median non-calf population size of 130 individuals in 2008, assuming current demographic and population trends continue (Cooke *et al.* 2008). This population was listed as Critically Endangered by the IUCN in 2000 (Weller *et al.* 2002, Baillie *et al.* 2004), and its continued survival is jeopardized by problems associated with small population size (reviewed in Clapham *et al.* 1999), as well as by a wide range of potential anthropogenic threats, including the rapid expansion of oil and gas development on its summer feeding ground off Sakhalin Island, Russia (Weller *et al.* 2002, Reeves *et al.* 2005, IISG 2006) and mortality due to net entrapment while on the migratory route off Japan (Brownell *et al.* 2007, Weller *et al.* 2008b).

Concern for the conservation status of the western population led to the initiation of a joint Russia-U.S. research program in 1995. This program is based on the summer feeding ground off Sakhalin Island, Russia and has incorporated both photo-identification studies and biopsy sampling (Weller *et al.* 1999, 2002). Photo-identification research has shown that most whales demonstrate high rates of annual return and pronounced seasonal site fidelity to the Sakhalin feeding ground (Weller *et al.* 1999, 2002). The majority (83% of identified whales (n=169) have also been genetically sampled, allowing a male bias (58% males) to be documented among sampled individuals (Weller *et al.* 2002, 2008). This male bias is particularly pronounced in individuals first identified as calves, of which 66% are males (Weller *et al.* 2008).

Biopsy samples collected between 1995 and 1999 have been used to show that the eastern and western populations are genetically distinct based on mitochondrial DNA (mtDNA) haplotype frequencies (LeDuc *et al.* 2002). This study found that western gray whales have retained a relatively high number of mtDNA haplotypes for such a small population. Genetic differentiation between the eastern and western populations was based on differences in the frequency distributions of haplotypes within each population. While haplotypes were apportioned relatively evenly among the eastern gray whale samples, the haplotype distribution found within the western gray whale samples was highly skewed, with two haplotypes found in very high frequencies and the remaining haplotypes identified in only one or two individuals (LeDuc *et al.* 2002).

The work presented here used thirteen microsatellite markers to further examine population structure of gray whales. Unlike mtDNA, which is maternally inherited and provides information about historic gene flow of females only, microsatellites are nuclear bi-parentally inherited markers and reflect gene flow of both males and females. The primary goal of this study was to examine genetic differentiation between eastern and western populations using microsatellites, as well as to assess factors which might contribute to that differentiation. Secondly, levels of nuclear genetic diversity were compared between the two populations to determine if substantial genetic variability has been lost in the much smaller western population and could thus be affecting its ability to recover. Finally, since additional western gray whale samples have been collected since the LeDuc *et al.* (2002) study, further analysis of population structure and genetic diversity using mtDNA was also conducted.

MATERIALS AND METHODS

Sample collection and DNA extraction

One hundred forty-two western gray whale samples were collected between 1995 and 2007 via biopsy darting of free-ranging whales on the population's feeding ground off Sakhalin Island, Russia. All except for one of the western gray whale samples are linked to a photographically identified animal, and this sample set represents 83.4% of all animals (n=169) identified on the western feeding ground through 2007. One hundred thirty-seven eastern gray whale samples obtained from the archive at the Southwest Fisheries Science Center were used for comparison to the western population. These samples were taken primarily from stranded animals (n=105), with some samples obtained from directed subsistence takes (n=12), fisheries bycatch (n=3), and biopsies (n=17) from free ranging whales. Collection locations ranged from southern California north to the Chukotka Peninsula in Russia.

DNA had been previously extracted for 120 of the eastern gray whale samples and 45 of the 142 western gray whale samples (those collected between 1995 and 1999) for use in an earlier study (LeDuc *et al.* 2002). For the remaining samples, whole genomic DNA was extracted using either the QIAGEN DNeasy™ tissue kit or the Corbett Robotics X-tractor Gene robot with the recommended protocols.

Molecular sexing and mtDNA control region sequencing

For those samples (n=114) not analyzed in the prior study by LeDuc *et al.* (2002), molecular sexing and mtDNA control region sequencing were conducted. For all of the eastern gray whale samples as well as the western gray whale samples which were collected prior to the 2006 season (n=94), a polymerase chain reaction (PCR) was used to determine sex utilizing primers described in Fain and Lemay (1995) and following the methods described in Gilson *et al.* (1998). For western gray whale samples collected in 2006 and 2007 (n=20), the protocol described in Morin *et al.* (2005) was used to determine the sex of individuals.

PCR was used to amplify a 523-base-pair fragment from the mtDNA control region using the primers 5'-TACCAAATGTATGAAACCTCAG-3' (H00034, Rosel *et al.* 1995) and 5'-CCTCCCTAAGACTCAAGGAAG-3' (L15812, Escorza-Trevino *et al.* 2005). Amplification products were cleaned through purification columns (QIAquick, Qiagen) and then sequenced using standard protocols with ABI-PRISM® Dye-DeoxyTerminator Big Dye™ v3.1 (Applied Biosystems) and the same primers. Following ethanol precipitation, sequenced products were run on an ABI 3100 or ABI3130 capillary sequencer. Consensus sequences for both strands were generated using ABI SEQSCAPE v2.5 software.

Microsatellite genotyping

Thirteen microsatellite loci isolated from other cetacean species were used to genotype the samples (*Table 1*). Reactions were performed in 25-µL volumes containing approximately 100 ng of genomic DNA and 2.5 µL of 2.0 mM MgCl₂ buffer, 1.5 µL of 10 mM dNTPs, 0.75 µL of each primer (at 10µM concentrations, with the forward primer of each pair fluorescently labeled), and 0.25 µL Taq. The thermal cycling profile included an initial hot start of 94°C for 2 min followed by 35 cycles of 94°C for 45 s, 1 min at the annealing temperature (see *Table 1*), and 1.5 min at 72°C, with a final 5-min extension at 72°C. Amplified products were mixed with a size standard and loaded onto an ABI 3100 or ABI 3130 sequencer. Sizing and binning of allele fragments using ABI GENESCAN and GENOTYPER analysis software were automated and relied on the use of internal lane standards, with subsequent manual evaluation of all labeled peaks.

Microsatellite scoring errors and identification of replicate samples

Prior to inclusion in this study, photo-identification data collected during biopsy sampling was used to identify and remove any duplicate samples (*i.e.*, samples taken from the same individual) from the western population sample set. Genotypic data were used to search for duplicates within the eastern gray whale sample set using MS Excel Toolkit v3.1 (Park 2001); one duplicate was identified and removed prior to

analyses, leaving a total of 136 eastern gray whale samples. Microsatellite data were also examined for signs of large-allele dropout and null alleles using MICRO-CHECKER v2.2.1 (van Oosterhout *et al.* 2004).

Genetic variability within populations

ARLEQUIN v3.01 (Excoffier *et al.* 2005) was used with the mitochondrial control region data to calculate standard indices of genetic variation (nucleotide diversity, π , and haplotype diversity, h ; Nei 1987) for each population. Genetic diversity at the nuclear level was characterized by generating the number of alleles, observed heterozygosity, and expected heterozygosity for each microsatellite locus in each population using ARLEQUIN. Within each sample set, a Markov-chain approximation of an exact test, as implemented in GENEPOP v3.4 (Raymond and Rousset 1995a), was used to test for departures from Hardy Weinberg expectations and for linkage disequilibrium between all pairs of loci.

Bottleneck analyses

Populations which have undergone recent bottlenecks are expected to exhibit genetic signatures characteristic of a reduction in effective population size (Cornuet and Luikart 1996, Luikart and Cornuet 1998, Luikart *et al.* 1998, Garza and Williamson 2001). One such signature is a transient excess of heterozygosity (H_e) relative to that expected in a population of constant size, which results from the rapid loss of rare alleles contributing little to overall heterozygosity (Cornuet and Luikart 1996). Here we utilized the program BOTTLENECK v1.2 (Piry *et al.* 1999) to determine if the gray whale microsatellite data demonstrated evidence of population bottlenecks. As recommended (Piry *et al.* 1999), a two-phase model assuming 95% single-step mutations and 5% multiple-step mutations was employed, with the variance among multiple steps set to 12. The distribution of gene diversity at equilibrium was estimated using a coalescent process with 10,000 simulations, and a one-tailed Wilcoxon test was used to determine if an excess of heterozygosity, relative to that expected in populations at equilibrium, was present (Cornuet and Luikart 1996).

The loss of rare alleles during a population bottleneck may also result in gaps in the size distribution of microsatellite alleles. This can be measured as the mean ratio (M) of the number of alleles to the allele size range across all loci (Garza and Williamson 2001); bottlenecked populations demonstrate reduced M values. Here we used ARLEQUIN to calculate M for both gray whale populations and then compared our values to those reported for reduced and stable populations by Garza and Williamson (2001).

Genetic differentiation among populations:

Two approaches were used to assess the degree of genetic differentiation between the two sampling regions. In the first approach, samples were divided *a priori* into populations based on the geographic location in which they were collected. The extent of genetic differentiation between populations was then examined using both mtDNA sequences and microsatellite data. For mtDNA data, an analysis of molecular variance (AMOVA, Weir and Cockerham 1984, Excoffier *et al.* 1992) was used to generate frequency-based (F_{ST}) estimates of differentiation using the program ARLEQUIN (20,000 permutations were used to test for significance). For microsatellite loci, genetic differentiation was examined using an AMOVA (ARLEQUIN) and allelic frequencies (with 20,000 permutations to test for significance) to generate F_{ST} values (Weir and Cockerham 1984). Modified exact tests based on genotype counts, as implemented in GENEPOP v3.4 (Raymond and Rousset 1995b), were also utilized to measure levels of differentiation. Significance was tested using 10,000 permutations. Since the western gray whale sample set included 57 mother-calf pairings, analyses of genetic differentiation were repeated after removal of the sample representing the calf in each pair, in order to avoid biasing the results by including known first-degree relatives.

As an alternative to *a priori* stratification of samples by geographic location, population structure was also explored using a Bayesian model-based clustering approach (STRUCTURE v2.2, Pritchard *et al.* 2000) with the microsatellite data. STRUCTURE assumes that within a set of samples there are K populations, each of which is characterized by allele frequencies at each locus. The program then divides all samples into K genetically distinct clusters by assigning individuals to putative populations such that Hardy-

Weinberg and linkage disequilibrium are minimized within each group. Five independent runs of $K=1-5$ were performed with a burn-in period of 50,000 iterations followed by 100,000 Markov-chain Monte Carlo repetitions, using a model based on admixture with correlated allele frequencies (Falush *et al.* 2003). After averaging across runs, the log probability of the data given K ($\ln P(X|K)$) was used as the criterion to infer the number of clusters (K) most compatible with the our data.

Detection of sex-biased dispersal

The potential for sex-biased dispersal between populations was investigated using the microsatellite data with the methods described by Goudet *et al.* (2002) and implemented in FSTAT v2.9 (Goudet 2001). Since the signal of sex-biased dispersal disappears with mating (Goudet *et al.* 2002), animals first sampled as calves in the western population were omitted prior to analysis. This program generates a number of statistics aimed at identifying patterns of sex-biased dispersal. The statistics utilized here were 1) F_{st} , the proportion of genetic variation among populations; 2) the mean corrected assignment index (mAIC) and 3) the variance around the assignment index (vAIC) (Favre *et al.* 1997, Mossman and Waser 1999). The p values were estimated using 10,000 randomizations, and a one-tailed test was utilized based on the expectation that, as in most mammals, dispersal is biased toward males. F_{st} and mAIC are expected to be higher in the more philopatric sex, while vAIC should be lower (Goudet *et al.* 2002).

To further explore the potential for sex-biased dispersal between populations, sex-specific estimates of genetic differentiation were generated using the methods outlined above with both the mtDNA and microsatellite data. In addition, values of cluster membership (Q) produced by the STRUCTURE model assuming $K=2$ clusters were compared between males and females.

RESULTS

Genetic diversity

Forty haplotypes defined by 39 variable sites were identified from the 278 gray whale samples. Thirty-five haplotypes were found among the eastern gray whale samples, while 22 haplotypes were found in the western gray whale sample set. Seventeen haplotypes were shared between the two populations. The frequency of haplotypes in each population is shown in Table 2. When all samples were combined, nucleotide diversity (π) was 0.018 (SD=0.0092), while haplotypic diversity (h) was 0.89 (SD=0.012). When subdivided by population, nucleotide diversity was relatively similar in both populations ($\pi=0.016 \pm 0.0081$ SD, eastern population; $\pi=0.018 \pm 0.0093$ SD, western population), while measures of haplotype diversity were higher in the eastern ($h=0.95 \pm 0.006$ SD) than the western ($h=0.77 \pm 0.025$ SD) population (Table 3). Sex-specific diversity measures indicated that although haplotypic diversity was similar between the male ($h=0.96$) and female ($h=0.95$) subsets of the eastern population, lower levels of haplotype diversity were found among the western female subset ($h=0.77$) when compared to the western male subset ($h=0.83$).

No signal of large-allele dropout or null alleles was identified by MICROCHECKER for any locus in either of the two populations. No deviation from Hardy-Weinberg Equilibrium was detected in either population after controlling for the False Discovery Rate (FDR, Benjamini and Hochberg 1995). After correcting for the FDR, only one loci combination was found to be in significant linkage disequilibrium in the eastern population. However, significant linkage disequilibrium was detected for eight loci combinations in the western population. Given that the same loci pairs were not in disequilibrium in both populations, it is unlikely that this result was derived from physical linkage. Linkage disequilibrium can result from inclusion of related individuals within a sample set. Therefore, known relatives were removed and the tests were rerun on the remaining genotypes. Six loci combinations remained out of linkage disequilibrium after controlling for the FDR.

After averaging across loci, measures of microsatellite diversity were higher in the eastern population ($H_o=0.74$, $H_e=0.74$, $K=9.8$) than in the western population ($H_o=0.71$, $H_e=0.70$, $A=8.8$); however, these differences were relatively small (Table 4). A total of 18 private alleles were observed in the eastern population, while only 5 private alleles were found in the western population.

Statistical analysis of the microsatellite allele frequency data using the program BOTTLENECK did not detect evidence of a recent ($2-4N_e$ generations) bottleneck in either population. Under the model utilized, heterozygosity excess was not observed in the eastern (Wilcoxon test, $P=0.989$) or the western population (Wilcoxon test, $P=0.999$). In addition, the calculated M values (0.823 ± 0.15 and 0.808 ± 0.17) in the eastern and western populations, respectively) were more consistent with those described for stable populations and were considerably higher than the upper bound (0.70) that Garza and Williamson (2001) derived for reduced populations.

Genetic differentiation among populations

Significant genetic structuring between eastern and western populations on the basis of both mtDNA haplotypes and microsatellite allele frequencies was observed (Table 5). Similar results were also observed for the microsatellite data when genetic differentiation was assessed using the exact test; the overall results were significant ($p \leq 0.001$), with 11 of the 13 loci showing significant differences when analyzed independently (data not shown). These comparisons remained significant ($P \leq 0.001$) after known relatives ($n = 57$ calves which had sampled mothers) were removed from the analysis (Table 5); however, only three of the thirteen loci showed significant differences when analyzed independently.

STRUCTURE analyses (Pritchard *et al.* 2000, Falush *et al.* 2003) supported the presence of two populations ($P \sim 1.0$), with a clear increase in the log-likelihood of the data for $K = 2$ when compared to that for other numbers of clusters (Table 6). The probability that the data contained only one cluster was < 0.001 , suggesting that eastern and western populations are not panmictic. When Q values, which represent the proportion of each individual's genotype that can be attributed to each of the clusters, were used to assign individuals into clusters, 80% ($n = 109$ of 136) of animals sampled in the east were grouped into the same cluster while 65% ($n = 92$ of 142) of animals sampled in the west were grouped into a cluster (Figure 1). However, average source population Q values were relatively low for both populations; they averaged $0.69 (\pm 0.209SD)$ for animals sampled in the east and $0.60 (\pm 0.296SD)$ for animals sampled in the west.

Sex-specific comparisons

Sex-specific estimates of differentiation were much more marked among females than among males. Using mtDNA haplotype frequencies (Table 5), both the male and female comparisons were highly significant, although the F_{st} value estimated for females ($F_{st} = 0.078$) was more than twice as high as that estimated for males ($F_{st} = 0.033$). Interestingly, while the male-specific comparisons remained significant ($P = 0.029$) in the microsatellite exact test, F_{st} estimates based on microsatellite allele frequencies suggested no significant differences between eastern and western males. The sex-biased dispersal tests in FSTAT also supported greater philopatry among females when compared to males. While difference in males and females were not significant for the mean assignment index ($P = 0.365$) or the variance in the mean assignment index ($P = 0.9262$), females demonstrated significantly higher F_{st} values ($P = 0.0176$).

Results of the STRUCTURE analysis provided further evidence that male-biased dispersal may be occurring. After removing animals first identified as calves, average Q values were similar between eastern males ($Q_{EM} = 0.70 \pm 0.211SD$) and females ($Q_{EF} = 0.67 \pm 0.208SD$, $P = 0.26$, t-test); 80% and 87% of males and females were assigned to their source population. In contrast, average Q values were lower for western males ($Q_{WM} = 0.47 \pm 0.339SD$) than for western females ($Q_{WF} = 0.63 \pm 0.250$; $P = 0.010$, t-test). Only 40% of western males had $Q \geq 0.50$ for the cluster representing the western population, in contrast to 75% of western females.

DISCUSSION

Genetic variability

Populations reduced to small sizes can suffer from a loss of genetic diversity, which in turn may compromise their ability to respond to changing environmental conditions (Willi *et al.* 2006) and negatively influence long-term viability (Spielman *et al.* 2004, Frankham 2005). Although little is known

about the level of genetic diversity maintained in the western gray whale population prior to its depletion by commercial whaling, comparison of the levels of diversity found in this small population with those maintained in the much larger population in the eastern Pacific can provide some insight into whether reduced genetic diversity may influence its recovery. Previous studies utilizing mtDNA indicated that while the western gray whale population had retained a relatively high number of mtDNA haplotypes and levels of nucleotide diversity which were concordant with those found in the eastern population, the population had reduced haplotype diversity when compared to its eastern counterpart (LeDuc *et al.* 2002). Our results, using an extended sample set that included ~83% of photographically identified western gray whales, support these earlier findings. As previously noted, the reduced haplotype diversity found in the western population was not a reflection of the number of haplotypes present but rather of the skewed distribution of those haplotypes (LeDuc *et al.* 2002). This skew was even more marked with the added samples. While the frequencies of the two most common haplotypes changed little, new low frequency haplotypes were added, with 14 of the 22 western gray whale haplotypes being found in only one or two animals.

While approximately half (49%) of the mtDNA haplotypes identified in the eastern population were shared with animals sampled in the western North Pacific, a much larger proportion (77%) of the mtDNA haplotypes found in the western population were also identified in eastern animals. Given the relatively thorough sampling of animals on the western feeding ground, it is likely that most if not all haplotypes present in that area have been identified, indicating that the mtDNA haplotypes found only in the eastern Pacific are likely to be unique to that population. In contrast, the low proportion of animals sampled in the eastern population suggests that those haplotypes currently identified only among western animals (n=5) might also be discovered in the eastern population with additional sampling.

Although the relationship between population size and mtDNA diversity is not straightforward (Bazin *et al.* 2006; Nabholz *et al.* 2008), the number of haplotypes (n=22) found in the western gray whale population is surprising given its small size and history of exploitation. In a similar study of endangered North Atlantic right whales (*Eubalaena glacialis*), which are thought to number approximately 400 individuals, only five haplotypes have been documented (n = 180 samples, Malik *et al.* 2000). While sampling in other populations has been less comprehensive, similar patterns have been found in other small mysticete populations, including the Okhotsk Sea bowhead whale population (*Balaena mysticetus*), in which only four different haplotypes were found (n = 25 samples, LeDuc *et al.* 2005), as well as the Sea of Cortez fin whales (*Balaenoptera physalus*), in which three haplotypes have been identified (n = 56 samples, Berube *et al.* 2002). The number of haplotypes found in the western gray whale population is more consistent with numbers found in larger populations, such as the stock of right whales (*Eubalaena australis*) breeding off South Africa, which contains 21 haplotypes (n = 41 samples, Patenaude *et al.* 2007) and has an estimated abundance of 3400 animals (Best *et al.* 2005).

Although the number of haplotypes currently found in the western population is higher than might be expected, this pattern may not persist into the future. Eleven of the 14 haplotypes found in low frequencies have been identified only in a single male. Although little specific information is available on gray whale longevity, they are generally thought to live for approximately 40 to 60 years. It is possible that some of these “rare haplotype” males could be animals that escaped being killed by whalers which hunted gray whales until at least 1966. Given the maternal inheritance pattern of mtDNA, and assuming that these males are indeed the only animals in the population with these haplotypes, the eventual loss of these individuals has the potential to substantially decrease levels of mtDNA diversity in the future.

The level of nuclear genetic diversity found in the western population was slightly lower than, but very similar to, that found in the much larger eastern population. The number of microsatellite alleles found exclusively in the eastern population, however, was markedly higher than the number found in the western population. Given that the western population has been relatively thoroughly sampled, these results suggest that the western population’s depletion and continued small size may have resulted in the loss of rare alleles from the population. No genetic signature of a bottleneck was detected in the western population using the microsatellite data. However, simulations have shown that detection of bottlenecks using genetic methods is dependent on a wide range of conditions, including duration of the bottleneck, mutation rate, pre-bottleneck size, and post-bottleneck recovery (Williamson-Natesan 2005), and many studies have failed to

detect the genetic signature of a bottleneck even when demographic data indicate population size collapse (e.g., Queney *et al.* 2000, Spong and Hellborg 2002).

Overall, the western population appears to have retained relatively high genetic diversity despite its history of exploitation and continued small population size. In other populations, the maintenance of genetic diversity in the face of population decline has been attributed to long generation times (Dinerstein and McCracken 1990, Hailer *et al.* 2006, Lippe *et al.* 2006), which are characteristic of baleen whales and may have buffered the population against the rapid loss of variation. However, the relatively high level of genetic diversity that appears to have been maintained in the western population could also be the result of dispersal of eastern animals onto the western feeding ground. Even at low levels, dispersal has been shown to obscure bottleneck signatures (e.g., Kellar *et al.* 2001, Busch *et al.* 2007) and genetically “rescue” populations from the loss of genetic diversity (Vila *et al.* 2003). Further exploration of this possibility is detailed below.

Population structure

The inclusion of additional samples to analyses employing mtDNA supported the previous conclusion that the two populations are genetically distinct (LeDuc *et al.* 2002). Nuclear differentiation estimates further confirm differences between the two populations and indicate that genetic separation between populations is not derived solely from female philopatry. These measures of differentiation remained significant after known first degree relatives (*i.e.*, the calf from sampled mother-calf pairs) were removed from the dataset, suggesting that such differences are not solely an artifact of the inclusion of highly related individuals in the analysis.

Although highly significant, the degree of nuclear differentiation, as measured by F_{ST} values, between the two populations is relatively small. This pattern of differentiation is similar to that found in North Pacific bowhead whale populations, which also demonstrate a significant but small degree of differentiation between a smaller western population inhabiting the Okhotsk Sea and a much larger eastern population in the Bering-Chukchi-Beaufort Seas (LeDuc *et al.* 2005). The relatively small but highly significant genetic differences observed in gray whales, particularly when combined with the similar pattern observed in North Pacific bowhead populations, suggests that past Arctic environmental changes may have played a role in influencing patterns of historic mixing and separation of eastern and western animals. Both stranding records and radio-carbon dating of remains have indicated that changes in sea ice distribution may have mediated bowhead whale distribution in the Canadian Arctic (Dyke *et al.* 1996, SaVelle *et al.* 2000). Within the North Pacific, Arctic-wide cooling and glaciation brought on by the “Little Ice Age” (~400-750 years ago) may have resulted in a southern shift in sea ice distribution and reduced sea level (Overpeck *et al.* 1997), potentially facilitating mixing between eastern and western whales. Sea ice expansion during the Neoglacial (~4700 to 2500 years ago) may also have limited access to parts of the Bering Sea and has been hypothesized to have altered the distribution of North Pacific pinnipeds and cetaceans (Crockford and Frederick 2007).

A second explanation for the low level of differentiation is that some limited gene flow could be occurring between the two populations. Given the small size of the western population, it seems likely that even minimal gene flow from the eastern to the western population would quickly homogenize allele frequencies. However, genetic drift also acts more strongly on small populations, allowing differences between populations to develop more rapidly. As such, genetic drift could be acting to counterbalance some restricted degree of genetic interchange between populations.

A third scenario which might also explain our results involves dispersal of whales between feeding areas without genetic exchange. Since breeding in gray whales is thought to primarily occur along migratory corridors (Rice and Wolman 1971), movement between feeding regions does not necessarily imply gene flow between the populations. Given that all of the western gray whale samples were obtained on the feeding ground, low differentiation levels could potentially be generated by a small number of eastern gray whales traveling to the western gray whale feeding ground during summer months and consequently being sampled while mixed with members of the western population. If these eastern dispersers visit the western

feeding ground but return to the eastern Pacific to breed, such extralimital movements would act to reduce measured levels of genetic differentiation between populations in the absence of significant gene flow.

Some support for a limited degree of dispersal and/or gene flow between populations can be derived from the results of the sex-specific comparisons. If the observed low level of differentiation were due to recent divergence, similar patterns of differences should be observed for males and females. Contrary to this expectation, all measures of differentiation were at least twice as high for female-only versus male-only comparisons. In addition, although comparisons between males remained significant for mtDNA, the F_{st} -based comparison of microsatellite allele frequencies did not identify significant differences among males, suggesting that some degree of male-biased dispersal may be occurring between populations. Such a pattern could also provide an explanation for the large proportion of mtDNA haplotypes (11 of 22) in the western population which are represented only by a single male. Given the higher diversity and number of mtDNA haplotypes found in the eastern population, any dispersers from the east would have a relatively high probability of carrying haplotypes considered “rare” in the west (LeDuc *et al.* 2002). Eight of the eleven haplotypes carried by only a single male in the west were also found in the east; given the low proportion of sampled animals in the east, it is plausible that the other three haplotypes would also be identified among eastern animals with additional sampling.

Although the analyses summarized here are not able to discriminate between gene flow and feeding ground dispersal, a combination of genetic assignment tests and parentage analysis in the future may be useful to distinguish between these two possibilities. In addition, simulation modeling could be utilized in the future to determine the degree of gene flow or feeding-ground dispersal which could occur while still allowing the two populations to maintain genetic distinctiveness.

Conclusions and conservation implications

The results presented here support past work indicating that eastern and western populations are genetically distinct, further highlighting the need for continued conservation and expanded protection of the critically endangered western gray whale population. Although highly statistically significant, the level of differentiation between the two populations is relatively low, which may reflect recent divergence of the two populations, perhaps mitigated by past environmental changes, but could also suggest that some limited degree of dispersal and/or gene flow may occur between the two populations. Discrimination between these proposed explanations is important, given that each scenario could have different effects on the recovery of the critically endangered western population. If a restricted amount of gene flow is taking place, that interchange could be important in providing “genetic rescue” for the western population, helping to maintain relatively high levels of genetic diversity in a small population which would otherwise likely suffer from inbreeding and a subsequent loss of fitness. However, if dispersal between feeding grounds without any gene flow is occurring, then any eastern dispersers are not contributing to the gene pool but could be artificially inflating our estimates of both genetic diversity and population size, which would suggest that the western population is even more vulnerable than currently thought. Given the wide range of threats, including entrapment in fishing nets as well as expanding oil and gas development, which challenge the recovery of the western gray whale population, further exploration of possible mechanisms of intermixing is needed to better understand the dynamics of this critically endangered population.

ACKNOWLEDGEMENTS:

Much appreciation goes to the many participants of the western gray whale research team, especially A. Bradford, Y. Ivashchenko, H.W. Kim, S. Reeve, M. Sidorenko, and G. Tsidulko. Support and funding for western gray whales studies have been provided by (in alphabetical order): Alaska SeaLife Center, Animal Welfare Institute, Exxon Neftegas Limited, the International Fund for Animal Welfare, the International Whaling Commission, the Marine Mammal Commission, the Marine Mammal Research Program at Texas A&M University at Galveston, the National Fish and Wildlife Foundation, the National Marine Fisheries Service, the NOAA Dr. Nancy Foster Scholarship Program, Ocean Park Conservation Foundation Hong Kong, Sakhalin Energy Investment Company, the U.S. Environmental Protection Agency, and the Washington Cooperative Fish and Wildlife Research Unit. This project was conducted as part of the

Marine Mammal Project under Area V: Protection of Nature and the Organization of Reserves within the U.S.-Russia Agreement on Cooperation in the Field of Environmental Protection.

ABSTRACT

Previous studies have documented genetic differentiation between gray whales in the eastern and western North Pacific on the basis of both mtDNA haplotype and microsatellite allele frequencies. In these studies, the eastern North Pacific (ENP) population of gray whales has been represented by a sample set comprised primarily of samples from animals that stranded along the migratory route. Recent studies assessing population substructuring of gray whales within the ENP have resulted in the collection and analysis of additional samples from ENP gray whales feeding north of the Aleutian Islands (n=106 sampled individuals). Here we update previous assessments of genetic differentiation between ENP and western North Pacific (WNP) gray whales using these additional ENP samples and samples collected from whales (n=142 individuals) feeding off the northeastern coast of Sakhalin Island, Russia. In addition, comparison of the mtDNA haplotype, sex, and genotypes (8 to 13 loci) of all analyzed samples (n=380) was used to identify samples with identical genetic profiles, and these genetic matches were used to infer movements of individuals between areas. Consistent with the results of previous studies, significant levels of differentiation were found between WNP and ENP gray whales using both mitochondrial (e.g., Sakhalin versus Chukotka, $F_{ST} = 0.082$, $p < 0.0001$; $\Phi_{ST} = 0.037$, $p < 0.001$) and nuclear (e.g., Sakhalin versus Chukotka, $F_{ST} = 0.010$, $p = 0.001$; $F_{ST}' = 0.037$, $p = 0.001$) markers (n=8 loci). Seven pairs of samples shared identical genetic profiles, including one match between an animal sampled off the coast of San Diego and an animal taken in the Chukotka hunt, four matches between animals biopsied on the Sakhalin feeding ground and animals biopsied off southeastern Kamchatka, and two matches between animals biopsied on the Sakhalin feeding ground and animals biopsied off the coast of southern California. While the significant levels of genetic differentiation support demographic independence and a degree of reproductive isolation between whales feeding in the WNP and the ENP, the putative movements detected here, in combination with information derived from photo-identification comparisons and telemetry studies, suggest that some of the animals summering off Sakhalin overwinter in the ENP in at least some years. Given that recent records document gray whales in Japanese waters during winter and spring, these results suggest that population structure in gray whales may be more complex than previously believed, such that not all of the animals which feed off Sakhalin share a common wintering ground, or that some animals may switch between wintering grounds. Thus, the number of gray whales remaining in the WNP year-round may be lower than previously thought, highlighting the need for additional studies focusing on identifying migratory routes and wintering ground(s) used by gray whales in the WNP.

INTRODUCTION

Like many species of baleen whales, gray whales (*Eschrichtius robustus*) exhibit seasonal movements between high- latitude summer feeding grounds and low- latitude wintering areas. The current distribution of this species is limited to the eastern and western margins of the North Pacific (Rice & Wolman 1971), where two populations are recognized. Although both populations were greatly depleted by commercial whaling, the population in the eastern North Pacific (ENP) currently numbers ~19,000 animals, (based on surveys in 2006/2007; Laake *et al.*, 2009). Most animals in the ENP population feed in the waters of the Bering, Beaufort, and Chukchi Seas during summer and early fall and then migrate south to the lagoons and coastal waters off Baja California, Mexico to spend the winter months. However, a small number of animals (~200, Calambokidis *et al.*, 2010), referred to as the Pacific Coast Feeding Group (PCFG) of gray whales (IWC, 2010), demonstrate consistent return to more southern waters between northern California and southeastern Alaska during the summer feeding season (Darling, 1984; Calambokidis *et al.*, 2002, 2010). Recent genetic studies have demonstrated significant mtDNA differentiation between the PCFG and ENP gray whales feeding in areas north of the Aleutians (Lang *et al.*, 2011), as well as between the PCFG and a sample set comprised primarily of whales which stranded along the migratory route in the ENP (Frasier *et al.*, 2011). No significant differentiation in nuclear markers was identified, however, suggesting that PCFG whales may interbreed with animals feeding north of the Aleutians (Lang *et al.*, 2011).

The population of whales in the western North Pacific (WNP) was reduced to much lower numbers than its eastern counterpart during commercial whaling. This population has been estimated to contain only about 130 animals of age one or older (Cooke *et al.*, 2008) and is currently listed as Critically Endangered by the IUCN (Weller *et al.*, 2002; Baillie *et al.*, 2004). Much of what is known about this population is derived from combined photo-identification and genetic studies of individuals on the population's primary feeding ground in the coastal waters of northeastern Sakhalin Island, Russia (Weller *et al.*, 1999; Weller *et al.*, 2008a; LeDuc *et al.*, 2002; Lang *et al.*, 2010). Photo-identification studies have documented seasonal site fidelity and annual return of individuals to this feeding area (Weller *et al.*, 1999). Reproductive females are known to utilize the Sakhalin feeding ground year after year when they are accompanied by calves as well as when they are pregnant or resting, and the return of many individuals first identified as calves accompanying their mothers has been documented (Weller *et al.*, 2009). Some of the whales feeding in the coastal waters off Sakhalin are also known to utilize feeding areas slightly offshore, as well as off the southern and eastern coast of Kamchatka (Tyurneva *et al.*, 2010; Burdin *et al.*, 2011). The whales identified off Kamchatka include some mother-calf pairs also identified on the Sakhalin feeding ground (Tyurneva *et al.*, 2010). However, not all of the whales photographed off Kamchatka have been identified off Sakhalin, and their population affiliation is unknown.

Genetic samples have been collected from 83 % (n=142) of the whales identified on the Sakhalin feeding ground between 1995 and 2007 (Lang, 2010). Comparison of this sample set with samples collected from whales in the eastern North Pacific (ENP) have supported recognition of the two populations as distinct, with differentiation in both mtDNA haplotype and microsatellite allele frequencies (LeDuc *et al.*, 2002; Lang *et al.*, 2010). Assessment of the paternity of animals first identified as calves on the Sakhalin feeding ground between 1995 and 2007 (n = 57 sampled mother-calf pairs) resulted in the assignment of putative fathers for 46-53% of the calves, supporting interbreeding among animals that feed off Sakhalin but also raising questions about the identity of the unassigned fathers (Lang, 2010).

Little is known about the location of migratory routes and wintering ground(s) currently used by the whales that feed off Sakhalin. The coastal waters of southeastern Russia, the Korean Peninsula, and Japan are thought to have been used as migratory corridors historically, and some evidence exists suggesting that the coastal waters of southern China may have been used as wintering grounds (reviewed in Weller *et al.*, 2002). Aside from sightings of whales in feeding areas, the majority of recent records of gray whales in the WNP are of sightings, strandings, and entrapments in the coastal waters of Japan (see details in Kato *et al.*, 2010). Although little is known about the identity of most of the whales recorded off Japan, photographs of one animal which was entrapped off the Pacific coast of Japan in January 2007 were matched to an animal first

Do not cite without permission of authors

photographed as a calf on the Sakhalin feeding ground in 2006, providing the first known link between the Sakhalin feeding ground and a migratory route in the western North Pacific (Weller *et al.*, 2008b).

In October 2010, a team of scientists from Russia and the United States deployed a satellite tag on a gray whale off the coast of Sakhalin Island¹. The tagged individual (“Flex”) was a 13 year-old male that had been first identified as a calf off Sakhalin in 1997 and subsequently demonstrated repeated return to the Sakhalin feeding ground. “Flex” was tracked for ~4 months, during which time he traveled from the feeding ground off Sakhalin Island to the western coast of the U.S.^{1, 2, 3}. Subsequent comparison of photographs of “Flex” collected off the coast of Sakhalin with photographs collected by Cascadia Research Collective in the Pacific Northwest revealed that Flex had previously been photographed off the coast of Vancouver Island in April 2008 (Weller *et al.*, 2011). The satellite track and photographic record of “Flex” have since raised questions about the potential for movements of gray whales between the eastern and western North Pacific.

Prior analyses of genetic differentiation between ENP and WNP gray whales have been based on an ENP sample set in which the majority of samples were collected from animals which stranded along the migratory route (LeDuc *et al.*, 2002; Lang *et al.*, 2010). As part of recent efforts to better understand the potential for substructure in ENP gray whales (Lang *et al.*, 2011), additional samples were collected and analyzed from gray whales utilizing feeding grounds north of the Aleutians. This sample set provides the opportunity to update previous assessments of genetic differentiation between eastern and western gray whales and will allow direct comparisons to be made between animals utilizing feeding areas in the ENP and in the WNP. The expanded data set will also be used to identify samples with identical genetic profiles, which may provide information on movements of animals both within and between the eastern and western North Pacific.

METHODS

Sample Collection

The collection location for all samples utilized in the study is shown in Figure 1. Within the WNP, samples were collected between 1995 and 2007 via biopsy-darting of 142 individual whales on the feeding ground off Sakhalin Island, Russia. All except one of these samples are linked to a photographically identified animal, and this sample set represents 83% of all animals (n=169) identified on the Sakhalin feeding ground through 2007. Additional samples were collected via biopsy darting of whales between Kamenistaya Bay and Asacha Bay on the southeastern coast of Kamchatka, Russia during the summer months of 2004 (n=3 samples) and 2010 (n=12 samples).

Within the ENP, samples were collected from 228 individuals. Table 1 shows the year of sample collection as well as the collection method, with samples subdivided into those collected from animals south of the Aleutians (“CA->AK”) and those collected on the northern feeding ground(s) (“N of Aleutians”).

Lab Processing:

Details on protocols for extraction, sequencing, molecular sexing, and genotyping of the samples collected off Sakhalin Island and samples collected in the ENP between California and the Aleutians are provided in Lang *et al.* 2010. These samples were genotyped at 13 loci, including D17t, EV14t, EV37, EV94t, Gata028, Gata098, Gata417, Gt023, RW31, RW48, SW10t, SW13t, and SW19t.

Protocols used for generating data for the samples collected north of the Aleutians and those collected off of the coast of southeastern Kamchatka are described in Lang *et al.* 2011. These samples have been genotyped at 8 loci, including EV14t, EV94t, Gata028, Gt023, Gata417, RW31, SW13t, and SW19t. Genotypes for the additional five loci included in Lang *et al.* 2010 are currently being generated. Analysis of genetic diversity

and differentiation for nuclear markers used only the eight microsatellite loci which have been generated for all samples, although the calculation of probabilities associated with identifying genetic matches utilized the 13-loci dataset when available.

Analysis

Sample Stratification

Samples were separated into strata for analysis based on the geographic location of sample collection. Within the WNP, samples were subdivided into two strata. All samples collected from animals off the northeastern coast of Sakhalin Island were included in the Sakhalin stratum; the composition of this stratum is identical to that utilized in Lang *et al.*, 2011. Samples collected from whales off the southeastern coast of Kamchatka were included in a southeastern Kamchatka stratum.

Within the ENP, samples were first classified into two broad-scale strata, with all samples from feeding grounds north of the Aleutians included in the “north of Aleutians” stratum and all samples from animals obtained along the migratory route between southern California and southeastern Alaska included in the “CA->AK” strata. The “north of the Aleutians” stratum is identical in composition to the “North” stratum utilized in Lang *et al.*, 2011. The “CA->AK” stratum is similar in composition to the stratum used to represent ENP gray whales in previous comparisons (LeDuc *et al.*, 2002; Lang *et al.*, 2010; Frasier *et al.*, 2011); however, all samples which were collected from animals north of the Aleutians were removed and were retained in the “north of the Aleutians” stratum. Although all samples included in the “CA->AK” stratum were obtained from regions utilized as part of the migratory route in the ENP, the region between northern California and southeastern Alaska is also used as a feeding ground by the PCFG whales. While none of the samples included in the “CA->AK” stratum were known to be from PCFG whales (i.e., none of these samples were included in the “South” or “PCFG” strata utilized in Lang *et al.*, 2011), it is possible that some PCFG whales could be included in this stratum.

Little is known about whether or not additional substructuring occurs among whales feeding in different areas within the larger “north of the Aleutians” feeding ground. To avoid inadvertently using a stratum that may contain unrecognized structure, samples collected north of the Aleutians were further subdivided into the “Chukotka” and “Barrow” strata. These strata are the same as those used in Lang *et al.*, 2011, and additional details on the rationale for this stratification system are included in that manuscript.

The Microsoft EXCEL program MS_TOOLKIT (Park, 2001) was used to identify samples with genotypes that matched at all loci. The mtDNA haplotype and sex of animals with identical genotypes were used to confirm all identified matches. For those samples that shared identical genetic profiles and were collected within the same region (i.e., were included in the same stratum), one of each pair of matching samples was removed prior to analysis.

Genetic Diversity

For the mtDNA, haplotypic diversity (h) and nucleotide diversity (π) were calculated using Arlequin 3.5.1.2 (Excoffier *et al.*, 2005). For the 8-loci microsatellite dataset, the number of alleles per locus and observed and expected heterozygosities were calculated using custom R-code (eiaGenetics, available upon request¹). Deviations from Hardy-Weinberg equilibrium (HWE) were assessed for each microsatellite locus using Genepop (version 4.0.11, Rousset 2008). Both the probability test (Guo & Thompson, 1992) and the test for heterozygote deficiency (Rousset and Raymond 1995) were conducted using the program defaults for the Markov chain parameters (10,000 dememorization steps, 20 batches, 5000 iterations/batch). Genepop was also used to test for linkage disequilibrium (LD) for each pair of loci.

Genetic Structure

Pairwise estimates of genetic divergence were calculated using both F_{ST} and Φ_{ST} (based on pairwise differences between sequences as the measure of genetic distance) for the mtDNA data as implemented in Arlequin 3.5.1.2 (Excoffier *et al.*, 2005). Statistical significance was assessed using 20,000 permutations.

Do not cite without permission of authors

Fisher's exact test (Raymond & Rousset, 1995) was also used to test for mtDNA differentiation between strata using 100,000 replications to test for significance.

For the 8-loci microsatellite dataset, F_{ST} (Weir & Cockerham, 1984), normalized F_{ST} , Jost's D (Jost, 2008), and a χ^2 test were used to assess genetic differentiation. These tests were implemented using custom code (eiaGenetics⁴) written in the statistical program language R (R Core Development Team, 2009). Statistical significance was determined from 10,000 permutations of each data set.

Movements

As aforementioned, the EXCEL add-in MS_TOOLKIT (Park, 2001) was used to identify samples with genotypes that matched at all loci, and the mtDNA haplotype and sex of animals with identical genotypes were used to confirm all identified matches. Although the majority of the genetic matches detected were collected from animals within the same region, several were collected from animals in different areas and may represent movements of individuals. The program GENEAP (Wilberg & Dreher, 2004) was used to calculate the probability of identity using the microsatellite genotypes. The probability of identity (PID) is defined as the probability that two individuals drawn randomly from the dataset will have the same genotype at multiple loci. This statistic was initially calculated under the assumption of Hardy-Weinberg equilibrium (PID_{HW}, Paetkau & Strobeck, 1994). However, such estimates may be biased in the presence of population structure. Calculations assuming the presence of full siblings within the dataset (PID_{SIB}) are considered more conservative (Waits *et al.* 2001) and were calculated using the formula of Evett & Weir (1998).

The match probability (*e.g.*, individual probability of identity) is defined as the probability that given the genotype of one individual, a second individual will have the same genotype. For the genetic matches between samples collected in different areas, the match probability was calculated for all identified pairs of duplicate genotypes both under the assumption of Hardy-Weinberg equilibrium and assuming that the two individuals were full siblings (Woods *et al.*, 2009).

RESULTS

Population Structure –

Forty mtDNA haplotypes defined by 38 variable sites were identified among the 377 gray whale samples for which mtDNA sequences were produced (Table 2). Haplotype diversity (h) was high in all of the ENP strata ($h = 0.952-0.967$) but was reduced in the WNP strata ($h=0.77$, Sakhalin; $h=0.80$, southeastern Kamchatka). Nucleotide diversity (π) was also similar across all strata, although slightly higher in the WNP strata (1.8-1.9%) than in the ENP strata (1.2 – 1.6%).

The number of individuals with each haplotype in each stratum is shown in Table 3, with data for the PCFG stratum taken from Lang *et al.*, 2011. Within the Sakhalin stratum, two haplotypes were found in very high frequencies, with 36% of sampled animals having haplotype 1 and 31% having haplotype 2. Within the ENP strata, no haplotypes were found in frequencies greater than 14%. The three highest frequency haplotypes in the PCFG stratum were found in 10% and 13% of individuals.

Within the Sakhalin stratum, the number of known mother-calf pairs with each haplotype, relative to the total number of animals with each haplotype, is shown in Figure 2. Of the 51 animals with haplotype 1, 59% were part of a known mother-calf pair, while 66% of the individuals with haplotype 2 ($n=44$) were animals from a known mother-calf pair. With one exception, all haplotypes that were identified in more than two sampled animals in the Sakhalin stratum are composed of at least one known mother-calf pair.

The median-joining network shows the relationship among mtDNA haplotypes and their frequency in each

⁴ Contact E. Archer @Eric.Archer@noaa.gov

stratum (Figure 3). MtDNA haplotypes identified among animals feeding off Sakhalin are dispersed throughout the network, and no phylogeographic pattern is apparent.

Measures of microsatellite diversity for each stratum after averaging across the eight loci common to both datasets are shown in Table 4. Nuclear diversity was similar across all strata. None of the tests for HWE were significant after the correction for multiple tests was applied. Significant linkage disequilibrium was found for two pairs of loci (one in the “Sakhalin” stratum and one in the “north of the Aleutians” stratum) after the correction for multiple tests was applied. No significant LD was found for these two loci pairs in any of the other strata, so these loci were retained for the analysis.

The results of the mtDNA comparisons are shown in Table 5. All comparisons between ENP strata and the Sakhalin stratum were highly significant ($p < 0.001$). No significant differentiation was found when the CA->AK stratum was compared to either Chukotka ($F_{ST} = 0.010$, $p = 0.0883$; $\Phi_{ST} < 0.001$, $p = 0.5009$; χ^2 $p = 0.5466$) or the combined set of all samples collected north of the Aleutians ($F_{ST} = 0.005$, $p = 0.1488$; $\Phi_{ST} = 0.001$, $p = 0.3477$; χ^2 $p = 0.4049$).

Similar results were found in the microsatellite comparisons (Table 6). With one exception (Sakhalin versus all samples collected north of the Aleutians, Jost's $D = 0.0004$, $p = 0.1169$), all other comparisons between the ENP strata and the Sakhalin stratum were highly significant ($p < 0.001$ to $p = 0.002$). No significant differentiation was identified when strata within the ENP were compared.

Genetic Matches

Of the 380 samples genotyped, seven pairs of samples were identified that were collected in different areas and that shared identical microsatellite genotypes, mtDNA haplotypes, and sexes. These genetic matches included four matches between samples collected from the Sakhalin feeding ground and samples collected from southeastern Kamchatka, one match between an animal sampled off San Diego, California and an animal killed in the Chukotka hunt in Russia, and two matches between animals sampled off Sakhalin and animals sampled off the coast of southern California (Figure 1). The average probability of identity based on allele frequencies of all sampled animals was 1.35×10^{-8} (PID_{HW}) and 7.50×10^{-4} (PID_{SIB}) for the 8-loci dataset.

The individual match probabilities are shown in Table 7. For the 8-loci dataset, the individual match probabilities ranged from 6.74×10^{-4} to 1.24×10^{-3} (P_{SIB}) and 9.10×10^{-10} to 1.16×10^{-8} (P_{HW}). There were no samples that mismatched at only 1 allele but two pairs of samples were identified that mismatched at only 2 alleles and had identical mtDNA haplotypes and sexes. However, both pairs were part of the Sakhalin dataset analyzed in Lang *et al.* 2010, and when the 13-loci genotypes were compared the two pairs differed at 6 and 7 loci. Genotypes for the additional five loci are currently being generated for the Lang *et al.* 2011 dataset.

Although the 8-loci match probabilities assuming HW equilibrium were relatively low, the more conservative P_{SIB} measures are high, suggesting probabilities as great as 1 in 1000 that two individuals could share the same genotype by chance. Although P_{SIB} values are considered overly conservative in most cases (Rewe *et al.*, 2011), the genetic matches based on the 8-loci dataset should be considered only preliminary evidence of movements until the matches can be corroborated with the addition of more loci. However, although no photographs exist for the animal(s) included in the San Diego-Chukotka match, photographs were collected of the animals biopsied off Kamchatka. Comparison of these photographs to the Sakhalin photo-identification catalogue maintained by the joint Russia-U.S. research program verified that in all four cases the genetic matches represented samples collected from the same animal.

The two sets of matching samples identified between Sakhalin and southern California were genotyped at 13 loci. For both pairs, the genotypes were heterozygous for 10 of the 13 loci genotyped, and all other samples in the 13-loci dataset had genotypes that mismatched at five ($n=1$ pair) or more loci. Precautions, including replication of genetic profiles after re-extraction of the DNA from the tissue, were taken to ensure that the matching genotypes were not an artifact of lab error (detailed in Lang, 2010). The power of the microsatellite panel used to discriminate between individuals was high when the 13-loci dataset was analyzed ($PID_{HW} =$

8.65×10^{-14} ; $PID_{SIB} = 1.04 \times 10^{-5}$) and comparable to that used in other studies utilizing genetic tagging to infer movements of individuals between areas (*e.g.*, $PID_{ave} = 1.51 \times 10^{-7}$, Palsboll *et al.* 1997; $PID_{sib} = 2.8\text{--}3.11 \times 10^{-5}$, Pomilla and Rosenbaum 2005;). The more conservative estimates of the match probabilities (P_{SIB}) calculated from the gray whale microsatellite data suggest that the probability of finding two different animals with these identical genotypes is 1/50,000 (for the match between females) and 1/100,000 (for the match between males). The less conservative measures (P_{HW}) suggest that the probability is almost infinitesimally small. It is likely that the true probability lies somewhere between these two estimates, given that there is evidence for population structure in our data but it is unlikely that many full siblings were represented. Based on these considerations, the probability that the two sets of matching genotypes identified between the eastern and western North Pacific are an artifact of laboratory errors or a lack of resolution in the markers used is small.

Both of the biopsies from the ENP were collected during the same expedition. Sample #3947 was collected on 20 March 1995, and sample #3950 on 23 March 1995. Both samples were taken from whales in the Santa Barbara Channel off southern California, and the timing and location indicates that the samples were likely collected from animals which would have been migrating north after overwintering in the ENP. Although some video was taken during this sampling trip, it proved to be of too poor resolution to be useful in photographic comparisons. Sample #12186 was collected from an animal on the Sakhalin feeding ground on 14 August 1998. Photo-identification records link this whale to an animal that was first identified in that area on 19 August 1995. This male was sighted off Sakhalin during ten of the 12 seasons covered by the study. Sample #50728 was collected from a whale on the Sakhalin feeding ground on 27 August 2004. Photo-identification was used to link this animal to a whale first identified in that area in 1999. This female was then sighted off Sakhalin in all subsequent years of the study. Extensive photo and video documentation exists for both of these animals.

DISCUSSION

Population Structure –

The genetic signal of matrilineal fidelity among the whales sampled off Sakhalin is apparent both in the measures of mtDNA differentiation and in the distribution of haplotypes among individuals. Similar to the results of previous comparisons of samples collected in the WNP with samples obtained primarily from whales on migratory routes in the ENP (LeDuc *et al.*, 2002; Lang *et al.*, 2010), mtDNA comparisons between the Sakhalin stratum and strata comprised of animals feeding north of the Aleutians were highly significant. The magnitude of mtDNA differentiation between the Sakhalin stratum and the ENP strata (WNP v. North, $F_{ST}=0.086$, $p<0.0001$; Fisher's exact test, $p<0.0001$; WNP v. Chukotka, $F_{ST}=0.082$, $p<0.0001$, Fisher's exact test, $p<0.0001$) is greater than that seen in comparisons between whales utilizing different feeding grounds within the ENP (PCFG v. North, $F_{ST}=0.01$, $p=0.005$; Fisher's exact test, $p=0.008$; PCFG v. Chukotka, $F_{ST}=0.01$, $p=0.012$; Fisher's exact test, $p=0.030$; Lang *et al.*, 2011).

As has been previously described (LeDuc *et al.*, 2002; Lang *et al.*, 2010), the distribution of haplotypes among sampled individuals in the Sakhalin stratum is highly skewed, with two haplotypes found in very high frequencies, representing 36% and 31% of all animals sampled from that area. Given the maternal inheritance of mtDNA, this pattern would be expected if utilization of this area was driven in large part by the continued return over time of a small number of females and their offspring (and eventually their offspring's offspring). Examination of the haplotypes carried by sampled individuals revealed that 16 of the 23 known reproductive females identified between 1995 and 2007 (Weller *et al.*, 2008a) share one of these two common haplotypes (Lang, 2010), and known mother-calf pairs comprise a large proportion of animals with the two common haplotypes. Within any of the strata representing the ENP, there were no haplotypes found in frequencies greater than 14% of sampled individuals. This was also true of the PCFG, in which the three highest frequency haplotypes were found in 10 and 13% of sampled animals (Lang *et al.*, 2011).

Similar to results of previous comparisons of samples collected in the WNP with those obtained primarily from animals along the migratory route in the ENP (based on $n=13$ loci, Lang *et al.*, 2010), significant levels of

Do not cite without permission of authors

nuclear differentiation were also found between animals feeding north of the Aleutians and those feeding off of Sakhalin. Although highly statistically significant, the magnitude of nuclear differentiation was relatively low, which has led to speculation that some limited degree of dispersal or gene flow could be occurring between the WNP and ENP populations (LeDuc *et al.*, 2002; Lang *et al.*, 2010; Lang, 2010). However, the significant differences identified in both the mtDNA and the microsatellite comparisons indicate that the group of animals feeding off Sakhalin is not only demographically independent from animals feeding in the eastern North Pacific, but also that a degree of reproductive isolation is occurring. This differs from what has been reported thus far within the ENP (Lang *et al.*, 2011), where comparisons of microsatellite differentiation have suggested that animals feeding in different areas of the ENP may interbreed.

One limitation of this analysis is that all of the WNP samples were collected from animals on feeding grounds. A preliminary mtDNA analysis of six samples collected from gray whales (five females and one of unknown sex) which were stranded or entrapped in Japanese coastal waters found high haplotype ($h=0.933$) and nucleotide ($\pi=1.85\%$) diversity (Kanda *et al.*, 2010). No significant differentiation was found when these Japanese samples were compared to their samples ($n=7$) collected from whales taken in the hunt off Chukotka, although the small sample sizes used in the comparison limited the conclusions that could be drawn (Kanda *et al.*, 2010). One of the whales included in the analysis was the animal that was entrapped off the Pacific coast of Japan in January 2007 and that had previously been identified off Sakhalin. This animal has a haplotype (Haplotype 2 or B) which is common among animals sampled off Sakhalin. Although one of the other samples analyzed had a haplotype (Haplotype 1 or A) that is found in high frequencies among animals sampled off Sakhalin, the other four animals had haplotypes which have been identified in only one or two animals sampled off Sakhalin.

Movements –

Within the WNP, comparison of the genetic profiles of sampled animals indicates that four of the ten whales biopsied off southeastern Kamchatka were also sampled while on the Sakhalin feeding ground. These four genetic matches, which were confirmed photographically, include samples collected from two animals (one male and one female) first identified as calves on the Sakhalin feeding ground in 2007, indicating that these animals would have been ~3 years old when they were sampled off Kamchatka in 2010. The mother of one of these calves is also the mother of one of the animals first identified as a calf off Sakhalin and later photographed in the ENP (Weller *et al.*, 2011). The other two samples were collected from males first identified as non-calves off Sakhalin in 1994 and 1995. One of these males has also been photographed in the ENP (Weller *et al.*, 2011). The remaining six samples could not be matched to the genetic profiles of whales sampled off Sakhalin. These samples may represent animals that do not utilize the Sakhalin feeding ground, or they could be from animals known to feed off Sakhalin but from which no genetic sample has been collected. These results are consistent with patterns identified in photo-identification comparisons between southeastern Kamchatka and Sakhalin, in which 61 of the 116 animals identified off Kamchatka between 2004 and 2009 had also been sighted on the Sakhalin feeding ground (Tyurneva *et al.*, 2010). Photo-identification work has also documented the use of the southeastern Kamchatka area by young whales (Tyurneva *et al.*, 2010; Burdin *et al.*, 2011).

The detection of two pairs of matching samples between the ENP and WNP was more surprising. If these genetic matches do represent movements of individuals, they suggest that these animals, both of which are known to demonstrate fidelity to the western Pacific during the feeding season, have overwintered in the eastern Pacific for at least one season. Although the results presented here, as well as those from previous studies (LeDuc *et al.*, 2002; Lang *et al.*, 2010), have confirmed that the eastern and western gray whale populations are genetically differentiated, the relatively low level of differentiation observed at nuclear markers suggested that some degree of dispersal of eastern animals onto the western feeding ground may occur (Lang *et al.* 2010, Lang, 2010). In the past, this dispersal was hypothesized to have been mediated largely by males, as supported by observations that the majority of haplotypes found in only one or two individuals are represented only by males (LeDuc *et al.*, 2002; Lang *et al.*, 2010) as well as by the lower levels of differentiation found when only males were compared between ENP and WNP strata (Lang, 2010). However, the putative movements associated with these genetic matches suggest that both males and females

Do not cite without permission of authors

may travel between these two areas. Other factors, such as age and oceanographic conditions, may also influence any movements.

In addition, the female associated with sample #50728 is a known reproductive female and was identified (both behaviorally and genetically) as the mother of three calves between 2003 and 2007. Although two of her calves were not assigned a putative father among the sampled western animals in the paternity analysis, her 2007 calf was assigned a putative father that has been sighted regularly on the Sakhalin feeding ground (Lang, 2010). The paternity analysis assigned the male associated with sample #12186 as the putative father of a calf born in 2007 (Lang, 2010). This calf was one of the two animals first identified as calves off of Sakhalin which were genetically and photographically matched to the southeastern coast of Kamchatka in 2010. This evidence suggests that both of the whales sampled off Sakhalin interbred at least one time with other animals which feed in the WNP.

Even if all 130 of the animals which feed off Sakhalin were to have visited the eastern Pacific during the study period, it would seem unlikely that one of the western animals would have been sampled given the size of the eastern population and the relatively low proportion of animals sampled in the eastern Pacific. If samples obtained from stranded or harvested animals in the ENP prior to 1995 ($n=24$) are excluded, samples were obtained from only 203 individuals in the ENP during the period of time (*i.e.*, in 1995 or later) in which an animal identified on the western feeding ground could have feasibly been sampled (Table 1). Only 48 of these samples were collected via biopsy-darting, while the rest were collected from animals which were stranded, hunted, or taken in fishing gear. The probability of sampling one of ~ 130 Sakhalin animals among an estimated 19,000 eastern gray whales is approximately $1/150$; assuming the two events are independent, the probability of capturing two Sakhalin animals is approximately $1/22500$. These probabilities would be even lower if only a small number of the animals identified in the WNP travel to the ENP.

However, if the genotype matches do represent dispersal of whales between Sakhalin and the ENP, the short time span over which the two samples were collected in the ENP raises questions about the independence of the two events. One possible explanation is that some segregation takes place on the migratory route relative to the feeding location. Southbound migration timing has been correlated with feeding ground origin in North Atlantic humpback whales (Stevick *et al.*, 2004), which utilize two different feeding areas but a common breeding area in the West Indies. Animals that fed in the Gulf of Maine and eastern Canada had earlier mean sighting dates in the West Indies than did animals known to feed in Greenland, Iceland, and Norway, suggesting that the migration from feeding area to breeding area might be segregated. Although stratification of the gray whale migration relative to age, sex, and reproductive status is known to occur (Rice & Wolman 1971), no additional mechanisms for segregation have been identified.

Weller *et al.* (2011) presents the results of a comparison between the Sakhalin photo-identification catalogue and a catalogue of whales photographed in the Pacific Northwest that is maintained by Cascadia Research Collective. The results of this photographic comparison were similar in several regards to the findings from the genetic comparison. Six animals that were photographed off Sakhalin were also identified in the Pacific Northwest during months (late April and early May, when field efforts in this area are relatively low) when the animals would have been migrating north. Three of the animals were photographed on one day, while the other three were photographed on another day, further suggesting that some segregation with respect to feeding ground origin may occur on the northbound migration. The combined findings indicate that, despite the low probability of sampling or photographing one of ~ 130 Sakhalin animals while the majority of the 19,000 whales comprising the eastern population are migrating, as many as eight animals have been either photographed or sampled despite relatively low field effort. These results suggest that the potential for photographing or sampling a Sakhalin whale, at least while on the northbound migration, is higher than would be expected based on the assumption of random intermixing of animals with eastern versus western summer destinations.

While estimates of genetic differentiation support demographic independence and a degree of reproductive isolation between whales feeding in the WNP and the ENP, information from tagging¹, photo-identification comparisons (Weller *et al.*, 2011), and genetic comparisons suggest that some of the animals summering off

Sakhalin overwinter in the ENP in at least some years. Conception in gray whales is thought to primarily occur during a three week period from late November to early December (Nov 27 – Dec 13), although if no conception occurs during this first period, a second estrus may occur about 40 days later when whales are on or near their wintering grounds (Rice & Wolman, 1971). Rugh *et al.* (2001) estimated that the median (peak) sighting date for the southbound migration in the ENP is 12 December for Unimak Pass, Alaska, suggesting that many animals from the ENP are north of the Aleutians during the first mating period. With the exception of the 13 year-old male (“Flex”) that was tagged off Sakhalin this past fall and remained off northeastern Sakhalin until early December⁵, little is known about the current migratory timing of and route(s) used by any whales traveling between Sakhalin and the ENP. However, it is plausible that animals making this journey would be relatively far west during the first mating period, suggesting a mechanism by which some degree of reproductive isolation could develop between animals feeding off Sakhalin and those feeding in eastern areas even if they shared a common wintering destination.

Recent records of gray whales off Japan, however, indicate that some whales remain in the WNP during winter months. Since 1955, there have been 19 reports of gray whales in Japanese waters, most of which (n=13) occurred in 1990 or later (Kato *et al.*, 2010). These reports span the months of November through August, although the majority (n=11) were recorded between March and May, when animals would likely be migrating north. At least one of the whales, an approximately one year old female that was entrapped off the coast of Honshu in January 2007, is known to have also visited Sakhalin with her mother the summer prior to her entrapment (Weller *et al.*, 2008b). Although it is not known what proportion of the other gray whales reported in Japanese waters were also animals that visited Sakhalin, this link indicates that not all of the gray whales feeding off Sakhalin show fidelity to wintering destinations in the ENP.

These observations suggest that population structure in gray whales may be more complex than previously thought, such that animals utilizing the Sakhalin feeding ground may not all share a common wintering ground. Photo-identification and genetic studies of humpback whales in the North Pacific have revealed similar, albeit more complicated, patterns (Calambokidis *et al.*, 2008; Baker & Steel, 2010). Significant differences in mtDNA haplotype frequencies (overall $F_{ST} = 0.179$) have been used to define 7 different “eco-stocks” among the feeding grounds. Differences in both mitochondrial and nuclear DNA have also been used to delineate five reproductive units or “breeding stocks” on the wintering grounds (overall $F'_{ST} = 0.034$ for nuclear comparisons, Baker & Steel, 2010). However, some feeding grounds (e.g., Kodiak) are comprised of individuals from different breeding stocks (Calambokidis *et al.*, 2008).

Conclusion

Although questions remain about the movements of Sakhalin gray whales when they are not on the feeding range, the significant mtDNA and nuclear genetic differences between animals utilizing the Sakhalin feeding ground and those summering in the ENP support the continued recognition of the Sakhalin animals as a distinct unit. Additional satellite tagging of Sakhalin gray whales, along with continued collection and analysis of photo-identification and genetic data, especially from Japan, is needed to address these questions. If some proportion of the animals that feed off Sakhalin overwinter in the ENP, then the number of animals remaining in the WNP year-round may be smaller than previously estimated, and the impact of potential threats to this group of animals may be greater than predicted. As such, learning more about migratory routes and wintering grounds in the WNP should be a priority of future work.

ABSTRACT

Although most eastern North Pacific (ENP) gray whales feed in the Bering, Beaufort, and Chukchi Seas during summer and fall, a small number of individuals, referred to as the Pacific Coast Feeding Group (PCFG), show intra- and interseasonal fidelity to feeding areas from northern California through southeastern Alaska. We used both mitochondrial DNA (mtDNA) and 12 microsatellite markers to assess whether stock structure exists among feeding grounds used by ENP gray whales. Significant mtDNA differentiation was found when samples representing the PCFG ($n = 71$) were compared with samples ($n = 103$) collected from animals feeding further north ($F_{ST} = 0.012$, $P = 0.0045$). No significant nuclear differences were

¹Corresponding author (e-mail: aimee.lang@noaa.gov).

detected. These results indicate that matrilineal fidelity plays a role in creating structure among feeding grounds but suggests that individuals from different feeding areas may interbreed. Haplotype diversities were similar between strata ($b_{\text{PCFG}} = 0.945$, $b_{\text{Northern}} = 0.952$), which, in combination with the low level of mtDNA differentiation identified, suggested that some immigration into the PCFG could be occurring. These results are important in evaluating the management of ENP gray whales, especially in light of the Makah Tribe's proposal to resume whaling in an area of the Washington coast utilized by both PCFG and migrating whales.

Key words: *Eschrichtius robustus*, gray whale, population structure, mitochondrial DNA, microsatellites, demographic independence.

A single stock of gray whales (*Eschrichtius robustus*) is currently recognized in U.S. waters (Carretta *et al.* 2013). This stock, which is referred to as the eastern North Pacific (ENP) stock, is estimated to contain approximately 19,000 individuals (Laake *et al.* 2009). Most of these whales feed in the Bering, Beaufort, and Chukchi Seas during summer and fall and then migrate south along the coast of North America to overwinter in the lagoons and coastal waters of Baja Mexico. However, a small number of individuals feed in more southern waters from northern California through southeastern Alaska during summer and fall (Gilmore 1960; Pike 1962; Hatler and Darling 1974; Darling 1984; Calambokidis *et al.* 2002, 2012). Photo-identification research, which commenced in the early 1970s and continues to date, has identified a subset of whales that have returned to this southern feeding ground in multiple years and account for the majority of sightings in the area during summer and fall months (Hatler and Darling 1974; Darling 1984; Calambokidis *et al.* 2002, 2012). These whales are referred to as the Pacific Coast Feeding Group (PCFG; IWC 2011a). Recent estimates of annual abundance suggest that the PCFG includes approximately 200 animals (Calambokidis *et al.* 2012). Although PCFG whales account for the majority of sightings on this southern feeding ground during summer and fall, the area is also used by whales that are encountered in the region following the migration (*e.g.*, after 1 June) but are seen in only one year (Calambokidis *et al.* 2012). These individuals are generally seen for shorter time periods and in a more limited area than are PCFG whales, and they may represent stragglers from the larger group of animals that migrate through the southern feeding ground on their way to feeding areas further north (Calambokidis *et al.* 2012).

The PCFG includes some animals that were first identified as calves with their mothers on the southern feeding ground and that have returned to feed in the area in subsequent years (Calambokidis *et al.* 2012). This pattern of behavior, which is often called matrilineal fidelity, likely results from calves learning the location of suitable feeding/calving grounds from their mothers. Matrilineal fidelity to feeding and/or calving areas has been documented in other baleen whales (*e.g.*, Gulf of Maine humpback whales, Clapham and Mayo 1987; southern right whales, Valenzuela *et al.* 2009). Understanding patterns of matrilineal fidelity may be important in shaping management decisions, as it is thought that the lack of recovery or repopulation of baleen whales in some areas heavily impacted by commercial whaling is related to the loss of knowledge of where suitable habitat is located (Clapham *et al.* 2008).

Concern for PCFG whales has arisen in part from recent interest in the resumption of whaling by the Makah Tribe in northwest Washington, an area used by virtually all migrating whales as well as by foraging whales considered part of the PCFG. The current proposal by the Makah Tribe includes time/area restrictions designed to

reduce the probability of killing a PCFG whale by focusing hunt effort on the much larger group of whales migrating to/from feeding areas further north. However, PCFG whales are present during the migratory season, and it is impossible to ensure that no PCFG whales would be killed. The Makah Tribe also proposes to compare photographs of any whales harvested in the hunt to a photo-identification catalog of known PCFG whales and to suspend the hunt if needed to prevent the number of PCFG whales harvested from exceeding the annual allowable bycatch level for that year (IWC 2011b).

Evaluating whether any kills would, over time, have the potential to deplete the PCFG requires an understanding of how individuals are recruited into the group. If recruitment into the area is exclusively internal, such that use of the area is driven by calves learning the location of feeding grounds from their mothers, then a PCFG individual that is removed would not be replaced by immigration. However, if recruitment is largely external, then it is possible that any takes from the PCFG could be offset by immigration into the PCFG by whales that in previous years fed in northern areas. As aforementioned, some PCFG individuals were first identified as calves on the feeding ground and have returned to the area to feed in subsequent years. However, the origin of other individuals is unknown, and “new” (previously unidentified) noncalf whales are identified each year, some of which have returned to the southern feeding ground in subsequent years (Calambokidis *et al.* 2012). Although these whales may be individuals who were “missed” as calves (*e.g.*, not identified as a calf or not photographed that season), they could also represent whales that previously fed further north but now demonstrate fidelity to the PCFG range.

Genetic studies have provided some insight into mechanisms of recruitment into the PCFG. Initial work utilizing a simulation-based approach indicated that if the PCFG originated from a single recent colonization event in the past 40–100 yr, with no external recruitment into the group, detectable mtDNA genetic differentiation would be generated (Ramakrishnan and Taylor 2001). Subsequent empirical analysis, however, failed to detect such a signal when comparing 16 samples collected from PCFG whales using Clayoquot Sound, British Columbia, with samples ($n = 41$) collected from individuals presumed to feed in more northern areas (Steeves *et al.* 2001). More recently, Frasier *et al.* (2011) used mtDNA to compare samples collected from 40 individuals considered part of the PCFG with published data generated from 105 samples collected from ENP gray whales, most of which stranded along the migratory route (LeDuc *et al.* 2002). All haplotypes identified among the PCFG samples were also found in the larger ENP sample set, and haplotype diversity found in the PCFG ($h = 0.93$) was lower than, but similar to, that found among the samples representing the larger ENP population ($h = 0.95$). However, significant differences in estimates of long-term effective size and mtDNA haplotype frequencies were identified between the two groups. These results suggest that matrilineally directed fidelity plays a role in use of this area, and the authors concluded that the PCFG should be recognized as a distinct management unit (Frasier *et al.* 2011).

One limitation of previous genetic studies on the PCFG is that they utilized samples primarily collected from gray whales that stranded while on the ENP migratory route as representative of the larger ENP population in their comparisons. Although the likelihood that any of these stranded animals were part of the PCFG is low given the large size of the ENP gray whale population, this possibility could not be ruled out based on the location where most of the ENP samples were collected. More importantly, the limited number of samples available from the feeding ground(s)

north of the Aleutians precluded previous studies from making a direct comparison between animals utilizing different feeding grounds.

At the end of the feeding season, PCFG whales are thought to join the southbound migration to Mexican waters and have therefore been presumed to interbreed with the larger ENP population (Calambokidis *et al.* 2002, 2012). Earlier genetic studies of the PCFG relied exclusively on mtDNA, however, and the assumption that PCFG whales interbreed with gray whales feeding in other areas was not assessed. Conception in gray whales is thought to occur primarily during a 3 wk period between late November and early December (27 November to 13 December), although if no conception occurs during this first period, a second estrus may occur about 40 d later when whales are on or near their wintering grounds (Rice and Wolman 1971). Rugh *et al.* (2001) estimated that the median (peak) sighting date for the southbound migration is 12 December for Unimak Pass, Alaska, suggesting that many gray whales would be north of the PCFG seasonal range during the first mating period and raising the possibility that some segregation in breeding could occur with respect to feeding ground origin.

Here we contribute to the understanding of stock structure of gray whales by (1) comparing samples collected from gray whales feeding north of the Aleutians with samples collected from PCFG whales to directly address whether structure exists among feeding grounds used by ENP gray whales, and (2) using nuclear markers ($n = 12$ microsatellites) to test the assumption that PCFG whales interbreed with whales from other feeding grounds. We also increased the number of samples collected from PCFG whales and, for those samples linked to photographed individuals, were able to further refine our representation of the PCFG by incorporating sighting histories of known individuals in the comparisons. Although other scenarios are possible, here we test the following three hypotheses:

(1) No population structure (*e.g.*, panmixia) is present among feeding grounds used by ENP gray whales; individuals move between feeding areas and exhibit random mating. This hypothesis would be supported by a finding of no nuclear or mitochondrial differentiation between samples from PCFG whales and those collected from animals feeding further north.

(2) Utilization of feeding areas is influenced by internal recruitment, with calves following their mothers to feeding grounds and returning in subsequent years. Mating is random with respect to feeding ground affiliation. This hypothesis would be supported by a finding of significant differences in mtDNA haplotype frequencies when comparing samples from PCFG whales with those collected from animals feeding further north, but no significant differences in microsatellite allele frequencies between these groups.

(3) Utilization of feeding areas is influenced by matrilineal fidelity and mating is not random with respect to feeding ground affiliation. This hypothesis would be supported by a finding of significant differences in both mtDNA haplotype and microsatellite allele frequencies.

METHODS

Samples

The initial sample set consisted of 277 samples collected between 1994 and 2010, with collection locations ranging from northern California to Barrow, Alaska and

Chukotka, Russia (Fig. 1, Table S1). Although some samples were collected from individuals taken as part of a subsistence hunt off Chukotka ($n = 75$ samples) or from stranded individuals ($n = 17$), the majority of samples ($n = 185$, including all samples collected between northern California and British Columbia, Canada) were collected as biopsies from free-ranging individuals. During biopsy sample collection, efforts were made to obtain a photograph of each biopsied whale. These photographs were compared to a photo-identification catalog maintained by Cascadia Research Collective and containing photo-identification images primarily collected between 1998 and 2009. This catalog focuses on the PCFG whales but also includes some migrating whales that were photographed in the spring (March through May) during their northward migration.

Linking biopsy samples to photographed whales allowed the sighting history of individuals to be evaluated when determining which samples should be used to represent the PCFG whales. As noted earlier, whales utilizing the PCFG's seasonal range fall into two categories: (1) whales that return frequently and account for the majority of sightings, and (2) apparent stragglers from the migration that are sighted in only one year (Calambokidis *et al.* 2012). To ensure that our PCFG stratum was representative of the first category of whales, samples were screened using two criteria: (1) the sample had to be linked to a photo-identified animal, and (2) the photo-identified

Figure 1. Locations where samples were collected, with key areas mentioned in the text labeled.

animal to which the sample was linked had to have been sighted in two or more years within the defined season (1 June to 30 November) and area (between 41°N and 52°N, in concordance with the boundaries used by the International Whaling Commission's Scientific Committee, IWC 2012) representative of PCFG whales. Samples collected on the southern feeding ground but not meeting these criteria ($n = 36$) were removed prior to data analysis, leaving 113 samples collected from whales considered to represent the PCFG in the sample set.

Samples collected from gray whales on the northern feeding area were stratified in two ways. First, all samples collected from whales that were north of the Aleutian Island chain between June and November were included in a "North" stratum ($n = 128$). This stratification assumes that whales use the northern feeding area in a relatively uniform manner, such that sampling location within this area does not matter. However, little is known about whether gray whales exhibit fidelity to smaller regions within the northern feeding area. If multiple feeding aggregations exist north of the Aleutians, then sampling location within that larger area is important. Although the original design of the study was to have a stratum representing Chukotka, Russia, and a stratum representing Barrow, Alaska, the sample size for the latter ($n = 14$ individuals) was insufficient to characterize genetic frequencies from that area. As such, we were unable to directly address hypotheses about whether additional structure exists north of the Aleutian Islands. However, we did include a comparison of the PCFG stratum to the Chukotka stratum ($n = 75$ samples) to avoid including unrecognized heterogeneity in our representation of animals feeding in the north.

Laboratory Processing

DNA extraction, PCR amplification and sequencing—Genomic DNA was extracted from samples using either sodium chloride protein precipitation (Miller *et al.* 1988) or silica-based filter purification (Qiaxtractor DX reagents, Qiagen, Valencia, CA) following the manufacturers' instructions. Extractions were performed on a JANUS automated work station (Perkin-Elmer, Waltham, MA). MtDNA sequences for eight of these samples had been generated previously for another study (LeDuc *et al.* 2002); however, to provide consistent quality control, these samples were resequenced for our analyses. The 5' end of the hyper-variable mtDNA control region was amplified from extracted genomic DNA, using the polymerase chain reaction (PCR) and the primers used in the LeDuc *et al.* (2002) study (H00034, Rosel *et al.* 1994; L15812, Chivers *et al.* 2005). DNA was amplified using a 25 μ L reaction of ~ 100 ng DNA, 1 \times PCR buffer (50 mM KCl, 10 mM Tris-HCl, pH 8.3, and 1.5 mM MgCl₂), 0.6 mM dNTPs, 0.3 μ M primers, and 0.25 units of Taq DNA polymerase (New England BioLabs, Inc.). The PCR cycling profile consisted of 90°C for 2 min, followed by 35 cycles of 94°C for 50 s, an annealing temperature of 60°C for 50 s, and 72°C for 1 min, then a final extension of 72°C for 5 min. Sequencing of amplified products followed standard techniques (Saiki *et al.* 1988, Palumbi *et al.* 1991), and both strands of the amplified DNA product were sequenced independently on an Applied Biosystems, Inc. (ABI) model 3730 sequencer. If a sample was identified as having a mtDNA haplotype that was not found among any of the other samples, mtDNA amplification and sequencing were replicated to confirm the haplotype identity. All sequences were aligned using Sequencher v4.8 (Gene Codes Corp. 2000), resulting in final sequences that were 523 base pairs long.

Nuclear DNA processing—Twelve microsatellite loci isolated from other cetacean species were used to genotype the samples (see Table S2): EV14, EV37, and EV94

(Valsecchi and Amos 1996); Gata028, Gata098, Gata417, and Gt023 (Palsbøll *et al.* 1997); RW31 and RW48 (Waldick *et al.* 1999); and SW10, SW13, and SW19 (Richard *et al.* 1996). For all reverse primers except those amplifying Gata098 and EV37 (which failed to amplify with modified primers), the primer sequence was modified from the original design by placing the sequence GTTCTT on the 5' end to facilitate complete adenylation and thus more consistent scoring (Brownstein *et al.* 1996). Forward primers were fluorescently labeled. Extracted DNA was amplified using a 25 μ L reaction of \sim 100 ng of DNA, 1 \times PCR buffer (50 mM KCl, 10 mM Tris-HCl, pH 8.3, and 1.5 mM MgCl₂), 0.6 mM dNTPs, 0.3 μ M primers, and 0.5 units of Taq DNA polymerase (New England BioLabs, Inc.). The PCR cycling profile included 90°C for 2.5 min, followed by 35 cycles of 94°C for 45 s, 1 min at the optimal annealing temperature (see Table S2), and 72°C for 1.5 min, then a final extension of 72°C for 5 min. Only one locus was amplified per reaction, and each PCR product was assessed electrophoretically on a 2% agarose gel for size and quality before loading onto an ABI 3730 Genetic Analyzer. ABI GeneMapper software (version 4.0) was used along with an internal size standard (GeneScan-500 ROX, ABI) to determine allele fragment size. Two positive control samples were included on each plate to ensure consistent sizing between runs.

Sex determination—Samples were genetically sexed by amplification and Real-Time PCR (MX3000p, Stratagene Inc.) of the zinc finger (ZFX and ZFY) genes. Samples from one male and one female for which sex had been determined *via* examination of a stranded animal were included as positive controls in all amplifications. Sex was determined by the amplification pattern: males had two products and females had one (Morin *et al.* 2005).

Analysis

Data review—Quality control and sample tracking procedures, as detailed in Morin *et al.* (2010), were implemented during data generation. A randomly chosen set of samples, representing 13% of all samples processed, was sequenced, sexed, and genotyped a second time, and these records were reviewed for consistency. For the microsatellite data, replicate and original genotypes were compared, and a per-allele error rate was calculated by determining the number of discrepant allele calls divided by the total number of allele calls compared across all loci. In addition, all microsatellite genotypes were scored independently by two experienced genotypers. The allele calls from each genotyper were compared, and calls that did not match were reviewed jointly by both genotypers. Inconsistencies that could not be resolved upon review were treated as missing data.

After genotyping of samples was complete for eight of the twelve loci (EV14, EV94, Gata028, Gata417, Gt023, RW31, SW13, and SW19), the program GENE-CAP (Wilberg and Dreher 2004) was used to calculate the probability that two randomly chosen individuals would share the same multilocus genotype under both the assumption of Hardy-Weinberg equilibrium (PID_{HW} , Paetkau and Strobeck 1994) and under the more conservative assumption that full siblings may be present within the data set (PID_{SIB} , Waits *et al.* 2001). Samples with identical genotypes, indicating that they may have been collected from the same animal, were flagged for further review. These sample pairs were checked to see if they also shared the same mtDNA haplotype and sex, and, when possible, photo-identification records were used to confirm the genetic match. For all samples that shared identical mtDNA haplotypes, sexes, and nuclear genotypes at the eight loci, one sample from each pair

was removed and then the remaining samples were genotyped at the additional four loci prior to further analysis.

After genotyping at all 12 microsatellite loci was complete, the data set was reviewed to identify samples that were missing data for $\geq 25\%$ of the markers; these samples were considered to be of poor quality and were removed prior to further analysis. The program MSTOOLS (Park 2001) was used to identify any additional samples whose genotypes matched at eight or more loci (using the full 12 microsatellite data set) and thus might represent duplicate samples that were not detected in the earlier analysis. Deviations from Hardy-Weinberg equilibrium (HWE) were assessed for each locus using Genepop (version 4.0.11, Rousset 2008). Both the probability test (Guo and Thompson 1992) and the test for heterozygote deficiency (Rousset and Raymond 1995) were conducted using the program defaults for the Markov chain parameters (10,000 dememorization steps, 20 batches, 5,000 iterations/batch). Genepop was also used to test for linkage disequilibrium (LD) for each pair of loci. All tests were run for the combined data set as well as for each stratum. The false discovery rate (FDR) adjustment (Benjamini and Hochberg 1995) was used to control for multiple testing when the results of the HWE and LD analyses were assessed.

Genetic diversity—For the mtDNA data, nucleotide (π) and haplotype (h) diversities (Nei 1987) were calculated using Arlequin 3.1 (Excoffier *et al.* 2005). To look for phylogeographic patterns among the mtDNA data, the software package Network 4.5.1.0 (available at <http://www.fluxus-engineering.com/sharenet.htm>) was used to generate a median-joining network of haplotypes using the algorithm of Bandelt *et al.* (1999). For the microsatellite data, the number of alleles per locus and observed and expected heterozygosities (Nei and Roychoudhury 1974) were calculated using custom code (eiaGenetics²) written in the statistical programming language R (R Core Development Team 2009).

Genetic structure—Pairwise estimates of genetic divergence were calculated using both F_{ST} (Weir and Cockerham 1984) and the AMOVA Φ_{ST} (Excoffier *et al.* 1992) for the mtDNA data using Arlequin v3.1 (Excoffier *et al.* 2005). For the Φ_{ST} pairwise distance calculations, the program jModelTest v2.1.4 (Guindon and Gascuel 2003, Posada 2008, Darriba *et al.* 2012) was used to select the best nucleotide substitution model based on the Akaike Information Criterion (AIC). Statistical significance was assessed using 10,000 permutations. Fisher's exact test (Raymond and Rousset 1995) was also used to test for mtDNA differentiation between strata using Arlequin 3.1 (Excoffier *et al.* 2005); 10,000 replications were used to test for significance. For the microsatellite data, F_{ST} (Weir and Cockerham 1984), F'_{ST} (Hedrick 2005, Meirmans 2006), and a χ^2 test were used to assess genetic differentiation using custom R-code (eiaGenetics). Statistical significance was determined from 5,000 permutations of each data set.

RESULTS

Data Review

Fourteen samples (including 11 samples collected from stranded whales) did not produce useable mtDNA sequence data and also failed to amplify at >4 microsatellite

²Available on request from E. Archer at eric.archer@noaa.gov.

loci; these samples (identified as “poor quality” samples) were removed from all subsequent analyses and data review (Table S1, S3).

Based on the genotypes of the remaining samples ($n = 227$) at the initial eight loci, the probability of two individuals possessing the same multilocus genotype was 9.08×10^{-9} for unrelated individuals (PID_{HW}) and was 6.97×10^{-4} for full siblings (PID_{SIB}), indicating that the microsatellite loci were adequate for identifying unique individuals. These samples were screened for duplicates (*i.e.*, samples considered to be from the same animal) after genotyping of the first eight loci was complete. Fifty samples had microsatellite genotypes that were identical to at least one other sample in the data set. In all cases, the mtDNA haplotypes and sexes of each pair also matched. Forty-two of the duplicate samples were identified in the PCFG stratum; 74% of these ($n = 31$) were confirmed to be the same animal using photo-identification records. All 50 duplicate samples were removed from further analysis. No movements of animals between regions representing different strata were identified based on genetic matches (*i.e.*, all samples sharing identical genetic profiles were part of the same stratum). The number of unique individuals ($n = 177$) remaining after removal of duplicates is shown in Table S3.

The proportion of missing genotypes at each locus was $\leq 2\%$ for all loci (Table S2). Using the samples randomly selected for replication, a per-allele error rate of 0.11% was detected for the full microsatellite data set. After controlling for the FDR, no loci demonstrated significant deviations from HWE for either the probability test or the test for heterozygote deficiency. One pair of loci (EV94-SW19) showed significant linkage disequilibrium (LD) in the Chukotka and the North strata, while three pairs of loci (EV14-Gt023, EV94-RW48, and EV94-Gata098) demonstrated significant LD in the PCFG stratum. All loci were retained in subsequent analyses.

Further review of the microsatellite data set did not identify any samples that were identical for ≥ 7 loci. Two samples amplified at ≤ 8 loci and were removed from the microsatellite analyses, leaving a total of 175 unique individuals for the microsatellite analyses. These samples did produce useable mtDNA sequence data and were thus retained in that data set.

No discrepancies were identified when the replicated and original mtDNA haplotype sequences were compared. The mtDNA haplotype could not be resolved for three of the 177 individuals, and these individuals were removed from the mtDNA data set but retained in the microsatellite data set. Sex was determined for all of the 177 individuals.

Genetic Diversity

Thirty-six mtDNA haplotypes defined by 36 variable sites were identified among the 174 individuals for which mtDNA haplotypes were resolved (Table 1). Thirty-two (NCBI Accession numbers AF326789–326824) of these haplotypes had been previously identified in LeDuc *et al.* (2002). The frequency of each haplotype in the defined strata (including Barrow) is shown in Table 2. Nineteen haplotypes were shared between the North and the PCFG strata, with four haplotypes found only in the PCFG. For all strata, many haplotypes were found in only one individual ($n = 13$ haplotypes in the North, $n = 12$ haplotypes in Chukotka, and $n = 8$ haplotypes in the PCFG, including three of the haplotypes found only in the PCFG). Haplotype diversity (h) was high in all strata defined for the analysis (0.945–0.953). Nucleotide diversity (π) was also similar among the three defined strata (0.0144–0.0154). The median-joining network shows the relationship among mtDNA haplotypes and their

Table 1. Number of mtDNA control region haplotypes, haplotype diversity (\pm SE), and nucleotide diversity (\pm SE) within each stratum.

Strata	No. of samples	No. of haplotypes	Haplotype diversity (h)	Nucleotide diversity (π)

^aSamples from Chukotka are included as part of the North stratum.

frequency in each stratum (Fig. 2). MtDNA haplotypes from both Chukotka and the PCFG are dispersed throughout the network, and no phylogeographic pattern was apparent.

A summary of nuclear diversity for each microsatellite locus is shown in Table S2. Measures of nuclear diversity for each stratum after averaging across loci are shown in Table 3. As in the comparisons of mtDNA haplotype and nucleotide diversity, nuclear diversity was similar across all strata. Nine alleles were found only among whales that were part of the North stratum (six of these were from Chukotka), and three alleles were identified only among PCFG whales.

Figure 2. Median-joining network showing relationships among the mtDNA haplotypes. The numbers next to the nodes correspond to the haplotype IDs listed in Table 4. The size of the nodes is proportional to the frequencies of the haplotypes, and each node is shaded to indicate the fraction of individuals with that haplotype from each strata. The small black diamonds (unlabeled) indicate haplotypes that were inferred by the program but were not found among our samples. The length of lines connecting nodes is proportional to the inferred number of mutations separating haplotypes; for all haplotypes separated by more than one mutation, hash marks are used to represent the number of mutational events.

Table 3. Estimates of the number of alleles, observed heterozygosity (H_o), and expected heterozygosity (H_e) averaged across loci within each stratum for the microsatellite data. The genotypes of two samples that were used in the mtDNA analysis were removed because they amplified for ≤ 8 loci.

Strata	No. of samples	Mean number of alleles	Mean H_o	Mean H_e
North ^a	105	8.75	0.72	0.73
Chukotka	70	8.33	0.73	0.73
PCFG	70	8.00	0.74	0.73

^aSamples from Chukotka are included as part of the North stratum.

Sex Ratio

All strata were comprised of more females than males, with ratios of 1.4 females per male in each stratum (Table S3). This female bias is similar to that (1.47 females per male) described in Frasier *et al.* (2011). Although the female bias was not significantly different from the expected 1:1 ratio in any of the strata, when all samples were combined the female bias was significantly different from parity ($\chi^2 = 5.43$, $P < 0.05$).

Genetic Structure

The results of the mtDNA comparisons are shown in Table 4a. The Tamura and Nei model of nucleotide substitution (Tamura and Nei 1993) with invariant sites (TrN + I) was selected as the most appropriate model of sequence evolution and was used in calculating Φ_{ST} . When the PCFG stratum was compared with the North stratum, significant differences in mtDNA haplotype frequencies were detected using F_{ST} and the exact test ($F_{ST} = 0.012$, $P = 0.0045$; Fisher's exact test $P = 0.0067$), but no significant differences were found in the Φ_{ST} comparison ($\Phi_{ST} = 0.012$, $P = 0.0740$). Statistically significant differences were detected in all mtDNA comparisons of the PCFG stratum with the Chukotka stratum ($\Phi_{ST} = 0.020$, $P = 0.0386$; $F_{ST} = 0.010$, $P = 0.0348$; Fisher's exact test $P = 0.0254$). None of the comparisons across strata utilizing the microsatellite data were significant (Table 4b).

DISCUSSION

Given that PCFG whales share the same migratory routes and wintering grounds used by other ENP whales, it has generally been thought that PCFG whales interbreed with whales that feed further north (*e.g.*, Calambokidis *et al.* 2002, 2012). Here we were able to test that assumption directly by using microsatellite markers to compare PCFG whales with whales feeding north of the Aleutians. No significant nuclear differences between the two groups were identified, indicating that gray whales feeding in these areas likely represent a single interbreeding population. Significant differences in mtDNA haplotype frequencies were identified between the PCFG and northern feeding whales, however, suggesting that some structure exists among

Table 4. Results of pairwise comparisons across strata using (a) mtDNA and (b) 12 microsatellites. Comparisons that are statistically significant are shown in bold.

Pairwise comparison	Φ_{ST}	<i>P</i> -value	F_{ST}	<i>P</i> -value	Fisher exact test <i>P</i> -value
(a)					
North ^a (103) <i>vs.</i> PCFG (71)	0.012	0.0740	0.012	0.0045	0.0067
Chukotka (69) <i>vs.</i> PCFG (71)	0.020	0.0386	0.010	0.0349	0.0254
Pairwise comparison	F_{ST}	<i>P</i> -value	F_{ST}'	<i>P</i> -value	χ^2 <i>P</i> -value
(b)					
North ^a (105) <i>vs.</i> PCFG (70)	0.000	0.5269	0.000	0.5271	0.3491

^aSamples from Chukotka are included as part of the North stratum.

feeding grounds used by ENP gray whales. Within the PCFG, this finding is concordant with photo-identification records that indicate that many animals first identified as calves return to the PCFG feeding area in subsequent years (Calambokidis *et al.* 2012). When combined, these findings are consistent with the second proposed hypothesis, and suggest that while mating is random with respect to feeding ground affiliation, utilization of feeding areas is influenced by internal recruitment.

The results of our mtDNA comparisons are similar to those presented in Frasier *et al.* (2011), who also found evidence of maternally driven structure when comparing samples from whales that were considered to represent the PCFG with a sample set comprised primarily of animals that stranded along the migratory route in the ENP. All of the samples utilized in the Frasier *et al.* (2011) study to represent the PCFG were collected from whales in Clayoquot Sound, which is located off the central west coast of Vancouver Island, British Columbia. In contrast, 89% of the samples representing the PCFG in this study were collected from animals in the waters off northern California, Oregon, and Washington, with only 12 samples (11%) collected off southern Vancouver Island. While the majority of PCFG whales photographed off southern Vancouver Island (52%) and northern Washington (60%) have also been sighted off western Vancouver Island, interchange between more distant areas (*e.g.*, comparison of northern California and western Vancouver Island) has been documented less frequently (Calambokidis *et al.* 2012). In addition, while some whales are known to move throughout the range of the PCFG, sightings of other whales are concentrated within subareas (Calambokidis *et al.* 2012), suggesting that individual gray whales may not use the range of the PCFG randomly. Thus while there is likely overlap among the individuals sampled in Frasier *et al.* (2011) and the current study, neither represents random sampling across the range of the PCFG. In the future, the collection of additional samples from whales in the northern portion of the PCFG range and/or integration of our sample set with that utilized by Frasier *et al.* (2011) would provide more evenly distributed sample coverage throughout the range of the PCFG and could provide insight into whether additional substructuring within the PCFG exists.

Despite the fact that the estimated abundance of the PCFG is roughly 1% of that of the ENP population as a whole, the haplotype diversity identified in the PCFG is similar to that found among strata representing the larger ENP population. This high haplotype diversity seems inconsistent with what might be expected if the PCFG was founded by a small number of individuals and has remained isolated (*e.g.*, all recruitment into the group is internal) for many generations. Under such a scenario, the mtDNA haplotypes carried by founders that were males or nonreproducing females would be lost over time, while haplotypes found in successfully reproducing females and their returning offspring would build to higher frequencies, resulting in reduced haplotype diversity in the group. However, the mtDNA haplotype diversity found within the PCFG, as well as the significant but relatively low level of mtDNA differences identified between the PCFG and northern feeding whales, could suggest that colonization of the PCFG range occurred relatively recently. Under this scenario, strong mtDNA differences between PCFG whales and individuals feeding further north may have had insufficient time to develop, and the number and distribution of haplotypes in the PCFG would not have been strongly affected by genetic drift. Little is known about the history and origin of the PCFG. Gray whales have been recorded feeding in the southern portion of the PCFG range as early as 1926, when a single gray whale, which was reported to have been feeding with four other whales, was taken by the Trinidad whaling station off the entrance to the Crescent City Harbor

in July (Howell and Huey 1930). Additional sightings of whales within the PCFG range during summer and fall were reported in the 1940s, 50s, and 60s (Gilmore 1960, Pike and MacKaskie 1969, Rice and Wolman 1971). The repeated return of individual whales to the area was first documented starting in the 1970s (Hatler and Darling 1974, Darling 1984). This time period marked the beginning of photo-identification studies for gray whales, and thus it is unknown if fidelity to the PCFG area occurred prior to this time or if the sightings recorded earlier were of animals that only visited the area during a single feeding season.

It is unclear what oceanographic conditions would have been present during the last century that would have precipitated use of the PCFG feeding area. Pyenson and Lindberg (2011) reconstructed the carrying capacity of gray whales over the past 120,000 yr by quantifying what feeding habitats would have been available during that time. They hypothesized that gray whales survived glacial fluctuations during the Pleistocene by employing generalist filter-feeding strategies that allowed them to take advantage of alternative food sources and feeding areas, similar to foraging strategies and areas used by PCFG whales today (*e.g.*, Darling *et al.* 1998, Dunham and Duffus 2001). More recently, access to the Bering Sea feeding areas would have been limited by heavy ice during parts of the “Little Ice Age” (*ca.* 1450–1850). Even if the PCFG seasonal range was colonized prior to the start of commercial whaling, this group of animals may have been greatly depleted or eliminated prior to the end of commercial whaling. Thus, it is plausible that the PCFG range may have been colonized multiple times in the past as a response to environmental changes and/or to depletion due to whaling.

The low level of mtDNA differentiation and high diversity are also consistent with a scenario in which matrilineal fidelity plays a role in determining use of the PCFG area but in which external recruitment also occurs. Given that the migratory route for whales traveling to the northern feeding ground(s) passes through the PCFG range, such recruitment could take place if migrating whales encounter a productive source of food within the PCFG range, remain in the area for the remainder of the season, and return in subsequent years (Calambokidis *et al.* 2002, 2012). External recruitment would slow the accumulation of genetic differences between PCFG whales and individuals feeding further north. Also, external recruits (at least initially) would likely carry haplotypes not previously identified among PCFG individuals, increasing the number and diversity of haplotypes found as well as the proportion of haplotypes currently shared between the PCFG and the animals feeding north of the Aleutians. Examination of the photo-identification data provides some information relevant to evaluating whether external recruitment into the PCFG could be occurring. Although photo-identification studies of the PCFG started in the early 1970s (Hatler and Darling 1977, Darling 1984), consistent efforts covering a larger portion of the PCFG seasonal range did not begin until 1998 (Calambokidis *et al.* 2012). Between 1998 and 2010, “new” (*i.e.*, previously unidentified) noncalf whales continued to be identified in the PCFG area each year, and many of these whales returned to the area in subsequent years (mean = 11 whales per year, 2002–2009, northern California to northern British Columbia; Calambokidis *et al.* 2012). It is unknown what proportion of these new whales could be immigrants into the group (*e.g.*, external recruits) and what proportion may be animals that were internally recruited but were not identified as calves during their first year (*e.g.*, “missed calves”). Although the number of calves identified on the PCFG range each year is low (mean = 3 calves per year, range 0–9, 2002–2009, northern California to northern British Columbia), calves may wean from their mothers as early as June or July, making them difficult to

identify as calves (*vs.* yearlings or young animals) and leading to underestimates of the number of calves present (Calambokidis *et al.* 2012). Indices of gray whale calf production based on estimates of the number of northbound calves past Piedras Blancas, California, are highly variable and averaged 4.3% (calf estimate/total population estimate, range 1.55%–6.8%) between 1994 and 2000 (Perryman *et al.* 2002). These estimates are likely high relative to the total number of gray whale calves that survive the full migration, as mortality of calves due to killer whale predation is known to occur in areas north of Piedras Blancas, including Monterey Bay, California (see summaries in Jefferson *et al.* 1991, Ford and Reeves 2008), an area that both PCFG and ENP whales traverse while migrating. While it is unknown how these estimates relate to calf production among PCFG whales, applying these indices to a group of 200 animals would result in a mean of 9 calves per year (range 3–13 calves per year).

In addition, comparison of nine whales photographed off Barrow, Alaska in 2006 and 2010 with the photo-identification catalog of animals identified within the PCFG range resulted in two matches (Calambokidis *et al.* 2012). One of these animals was photographed off Vancouver Island during March on a single occasion and thus may have been migrating through the area and would not be considered part of the PCFG. The second animal, however, had previously been sighted in multiple years during summer/fall in the PCFG area. While the significance of this match is difficult to interpret given the limited photo-identification data available from Barrow, it does indicate that at least this one individual has utilized more than one feeding ground during its lifespan.

Based on the genetic results presented here, it is not possible to determine the extent of immigration into the PCFG that could occur while still allowing mtDNA differences to be detected. While dispersal can be indirectly estimated from F_{ST} values (Wright 1931), the assumptions (*e.g.*, equal population sizes, equilibrium) of the underlying model are unlikely to be valid in wild populations (Whitlock and McCauley 1999). In addition, if the PCFG was isolated from the rest of the ENP population in the past, then the underlying level of genetic divergence would be related to the length of time the two groups had been separated and their effective sizes (Nei and Chakravarti 1977). As the underlying level of genetic divergence increases, the amount of recent immigration that could occur without obscuring the signal of mtDNA differentiation also increases. This highlights the fact that there are multiple scenarios (*e.g.*, colonization histories, number of founders, and immigration rates) that could lead to the pattern of mtDNA differentiation seen in the comparisons of the PCFG and the ENP samples. Given the information that is currently available, we are not able to discriminate among these possibilities.

A remaining question is whether additional structure exists within the northern feeding area. If there is no structure on the feeding grounds north of the Aleutians, then the northern strata (both “North” and “Chukotka”) could be considered representative of the genetic diversity of whales feeding throughout the northern feeding area and the mtDNA differences observed here would be driven by fidelity of individuals to the PCFG seasonal range. However, if structuring is present among northern feeding areas, then the differences demonstrated here may be influenced by fidelity of individuals in either or both areas (PCFG and Chukotka). While the results of photo-identification studies of the PCFG are consistent with the occurrence of some internal recruitment, the collection of additional samples from northern feeding areas would be valuable in further elucidating the mechanisms creating the observed differences and in evaluating whether structuring is present among whales utilizing the northern feeding grounds.

Implications for Management

Understanding recruitment into the PCFG is relevant to management under the Marine Mammal Protection Act (MMPA). The goal of the MMPA is to maintain population stocks as functioning elements of their ecosystem. The National Marine Fisheries Service (2005) considers stocks to be demographically independent units, such that the population dynamics of the affected group is more a consequence of births and deaths within the group (internal dynamics) rather than of immigration or emigration (external dynamics). This definition is similar to that described for management units by Palsbøll *et al.* (2007) and for a population under the ecological paradigm by Waples and Gaggiotti (2006).

Traditionally, the most commonly used approach to evaluate demographic independence using genetic data has been null hypothesis testing, in which significant divergence of allele frequencies between groups is considered evidence supporting the delineation of separate management units (Moritz 1994). This approach assumes that if the migration rate is large enough to lead to demographic dependence, then genetic comparisons will not be able to reject the null hypothesis. Under this criterion, our findings support recognition of the PCFG of gray whales as demographically independent based on the significant differences in mtDNA between the PCFG and whales feeding further north.

Critical to our understanding of whether two groups are demographically independent, however, is the rate of dispersal between them. As noted in Waples and Gaggiotti (2006), there is no general framework for determining at what dispersal rate populations become demographically correlated, although it has been suggested that demographic correlation occurs when the proportion of immigrants in a group is greater than 10% (Hastings 1993). However, simulations have shown that, at least in cases where multiple microsatellite loci are used, it may be possible to reject panmixia even when dispersal rates are higher than this level (Palsbøll *et al.* 2006, Waples and Gaggiotti 2006). These results suggest that while genetic comparisons like those conducted here can provide insight into demographic connectivity, they should be interpreted carefully and integrated with other available information on the demography of the groups being considered (Lowe and Allendorf 2010).

When the significant mtDNA differences identified between the PCFG and the northern feeding strata are put into context with the other available evidence, questions arise about the balance between internal recruitment and external immigration. The significant mtDNA differences, as well as the observations of animals first identified as calves returning to the PCFG (Calambokidis *et al.* 2012), indicate that internal recruitment into the group occurs. However, the low level of mtDNA differences identified, the similarity in haplotype diversities between the PCFG and other groups thought to represent the larger ENP population, and the continued identification of “new” whales each year (Calambokidis *et al.* 2012) suggest that external immigration into the group may also be taking place. While other explanations (*e.g.*, recent colonization and a high rate of “missed” calves) exist that could be consistent with demographic independence of the PCFG, discriminating between these explanations is not currently possible.

Although uncertainty remains, our results indicate that it is plausible that the PCFG represents a demographically independent group and suggest that caution should be used when evaluating the potential impacts of the proposed Makah harvest on this group of animals. Continued monitoring of the PCFG, including the collection of additional photographs and genetic samples, is warranted. Future work

should focus on estimating dispersal rates and levels of internal recruitment in the PCFG. The lack of differentiation in nuclear markers identified in our study limits the use of some approaches (e.g., assignment tests) commonly used to estimate dispersal. However, with the collection of additional samples from PCFG whales, a parentage-based approach, similar to that used by Peery *et al.* (2008), may be valuable in documenting internal recruitment into the group and thus in assessing the demographic independence of the PCFG.

ACKNOWLEDGMENTS

This work was supported by the Southwest Fisheries Science Center, National Marine Fisheries Service, National Oceanic and Atmospheric Administration; the Northwest Regional Office, National Marine Fisheries Service, National Oceanic and Atmospheric Administration; and by a Species Recovery Grant to Tribes. Samples utilized in this project were collected under MMPA permit #14097 granted to the Southwest Fisheries Science Center, permit #14366 granted to the National Marine Mammal Laboratory, permit #540-1811 granted to John Calambokidis of Cascadia Research Collective, permit # 369-1757 granted to Bruce Mate of Oregon State University, and permit #38 granted by the Russian agency Rosprirodnadzor to the Kamchatka Branch of the Pacific Geographical Institute of Russian Academy of Sciences on 6 April 2010. Samples collected in Russian waters were imported under CITES permit #1OUS77422319, held by the Southwest Fisheries Science Center. SUPPORTING INFORMATION

The following supporting information is available for this article online at <http://onlinelibrary.wiley.com/doi/10.1111/mms.12129/supinfo>.

Table S1. Samples used in the study, including the SWFSC accession number, GeneticID, collection method (B = biopsy, H = harvest, S = stranding), date of collection, location of collection, strata, and whether the sample was retained in the final analysis. Samples were removed because they were considered duplicates (code 1), due to poor quality (code 2), or because they could not be assigned to a stratum (code 3, which includes whales that were sampled in the PCFG range but did not meet the criteria for being included in the PCFG stratum). GeneticID represents a unique identifier for individuals, such that samples that were considered to be from the same individual were assigned the same GeneticID. The strata specified include: North, CHK (Chukotka), PCFG, and South. Samples considered part of the CHK stratum were also included in the North stratum in the analyses. The South stratum includes samples collected from whales within the PCFG seasonal range but which did not meet the criteria for being classified as PCFG whales (see text for further explanation).

Table S2. Characteristics of the microsatellite loci used in the study, including the species for which primers were initially designed, the size of repeats, the annealing temperature used in the study (T_a), the reference listing primer sequences, the number of alleles per locus, the proportion of missing genotypes, the expected heterozygosity (H_e), the observed heterozygosity (H_o), and the results of the test for heterozygote deficiency (HWE; Rousset and Raymond 1995).

Table S3. The total number of samples in each stratum, the number of samples removed from the study due to poor quality (see criteria described in text), the number of duplicate samples removed, and the number of individuals remaining in each stratum for each analysis. Duplicate samples (*i.e.*, samples from the same individual) were identified based on genotyping of eight microsatellite loci. Samples collected on the southern feeding ground but not considered to represent the PCFG ($n = 36$) are not included in the table.

Genetic differences between western and eastern gray whales (*Eschrichtius robustus*)

ABSTRACT

Molecular data were used to examine the differentiation between the western and eastern gray whale (*Eschrichtius robustus*) populations. Control region sequences were generated from samples collected in the western Pacific ($n=45$) and eastern Pacific ($n=120$). There were 36 unique haplotypes identified. Ten haplotypes were represented in the western samples, and 33 in the eastern samples. Seven of these haplotypes were shared between populations, leaving three haplotypes that were only seen in the western samples and 26 only in the eastern. Although there were no fixed (diagnostic) differences between the western and eastern groups, they were significantly different in their haplotype frequency distributions and should be considered as separate populations. None of the 33 haplotypes found in the eastern samples had a frequency of over 11%, yielding an estimated haplotypic diversity of 0.95. This finding indicates that the reduction in abundance due to whaling may not have had a great effect on the haplotypic diversity of the eastern population, although the loss of rare haplotypes may still have occurred and would be difficult to detect. In contrast, the western group was dominated by two haplotypes, which represented over 77% of all individuals sampled, resulting in a substantially lower haplotypic diversity of 0.70. The lack of fixed differences between the two populations and frequency of shared haplotypes renders these data inappropriate for forensic applications at the population level.

KEYWORDS: GRAY WHALE; GENETICS; POPULATIONS; CONSERVATION; NORTH PACIFIC

INTRODUCTION

Although the gray whale (*Eschrichtius robustus*) once occurred in both the North Atlantic and North Pacific, it became extinct in the Atlantic several hundred years ago (Mead and Mitchell, 1984), is severely depleted in the western Pacific (e.g. Weller *et al.*, 2002), and was greatly reduced in the eastern Pacific before its recovery (IWC, 1998). Currently, gray whales are considered as two separate management stocks living along the eastern and western boundaries of the North Pacific. While both were reduced by historical whaling, only the eastern gray whale has recovered to near pre-exploitation levels (IWC, 1998). The western gray whale was thought to be extinct as recently as the early 1970s (Bowen, 1974) but is known to survive today as a remnant population (see review in Weller *et al.*, 2002). Although studies of the behaviour and biology of both eastern and western gray whales have been conducted (see Swartz *et al.*, 2000 for review), questions about the level of genetic differentiation between eastern and western gray whales, or how their exploitation may have affected genetic diversity, have remained largely unaddressed. Contemporary gene flow between them is not likely in that the geographic distributions do not overlap, and the migratory routes are disjunct and lead to opposite sides of the North Pacific basin. However, the possibility of dispersal has yet to be tested with genetic data. If gene flow is negligible or non-existent and the stocks have differentiated genetically since becoming allopatric, an additional question is whether they have diverged enough to allow individual whales from unknown localities (e.g. market samples of meat) to be characterised as eastern or western. As part of an ongoing US-Russia research project studying western gray whales in the Okhotsk Sea, biopsy samples have been routinely taken from animals summering off Sakhalin Island, Russia (Weller

et al., 2002). In addition, many samples are available from the eastern gray whale population. Together, these datasets provide an opportunity to characterise the genetic makeup of eastern and western gray whales and to quantify their degree of differentiation.

MATERIALS AND METHODS

Samples from the western population were obtained as biopsies from free-ranging animals on their summer feeding grounds off the northeastern coast of Sakhalin Island, Russia, primarily during 1998 and 1999. Since the biopsied animals were photographed at the time of sampling, cross-matching with the photo-identification catalogue (Weller *et al.*, 1999) enabled the removal of duplicate samples prior to sequencing, giving a total of 42 samples. Three biopsy samples from the same study area were collected in 1995 (Brownell *et al.*, 1997). In the absence of identification photographs, these were only added to the western samples after microsatellite analysis (not described) confirmed they were not from individuals sampled in 1998-1999. This resulted in a total of 45 western samples. A total of 120 eastern samples were collected from many localities between southern California and the Chukotka Peninsula in Russia. These samples were taken primarily from strandings, as well as a few from directed subsistence takes, fishery bycatch and biopsies of living whales. A similar check of individual identity was not done for the eastern North Pacific samples due to the lack of a comprehensive photo-identification catalogue. However, given that over 90% of the eastern samples were collected from dead animals, and given an estimated population size of over 26,000 (Rugh *et al.*, 1999), the effect of any possible duplicate sampling is negligible.

In addition to these samples, sequences of a 361 base pair (bp) segment of the mitochondrial control region from two gray whales that were sampled in Japan (M. Goto and L. Pastene, pers. comm.) are used here in our discussion of the gray whale market samples sequenced by Baker *et al.* (2002). One whale stranded on the eastern side of Hokkaido in 1995 (Anon., 1997), and the other was an animal harpooned in the Sea of Japan off western Hokkaido in 1996 (Brownell and Kasuya, 1999). These sequences were not used in the population genetic analyses.

Using standard protocols, DNA was extracted from each sample, and a 523 bp region of the 5' end of the mitochondrial control region was amplified and sequenced. The primers used for amplification and sequencing were 5'-TACCAAATGTATGAAACCTCAG-3' (Rosel *et al.*, 1995) and 5'-CCTCCCTAAGACTCAAGGAAG-3' (designed at SWFSC). Haplotypic diversity was calculated using the computer program Arlequin (Schneider *et al.*, 2000), which was also used to calculate the divergence between populations with F_{ST} , ϕ_{ST} (an F_{ST} analogue) and χ^2 , as well as to create a minimum spanning tree based on the number of differences between haplotypes. Haplotypic diversity (h) is calculated by the formula $h = 1 - \sum p_i^2$, where p_i is the frequency of the i^{th} haplotype (Nei, 1987).

RESULTS

A total of 36 haplotypes defined by 37 variable sites were found among the 165 samples examined. Thirty-three of these haplotypes occurred in eastern samples and 10 in the western samples; seven haplotypes were shared between the two samples. Fig. 1 shows the minimum spanning network of the 36 haplotypes. Fig. 2 shows the frequencies of the different haplotypes in the eastern and western samples. Haplotypic diversity differed greatly with the eastern samples showing a diversity of 0.95 ± 0.01 and the western samples having a value of 0.70 ± 0.05 . The average percent difference (i.e. nucleotide diversity) between individuals differed little, with the eastern samples averaging 1.6% sequence difference from each other and the western samples averaging 1.7%. The average percent difference for between-population pairwise comparisons was 1.9%. In genetic studies, one must be cautious that some results, such as the much lower level of diversity found in the western gray whale population, are not caused by inadequate or biased sampling. However, it is doubtful that this is the case here. The 120 eastern samples actually represent a much lower overall proportion of the eastern gray whale population than the 45 samples do from the western population, which may number less than 100 animals (e.g. see Weller *et al.*, 2002). Therefore, the probability of there being appreciable amounts of unsampled variation in the western population is relatively low, despite the smaller number of samples. Finally, examination of the degree of genetic sub-division between the eastern and western samples indicated that they are significantly different from each other ($\phi_{ST} = 0.117$, $p < 0.001$; $\chi^2 = 65.9$, $p < 0.001$; $F_{ST} = 0.087$, $p < 0.001$).

DISCUSSION

The results presented here show that the eastern and western gray whales are genetically differentiated at the population level. The significant difference found between the two populations and the negligible levels of gene flow that it implies, agrees well with their very different recovery histories; dispersal, that is significant in any management

Fig. 1. Minimum spanning tree of the 36 haplotypes from this study. Numbers beside circles indicate the number of individuals having that haplotype in western (light gray) and eastern (dark gray) sample sets. Circles without numbers indicate haplotypes only represented by single individuals. The scale gives number of changes along connecting branches.

sense should not be expected to occur. However, the statistical population differentiation arises primarily from differences in haplotypic frequencies (Fig. 2) and reflected in their respective haplotypic diversity indices. The populations have apparently not been isolated for a sufficiently long period of time for the shared haplotypes to be removed via genetic drift, and therefore no diagnostic character or characters within the 523 bp region can be reliably used to distinguish one population from another, or to determine the source of a gray whale of unknown affinity (e.g. a forensic analysis of market meat). The case could be made that if a test animal has a haplotype unique to the eastern samples, then it probably arose from there, since the absence of that haplotype in the western population is based on a fairly thorough sampling scheme (perhaps 50% of the population sampled so far). However, the converse (a test animal having a haplotype unique to the western sample set being from the Okhotsk Sea population) is more difficult to

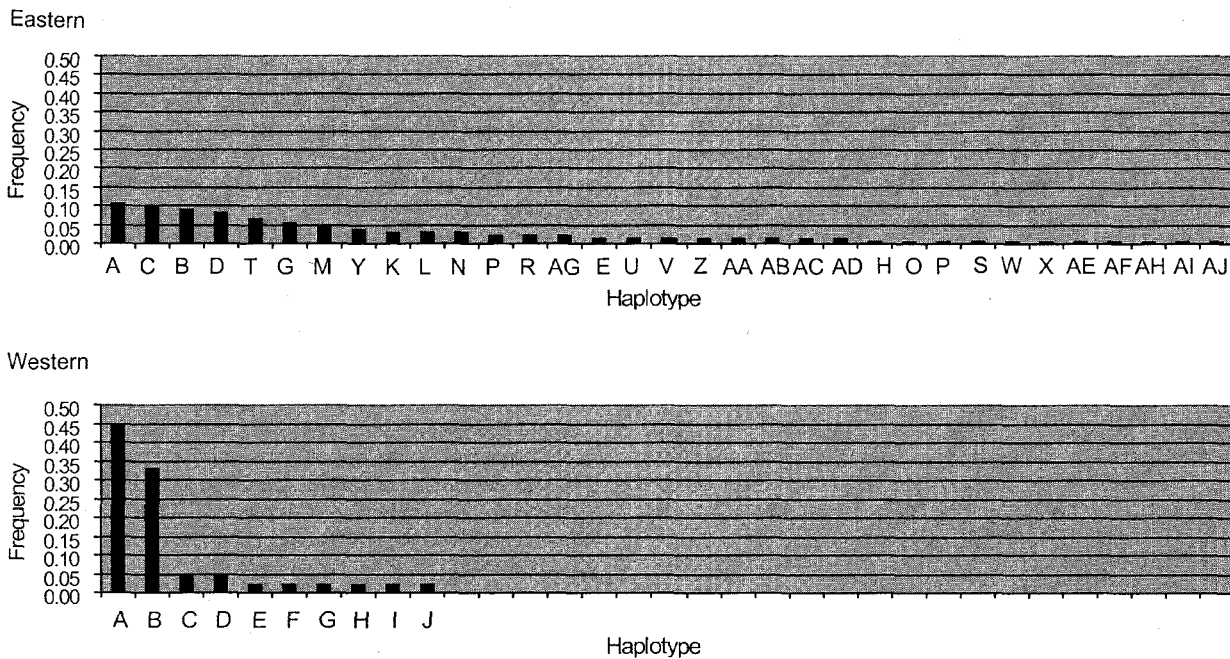

Fig. 2. Frequency distributions of haplotypes in each of the gray whale populations.

argue, since the very high diversity in the eastern population allows for the presence of many unsampled haplotypes. Although the genetic differences between the populations are modal rather than absolute, the differentiation is large, and demographically they should be treated as isolated population units, especially for management purposes as they have been and are by the International Whaling Commission (e.g. IWC, 1998).

The differences between the two populations in their haplotypic diversities may reflect differences in their past levels of abundance and effects of exploitation. Haplotypic diversity (h) is affected by both the numbers of haplotypes present in the population and their relative frequencies, with numerous haplotypes and equal frequencies both serving to increase the value of h . In the present dataset, the differing values of h arise primarily from the differences in haplotype frequency distributions, which differed dramatically between the two populations (Fig. 2). In the eastern samples, the most common haplotype was only represented in 10.8% of the individuals, and seven of the 33 haplotypes were represented in over 5% of the samples. The overall effect is one of a fairly even frequency distribution of haplotypes. In contrast, the two most common haplotypes in the 45 western samples were represented by 20 (44.4%) and 15 individuals (33.3%), with the remaining eight haplotypes appearing in single animals or in pairs. If the 10 western haplotypes were evenly distributed in the sample set, h_{west} would increase from 0.70-0.90, but an equivalent redistribution of the 33 eastern haplotypes would only increase h_{east} from 0.95-0.97. In other words, given the differences in sample sizes, the western and eastern sample sets contained comparable numbers of haplotypes, albeit with very different frequency distributions.

The haplotypic diversity value (0.95) calculated for the eastern samples in the present dataset is similar to the value (0.94) found by Steeves *et al.* (2001) in their study of 57 samples of eastern gray whales. These relatively high values for contemporary eastern gray whales seem to indicate that there was little loss of genetic variation in this population due to historical whaling. However, it is possible that some

loss of diversity due to whaling may have occurred without a reduction in haplotypic diversity. In the calculation of haplotypic diversity, the frequencies of haplotypes are squared, so that the resulting value of h is not greatly affected by the occurrence or number of rare haplotypes, those contained in the population in very low frequencies. Therefore, although the eastern sample set contained 11 haplotypes only represented by single samples, the loss of other rare haplotypes cannot be ruled out.

In the western population, the lower haplotypic diversity value may be, but is not necessarily, a result of whaling. The lower value for the western animals may be related to their history of overexploitation, but it is also consistent with a smaller long-term effective population size (N_e). The amount of diversity that a population can maintain is directly determined by its N_e , which for the haplotypic and uniparentally-inherited mitochondrial genes, is approximately one-quarter of the N_e of nuclear genes. Although there are no reliable estimates for the pre-exploitation size of the western gray whale population, it was very likely to have been smaller than the eastern population (Weller *et al.*, 2002). Furthermore, the ten haplotypes found in the western sample set are not closely related to each other. Indeed, the two dominant western haplotypes (A and B) are very different from each other (Fig. 1). In a statistical sense, the occurrence of relatively few, but quite divergent, haplotypes explains why the western population exhibits an equal level of average sequence divergence when compared to the eastern population, despite its lower haplotypic diversity. Biologically, this pattern is consistent with either a loss of haplotypes due to long-term genetic drift or a whaling-induced bottleneck.

Although the haplotypic diversity is lower in the western population, the fact that 10 haplotypes still remain in a population this small is encouraging. It may indicate that a considerable amount of variation is still contained within the gene pool. In comparison, only five haplotypes have been observed in the western North Atlantic population of right whales, currently estimated at approximately 300 individuals (Malik *et al.*, 2000). However, the retention of 10

haplotypes in the western gray whale population has some relevance to another important issue, namely whether or not the western population is recovering. Weller *et al.* (2002) estimated that less than 50 of the western gray whales are mature, and that the current sex ratio of this population is approximately 60% male:40% female. This translates into an estimate of approximately 19 reproductive females; probably even less according to Weller *et al.* (2002). The recovering eastern population has been estimated to have had a maximum growth rate of 3.3% per year (for the interval 1967/68 to 1987/88), even higher if the aboriginal take of approximately 180/yr was taken into account (IWC, 1998). Applying a 3.3% recovery rate, and assuming that there are 19 reproductive females today in the western population, there would have been only about six reproductive females in the western population when whaling ended in 1966. That is an extremely unlikely scenario considering that there were still 10 extant western haplotypes in 1999, two of which are now in very high frequency. Even if there had been ten reproductive females extant in 1966, each with a different haplotype, reproductive success would have had to be extremely skewed towards two of those matrilineages.

There are a number of possible explanations for this many haplotypes persisting in such a small population. First, the current abundance estimate could be low. However, photographic identification data (Weller *et al.*, 1999; 2002) do not support the existence of an appreciably greater abundance off Sakhalin Island, although a still undiscovered feeding area cannot be ruled out. A second possibility is that the population has grown much more slowly than 3.3% since 1966 (i.e. the bottleneck was not as severe as six, or even ten, reproductive females). Although this scenario would bode well for the level of genetic diversity still contained in the population, it would nonetheless have serious implications for their viability. If the population in 1966 contained much more than six adult females, it raises the possibility that the population has only been holding steady or even continuing to decline since then rather than recovering. In other words, a population the size of the western gray whales that has been growing since 1966 would not be expected to contain as many as 10 haplotypes. These sub-optimal population trajectories suggest the existence of some yet to be determined source of mortality (e.g. bycatch in fisheries, direct kills, vessel strikes, etc.) or other impediment to recovery (e.g. habitat degradation as reviewed in Weller *et al.*, 2002).

Another possibility is that there is some dispersal from the eastern stock. In general, the gene pool of a small population is strongly influenced by even trivial amounts of gene flow from a larger neighbour, and the significant differences found between these populations would seem to contradict this possibility. However, given the maternal inheritance of the mitochondrial data examined here, male dispersal could still occur but would have little or no long-term effect on haplotype distributions (and mitochondrial differentiation). Indeed, of the eight western haplotypes represented by only one or two individuals, only two (*E* and *H*) came from females, with the remaining six only represented by males. Future work using microsatellite data may be able to test hypotheses of male dispersal. Because of the higher diversity and number of haplotypes in the eastern population, animals dispersing into the western population are most likely to carry haplotypes considered rare in the west (i.e. ones other than 'A' or 'B'). Animals with these rare haplotypes could be the focus of microsatellite-based assignment tests (e.g. Paetkau *et al.*, 1995), to see if they show greater affinity to

the eastern population than do the rest of the western animals. However, since it is the number of females that seems to have dropped to critical levels at present (Weller *et al.*, 2002), any influx of males that may occur would not be of immediate benefit to the western population, although it would mitigate any effects of inbreeding and loss of diversity in the nuclear genome. Overall, the present findings that the mitochondrial differentiation between eastern and western gray whales is large and female dispersal is negligible at best, coupled with the paucity of females in the western population (Weller *et al.*, 2002), underscores the critical status of the western gray whales (e.g. see IWC, 2002).

Based on molecular identification, Baker *et al.* (2002) determined that seven commercial market products purchased in Wakayama Prefecture, Japan in August and October 1999 were samples of gray whale meat. They noted that all seven products had the same haplotype as a GenBank gray whale sequence (Accession #L35611), from a whale sampled off the coast of Washington, USA. The GenBank sequence and the sequences from the Wakayama gray whale products are all identical to our haplotype 'A' (Figs 1 and 2), the most common haplotype in both the eastern and western sample sets (10.8% and 44.4%, respectively). The sequences are also identical to the sequence provided to us by M. Goto and L. Pastene (pers. comm.) for the whale harpooned off Hokkaido in 1996 (Brownell and Kasuya, 1999), the whale also referred to as the 'Suttsu' whale by Baker *et al.* (2002). This haplotype is shared between the two populations and it is not possible to definitively assign the Wakayama meat samples (or any given gray whale sample) to either population using mitochondrial sequence data. Nevertheless, given the match, and the apparent butchering of the carcass (Brownell and Kasuya, 1999), a reasonable explanation is that the meat from the Wakayama market originated from the whale harpooned off Hokkaido. This explanation can be tested by analysing both samples using microsatellite data, or any other molecular data that allow the genotyping of individual whales. Finally, the sequence sent to us by M. Goto and L. Pastene (pers. comm.) from the 1995 stranding in eastern Hokkaido matched both haplotype 'G' and 'O' of our dataset (the shorter sequence sent by Goto and Pastene did not include the variable sites that distinguish haplotype 'G' from haplotype 'O').

In summary, results presented here show that eastern and western gray whales can be genetically differentiated at the population level, and should be recognised as geographically isolated and demographically closed population units. However, because of shared haplotypes, it is not possible at this time to genetically identify an individual sample to either population. Furthermore, the presence of 10 western haplotypes in a population this small is inconsistent with a population that has undergone any appreciable growth.

ACKNOWLEDGEMENTS

We would like to thank the many organisations and people who provided us with tissue samples from the eastern population. In the NMFS Southwest Regional Stranding Network, the following groups provided tissue: Hubbs-Sea World, The Marine Mammal Center, Moss Landing Marine Laboratory, University of California Berkeley and Humboldt State University. In the Northwest and Alaska Regional Stranding Networks, the following provided samples for this study: Oregon State University, Cascadia Research Cooperative, National Marine Mammal Lab, Alaska Department of Fish and Game, and K. Wynne of the

University of Alaska Fairbanks. We also thank T. Steeves of the National Zoological Park in Washington, D.C. for providing biopsy samples. In addition, we also thank the observers and ship captains in the California gillnet observer programme who collected samples from fishery bycatch. Lastly, we thank S. Blokhin for the samples of eastern gray whales collected in Chukotka, Russia.

Thanks to the following people that helped collect western gray whale samples off Sakhalin Island, Russia: S. Blokhin, A. Bradford, Y. Ivashchenko, R. Pitman, S. Reeve, A. Trukhin and G. Tsidulko. Thanks also to V. Vladimirov for assistance with permits. Funding for the 1995 work was provided by the Bureau of Oceans and International Environmental and Scientific Affairs, US Department of State to the International Whaling Commission; National Marine Fisheries Service, NOAA; and the Humane Society of the United States. We gratefully acknowledge the financial support of Sakhalin Energy Investment Company and Exxon Neftegas Limited to Texas A&M University and the Kamchatka Institute of Ecology and Nature Management for related work on western gray whales between 1997-1999. The Russian State Committee of Environmental Protection in Moscow issued CITES export permits for the Russian samples. This project was conducted as part of the Marine Mammal Project under Area V: Protection of Nature and the Organisation of Reserves within the US-Russia Agreement on Cooperation in the Field of Environmental Protection 1972. We would also like to thank Doug DeMaster at the Alaska Fisheries Science Center for supporting preliminary genetic work on this project. Thanks also to B. Amos and an anonymous reviewer for their helpful comments. Haplotype sequences have been deposited in GenBank, Accession #AF326789-AF326824. This paper represents contribution no. 77 of the Marine Mammal Research Program, Texas A&M University.

Western North Pacific gray whales (WGWs), once considered extinct, are critically endangered with unknown migratory routes and reproductive areas. We attached satellite-monitored tags to seven WGWs on their primary feeding ground off Sakhalin Island, Russia, three of which subsequently migrated to regions occupied by non-endangered eastern gray whales (EGWs). A female with the longest-lasting tag visited all three major EGW reproductive areas off Baja California, Mexico, before returning to Sakhalin Island the following spring. Her 22 511 km round-trip is the longest documented mammal migration and strongly suggests that some presumed WGWs are actually EGWs foraging in areas historically attributed to WGWs. The observed migration routes provide evidence of navigational skills across open water that break the near-shore north–south migratory paradigm of EGWs. Despite evidence of genetic differentiation, these tagging data indicate that the population identity of whales off Sakhalin Island needs further evaluation.

1. Introduction

Gray whales (*Eschrichtius robustus*) occur in both the eastern and western North Pacific Ocean [1]. Considered separate populations, both were severely depleted by commercial whaling. Eastern gray whales (EGWs) have recovered and are now thought to be near carrying capacity [2]. Western gray whales (WGWs), once thought to be extinct, currently number approximately 130 individuals and are listed as critically endangered by the International Union for Conservation of Nature [3]. Historically, widely ranging along the Asian coast, contemporary WGW aggregations are known primarily from summer feeding grounds off Sakhalin Island (SI), Russia [4]. WGWs were thought to winter off southern China [4], but current winter reproductive areas and migratory corridors are unknown. Here, we use satellite-monitored tracking data to conduct the first investigation of WGW migratory corridors and breeding areas to better evaluate threats to the population. The tag data reveal extensive migrations to traditional EGW breeding habitats, calling into question the identity of the WGW stock.

2. Material and methods

The International Whaling Commission's WGW Satellite Tagging Steering Committee established tagging protocols followed throughout two expeditions [5,6]: from 1 September to 7 October 2010 and 21 August to 22 September 2011. Only adult males in good body condition [7] were considered 2010 tagging candidates. Prior to a tagging approach, we visually identified whales from unique pigmentation patterns,

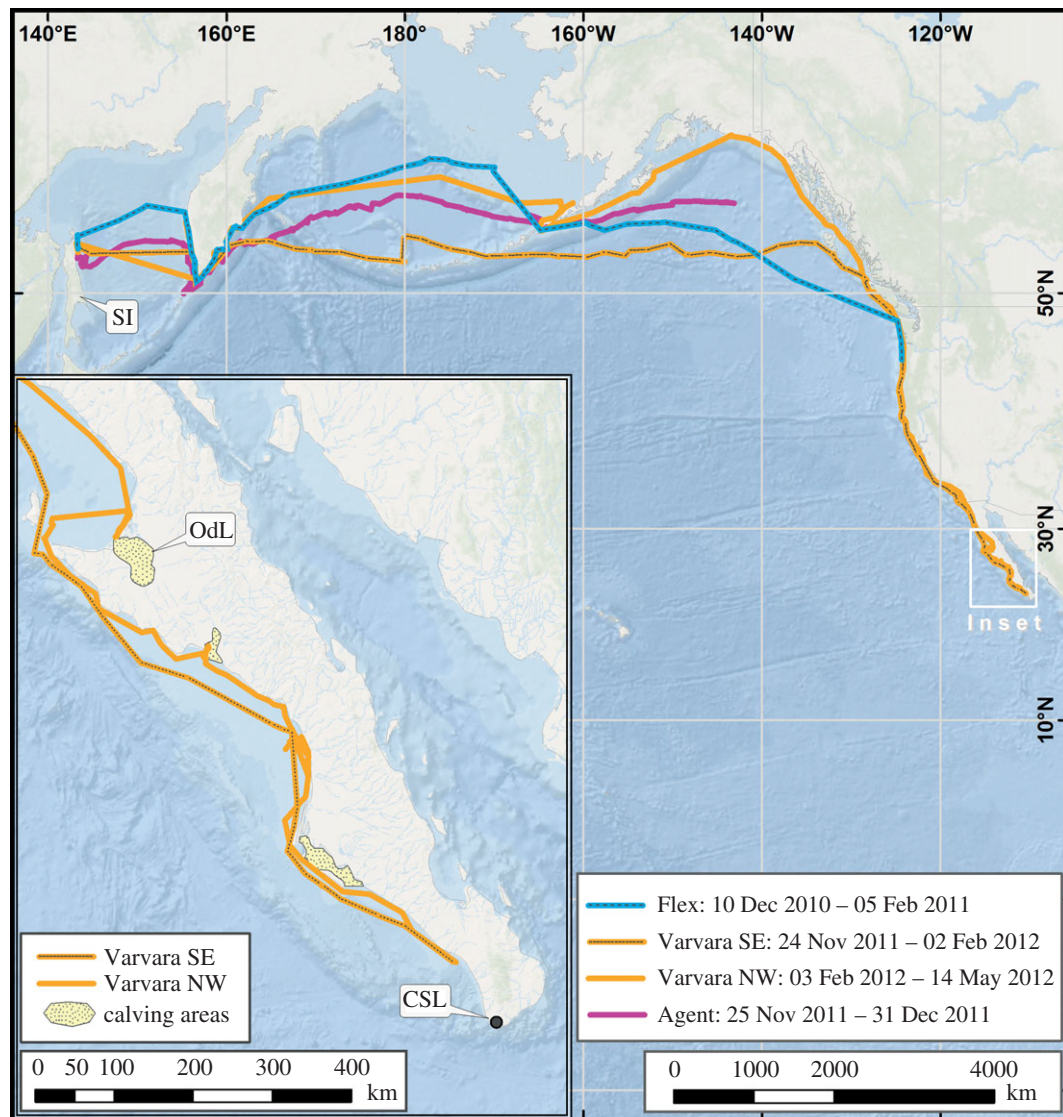

Figure 1. Routes of three western gray whales migrating from Sakhalin Island, Russia, to the eastern North Pacific. The legend depicts departure and arrival/end dates. Varvara visited all three major eastern gray whale reproductive areas off Baja California, Mexico (inset). (Online version in colour.)

using a WGW photo-identification catalogue. Sex is known for almost 80% of catalogued individuals from previous biopsy sampling, and many individuals were photographed as calves allowing age determination. Initially in 2011, only juveniles less than 6 years and females that had calves that year were not candidates. The latter criterion was later amended to allow tagging of females in good body condition that had weaned a calf.

We conducted tagging from a variety of small (less than or equal to 7 m) vessels powered by inboard diesel or four-stroke gas outboard engines, which were launched from the 50 m *Igor Maximov* support ship. We deployed tags from a distance of less than 4 m using a modified air-powered line-thrower [8]. Photos and videos were taken of tag deployments to document whale identity, tag penetration and location.

Tags consisted of a Wildlife Computers Spot-5 Argos transmitter and three Saft A-cell lithium batteries cast in an epoxy-filled stainless steel cylinder. The implantable tags were 28.2 cm long and 2.0 cm in diameter with attachments similar to those used for tagging other large whales [8]. To reduce the likelihood of infections, we partially coated tags with 2.5 g of Gentamycin sulfate, a broad-spectrum antibiotic, in a bio-soluble methacrylate for long-term release of the antibiotic into the tag site. Tags were sealed in gas-permeable bags for 12 h of ethylene-oxide sterilization.

Tags were programmed to transmit during four 1 h periods daily, coinciding with good satellite coverage over a broad range of possible North Pacific migration paths and destinations. Service

Argos calculated locations with estimated accuracy based on the timing and number of transmissions received during individual satellite passes [9]. Three of seven location classifications have specific accuracies from less than 150 m (LC 3) to approximately 1 km (LC 1) [10]. We filtered unreasonable data by removing poor quality locations and limiting swim speeds to less than 10 km h⁻¹ [8]. Distances travelled and swim speeds were calculated using ARC GIS 10.1 and are minimum estimates calculated from straight lines between consecutive locations.

3. Results

Three of seven tagged adult WGWs off SI during the two expeditions transmitted long enough to document migration away from SI after 68–89 days of near-shore movements: a male (13 year old 'Flex') in 2010 and two females (6 year old 'Agent' and 9 year old 'Varvara') in 2011. Each whale took different outbound routes across the Bering Sea, through the Aleutian Island chain, and across the Gulf of Alaska (figure 1), travelling an average of 6.2 km h⁻¹ (table 1).

Tags attached to Flex and Varvara functioned long enough to document the whales entering the EGW south-bound migration corridor. The last received location from Flex was 5 February 2011 off Lincoln City, OR, USA, after

Table 1. Tracking summary information of three western gray whales instrumented with satellite-monitored radio tags off Sakhalin Island, Russia.

whale	tracking segment	start date	end date	distance km (nmi)	days	speed km h ⁻¹ (nmi h ⁻¹)
Flex	feeding	4 Oct 2010	10 Dec 2010	938 (506)	68.0	0.6 (0.31)
Agent		28 Aug 2011	24 Nov 2011	2600 (1403)	88.7	1.2 (0.66)

Varvara	reproductive areas (end of migration—Ojo de Liebre)	2 Feb 2012	26 Feb 2012	1147 (619)	24.0	2.0 (1.1)
Varvara	northwest migration	26 Feb 2012	14 May 2012	10 484 (5661)	78.8	5.5 (3.0)

travelling at least 7661 km. Flex was re-sighted in good body condition during the 2011 SI tagging expedition. Varvara departed SI on 24 November 2011, 17 days earlier than Flex, and passed Lincoln City on 8 January 2012, during the peak of the EGW southern migration. She travelled 10 880 km south to within 103 km of Cabo San Lucas, Baja California Sur, Mexico (CSL), on 2 February 2012, 69.5 days after departing SI (figure 1). Varvara spent 42 days off Baja California, Mexico including 32 days of generally northward movement, passing all three major EGW reproductive areas [11]. From CSL to the northernmost breeding area at Laguna Ojo de Liebre (OdL), Varvara travelled 1147 km, averaging 2.0 km h⁻¹ (figure 1, inset). Her 10 484 km migration from OdL back to SI followed a different route from her eastward trip, crossing the eastern Bering Sea near the southerly face of the retreating ice edge and took 79 days, ending on 14 May 2012. Some slower movement segments were recorded along the north side of the Alaska Peninsula and while crossing the Bering Sea. The overall average speed for her spring migration was 5.5 km h⁻¹. The entire 22 511 km round-trip migration lasted 172 days.

4. Discussion

Varvara's 10 880 km autumn migration constitutes the longest recorded distance travelled during a mammal migration [12]. The linear travel segments over deep water made by tagged whales in this study indicate excellent navigation abilities [13] in sharp contrast with the slower-paced, near-shore and shallow-water migration of EGWs along North America [11]. Varvara's near-shore spring migration route until reaching the Bering Sea was typical of EGWs. However, her more northerly westward route across the Bering Sea indicates she was not obliged to return by the same specific route of her eastward migration, further reinforcing a strong ability to navigate. The occasional slow movement segments observed along the Alaska Peninsula and during the western crossing of the Bering Sea may indicate opportunistic feeding.

New-born gray whale calves follow their mothers during the spring migration to the mother's foraging area, where weaning occurs in late summer [11]. Juvenile and adult WGWs first identified as calves off SI have returned there to feed [4], indicating a very strong allegiance to their mother's migratory destination. Similar natal philopatry has been observed in humpback whale calves, in the North

Pacific and elsewhere, returning to their mothers' migratory destinations [14]. Thus, the three migratory tracks documented by this study strongly suggest the tagged whales were born in EGW reproductive areas.

The utilization of feeding areas in the western North Pacific by whales that winter in the eastern North Pacific raises questions about the present status of WGWs. Since these tracking data became available, a preliminary comparison between WGW and EGW photo-ID catalogues discovered 10 WGWs have been photographed near British Columbia and in San Ignacio Lagoon, Baja California, Mexico [15]. Those sightings, combined with two genetic matches, further strengthen the linkage between these two presumed stocks and question whether the present WGWs came from the population previously thought to be extinct or from recovered EGWs with an expanded range [16].

Recent evidence that 'true' WGWs (i.e. whales breeding in Asian waters) are extant includes: four fishing net deaths off the Pacific coast of Japan between 2005 and 2007, including a yearling first observed as a calf off SI [17]; a gray whale stranded in November 2011 off the Fujian Province in southern China [15], adjacent to the region speculated to serve as a reproductive area for WGWs [17]; and a March 2012 live sighting in Mikawa Bay, Japan [15]. EGWs have been sighted well outside their established ranges [18], so it is possible that WGWs are extinct and these western North Pacific sightings represent a wider EGW foraging range, and more variable migratory timing than is presently thought. It is also possible that the SI region is a foraging area where EGWs and a smaller-than-estimated 'true' WGW population co-mingle, with the latter group making a southerly migration along the Asian coast to an as yet undiscovered breeding area or that spatial and temporal concentrations of whales from SI, during their occupancy in the regular winter range of EGWs, allow them to maintain genetic separation from other EGWs. Overall, the tagging and photo-ID data indicate that the population identity of whales off SI needs further evaluation.

Ethics statement. The procedures used in this study were reviewed and approved by the International Whaling Commission's Western Gray Whale Satellite Tagging Steering Committee and the Oregon State University Institutional Animal Care and Use Committee.

Data accessibility. Data for this study are archived at the International Whaling Commission (<http://iwc.int/data-availability>) and at the Oregon State University Marine Mammal Institute.

Acknowledgements. We are grateful for multiple Russian permits that authorized this research. We thank C. Hayslip, T. Follett, and the scientists and crew aboard the *Igor Maximov* for assistance. We appreciate valuable scientific advice offered by the IWC WGW Satellite Tagging Steering Committee and individual life history data for tagged whales provided by A. Burdin.

Funding statement. Contracting for this research was undertaken by the International Whaling Commission with funds provided by Exxon Neftegas Limited and Sakhalin Energy Investment Company, as well as the Office of Naval Research for data recovery costs and donors to the OSU Marine Mammal Institute.

Author contributions. B.M. participated in the conception, design and coordination of the study, participated in field work and drafted the manuscript. V.I. participated in the conception, design and coordination of the study and reviewed the manuscript. Introduction

The gray whale (*Eschrichtius robustus*), common in the north Pacific at the present time, was first known to science on the basis of subfossil remains from Europe. There are historical references to gray whale in the North Atlantic, such as the "sandloegja" of Iceland (Fraser, 1970) and the "scrag whale" (Dudley, 1725) of early New England whalers. In the early literature pertaining to the North Atlantic, there are a few reports of whales that do not seem to correspond to Atlantic species. Some of these are, no doubt, erroneous and garbled accounts of species that are known from that ocean, but some may represent unrecognized accounts of the Atlantic gray whale. We will go through the historical accounts and add newly found subfossil specimens that demonstrate the existence of a population of gray whales in the western North Atlantic until relatively recent times.

To make sense of these reports, one must have criteria to differentiate accounts of gray whales from those of other whales. The main external characters that set gray whales apart from other large cetaceans are

1. Appearance of the dorsal region. Most species of whale have a well-formed dorsal fin. Gray whales have a series of low knob-like crenulations on the back starting where the dorsal fin would be. There are three species of whale that could be mistaken for a gray whale; the sperm (*Physeter catodon*), humpback (*Megaptera novaeangliae*), and right whale (*Balaena glacialis*). The sperm whale has a low dorsal fin or hump followed by a series of crenulations. On closer examination, it may be distinguished from a gray whale by the shape of its head and the presence of teeth. Some humpback whales have a low triangular dorsal fin that could be interpreted by persons not familiar with whales as not being a dorsal fin. In the North Atlantic Ocean, the humpback's

33

extremely long white flippers are markedly different from gray whales' short gray flippers. Right whales have no dorsal fin at all. Their smooth black back sets them apart from gray whales, which have mottled gray backs.

2. Ectoparasites and pigmentation. Gray whales are heavily infested with barnacles (*Cryptolepas rhachianecti*) and whale lice (*Cyamus scammoni*, *C. ceti*, and *C. kessleri*). This, coupled with their coarsely mottled pigmentation, is one of the species' most distinctive traits. The only other whales with ectoparasite infestations sufficiently dense to cause them to be confused with grays are humpbacks and right whales. However, ectoparasites are generally confined to the head in right whales and to the flukes, flippers, chin, and genital slit in humpbacks, whereas the ectoparasites may be distributed over the entire body of gray whales. Other species of large whales are usually dark on the back and lighter below. Gray whales are coarsely mottled with varying shades of gray both above and below.

3. Color of the baleen. Gray whale baleen is "cream to pale yellow," similar in color to the baleen of finbacks (on part of their right sides) and most minke whales, but it is much thicker and coarser in grays.

Balaenopterids can be mistaken for gray whales. While working at a whaling station in Newfoundland in 1971, one of us (Mead) was approached by the skipper (Clarence George) of one of the small vessels used to take minke whales and asked what would happen if he took a gray whale. Several years before he had seen an animal with white markings over its body and no dorsal fin but rather a series of bumps in its place. He had looked it up in a book and come to the conclusion that it had to be a gray whale, and besides he had killed at least one of everything else in the temperate North Atlantic (including the right whale) and "knew" it was none of those. He knew that the gray whale was protected in the Pacific but wondered if that protection extended to the Atlantic. A few days later Mead happened to be on board the regular catcher vessel which worked out of that station (*M. V. West Whale 8*) and asked the skipper (Arne Borgen), who had whaled out of a station on Vancouver Island and was familiar with gray whales, if he had ever seen anything that looked like a gray. He at first said he had not and wondered why Mead asked. When Mead told him Clarence George's story, his face lit up and he said that he remembered that whale. He had seen it a few miles out of the station and had initially been surprised because it looked for all the world like a gray whale. He followed it and finally came to the conclusion that it was an injured balaenopterid. He harpooned it and when it was hauled up on the station slipway it turned out to be an emaciated finback that had lost the dorsal fin and was scarred over large portions of the body.

To clarify past accounts, we shall review the pertinent literature in chronological order.

Literature Accounts without Specimens

The earliest account of cetaceans in the North Atlantic containing information relevant to this problem of the existence of gray whales in the North Atlantic is the "Speculum Regale" (kongespiel; konungs-skuggsjá; kings' mirror), an Icelandic manu-

script of the mid-thirteenth century. This work has been commented upon in some detail by Eschricht and Reinhardt (1866, pp. 23–34). The manuscript contains a list, with descriptions, of the cetaceans of Iceland which number some 20 species. It apparently also once contained illustrations that have since been lost. We have examined an English translation of the *Speculum Regale* (Larson, 1917) and found no descriptions that are obviously of gray whales. There are one or two that could potentially be gray whales but there is insufficient information given to allow verification.

Eschricht and Reinhardt (1866, p. 31) mention a list of the cetaceans of Iceland that was written in the seventeenth century and sent by an Icelandic cleric to Qlaus Worm. This list appears to have formed the basis for the chapter on cetaceans in Worm's *Museum Wormianum*, published in 1655 (see Allen, 1882, p. 417 for comments). As abridged and amended by Worm the information presented consists merely of a list of 22 species, many of which have no description and none of which can be related to the gray whale.

In 1611, The Muscovy Company of England sent an expedition consisting of two ships under the command of Thomas Edge to Spitzbergen to investigate the possibility of whaling there. The instructions for this expedition included a list of the various whales that they might encounter and their relative commercial values (Lubbock, 1937, pp. 60–63; Allen, 1882, p. 412). Allen indicated that these instructions appeared in "Purchas His Pilgrimes" in 1625, bearing the date of issue of 31 March 1611. Lubbock quoted portions of this list which clearly describe the Greenland right whale (*Balaena mysticetus*: bearded whale), the right whale (sarda), the sperm whale (trumpa), one of the finner whales (*Balaenoptera* sp.: gibarta), another finner whale, possibly the blue whale (*Balaenoptera musculus*: sedeva), and what was apparently the humpback (sedeva negro). In addition to these six there was another sort of whale described, the otta sotta, which Lubbock was unable to identify. We repeat the account quoted by Lubbock (1937, p. 63) from the instructions given to Edge:

The fourth sort of whale is called Otta Sotta, and is of the same colour as the Trumpa having finnes in his mouth all white but not above halfe a yard long, being thicker than the Trumpa but not so long. He yeeldes the best oyle but not above 30 hogs' heads.

The color and size of the baleen and oil yield are more consistent with an identification of a gray whale than with any other known species. The only other whale with all-white baleen is the minke whale, which is shorter, of a uniform darker color dorsally and white ventrally, and has a much lower oil yield. Of particular note is the statement about the quality of the oil, which indicates that it was not only taken commercially but that it was particularly sought after.

The commission from the Muscovy merchants to Thomas Edge bears further examination in the of the state of knowledge about Spitzbergen at that time. Eschricht and Reinhardt (1866, p. 26) stated that news of the abundance of whales in Spitzbergen was brought by Jonas Poole who visited there in 1610. Thus it seems unlikely that the commission of 1611 was based on information derived from activities at Spitzbergen. Edge took with him to Spitzbergen a number of Basques known for their skill in pursuit of whales, and it is likely that the information of the commission was obtained from Basque sources.

Also of interest is an engraving (Fig. 1), unfortunately of somewhat dubious origin, which has appeared in a variety of publications (e.g., Walton Advertising and Printing Company, 1915, p. 15; Dow, 1925, Plate 44). It appears to have come from Churchill's *Voyages*, a collection of narratives of travel and exploration published in various editions from 1704 onward. In the edition that we have examined, this engraving is associated with an account of the voyage of John Monck (Jens Munk) to Hudson Bay in 1619 and 1620 (Churchill and Churchill, 1704, pp. 541–569). Appended to the narrative of the voyage is an account of uncertain origin of whaling at Spitzbergen. The title page bears the comment "translated from the High-Dutch original, printed at Frankfort upon the Maine, 1650." The compilers of this edition have associated it with Monck, but neither the authorship nor the source of the engraving is clear. The engraving shows a whale on the beach surrounded by what appear to be whalers and merchants. The whale pictured clearly represents none of the balaenopterids or the black right whale. This leaves only the Greenland right whale and the scrag whale. If we assume for the moment that the scrag whale is the gray whale and use this species as the basis for comparison with the engraving, some interesting features become apparent. In the engraving the head is relatively less bowed than in the Greenland right whale and in general is more similar to the gray whale, particularly in the relative depths of the lower jaw and rostrum. The pigmentation pattern, generally light along the whole ventral surface, is also more similar to the gray whale than to the Greenland right whale, in which the underside of the tip of the lower jaw and sometimes the ventral surface of the tailstock are usually

Fig. 1. Dutch engraving.

much lighter than the rest of the ventral surface, which is usually black. The shape of the flipper is more similar to that of the gray whale than to the broad flippers of the Greenland right whale. The pigmentation shown on the flippers and flukes resembles the mottling seen on the appendages of the gray whale.

Unfortunately the engraving turns out to be a copy of a portion of a painting of a Danish whaling station at Spitzbergen done in 1634 (Dalgård, 1962; Plate 4). There are numerous resemblances between the original painting and the engraving in Churchill, from the arrangement of the people and their dress to the equipment shown scattered about. The one thing that has changed is the whale. In the original painting it is much more like a Greenland right whale than a gray whale. The resemblance of the image in the copy to a gray whale was apparently solely the result of the engravers' inability to copy accurately the whale in the painting.

Fraser (1970, p. 17) gave the translation of Gudmundsson's seventeenth century (about 1640) description of a whale that the Icelanders referred to as the "sandloegja":

Sandloegja (fig. 5). Good eating. It has white baleen plates, which project from the upper jaw instead of teeth, as in all other baleen whales, which will be discussed later. It is very tenacious of life and can come on land to lie as seal like to rest the whole day. But in sand it never breaks up.

It is sufficient to say that we agree with Fraser's conclusion that the sandloegja of Gudmundsson represents the gray whale, indicating that this animal was known to the Icelanders at this time by the palatability of its flesh, its habits, and its physical characteristics. We initially thought this information might have derived from earlier Icelandic works, specifically the "Speculum Regale," but as stated earlier we could find no accounts in that work from which this information could have come.

De Vries (1853) gave an account of whaling in Delaware Bay (a large embayment formed at the mouth of the Delaware River and bounded by the states of New Jersey and Delaware) in the early part of the seventeenth century. Whales were apparently very numerous there, but as de Vries points out in several places, yielded very little oil. At one point he mentions the capture of seven whales which yielded only 32 "cartels" (65 barrels) of oil. De Vries paid considerable attention to documenting economical aspects of whaling in Delaware Bay, with much comment on the low oil yield of the whales. From the fact that baleen, which was extremely valuable at that time, was not mentioned, we can conclude that the whales taken may not have been right whales.

Van der Donck (1841) presented considerable information on whaling in "New Netherlands" (New York state) in the mid-seventeenth century. He spoke of a good whale fishery in Delaware Bay and described the whales there in the following terms: "Whales are numerous in the winter on the coast; and in the bay where they frequently ground on the shoals and bars; but they are not as fat as the Greenland whales." Van der Donck also mentioned an instance in March of 1647 in which two whales "of common size" swam 43 miles up the Hudson River. One of these stranded there; the other returned to within 12 miles of the sea before it also stranded ("near which place four others also stranded the same year"). As from de Vries' account (1853), one gathers from van der Donck that whaling took place only in the winter. It is notable that there is no mention of baleen as a product of this industry, although considerable stress is

placed on the economics of the venture. This leads to the conclusion that they also may not have been right whales.

Dudley (1725), in his famous letter relating to the whales of the coasts of New England, provided the first mention of an enigmatic whale known as the scrag whale. Dudley gives accounts of recognizable right, sperm, finback, and humpback whales. In addition he describes another kind of whale in these words (1725, p. 258):

The Scrag whale is near a-kin to the Fin-back, but instead of a Fin on his Back, the Ridge of the After-part of his Back is scragged with a half Dozen Knobs or Knuckles; he is nearest the right Whale in Figure and for Quantity of Oil; his Bone is white, but won't split.

There has been much written about the identity of the "scrag whale of Dudley." Authors fall into two groups, those who thought the scrag whale was the gray whale and those who did not believe one could determine its identity. We intend to demonstrate that there is enough evidence that gray whales existed along the American coast to ascertain that what Dudley meant by scrag whale is in fact the gray whale.

Douglass (1760, p. 58), in a discussion of the British territories in North America, gave an account of the whales and the whaling industry in which he mentions the "bunch" of the humpback and merely states "the scrag whale has several of these bumps."

St. John (1782, p. 169) presented a list of the whales known at Nantucket that included right, humpback, finback, sulphur-bottom, and sperm whales, but nothing which could pertain to the gray whale. As True (1904, p. 43) noted, St. John seems to have had first-hand knowledge of whaling in this area, which may indicate that the gray whale was no longer present in any numbers at this time.

In his history of the colony of Nantucket, Macy (1835, p. 28) mentioned that in the early days of the colony (prior to 1672) a whale of the kind called "scragg" entered the harbor and was pursued and killed by the settlers. He remarks that this instance provided the start of the Nantucket whaling enterprise. It is unclear, in the reference of Macy (1835, p. 28) to scrag whales at Nantucket, Massachusetts prior to 1672, whether the term was in use in 1672 or was simply supplied by Macy at the time of his writing.

Cuvier (1836, p. 309) dismissed Dudley's scrag whale as probably an erroneous account of a balaenopterid. Cuvier had interpreted Dudley's remark about the protuberances on the back of the scrag whale to mean they were bony, leading him to discredit the rest of Dudley's account as improbable.

Gray (1850) commented on the validity of *Balaena gibbosa* (the scientific name based on Dudley's account of the scrag whale), which he felt was "a *Balaena*, probably well known formerly." To support his case he cited Beale (1839) as saying that the scrag whale was known to contemporary whalers. We have read Beale (1835, 1839) and were unable to locate this information. Gray himself seems to have had no original information on this subject.

Eschricht and Reinhardt (1866, p. 42) commented upon the usage of the term "scrag whale" by whalers in the Pacific and concluded that most of these could be simply references to young right whales. They stated (1866, p. 43) that

Scrag and Scrag-whale have been common appellations during at least 150 years, and, like the name of the right-whale itself, have at different times and in different places been applied to cetaceans quite different from one another.

It seems from their account that some of the whales termed "scrag" may have been gray whales. Brown (1868, p. 547), in a discussion of the whales of Davis Strait and Baffin Bay, said that he could not imagine what Dudley's scrag whale was, as the whalers did not know of such an animal.

The comparisons which Cope (1868c) (see p. 44) made between the *Agaphelus gibbosus* specimens and the Pacific gray whale material to which he had access are sufficient to indicate that *A. gibbosus* was quite different. In our opinion the shape of the base of the baleen plates, the nature of the coronoid process, the shape of scapula, and the pattern of pigmentation of Cope's *A. gibbosus* are definitely balaenopterid. The supposed lack of dorsal fin and ventral grooves is most certainly due to errors arising from the description which Cope received of the badly decomposed and mutilated carcass of the Long Beach specimen.

It is not entirely clear, however, which species of balaenopterid was represented by the Long Beach stranding. Based on the white color of the baleen there are two possibilities; the finback and the minke whale. Cope's size estimate of 43 feet (13 m), plus the information that the vertebral epiphyses were unfused, strongly suggests that the specimen was a young finback. The size of the auditory bulla, the pigmentation pattern, and the size of the baleen, however, indicate that it was a minke. If it were the latter, it would have been an extremely large animal (adults of this species rarely exceed 10 m in length); this is contrary to the other evidence that this was a very young animal.

All evidence argues that the Long Beach stranding was probably a minke, the details of which were perhaps confused with defective information or remains of an independent stranding of a finback. This conclusion agrees with Cope's initial (1867) and final (1884) diagnoses, with the detailed account of True (1904, p. 105), and the discussion of Hershkovitz (1961).

Captain Atwood of Provincetown, Massachusetts wrote (in Allen, 1869, p. 203) of a scrag whale sometimes taken near that locality. He said that some of the whalers were of the opinion that it was a right whale. However, he stated that its most prominent feature was a small number of projections on the dorsal ridge near the tail, "having some resemblance to the teeth of a saw." Allen had sent the account of Atwood to Cope, who attached the name *Agaphelus gibbosus* to this animal.

Allen (1869, p. 203) placed *Eschrichtius robustus* on the list of mammals of Massachusetts on the basis of the jaw which Cope mentioned from the New Jersey coast (not the "Agaphelus" stranding at Long Beach). In 1869 Cope published further descriptions of fossil material which he assigned to *Eschrichtius*, still not recognizing its relationship to *Agaphelus* (Cope, 1869a; see Chapter 1, this volume).

Gray (1870) stated that the scrag whale (*A. gibbosus*) was abundant in America and was still caught now and then by whalers. This was probably derived from the account of Atwood in Allen (1869). Gray (1871) included *Eschrichtius robustus* as a part of the recent Atlantic cetacean fauna based on Cope (1868b).

Flower (1872) described subfossil material of *Eschrichtius* from Cornwall and cited the jaw from the New Jersey coast (Cope, 1868b) as evidence of the occurrence of this species on the western coasts of the Atlantic. He did not, however, make the connection between the species and the Pacific gray whale.

Ten years later Cope (1869b), having examined more material of the Pacific gray whale, recognized its distinctness from the specimen which he had assigned to *Agaphelus gibbosus* and formed the new genus *Rhachianectes* for it. In so doing he lost the one fortuitous correlation he had made, that of the scrag whale and the Pacific gray whale.

Van Beneden and Gervais (1880, p. 236) considered *Agaphelus gibbosus* to be a young right whale. This conclusion is certainly based on the earlier idea of "scrag" whales as young or emaciated right whales rather than on any evaluation of the basis of Cope's taxon. They cited (1880, p. 236) the jaw from New Jersey which Cope (1868b) referred to *Eschrichtius robustus*. References to this specimen have probably been confused with the variety of fossil cetaceans from the Miocene which Cope assigned to *Eschrichtius* (see Barnes and McLeod, this volume). Fischer (1881, p. 35) noticed the account of *Agaphelus* from Cope's works and included it in his list of cetaceans from the southwest of France, without adding anything new to the account.

Finally, in 1884, Cope recognized the errors in the account of the Long Beach stranding and referred the specimen to *Balaenoptera rostrata* (minke), as he had originally done in 1867. He noted that "the species may, however, be the *Balaena gibbosa* of the old authors," indicating that the scrag whale question remained unsettled in his mind.

True (1884, p. 628) provided a good indication of the state of knowledge of the problem in a tabular presentation of the cetaceans of North America and their distribution. In this table he listed *Rhachianectes glaucus* (Pacific gray whale) as occurring only in the Pacific, *Agaphelus gibbosus* (the scrag whale of Dudley and Cope) only in the western Atlantic, and *Balaenoptera robusta* (the subfossil *Eschrichtius* material) as occurring on both sides of the Atlantic but not in the Pacific. Clearly he had noted all of the specimens in the literature but, like his predecessors, had made none of the connections.

Lydekker (1894, p. 1185) was apparently the first to make the connection between *Eschrichtius robustus* and the Pacific gray whale. He said, of the geographic distribution of gray whale:

from the evidence of certain bones found in the superficial deposits of the British Islands, and described under the name of *Eschrichtius*, it is, however, not improbable that it formerly frequented the Atlantic.

True (1904) commented extensively on both the scrag whale and *Agaphelus gibbosus*. He was of the opinion that the scrag whale was an aberrant right whale. He presented a detailed analysis (1904, p. 105) of the history of *Agaphelus gibbosus*, concluding that it was a mutilated specimen of a minke. On p. 48 of this work he presented a list of the whales that Gray (1871) considered to inhabit American waters, a list which contained *Eschrichtius robustus*. True commented that the inclusion of this species must rest on the statement of Cope that there was a jaw of this form in the

Rutgers museum. Although True presented measurements of some of the material at Rutgers, he apparently never examined the collection himself as he made no further mention of this jaw and did not include *E. robustus* in his account of the Atlantic fauna. In addition, True's monograph contains numerous useful references to early whaling along the Atlantic coast of North America, many of which have information in them on the scrag whale question.

Allen (1916) was of the opinion that "scrag whale" referred to small or emaciated individuals of the right whale, and went so far as to illustrate (Plate 9) a "scrag whale" (an immature female of a right whale). He also made note of the confused state of *Balaena gibbosa* Erxleben (1777), which included some accounts of what were probably the humpback. He included Gray's (1865) specimen of *Eschrichtius robustus* in his synonymy of *Megaptera nodosa*, but gave no reasons for this decision. He also assigned *Balaenoptera robusta* Lilljeborg (the holotype of *Eschrichtius robustus*) to *Balaenoptera physalus*, again with no discussion of the obvious differences between the two.

The question of the relationship of the subfossil occurrence of *Eschrichtius robustus* to the Pacific gray whale was finally examined by van Deinse and Junge (Junge, 1936; van Deinse and Junge, 1937). They reviewed all of the known occurrences of *E. robustus* in the eastern Atlantic and concluded that this material could not be differentiated from the Pacific gray whale. In conclusion they state:

Provided with these facts we can state, therefore, that *Eschrichtius gibbosus* [= *robustus*] must have occurred still along the European coasts in the first centuries A.D. Along the American coast of the Atlantic this species still must have been present in the beginning of the 18th century, for at that time it was still caught by the whalers. And we think it not at all improbable that along the Atlantic coasts of North America in future skeleton fragments of this species will be found. (emphasis ours)

Cederlund (1938) made a detailed comparison of the *Eschrichtius robustus* remains described by Lilljeborg with Andrews' (1914) description of the gray whale and with two European skeletons of the gray whale. He concluded that the material of the holotype, although lacking any skull remains, was remarkably similar to comparable elements of gray whale. He also discussed the question of the scrag whale and concluded that this term had been applied to both the Atlantic gray whale and to aberrant individuals of the right whale.

Hubbs (1959), in a review of the natural history of gray whale, stated that gray whales were present in the Atlantic until early whaling and might still be there, but he did not document his conclusions. In his account of the description of the sandloegja, Fraser (1970) equated it with both the scrag whale and gray whale. He suggests, on the basis of the account of the sandloegja, that the North Atlantic gray whale may have been exterminated at an early date by human predation.

Eastern Atlantic Specimens

The first scientific mention of gray whale came in 1861 (Table I), when Lilljeborg described remains found on the coast of the Gulf of Bothnia at Gräsö, Roslagen,

Table 1
Subfossil Specimens of Atlantic Gray Whales

Year found	Locality	Material	Age (years BP)	Authority	
European material					
1829	Pentuan, England	Partial skeleton	4000–6000	Flower (1872)	
1859	Gräsö, Sweden	Partial skeleton		Lilljeborg (1861)	
1861	Babbacombe Bay, England	Vertebra		Gray (1864)	
1865	Babbacombe Bay, England	Vertebra		Gray (1866)

1979	Cape Lookout, North Carolina	Partial skull		This chapter	

^aCarbon 14 dates on the North American specimens determined by the Radiocarbon Laboratory, Smithsonian Institution. Samples were run on collagen fraction remaining in the bone.

Sweden (Fig. 2) under the name *Balaenoptera robusta*, in the belief that it was a new species of finner whale (Lilljeborg, 1861). The remains included the mandibles and most of a postcranial skeleton but no skull fragments. All seem to have belonged to a single physically mature individual, inasmuch as all vertebral epiphyses remained attached to the centra. The description was subsequently translated into English (Lilljeborg, 1866) with some additional figures added. A complete description of all the elements was prepared and published in English (Lilljeborg, 1867).

Lilljeborg's material was found in a field, 10–15 ft (3–5 m) above sea level and 840 ft (260 m) from the current shoreline. The remains were in a stratum of sand and clay 2–4 ft (60–120 cm) beneath the surface, associated with shells of *Mytilus edulis* and *Macoma balthica*. Lilljeborg considered this deposit to be postglacial and estimated its age at 4000–6000 years. Van Deinse and Junge (1937) reconsidered the age of this find and agreed that Lilljeborg's estimate was essentially correct.

Although it was not described until 1872, the first specimen of gray whale to be found along the northeast coast of the Atlantic was a partial skeleton excavated in 1829 from the Happy Union Tin Stream Works at Pentuan, Cornwall, England. The specimen consisted of the right lower jaw, a lumbar vertebra, a humerus, radius, and two metacar-

Fig. 2. Location of eastern Atlantic specimens.

pals, all probably from the same individual. According to Flower (1872), who described this material, it was slightly smaller than Lilljeborg's specimen from Gräsö and was a somewhat younger individual, as the vertebral epiphyses were not fused to the centra. These remains came from a depth of about 7 m in a stratum of marine sands, about 850 m from the present shoreline (Colenso, 1832, p. 36). The overlying sediments consisted of river sands and gravels, and the immediately underlying sediments were sands containing the remains of a number of terrestrial mammals, including man.

The third specimen to be described of this species from the northeast Atlantic was a cervical vertebra washed ashore at Babbacombe Bay, England and found by a Mr. Pengelly on November 24th, 1861. This vertebra was sent to Gray who immediately associated it with Lilljeborg's material on the basis of the extremely wide neural canal. Gray (1864, p. 350) initially thought that it was from a species of humpback whale and accordingly designated it "*Megaptera? robusta*." He felt it was sufficiently different to warrant a subgeneric distinction and accordingly proposed the subgenus *Eschrichtius*, which he subsequently (1865, p. 41) elevated to full generic rank. In June of 1865, Mr. Pengelly recovered from the same locality another cervical vertebra which Gray (1866, p. 373) also identified as *Eschrichtius*. No estimates have been made of the age of this specimen.

No further remains of Atlantic gray whales came to light until 1937, when van Deinse and Junge published on a series of finds from the Netherlands. Stimulated by a

recently found specimen, they searched museum collections and uncovered some earlier material. The first was a partial skull of a juvenile, found in 1879 at IJmuiden on the North Sea coast of the Netherlands, just west of Amsterdam. Unfortunately there was no information on the circumstances under which this specimen was found on which to base an estimate of its age. The second was also from IJmuiden and was a partial skull of an adult found in 1916 at a depth of about 1 m during excavation for a new harbor. Van Deinse and Junge (1937, p. 184) suggested an age of about 500 AD, based upon the amount of accumulated silt overlying it. The final specimen was a partial skeleton, consisting of a broken skull, mandible, hyoid, miscellaneous vertebrae, ribs, and limb elements, found by a farmer in 1935 while plowing a field in the Wieringermeer-Polder, a portion of the Zuiderzee about 40 miles (60 km) north of Amsterdam which had been drained in 1930. Van Deinse and Junge estimated the length of this animal at 8 m. Based on a pollen analysis of associated sediment, they estimated an age of 4000–6000 years (van Deinse and Junge, 1937, p. 184).

Fredén (1975) examined a number of subfossil remains of seals and whales from the west coast of Sweden. Although he did not present information on any specimens identified as gray whales and specifically excluded any material found along the current coastline, he did list a number of finds of unidentified whales, some of which might prove to be this species.

Western Atlantic Specimens

Edward Drinker Cope (1867) assigned a series of Miocene fossil cetaceans to the subgenus *Eschrichtius*, which Gray had formed for subfossil remains from Europe. These have been determined to be unrelated to the gray whale (see Chapter 1, this volume). Gray and Cope were deliberating on the strength of certain resemblances of these remains to the humpback. Thus when Cope first encountered recent material of *Eschrichtius* in the form of the Pacific gray whale, he did not make the connection between the two. It is in this same paper (Cope, 1867, p. 147) that Cope first mentioned a whale stranded at Long Beach, New Jersey. He referred this specimen to the minke whale.

In the next year Cope (1868a) made an informal announcement of a new genus *Agaphelus*, based upon the Long Beach stranding, the scrag whale of Dudley, and the Pacific gray whale. Subsequently another short notice appeared (Cope, 1868b) mentioning *Agaphelus* and giving a brief reference to a whale jaw, which Cope assigned to *Eschrichtius robustus* (Lilljeborg). In a third paper of the same year, Cope (1868c) formally defined *Agaphelus* and described the two species, *A. gibbosus* (based upon the Long Beach stranding and the scrag whale of Dudley) and *A. glaucus* (based upon the Pacific gray whale). It must be borne in mind that much of Cope's concept of *Agaphelus* was based upon the scrag whale of Dudley, and although he was familiar with remains of *Eschrichtius* described by Lilljeborg, he never made the connection between it and *Agaphelus*.

The specimen of *Eschrichtius robustus* that Cope (1868b) mentioned was a jaw sent

Fig. 3. Location of western Atlantic specimens.

to the Rutgers College museum by a Mrs. Dunham sometime about 1855. The data associated with this specimen are limited to those found on the paper label glued to the specimen and include only the name of the donor and the locality, Toms River, New Jersey (Fig. 3). There are a number of other bones in the museum collection which were contributed by the same donor, all apparently from Toms River. The jaw was examined by Cope (1868b, p. 194) who commented on it in a list of the recent mysticetes of the Atlantic coast of the United States:

The *Eschrichtius robustus* is admitted on the evidence of a ramus of the under jaw in the Museum Rutgers College, which is of peculiar form, and closely resembles the figure given by Lilljeborg of that portion of this rare species.

Although this reference was cited in numerous subsequent works (Gray, 1871, p. 52; Flower, 1872, p. 442; van Beneden and Gervais, 1880, p. 236; True, 1904, p. 48) the jaw was apparently never reexamined and the connection between it and the Pacific gray whale was never made.

Fig. 4. Photographs of North American specimens of the Atlantic gray whale. Scale bars = 20 cm. (A)–(D) are lateral views of left mandibles. (A) USNM 187448, Toms River, New Jersey; (B) USNM 23260, Myrtle Beach, South Carolina; (C) USNM 244465, Nags Head, North Carolina; (D) USNM 244307, Southampton, New York; (E) posterodorsal view of partial skull of USNM 299838, Corolla, North Carolina; (F) ventral view of partial skull of USNM 187449, Chesapeake Bay, Virginia.

The specimen is a left mandible (Fig. 4A), 272 cm long and in excellent condition. Comparing its length with the mandible of the Korean specimen described by Andrews (1914, p. 264), a 1250-cm male with a mandibular length of 243 cm, the total length of the Rutgers specimen is estimated as 1400 cm. This specimen has been transferred to the United States National Museum (USNM 187448)¹ (Table I).

The second specimen of a gray whale from the western north Atlantic was found September 7, 1959 by amateur divers at Myrtle Beach, South Carolina. This specimen, apparently including most of a skeleton, was discovered about 50 ft (15 m) offshore in about 5 ft (1.5 m) of water. The divers recovered the posterior portion of the mandible (Fig. 4B) and brought it to the Smithsonian Institution where Charles Handley identified it as from a gray whale. As encouraged by Handley, the divers returned to attempt to recover more of the specimen but discovered that a storm had disrupted the locality; they were unable to locate any further remains. This specimen (USNM 23260) is from a large adult, comparable in size to the Rutgers specimen.

In 1969 Captain Floyd Durette recovered a partial skull of a juvenile gray whale which he sent to the United States National Museum (USNM). Exact locality data are unavailable, but it is presumably from near the mouth of Chesapeake Bay, Virginia, as this was the general area of Captain Durette's work at the time. The specimen (USNM 187449; Fig. 4F) consists of the posterolateral portion of a cranium with most of the dorsal and ventral elements missing (i.e., it consists of squamosals, exoccipitals, parietals, and the basioccipital). This is the oldest specimen of the Atlantic gray whale that we have radiocarbon dated. The age of the specimen is $10,140 \pm 125$ years BP.

A fragment of a right squamosal of a young gray whale was found on the beach at Corolla, North Carolina on 26 March 1976 by Ayeon Meekins. He took it to the North Carolina Marine Resource Center in Manteo, North Carolina, where one of us (Mead) examined it. We borrowed the specimen and compared it to juvenile gray whale material in the USNM, ascertaining that it was from an animal about 25 feet long. A cast was made of the specimen (USNM 244308), and a sample was taken for radiocarbon dating. The original was returned to the North Carolina Marine Resource Center in Manteo, North Carolina.

A midportion of a badly weathered left mandible (Fig. 4D) of a juvenile was found by Mae St. Germaine on the beach at Southampton, Long Island, New York, on May 31, 1977. A cast was prepared (USNM 244307), a sample taken for radiocarbon dating, and the original specimen returned to Mrs. St. Germaine. The height at the coronoid process was 18.2 cm (plus approximately 2–3 mm for abrasion).

A complete left mandible (USNM 244465; Fig. 4C) of a juvenile was donated to the USNM by Betty Clark of Nags Head, North Carolina, who said it had been found by a friend in the vicinity of Nags Head in the 1970s. The length of the mandible was 120 ± 5 cm.

A cranium of an adult (Fig. 4E) was found on the beach at Corolla, North Carolina in the fall of 1977 by Virgil Lanning. The width across the zygomatic processes was about

¹USNM numbers refer to specimens that are in the collection of the Division of Paleobiology, United States National Museum, Washington, D.C.

141 cm (131 cm measured, plus about 10 cm estimated to have been lost by abrasion). The width across the articular condyles was 31 cm. This specimen was donated to the USNM (299838). We tried to radiocarbon date this specimen but it had been contaminated by current atmospheric radioactive carbon to such an extent that dates were useless.

A fragment of the squamosal of an adult was found on the beach at Rehobeth, Delaware in August of 1978. This was donated to the USNM (256749) by Gloria Waggener.

The cranium of a juvenile was discovered in April 1979 on the beach at Cape Lookout, North Carolina. The width across the zygomatic processes was 80 cm. This specimen is currently housed at the Hampton Mariners Museum in Beaufort, North Carolina.

We have just learned of an additional find of an Atlantic gray whale. It was found on Jupiter Island, Florida (approximate geographic coordinates 27° 3' north, 80° 6' west). Dr. Daniel Odell (University of Miami) sent some photographs of the specimen and the data to us in January 1983. The specimen consists of most of the cranium of what looks like an adult which was found on the beach after a storm. This extends the known distribution of the Atlantic population nearly 500 miles to the south. The specimen is currently in the possession of the Hobe Sound National Wildlife Refuge.

The radiocarbon ages for the samples from the western North Atlantic are shown in Table I. The most recent date (1675 AD) is from a period when colonists had settled in America and the next youngest is potentially so (1405–1585 AD). The oldest specimen that we radiocarbon dated was USNM 187449, which gave an estimated age of $10,140 \pm 125$ years. No sample was run on USNM 256749 because it was felt that the removal of so much bone would essentially destroy the specimen. The importance of these radiocarbon ages is not to define exactly the period of existence of gray whales in the north Atlantic but merely to give an idea of how recently they became extinct.

Taxonomy of the Atlantic Gray Whale

Eschrichtius

Eschrichtius Gray 1864, p. 350. [Subgenus of *Megaptera*. In the following year he elevated it to full generic rank (Gray, 1865)]. Type species *Balaenoptera robusta* Lilljeborg 1861, p. 602.

Agaphelus Cope 1868a, p. 159. Type species *Balaena gibbosa* Erxleben 1777, p. 610.
Rhachianectes Cope 1869a, p. 15. Type species *Agaphelus glaucus* Cope 1868a, p. 160.

Eschrichtius robustus

Balaenoptera robusta Lilljeborg 1861, p. 602. Type specimen the Gräsö whale preserved in the University Museum of Upsalla, Sweden.

Megaptera? robusta Gray 1864, p. 350.

Eschrichtius robustus Gray 1865, p. 42.

Agaphelus glaucus Cope 1868a, p. 160. Lectotype a side of baleen in the museum of the Essex Institute, Salem, Massachusetts (True, 1904, p. 81), which has subsequently been lost.

Rhachianectes glaucus Cope 1869a, p. 15.

Eschrichtius glaucus Maher 1961, p. 257.

One of the taxonomic problems concerning the Atlantic gray whale has been the disposition of the name *Balaena gibbosa* Erxleben (1777, p. 610). This has usually been associated with the scrag whale, which formed the basis for the species name *gibbosus* being applied to the gray whale. Allen (1882, p. 467) stated that Erxleben had included the scrag whale in the *species obscurae* part of his compilation and that *Balaena gibbosa* Erxleben was a *nomen nudum*. However, as True (1904, p. 42) pointed out, this was an error on the part of Allen, and indeed Erxleben included the scrag whale within the synonymy of *Balaena gibbosa*, although it is the last of nine items in the synonymy. Although Erxleben's compilation does not refer specifically to Dudley's work, he does give white baleen plates in his diagnosis of *Balaena gibbosa* which is one of the more striking characters in Dudley's (1725) description of the scrag whale. While there is good reason to believe the Dudley's scrag whale formed part of the basis of *Balaena gibbosa* Erxleben, the humpback whale also formed part of the basis of *B. gibbosa*. The confusion that has centered around the name *B. gibbosa* renders it highly undesirable. Should its validity arise again as a possibility, an appeal should be made to the International Commission on Zoological Nomenclature to suppress it in favor of *Eschrichtius robustus*, which has a type specimen and a long history of unambiguous usage.

We agree with Cederlund (1938, p. 282) that the holotype of *Eschrichtius robustus* is sufficient evidence to demonstrate the conspecificity of the extinct Atlantic and extant Pacific populations of the gray whale. This is contrary to the opinion expressed by Schevill (1952). In that paper he quotes van Deinsse and Junge (1937, p. 181) as follows:

We must emphasize that the bones we have now at hand we cannot give any argument that the Pacific and Atlantic representative of *Eschrichtius* should be specifically different.

Shevill (1952, p. 1) goes on to say that "But by the same token these bones cannot prove that these whales are specifically identical." We agree that proof of specific identity is not conclusive when only the bones of an extinct animal are at hand, but is commonly the usage in paleontology to judge animals specifically identical if differences judged by competent taxonomists to be specifically distinctive cannot be found between the bones of the animals. Geographic separation, in the case of sharks, large fish, marine birds, and whales, cannot in itself form the basis for a judgement of specific identity. Rice and Wolman, who did the last major work on the gray whale (1971), recognized the Pacific population as *Eschrichtius robustus*. Any further questions along this line can only be resolved by a critical comparison of all of the Atlantic gray whale material with a broad suite of specimens of the Pacific gray whale in order to take such variables as age and sex into account.

In the event that the Atlantic and Pacific populations of gray whales are demonstrated to warrant specific or subspecific distinction, the specific name *Eschrichtius*

glaucus (Cope) will be available for the Pacific form. The lectotype of the species, as designated by True (1904, p. 81), is a set of baleen in the museum of the Essex Institute, Salem, Massachusetts. It is probable that a neotype will have to be designated because the lectotype material cannot be found (W. Schevill, personal communication).

Conclusion

There are three accounts in the literature that we interpret to be reliable records of gray whales in the North Atlantic. One of these was an Icelandic record of the sixteenth century (Fraser, 1970), another was the account of Dudley in 1725, the third was a commission from the Muscovy Merchants to Thomas Edge in 1611 which dealt with a whale called the "otta sotta," which fits the description of a gray whale. There are several other reports which, although they do not give enough information to allow positive identification of the whales concerned, appear to describe gray whales.

The species was first known to science on the basis of subfossil specimens from Europe. It is now known in the Atlantic from a total of seven European specimens and nine American specimens. Six of the American specimens were found in the last 10 years, despite the fact that there has been no special effort to find them. Based upon these finds we conclude that the gray whale was, at some time, common in American waters and was sometimes known to whalers as the scrag whale. Radiocarbon dates show the most recent specimen to have existed in colonial times, around 1675 AD.

Summary

Eschrichtius robustus was first known to science on the basis of a subfossil skeleton from Gräsö, Sweden described by Lilljeborg in 1861. In subsequent years six more subfossil specimens were described from the coasts of England and the Netherlands. Van Deinse and Junge (1937) compared these remains to the Pacific gray whale and concluded that they could not be separated on a specific basis.

Dudley (1725), in a short paper enumerating the whales then known off New England, described a whale known as the "scrag" whale. This species was discussed at length by biologists, most of whom came to the conclusion that it represented young or emaciated individuals of the right whale. This was to a large part based upon the supposed lack of evidence of a western Atlantic population of *Eschrichtius*, but in fact Cope (1868a) had published on a jaw of this species that had been found on the New Jersey coast. Since that time there have been eight more discoveries of remains of *Eschrichtius* on the Atlantic coast of North America, upon which we report in this paper. Radiocarbon dates reveal that the youngest specimen died during colonial times (1675 AD).

Fraser (1970) published on a sixteenth century Icelandic account which he interpreted as evidence of the persistence of a gray whale (*sandloegja*) population in the North Atlantic at that time. Lubbock (1937) published a seventeenth century account of a

whale called the "otta sotta," whose description fits the gray whale. Several other more anecdotal accounts also fit the gray whale.

The conclusion is that a population of *Eschrichtius robustus* existed on both sides of the Atlantic and was present on the coasts of North America up to the seventeenth century AD.

Acknowledgments

This investigation was prompted by Clarence George's inquiry in 1971 about Atlantic gray whales. Since that time it has involved help from the following people: Doug Oliver, a student at Rutgers, who took photographs of the whale remains in the attic of their museum in response to our telephone requests; Dr. R. C. Murray of that same institution, who suggested that the remains be transferred to the United States National Museum; Dr. Robert Brownell, who kindly transported it to Washington; Dr. Charles Handley, who recognized the second specimen as a gray whale, asked the collectors, Mr. Maklison and Mr. Aleksandrov to try to obtain more of the specimen, and kindly made the specimen available to us; Dr. Lawrence Barnes, who brought an unidentified specimen in the United States National Museum to our attention; Charles Potter, who deserves special thanks for recognizing two of the specimens as being gray whales. We thank Floyd Durette, Betty Clark, Ayeon Meekins, Steve Daniels, Mae St. Germaine, Virgil Lanning, Gloria Waggenger, and Karen Davis, who were involved in the collecting of specimens.

Received February 28, 2014

Abstract—This article presents data on frequencies of mitotypes (control region and cytochrome b and ND2 genes) in groups of Gray Whales found off the Chukotka Peninsula, Koryak coast, eastern Kamchatka and Sakhalin Island. From north to south the number of mitotypes decreased dramatically, but mitotypes which were predominant in the south were the same as ones also abundant in northern samples. For the control region sequences only, our data and data presented in the literature suggest that breeding areas in Baja California may include diversity of both distant groups of mitochondrial lineages known for the species. On the other hand, the same control region sequences may be found in different mitochondrial genomes, and so conclusions based on this mtDNA fragment only may be incorrect.

INTRODUCTION

The gray whale (*Eschrichtius robustus*, Lilljeborg, 1861) is a representative of the Eschrichtiidae family of the suborder of baleen whales (Mysticeti). This species feeds on benthic animals, so during the feeding period, the whales keep close to shallow coastal areas. Also, gray whales perform the most distant migrations within the marine mammals from the feeding area to the reproduction area. Recently, the gray whale has inhabited the northern Pacific Ocean, where two stocks appeared after the last glacial period (Swartz et al., 2006) because of the separation of the feeding grounds. They are the eastern (or California-Chukchi) group, and the western (or Korean-Okhotsk) group. The population of the eastern group was primarily about 15000–20000 whales, according to the estimated data accepted by the International Whaling Committee (IWC). It had decreased as low as 2800 by 1900 because of whaling, but was restored after the total prohibition of commercial harvesting, and was about 27000 whales in the 1980s.

The pre-harvest population of the western group, mostly reproducing along the Chinese and Korean coasts, and the southern coast of Honshu Island, and

feeding in the Sea of Okhotsk, was about several thousands of individuals. The last western gray whale harvested was in the coastal zone of Korea in 1966. Since then, this group was considered to be extinct. However, single whales, pairs, and groups of three individuals were observed from time to time along the Japanese coast and in the Sea of Okhotsk up to the 1980s; later, larger groups of 4–34 whales were recorded (Maminov and Blokhin, 2004; Nambu et al., 2010). In the early 2000s this group was included in the Red List of the International Union for Conservation of Nature (IUCN) as a subpopulation in the critically endangered category (Reilly et al., 2013). Currently, the population of this group is estimated as 150–180 individuals.

The idea of the reproductive isolation of both the western and eastern groups has been criticized repeatedly (Nishiwaki and Kasuya, 1970; Omura, 1974). The registering of gray whales in the Laptev Sea (Shpak et al., 2013), along Franz Josef Land, in the Mediterranean Sea, and along the Namibian coast has allowed hypothesizing the beginning of the restoration of the historical geographical range of this species, particularly, by reinhabiting of the areas that belonged to the range of

the extinct western group by representatives of the California-Chukchi population (Ilyashenko, 2012).

Analysis of the genetic diversity of the gray whales of the eastern group observed both at their wintering grounds along the Baja California coast and northwards has been performed by several research groups (Steeves et al., 2001; Goerlitz et al., 2003; Alter and Palumbi, 2009; Alter et al., 2009, 2012). Meantime, data on the gray whales migrating along the Russian coasts are scarce (LeDuc et al., 2002), although there was a large amount of research performed in recent years, the results remain unpublished.

The aim of the present study was to analyze the data on the mitochondrial lineages of the gray whales inhabiting the Far Eastern seas of Russia.

MATERIALS AND METHODS

The tissues of gray whales harvested in the course of subsistence whaling by Chukotka indigenous hunters (Lorino, Sireniki, Novo-Chaplino, Yanrakynnot, and Lavrentia settlements, here and further, Chukotka) in 2001 (14 specimens), 2003 (13), 2004 (18), 2005 (17), 2007 (10), 2008 (6), and 2010 (34 specimens) were analyzed.

Also, the skin tissues sampled by the remote biopsy method in accordance with permission of the Russian Federal Supervisory Natural Resources Management Service (Rosprirodnadzor) in the following areas:

- along the Koryak Coast from Olyutorsky Cape to Khatyrka River estuary (Igla Cape, Dezhnev Bay, Khatyrka River estuary (here and further, Koryak Coast)) in June–August 2010 (21 samples);

- along the eastern coast of Kamchatka (Kamenistaya Bay, Olga Bay, Asacha Bay, and Avachinsky Gulf (here and further, Kamchatka)) in summer of 2004 (3 samples), 2010 (20 samples), and 2011 (one sample);

- along the coast of Sakhalin Island, Pil'tun Bay (here and further, Sakhalin) in summer of 2010 (9 samples) and 2011 (13 samples).

The tissues were stored in ethanol or in 20% solution of dimethyl sulfoxide (DMSO) in saturated solution of NaCl. The total DNA was extracted using the InviMag Tissue DNA Mini Kit/KF96 (STRATEC Molecular, Germany) on a KingFisher Flex/96 magnetic particle processor (Thermo Fisher Scientific, Finland).

Several loci of the mitochondrial DNA (mtDNA) were amplified for the following sequencing:

- the control region, using the primers MT4 (5'-cctccctaagactaaaggaag-3') and H00034 (5'-taccaatgtatgaacctcag-3') according to (LeDuc et al., 2002) at the primer annealing temperature of 54°C;

- the cytochrome b gene, using the primers cet_cbF (5'-aatgacatgaaaatcatcggtt-3') and cet_cbR (5'-ctccttttccggtttacaa-3') at an annealing temperature of 52°C;

- the subunit 2 of the NADH dehydrogenase gene (ND2), using the primers cet_nd2_F (5'-catcacccgaaaatgttggt-3') and cet_nd2_R (5'-tagggctttgaag-gctcttg-3') at an annealing temperature of 52°C.

The same primers were used for the sequencing reaction, and internal primers cet_cb_intF (5'-gaaacattggggaatcctactat-3') and cet_cb_intR (5'-gtttgctggggtgtagttatc-3') were additionally applied for the sequencing of cytochrome b gene.

The design of the original primers was performed using the software Primer3 (Rozen, Skaletsky, 2000). All PCR (polymerase chain reaction) were performed using standard mixtures MagMIX 2025 (Dialat Ltd., Russia), and the primers were synthesized by JSC Syntol (Russia). The sequencing reactions were performed using BigDye Terminator v. 3.1 kit (Applied Biosystems, United States), and the sequencing was done on Genetic Analyzer 3130 and Genetic Analyzer 3500 (Applied Biosystems, United States). Quality control of the automatic decoding of chromatograms, the merging of forward and reverse individual sequences, and their alignment and storage was done using BioEdit software (Hall, 1999).

The sex of the specimens was determined by simultaneous amplification of the X and Y chromosome fragments (Jayasankar et al., 2008) using the primers labeled with a fluorescent dye. The PCR results were visualized on the sequenator in the presence of the size standard to compare the lengths of the obtained fragments to those expected.

To avoid analyzing duplicate samples from the same whale, samples that were obtained by the remote biopsy method within one season in one locality and that shared the same sex and haplotype of the mtDNA control region were subjected to genotyping of five microsatellite loci (DlrFCB5, DlrFCB17, Ev94Mn, 417/418, and 464/465) using the method described earlier (Meschersky et al., 2013). When all five genotypes were the same, the sample was treated as originating from the same specimen. The possibility that duplicate samples of one whale were collected in different localities was not checked following the principle that each local sample represents the lineages that may be found in the area, disregarding the individual affiliation of the specimens.

The data were processed using the software Arlequin v. 3.1 (Excoffier et al., 2005), Network 4.6.0.0 (Bandelt et al., 1999), and MEGA v. 5.2.2 (Tamura et al., 2011).

RESULTS

Ten haplotypes of cytochrome b gene (1137 base pairs (bp), that is a complete gene sequence, excluding the stop-codon), nine haplotypes of ND2 gene (1044 bp, complete gene sequence) and 37 haplotypes of control region (the fragment including 65 bp of tRNA-Pro gene and 555–556 bp of the control region itself) were found for mtDNA of the studied specimens. The

Fig. 1. Median joining network of mitotypes of the gray whales (2802 bp). The circle diameter refers to the frequency of the mitotype in the total sample population, the sector sizes—to the regional samples. Different color tones indicate the haplotypes registered at Chukotka (1), Koryak Coast (2), Kamchatka (3), and Sakhalin (4). The number in the brackets indicates the number of the mutated positions differs between mitotypes 2 and 16; in the other cases, the minimal distance between the circles refers to one mutated position. A1, A2, and B are the mitotype groups.

sequences were deposited in GenBank under the accession numbers KJ865243–KJ865298. These sequences were combined in 44 mitotypes within the individual mitochondrial genomes (Table 1).

The overall characteristic of the specimens studied in different regions and included in the analyses is presented in Table 2. The sequences of all three studied loci of mtDNA were obtained for all the whales from the Koryak Coast, Kamchatka, and Sakhalin, but several samples collected in these areas were excluded as belonging to the same individuals. Although there were 112 samples from Chukotka, only 85 specimens provided sequences for all three mtDNA loci, so only these samples were used in further analyses. For the 27 Chukotka whales that were excluded, the sequences of only one or two loci were obtained. For these whales 18 sequences of the cytochrome b gene and 12 sequences of ND2 gene (all were haplotypes found already), and 17 sequences of the control region, including the haplotypes W2x (KJ865271, two specimens) and NW8 (KJ865289, one specimen) were determined.

The median joining network of the defined mitotypes (Fig. 1, the mitotype numbers are given selectively) suggests two distinct groups; the group B is presented by only one mitotype referred to as 2, which differs from the closest mitotype 16 by the 25 altered positions (24 nucleotide substitutions and one indel). The other group (A) may be divided into two sub-

groups, A1 (mitotypes 4–11, 17, 19–21, 24–25, 27–30, 32, 39, 40, 44) and A2 (mitotypes 1, 3, 12–15, 18, 22–23, 26, 31, 33–38, and 41–43), while the position of mitotype 16 remains uncertain. However, the unity of both groups, A1 and A2, is low, i.e., the value of bootstrapping is less than 50 when applying the Neighbor Joining, Maximum Parsimony, and Maximum Likelihood methods (the results are not presented). The weighted average distances between the mitotype groups B and A1/A2 are 28.8 ± 5.3 and 27.6 ± 5.0 nucleotide substitutions, respectively, and between A1 and A2, there are 6.1 ± 2.3 substitutions. Along with that, the average intergroup distances for A1 and A2 are 6.6 ± 1.5 and 6.1 ± 1.3 substitutions, respectively. The mitotypes of all the mitotype groups are present, in one or another frequency of each one, in both northern (Chukotka and Koryak Coast) and southern (Kamchatka and Sakhalin) areas.

The comparison of haplotype frequencies (F_{st}) was applied for comparative analysis of the samples. The average pairwise difference (Φ_{st}) between the mitotypes was not applied, because the sampling sites were not the areas of the genetic diversity origin, i.e., ranges of long-term isolated populations.

Both sexes were found nearly equally in all the sample groups, when males comprised 47.6–57.9% of the studied specimens. There were no significant differences in haplotype frequency between the male/female sam-

“—”, mitotype was not registered.

ples in all regions ($P(Fst) = 0.52-0.15$). This allowed us to combine the data disregarding the whale gender in the total sample for each studied area.

We also combined the data for the samples obtained in Chukotka for different years. In most of the cases, there were no significant differences between these samples ($P(Fst) = 0.06-0.89$), although some mitotypes were registered here only in a single year. The only exception was the year 2007 (8 specimens), which differed significantly from 2001 (6 specimens, $P(Fst) = 0.04$) and from 2004 (16 specimens, $P(Fst) = 0.009$). The interannual and seasonal differences in genetic lineage occurrence in different areas are of great interest; however, our data do not allow us to apply such analysis due to the small amount of data.

The genetic diversity of the studied samples supports the highest diversity of mitotypes for the whales of Chukotka and Koryak Coast (Table 3). For the Koryak Coast, the absolute number of mitotypes was significantly lower, but their relative rate was even higher taking into account the difference in the sample size, and the decrease in the index of haplotype diversity in comparison to the Chukotka population was insignificant. The Kamchatka and Sakhalin populations showed the middle and the lowest diversity, respectively, of mitotypes. The high rate of nucleotide diversity in these areas reflected a high frequency of mitotype 2, which is significantly distinct from the other known sequences.

The pairwise comparison of the mitotype frequencies showed the significant differences between all the pairs of the areas except Chukotka/Koryak Coast (Table 4).

DISCUSSION

A decrease in the absolute number and diversity of the mitotypes of gray whales was observed when moving from the northern areas (Chukotka and Koryak Coast) southwards (eastern Kamchatka coast) and then westwards (Sakhalin) (Fig. 2). Along with that, the composition of the mitochondrial lineages presented in the different areas remained similar. Once one of the lineages was not present, the other ones, which were also present in the previous sample, but with low frequency, began to dominate. Only two exceptions were found, mitotypes 30 and 42; they were present in the sample obtained along the eastern coast of Kamchatka, but were totally absent in the samples from Chukotka and/or Koryak Coast. Each of these two mitotypes was found only once, and we cannot exclude the possibility that if another sampling will be performed in the northern areas, these mitotypes may be found. It is also known that the control region haplotypes A1 and X present in these mitotypes were found for the gray whales of California-Chukchi population (LeDuc et al., 2002).

No significant differences were found when comparing the composition and frequency of the mito-

Table 3. Diversity indexes of the mitochondrial lineages of the studied regional samples of the gray whale

Sampling area	<i>n</i>	<i>h</i>	<i>n/h</i>	<i>H</i>	π , %
Chukotka	85	41	2.07	0.971	0.345
Koryak Coast	17	11	1.55	0.945	0.288
Kamchatka	19	9	2.11	0.895	0.600
Sakhalin	21	4	5.25	0.648	0.604

n—number of specimens; *h*—number of mitotypes; *n/h*—number of specimens with same mitotype; *H*—index of haplotype diversity; π —index of nucleotide diversity.

Table 4. *Fst* values (above the diagonal) and significance level ($P(Fst)$, under the diagonal) obtained when comparing the regional samples.

	Chukotka	Koryak Coast	Kamchatka	Sakhalin
Chukotka		0.01040	0.03940*	0.12436*
Koryak Coast	0.10645		0.04918*	0.20222*
Kamchatka	0.0000*	0.01465*		0.16505*
Sakhalin	0.0000*	0.0000*	0.0000*	

The asterisk (*) indicates significant differences.

types of whales observed in Chukotka and the Koryak Coast. A decrease in the absolute number of the mitotypes noted for the whales of the Koryak Coast was not found for such parameters as “the number of specimens with the same mitotypes” and “the index of haplotype diversity,” and it is linked, probably, with the small sample size. Regard must be paid to the absence of statistical differences between the California-Chukchi population analyzed previously (LeDuc et al., 2002), when 120 specimens were included in the analysis (523 bp fragment, GenBank AF326789–AF326824), and our Chukotka ($Fst = -0.001$, $P(Fst) = 0.619$) and Koryak Coast ($Fst = -0.002$, $P(Fst) = 0.359$) samples when comparing the frequency of the haplotypes of the control region.

The gray whales feeding along the eastern coast of Kamchatka and Sakhalin differed significantly not only from the groups inhabiting Chukotka and the Koryak Coast, but also between each other. This was caused by the significant decrease of the number of mitochondrial lineages and their diversity parameters. Such a pattern and ambiguity of its interpretation have been noted since the beginning of the genetic studies of the Sakhalin population of gray whales (LeDuc et al., 2002).

The uncertainty is that both explanations, the presence of whales of the original, previously presumed extinct, Korean-Okhotsk population and the arrival of California-Chukchi whales that chose this area as a new feeding ground, may be true. In the first case, we are faced with the bottleneck effect, when the initial

Fig. 2. Ratio of the mitotype frequencies in the regional samples of the gray whales. (1) Mitotypes found exclusively on Chukotka or Koryak Coast; (2) only at Kamchatka; (3) both at Chukotka/Koryak Coast and at Kamchatka/Sakhalin. The numbers on the diagrams indicate the dominant mitotypes.

diversity was eliminated, and the current diversity is based on the single mitotypes of a small number of surviving whales. In the second case the same result may be explained by the initially low number of the newcomers. If the latter hypothesis is true, and the migration route will become a pathway for young individuals that come here with their mothers, the number of migrating whales will increase, but number of mitotypes will remain limited, and there will be no reason to suspect phylogenetic affinity between these mitotypes.

When analyzing the mitochondrial lineages as markers of distinct populations, regard must be paid to mitotype 2, which is the most distinct from all the other mitotypes known by now. This mitotype is registered frequently for the whales inhabiting the historical range of the Korean-Okhotsk population. However, analyzing the published data on the sequence of the control region of mtDNA in the gray whales studied in the reproduction area along the Baja California coast, we cannot make conclusions on the population or regional specificity of the haplotypes reported. For example, the haplotype of control region Hap1, the sequence of which coincides by 100% with the sequence of the homologous fragment of haplotype B/Bx in our mitotype 2 (Fig. 3a), was found in the Californian population of the gray whales (118 speci-

mens, GenBank EU807842–EU807866, 441 bp, (Alter et al., 2009). Haplotype Hap1 was one of the dominating haplotypes (7.6% by frequency) within those samples, but no related variants were found (Alter et al., 2009). In another sample of the same area (83 specimens, GenBank AY514457–AY514484, 305 bp), there was no sequence that referred directly to the haplotype B/Bx (Goerlitz et al., 2003). However, five other haplotypes that differed from B/Bx by 2–3 nucleotide substitutions and that formed the well supported (bootstrapping value of 99, Neighbor Joining method) clade with it (Fig. 3b) were found. The summarized rate of these five haplotypes in the sample was 12% (Goerlitz et al., 2003); i.e., it was also quite high.

Therefore, we assume that in the California-Chukchi population the mitochondrial lineages relative to mitotype 2 may be present in both a significant amount and of perceptible diversity. The last assumption is quite important, because this mitotype is present in whales inhabiting Chukotka, Kamchatka, and Sakhalin by a unique sequence that has no similar variants. Meantime, taking into account the significant genetic distance and, therefore, the evolutionary time of the mitotype existence, such variants evidently should exist in the modern gene pool of the studied species.

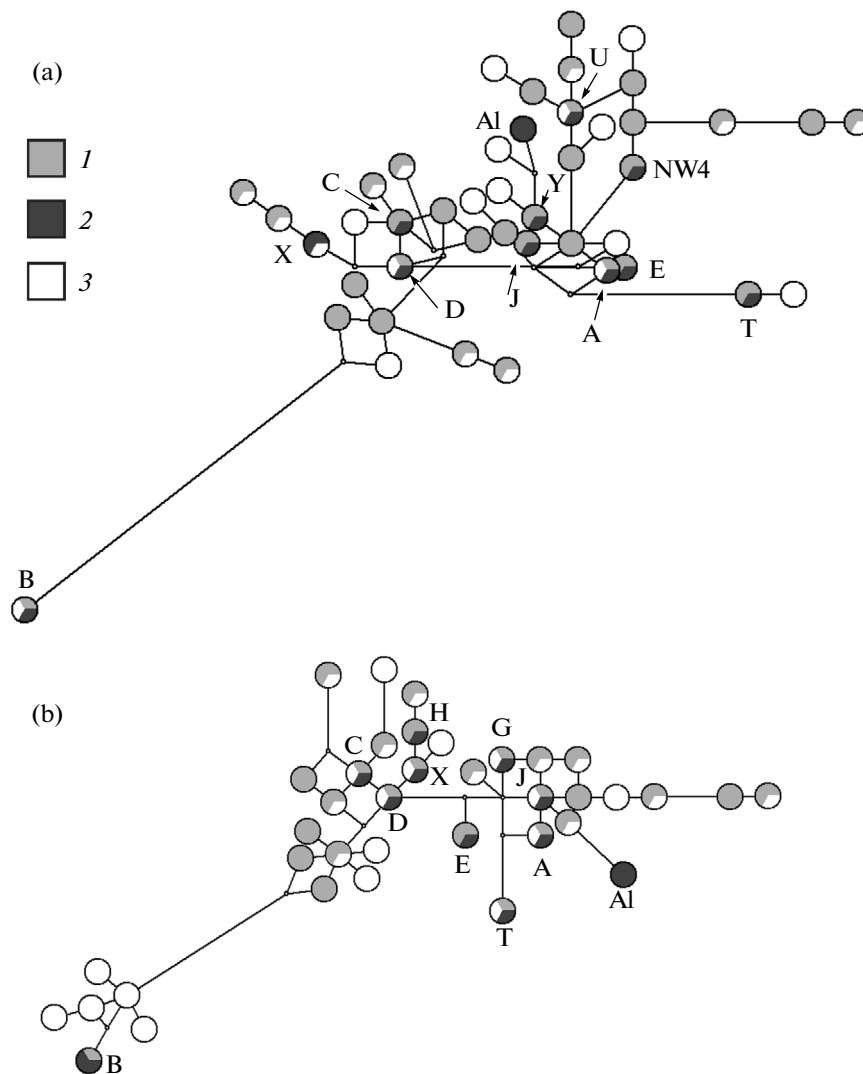

Fig. 3. Median joining networks of the mtDNA control region haplotypes known for gray whales in coastal waters of Chukotka and the Koryak Coast (1) and Sakhalin and Kamchatka (2) according to LeDuc et al., 2002 and the present study; and in the reproductive area of the gray whales in Baja California (3) accordingly to Alter et al., 2009 (a) and to Goerlitz et al., 2003 (b).

The hypothesis of the presence of such mitotypes in the California-Chukchi population of gray whales cannot be currently tested because of the absence of data on the longer sequences of the mtDNA of this population. Based on our data, an important conclusion may be made: the restriction of a genetic analysis to the sequences of the mtDNA control region only (as was done up until the present time) is insufficient to clarify the pattern of regional distribution of gray whale mitochondrial lineages. The same haplotypes of the mtDNA control region found in the historical range of the Korean-Okhotsk population and in Chukotka and the Koryak Coast, such as the haplotypes A, C, and D may be associated with different cytochrome b haplotypes in the different mitochondrial genomes (Table 1).

Unfortunately, the sequences of the ND2 gene of the gray whale are absent in GenBank, and the cytochrome b gene is represented by only 10 sequences, despite the fact that this locus is used traditionally to study the population structure of mammals. These sequences of cytochrome b reflect six haplotypes, five of which coincide with our data, except for one unusual substitution, which is common for sequences of EF165336–EF165341 and may appear as a result of a system error during sequencing in one of two labs. One of these five haplotypes, haplotype 2 (EF165337), matches the haplotype CB-02 presented in mitotype 2 (Table 1). This haplotype was found primarily in a sample of California-Chukchi whales, analyzed earlier (LeDuc et al., 2002) but unfortunately the authors of the later study (Alter and Palumbi, 2009) did not provide data on either the frequency of the haplotype

in the sample or of its coexistence with the haplotype of the control region in individual mitochondrial genomes.

The existence of two distinct mitotype groups in the Pacific populations of gray whales is an interesting fact that appears to be worth of further study. However, it is obvious that the initial divergence of these mitotype groups reflects much more distant times than development of the recent gray whale population structure in the Pacific Ocean, which is linked to the second part of the Holocene (Swartz et al., 2006). Probably, here we are faced with the result of bidirectional migrations of the gray whales of the Atlantic and Pacific populations during the interglacial periods. But recently the distance between haplotypes does not correlate with the different parts of this species' modern (pre-whaling) range. The data on the occurrence and frequency of the mitochondrial lineages of the gray whales inhabiting the Pacific Ocean may be used to compare their local diversity, but not to describe the current population structure of this species.

ACKNOWLEDGMENTS

The authors are grateful to A.M. Burdin and V.V. Vertyankin for the courtesy of some tissue samples they provided for analyses.

The sampling was supported by the National Marine Fisheries Service (United States) and a grant from the International Whaling Commission. The molecular-genetic analyses were performed within the framework of the Permanent expedition of the Russian Academy of Sciences studying Red Book animals and other focus species of Russia (The Beluga White Whale Program) and have been supported financially by the Russian Geographical Society.

About the NOAA Technical Memorandum series

The National Oceanic and Atmospheric Administration (NOAA), organized in 1970, has evolved into an agency which establishes national policies and manages and conserves our oceanic, coastal, and atmospheric resources. An organizational element within NOAA, the Office of Fisheries is responsible for fisheries policy and the direction of the National Marine Fisheries Service (NMFS).

In addition to its formal publications, the NMFS uses the NOAA Technical Memorandum series to issue informal scientific and technical publications when complete formal review and editorial processing are not appropriate or feasible. Documents within this series, however, reflect sound professional work and may be referenced in the formal scientific and technical literature.

SWFSC Technical Memorandums are available online at the following websites:

SWFSC: <https://swfsc.noaa.gov>

NOAA Repository: <https://repository.library.noaa.gov/>

NTIS National Technical Reports Library: <https://ntrl.ntis.gov/NTRL/>

Accessibility information

NOAA Fisheries Southwest Fisheries Science Center (SWFSC) is committed to making our publications and supporting electronic documents accessible to individuals of all abilities. The complexity of some of SWFSC's publications, information, data, and products may make access difficult for some. If you encounter material in this document that you cannot access or use, please contact us so that we may assist you.

ACKNOWLEDGEMENTS

We extend our gratitude to the NOAA Fisheries West Coast Regional Office and Southwest Fisheries Science Center for their contributions to, and support of, this work.

EXECUTIVE SUMMARY

Observations of gray whales (*Eschrichtius robustus*) from the western North Pacific (WNP) migrating to areas off the coast of North America (Alaska to Mexico) raised concerns that this small population could be encountered during a hunt of eastern North Pacific (ENP) gray whales proposed by the Makah Indian Tribe in northern Washington, USA. In 2013, an analysis was conducted to estimate the probability of striking (i.e. killing or seriously injuring) a WNP whale under the Makah Tribe's hunt proposal (Moore and Weller 2013). NOAA Fisheries is considering a draft proposal that would govern ENP gray whale hunts by the Makah for up to 10 years. Under the draft proposal, hunting seasons would alternate between winter-spring hunts in even-numbered years and summer hunts during odd-numbered years. It is presumed that only in even-numbered years (thus, for 5 of the 10 years) would WNP whales potentially be encountered during the hunt. In each of these years, the draft proposal would allow for up to 3 gray whales to be struck. Based on this alternative hunting scheme and the availability of updated gray whale data, this report re-estimates the probability of striking a WNP whale reported earlier (Moore and Weller 2013). One of the models from the 2013 analysis (Model 2A) was used to generate new estimates. We estimate that for an individual strike on a gray whale, the expected probability of it being a WNP whale is 0.004 (95% CRI: 0.002 – 0.007). For a single year's hunt (3 strikes), the expected probability of striking ≥ 1 WNP whale would be 0.012 (0.006 – 0.019). Across the 10-year hunt period (15 strikes), the probability of striking ≥ 1 WNP whale would be 0.058 (0.030 – 0.093).

INTRODUCTION

Two gray whale (*Eschrichtius robustus*) populations are recognized in the North Pacific Ocean. Significant mitochondrial and nuclear genetic differences have been found between whales in the western North Pacific (WNP) and those in the eastern North Pacific (ENP) (LeDuc *et al.*, 2002, Lang *et al.* 2010, Lang *et al.*, 2011). The ENP population ranges from wintering areas in Baja California, Mexico, to feeding areas in the Bering, Beaufort, and Chukchi Seas (Fig. 1). An exception to this generality is the relatively small number (100s) of whales that summer and feed along the Pacific coast between Kodiak Island, Alaska, and northern California (Weller *et al.*, 2013). These whales are collectively called the Pacific Coast Feeding Group (PCFG). The International Whaling Commission (IWC) has defined PCFG whales as individuals observed between 1 June and 30 November from 41°N to 52°N in two or more years (IWC, 2012), and NOAA Fisheries has adopted this definition in recent assessments (Weller *et al.*, 2013). The usual and accustomed (U&A) fishing grounds of the Makah Indian Tribe are off the coast of northern Washington, USA, and overlap with a portion of the PCFG summering area (Fig. 1).

Figure 1. Areas in the western and eastern North Pacific mentioned in the report.

The WNP population feeds in the Okhotsk Sea off Sakhalin Island, Russia (Weller *et al.*, 1999; Weller *et al.* 2012), and in nearshore waters of the southwestern Bering Sea off the southeastern Kamchatka Peninsula (Tyurneva *et al.*, 2010). The historical distribution of gray whales in the Okhotsk Sea greatly exceeded what is found today (Reeves *et al.*, 2008). Whales associated with the Sakhalin feeding area can be absent for all or part of a given feeding season (Bradford *et al.*, 2008), indicating they use other areas during the summer and fall feeding period. Some of the whales identified feeding in the coastal waters off Sakhalin, including reproductive females and calves, have been documented off the southern and eastern coast of Kamchatka (Tyurneva *et al.*, 2010). A small number of whales observed off Sakhalin have also been sighted off the northern Kuril Islands in the eastern Okhotsk Sea and Bering Island in the western Bering Sea (Weller *et al.*, 2003).

Mixing of whales identified in the WNP and ENP has been observed (Weller *et al.*, 2012). Lang (2010) reported that two adult individuals from the WNP, sampled off Sakhalin in 1998 and 2004, matched the microsatellite genotypes, mtDNA haplotypes, and sexes (one male, one female) of two whales sampled off Santa Barbara, California in March 1995. Between 2010 and 2012 three whales outfitted with satellite transmitters were tracked moving from Sakhalin in the WNP to the ENP (Mate *et al.*, 2015). Finally, photographic matches between the WNP and ENP, including matches between Sakhalin, Vancouver Island and Laguna San Ignacio (Fig. 1), have further confirmed use of areas in the ENP by whales identified in the WNP (Weller *et al.*, 2012, Urbán *et al.*, 2012). Despite this level of mixing, significant mtDNA and nuclear genetic differences between whales in the WNP and ENP have been found (LeDuc *et al.* 2002, Lang *et al.*, 2011).

In 1995, following the 1994 delisting of ENP gray whales under the U.S. Endangered Species Act, the Makah Indian Tribe notified NOAA Fisheries of its interest in re-establishing limited ceremonial and subsistence whale hunting. The decision-making history on this issue is complex and not described here except to note that in 2005, the Makah Tribe submitted a detailed proposal for hunting ENP gray whales in the coastal portion of its U&A off northern Washington, USA, as part of a request for a waiver of the U.S. Marine Mammal Protection Act's (MMPA) take moratorium (16 USC 1371(a)(3)(A)). Subsequently, observations of WNP gray whales migrating through areas off the coast of North America (Alaska to Mexico) emphasized the need to evaluate the probability of a WNP gray whale being encountered in aboriginal hunts for ENP gray whales (IWC, 2012). Following recommendations of the Scientific Committee of the International Whaling Commission (IWC), analyses were conducted to estimate such probability in the context of the Makah Tribe's hunt proposal (Moore and Weller, 2013). These analyses informed a draft Environmental Impact Statement (DEIS), completed in 2015 (NMFS, 2015), pertaining to the Makah Tribe's MMPA waiver request.

NOAA Fisheries is presently considering a MMPA waiver and associated draft proposal that would govern a modified version of the Tribe's hunt proposal. The objective of the analysis reported here was to provide updated estimates of the probability that one or more WNP whales might be subjected to strikes¹, unsuccessful strike attempts (i.e., harpoon throws that do not penetrate), and vessel approaches during hunts and hunt training exercises considered in the draft proposal. This report is based on the methods used by Moore and Weller (2013) and incorporates updated information about the population sizes of ENP and WNP gray whales and their occurrence within the proposed hunt area.

METHODS

Hunt proposal

NOAA Fisheries' draft proposal would govern a Makah Tribe hunt of ENP gray whales in the coastal portion of the U&A (i.e., the "hunt area") over a 10-year hunt period. In odd-numbered years, the hunt would take place from 1 July through 31 October, a period when no sightings of WNP whales have been recorded in the ENP, and when gray whales generally (apart from PCFG

¹ As described in NOAA Fisheries' DEIS (NMFS, 2015), the term "strike" is interpreted to be consistent with the IWC Schedule definition as meaning "to penetrate with a weapon used for whaling."

animals) are in northern feeding areas. Thus, hunted animals in these odd-numbered years would presumably belong to the PCFG and it is assumed that WNP whales would not be at risk from proposed hunt operations. In even-numbered years, the hunt would take place from 1 December through 31 May. This period coincides with both the southward (December to mid-February) and northward (mid-February to late May) migration of ENP whales and overlaps with the time when WNP gray whales have been sighted in the ENP. Thus, in even-numbered years there is a potential risk to WNP whales from proposed hunt operations. In each of the even-numbered years, a maximum of 3 gray whales per year could be struck (including “struck and lost” animals). Over the 10-year period of the proposed hunt, a maximum of 15 whales could be struck (in even-numbered years) that would have some probability of being WNP whales. We therefore evaluate the probability of striking at least one WNP whale per even-numbered year (out of 3 strikes) and for the 10-year period (out of 15 strikes). We also evaluate associated rates of WNP whales being subjected to aforementioned “unsuccessful strike attempts” (i.e., harpoon throws that do not penetrate) and “approaches” (i.e., whales approached by vessels during hunts and hunt training exercises).

Data

Abundance estimates - The most recent ENP abundance estimate (for 2015/2016) is 26,960 (CV = 0.05) (Durban *et al.*, 2017). The most recent WNP abundance estimate (for 2015) is 200 (CV = 0.03) for the 1+ population (i.e., excluding calves) (Cooke 2018). We then multiplied the WNP estimate by 1.099 to account for calves. This multiplier is based on the ratio of the population size with and without calves in 2012 (IUCN, 2012).

Mixing proportions based on sightings in the Makah Hunt Area - During spring surveys (March to May) in 1996-2012 there were 181 observed whale-days in the Makah hunt area (Calambokidis *et al.*, 2014). To clarify the term “whale-day” – all sightings of an individual on a particular day collectively count as 1 whale-day (e.g., multiple sightings of the same individual on the same day count as just 1 whale-day, but the same individual seen the next day would count as a second whale-day). None of the 181 whale-days observed included WNP whales²; 73 (40.3%) were considered PCFG whales; and the rest (108, or 59.7%) were assumed to be migrating ENP whales.

However, rather than use 40.3% as the expected PCFG proportion in the hunt area during an even-year hunt, we use 28% for this mixing proportion (i.e. 72% of animals encountered during an even-year hunt are likely to be non-PCFG animals). This value is based on analyses summarized in a 2018 IWC workshop (IWC, 2018).

Proportion of WNP whales migrating with ENP whales - The proportion of the WNP population that migrates along the North American coast is unknown but estimated to be at least 0.37 based on analysis by Cooke (2015) and reported to a 2015 IWC workshop on gray whale population structure (IWC, 2016).

² Although not in the Makah hunt area, Weller *et al.* (2012) report observing three WNP whales on 2 May 2004 and three more on 25 April 2008 near Barkley Sound off the west coast of southern Vancouver Island, British Columbia, Canada.

Model

Moore and Weller (2013) considered four models in their analysis but they based final inferences on what they termed Model 2B. Here, we use Model 2A instead. Models 2A and 2B are similar. The difference is that for Model 2A, the conditional probability of a non-PCFG whale being a WNP (rather than ENP) whale is simply based on the ratio of WNP:ENP population size. This is an intuitive estimator, though it does rely on the assumption that WNP and ENP animals migrating together are using the same migration corridors and behaving similarly. For Model 2B, this assumption is relaxed and we allow for broader uncertainty by stating that the conditional probability varies uniformly from zero (if the WNP whales do not migrate through the Makah area at all) to some maximum value that is based on (but not equivalent to) the ratio of WNP:ENP population size. However, it is difficult to define that maximum value, and allowing a lower probability of zero is not precautionary and arguably should not be considered without supporting evidence.

Model 2 (A and B) makes use of the mixing proportion/sightings data for the Makah hunt area, as well as WNP and ENP abundance estimates. WNP whales are assumed to be moving with the ENP migrants, so that the marginal probability of a WNP whale being struck is the probability that the struck whale is a migrant, P_{mig} (i.e., probability of not being a PCFG whale), multiplied by the conditional probability of being a WNP whale given that it is a migrant ($P_{\text{WNP}|\text{mig}}$). Thus, $P_{\text{WNP}} = P_{\text{mig}}P_{\text{WNP}|\text{mig}}$.

P_{mig} is defined as $1 - P_{\text{PCFG}}$, where P_{PCFG} is given by an informative prior: $P_{\text{PCFG}} \sim \text{Beta}(5.3648, 13.7952)$ which has a mean of 0.28 and SD of 0.1 (IWC 2018).

We assume that the per-capita likelihood of a migrating (non-PCFG) whale in the hunt area being a WNP whale (i.e., $P_{\text{WNP}|\text{mig}}$) is simply given by the proportion of the migrating population made up of WNP whales. This proportion depends on what fraction of the WNP population migrates along the U.S. West Coast, which we call m , and the relative size of the WNP to the ENP population. Thus, $P_{\text{WNP}|\text{mig}} = mN_{\text{WNP}} / (mN_{\text{WNP}} + N_{\text{ENP}})$. Let $m \sim \text{Uniform}(0.37, 1)$, based on Cooke *et al.* (2015). N_{WNP} and N_{ENP} are treated as lognormally distributed variables with means and CVs as given above.

Estimation

Earlier analyses (Moore and Weller, 2013) used Bayesian estimation. In the current exercise, analysis was conducted using OpenBUGS software, but estimation is not strictly Bayesian because there are no new data updating the informative prior inputs. Rather, the present analysis is essentially a Monte Carlo procedure, with distributions for the parameters of interest (e.g., probability of striking a WNP whale) being derived from random draws from informed prior distributions for the input parameters. Derived parameter distributions are summarized from two MCMC chains, each 25,000 samples in length (50,000 samples total).

Derived parameters

The key parameter of interest is the per-strike probability of striking a WNP whale. Derived from this parameter are the probabilities of striking at least one WNP out of 3 gray whale strikes (i.e., the annual probability of striking a WNP whale, for the even-numbered years) or out of 15 gray

whale strikes (i.e., probability for the whole 10-year period). These are calculated as $P(x > 0) = 1 - (1 - P_{WNP})^X$, where X is 3 or 15. Additionally, we can derive the expected number of WNP strikes as $E(x) = P_{WNP}X$. Using data collected during previous hunts (NMFS, 2015), the following two assumptions were used to calculate analogous estimates for vessel approaches and unsuccessful strike attempts: (1) there will be 353 vessel approaches per year (3530 across all 10 years)³, and (2) there will be 6 unsuccessful strike attempts for every strike in an even-year hunt⁴.

RESULTS

Parameter estimates

Estimated parameters from all model sets are in Table 1. Figure 2 shows the distribution for P_{WNP} . It is straightforward to integrate across the uncertainty in P_{WNP} to obtain a single probability estimate. We did this for the probability of striking ≥ 1 WNP whale over the entire 10-year hunt period (i.e., out of 15 strikes). This probability was 0.058.

Table 1. Distribution summaries for key model parameters. “Prob(WNP)” is the probability of at least 1 WNP animal being struck or subjected to unsuccessful strike attempts or vessel approaches given the specified number of events.

Parameter	Posterior mean	2.5% CRI	Posterior median	97.5% CRI
Prob(WNP) for a single interaction, i.e., P_{WNP}	0.004	0.002	0.004	0.007
Prob(WNP 3 strikes in 1 yr)	0.012	0.006	0.012	0.019
Prob(WNP 15 strikes in 10 yrs)	0.058	0.030	0.057	0.093
Prob(WNP 18 unsuccessful strike attempts in 1 yr)	0.070	0.036	0.069	0.110
Prob(WNP 90 unsuccessful strike attempts in 10 yrs)	0.299	0.167	0.298	0.442
Prob(WNP 353 approaches in 1 yr)	0.735	0.511	0.751	0.899
Prob(WNP 3530 approaches in 10 yrs)	~ 1.0	0.999	~ 1.0	~ 1.0
Expected WNP 3 strikes in 1 yr	0.012	0.006	0.012	0.019
Expected WNP 15 strikes in 10 yrs	0.060	0.030	0.059	0.097
Expected WNP 18 unsuccessful strike attempts in 1 yr	0.072	0.036	0.071	0.116
Expected WNP 90 unsuccessful strike attempts in 10 yrs	0.361	0.182	0.353	0.582
Expected WNP 353 approaches in 1 yr	1.416	0.714	1.386	2.283
Expected WNP 3530 approaches in 10 yrs	14.160	7.141	13.860	22.830

³ This number is conservative because it assumes that all approaches (hunting and training) in both even and odd years occur during the winter/spring period when WNP whales may be present. Realistically we would expect a substantial number of approaches to occur outside this period, i.e., during the summer when ocean conditions are more favorable and, in odd years, when hunting approaches are restricted to July - October.

⁴ We expect zero in odd years because the draft proposal limits training strikes (which count as unsuccessful strike attempts) to the summer-fall hunting season, when WNP whales are not expected to be present.

Figure 2. Posterior distribution for probability that any given strike is a WNP whale.

DISCUSSION

Estimates from our analysis may be precautionary since they assume that the Makah hunt will achieve proposed maximum strike limits, and because the assumption of Model 2A is that WNP whales are homogenously mixed with ENP whales. The likelihood of striking a WNP whale is overestimated if fewer total animals are struck or if in reality the WNP animals use a different migration corridor and are less likely to travel through the Makah hunt area. Given uncertainties associated with the model and scenario assumptions, these results serve as a rough approximation of the potential for WNP gray whales to be subjected to strikes, unsuccessful strike attempts and vessel approaches during a Makah hunt operating under a draft proposal currently being considered by NOAA Fisheries.

email: maureen.hinman@trade.gov.) This meeting is physically accessible to people with disabilities. Requests for sign language interpretation or other auxiliary aids should be directed to OEEI at (202) 482-5225 no less than one week prior to the meeting.

SUPPLEMENTARY INFORMATION: The meeting will take place from 8:30 a.m. to 3:30 p.m. EDT. The general meeting is open to the public and time will be permitted for public comment from 3:00-3:30 p.m. EDT. Those interested in attending must provide notification by Tuesday, March 15, 2016 at 5:00 p.m. EDT, via the contact information provided above. Written comments concerning ETTAC affairs are welcome any time before or after the meeting. Minutes will be available within 30 days of this meeting.

Topics to be considered: The agenda for this meeting will include discussion of priorities and objectives for the committee, trade promotion programs within the International Trade Administration, and subcommittee working meetings.

Background: The ETTAC is mandated by Public Law 103-392. It was created to advise the U.S. government on environmental trade policies and programs, and to help it to focus its resources on increasing the exports of the U.S. environmental industry. ETTAC operates as an advisory committee to the Secretary of Commerce and the Trade Promotion Coordinating Committee (TPCC). ETTAC was originally chartered in May of 1994. It was most recently re-chartered until August 2016.

Dated: February 25, 2016.

Man Cho,

Acting Office Director, Office of Energy and Environmental Industries.

National Oceanic and Atmospheric Administration

RIN 0648-XA937

Guidelines for Assessing Marine Mammal Stocks

AGENCY: National Marine Fisheries Service (NMFS), National Oceanic and Atmospheric Administration (NOAA), Commerce.

ACTION: Notice of availability; response to comments.

SUMMARY: NMFS has incorporated public comments into revisions of the

guidelines for preparing stock assessment reports (SARs) pursuant to section 117 of the Marine Mammal Protection Act (MMPA). The revised guidelines are now complete and available to the public.

ADDRESSES: Electronic copies of the guidelines are available on the Internet at the following address: <http://www.nmfs.noaa.gov/pr/sars/guidelines.htm>.

FOR FURTHER INFORMATION CONTACT: Shannon Bettridge, Office of Protected Resources, 301-427-8402, Shannon.Bettridge@noaa.gov.

SUPPLEMENTARY INFORMATION:

Background

Section 117 of the Marine Mammal Protection Act (MMPA) (16 U.S.C. 1361 *et seq.*) requires NMFS and the U.S. Fish and Wildlife Service (FWS) to prepare stock assessments for each stock of marine mammals occurring in waters under the jurisdiction of the United States. These reports must contain information regarding the distribution and abundance of the stock, population growth rates and trends, estimates of annual human-caused mortality and serious injury from all sources, descriptions of the fisheries with which the stock interacts, and the status of the stock. Initial stock assessment reports (SARs, or Reports) were first completed in 1995.

NMFS convened a workshop in June 1994, including representatives from NMFS, FWS, and the Marine Mammal Commission (Commission), to develop draft guidelines for preparing SARs. The report of this workshop (Barlow *et al.*, 1995) included the guidelines for preparing SARs and a summary of the discussions upon which the guidelines were based. The draft guidelines were made available, along with the initial draft SARs, for public review and comment (59 FR 40527, August 9, 1994), and were finalized August 25, 1995 (60 FR 44308).

In 1996, NMFS convened a second workshop (referred to as the Guidelines for Assessing Marine Mammal Stocks, or "GAMMS," workshop) to review the guidelines and to recommend changes to them, if appropriate. Workshop participants included representatives from NMFS, FWS, the Commission, and the three regional scientific review groups (SRGs). The report of that workshop (Wade and Angliss, 1997) summarized the discussion at the workshop and contained revised guidelines. The revised guidelines represented minor changes from the initial version. The revised guidelines were made available for public review

and comment along with revised stock assessment reports on January 21, 1997 (62 FR 3005) and later finalized.

In September 2003, NMFS again convened a workshop (referred to as GAMMS II) to review the guidelines and again recommend minor changes to them. Participants at the workshop included representatives of NMFS, FWS, the Commission, and the regional SRGs. Changes to the guidelines resulting from the 2003 workshop were directed primarily toward identifying population stocks and estimating Potential Biological Removal (PBR) for declining stocks of marine mammals. The revised guidelines were made available for public review and comment on November 18, 2004 (69 FR 67541) and finalized on June 20, 2005 (70 FR 35397, NMFS 2005).

In February 2011, NMFS convened another workshop (referred to as GAMMS III) to review the guidelines and again recommend changes to them. Participants at the workshop included representatives from NMFS, FWS, the Commission, and the three regional SRGs. The objectives of the GAMMS III workshop were to (1) consider methods for assessing stock status (*i.e.*, how to apply the PBR framework) when abundance data are outdated, nonexistent, or only partially available; (2) develop policies on stock identification and application of the PBR framework to small stocks, transboundary stocks, and situations where stocks mix; and (3) develop consistent national approaches to a variety of other issues, including reporting mortality and serious injury information in assessments. Nine specific topics were discussed at the workshop. The deliberations of these nine topics resulted in a series of recommended modifications to the current guidelines (NMFS, 2005). The main body of the GAMMS III workshop report includes summaries of the presentations and discussions for each of the nine agenda topics, as well as recommended revisions to individual sections of the guidelines (Moore and Merrick, 2011). Appendices to the workshop report provide a variety of supporting documents, including the full proposed revision of the guidelines (Appendix IV). On January 24, 2012 (77 FR 3450), NMFS made the GAMMS III workshop report available for public review, and requested comment on the proposed revisions in Appendix IV. The report is available at http://www.nmfs.noaa.gov/pr/pdfs/sars/gamms3_nmfsopr47.pdf.

Revisions to the Guidelines for Preparing Stock Assessment Reports

The paragraphs below describe the proposed guideline revisions that were recommended by the GAMMS III workshop participants, as well as a summary of how NMFS has or has not incorporated those proposed revisions into the final revised guidelines. They are organized by topic, as outlined in Appendix IV of the GAMMS III workshop report.

Topic 1: PBR calculations with outdated abundance estimates. For an increasing number of marine mammal stocks, the most recent abundance estimates are more than 8 years old. Under existing guidelines (NMFS, 2005), these are considered to be outdated and thus not used to calculate PBR. The current practice is to consider the PBR for a stock to be “undetermined” after supporting survey information is more than eight years old, unless there is compelling evidence that the stock has not declined during that time.

The workshop participants recommended and the proposed guidelines included the following revisions to calculate PBRs for stocks with old abundance information: (1) During years 1–8 after the most recent abundance survey, “uncertainty projections” would be used, based on uniform distribution assumptions, to serially reduce the minimum abundance estimate (N_{min}) by a small increment each year; (2) after eight years, and assuming no new abundance estimate has become available, a worst-case scenario would be assumed (*i.e.*, a plausible 10-percent decline per year since the most recent survey), and so a retroactive 10-percent decline per year would be applied; and (3) if data to estimate a population trend model are available, such a model could have been used to influence the uncertainty projections during the first eight years.

NMFS received a number of comments expressing strenuous objection to/concern with the proposed framework for stocks with outdated abundance estimates, which has led us to reevaluate the topic. As such, NMFS is not finalizing these recommended changes related to Topic 1 at this time. Rather, we will be further analyzing this issue, and should we contemplate changes to the guidelines regarding this topic, NMFS will propose them and solicit public comment in a separate action.

Topic 2: Improving stock identification. For most marine mammal species, few stock definition changes have been made since the initial SARs

were written. The proposed guidelines directed that each Report state in the “Stock Definition and Geographic Range” section whether it is plausible the stock contains multiple demographically independent populations that should be separate stocks, along with a brief rationale. If additional structure is plausible and human-caused mortality or serious injury is concentrated within a portion of the range of the stock, the Reports should identify the portion of the range in which the mortality or serious injury occurs. These revisions to the guidelines have been made.

The GAMMS III workshop also addressed the terms “demographic isolation” and “reproductive isolation.” Workshop participants agreed that the intended meaning of these terms when originally included in the guidelines was not of complete isolation, which implies that there should be no interchange between stocks. Therefore, they recommended and the proposed guidelines included clarification of terminology by replacing references to “demographic isolation” and “reproductive isolation” with “demographic independence” and “reproductive independence,” respectively. These revisions to the guidelines have been made.

Related to this topic, the workshop participants also recommended that NMFS convene a national workshop to systematically review the status of stock identification efforts and to identify and prioritize the information needed to improve stock identification. NMFS convened such a workshop in August 2014 (Martien *et al.*, 2015). See response to Comment 10.

Topic 3a: Assessment of very small stocks. The PBR estimate for some stocks may be very small (just a few animals or even less than one). In such cases, low levels of observer coverage may introduce substantial small-sample bias in bycatch estimates. The proposed guideline revisions included a table in the Technical Details section that provides guidance on the amount of sampling effort (observer coverage and/or number of years of data pooling) required to limit small-sample bias, given a certain PBR level. If suggested sampling goals (per the table) cannot be met, the proposed guidelines instructed that mortality should be estimated and reported, but the estimates should be qualified in the SARs by stating they could be biased. NMFS has incorporated this language into the revised guidelines.

The proposed guidelines suggested removing the following sentence from the Status of Stocks section: “In the

complete absence of any information on sources of mortality, and without guidance from the Scientific Review Groups, the precautionary principle should be followed and the default stock status should be strategic until information is available to demonstrate otherwise.” NMFS has incorporated this revision into the guidelines, as NMFS does not consider the original text to be consistent with the MMPA’s definition of “strategic.”

Topic 3b: Assessment of small endangered stocks. Some endangered species, like Hawaiian monk seals, are declining with little to no direct human-caused mortality, and the stock’s dynamics therefore do not conform to the underlying model for calculating PBR. Thus, PBR estimates for some endangered species stocks have not been included or have been considered “undetermined” in SARs. The proposed guidelines instructed that in such cases, if feasible, PBR should still be calculated and included in the SARs to comply with the MMPA. In situations where a stock’s dynamics do not conform to the underlying model for calculating PBR, a qualifying statement should accompany the PBR estimate in the SAR. NMFS has incorporated this language into the revised guidelines.

Topic 4: Apportioning PBR across feeding aggregations, allocating mortality for mixed stocks, and estimating PBR for transboundary stocks.

Feeding aggregations: Given the definition that a population stock consists of individuals in common spatial arrangements that interbreed when mature, population stocks of species that have discrete feeding and breeding grounds (*e.g.*, humpback whales) have generally been defined based on breeding ground stocks. However, given the strong maternal fidelity to feeding grounds, migratory species such as humpback whales can have feeding aggregations that are demographically independent with limited movement of individuals between feeding aggregations. Such feeding aggregations can consist of a portion of one breeding population, or of portions of multiple breeding populations, and can represent a single demographically-independent unit, or a mix of two or more demographically-independent units. Although this approach of identifying stocks based on feeding aggregations seemed feasible, workshop participants felt this approach added significant complexity without providing substantial management advantages. The workshop participants did not recommend any such changes to the guidelines at this point. None were

included in the proposed guidelines nor have any been made in the final revisions.

Allocating mortality for mixed stocks:

In some cases, mortality and serious injury occur in areas where more than one stock of marine mammals occurs. The proposed guidelines specify that when biological information is sufficient to identify the stock from which a dead or seriously injured animal came, the mortality or serious injury should be associated only with that stock. When one or more deaths or serious injuries cannot be assigned directly to a stock, then those deaths or serious injuries may be partitioned among stocks within the appropriate geographic area, provided there is sufficient information to support such partitioning. In those cases, Reports should discuss the potential for over- or under-estimating stock-specific mortality and serious injury. In cases where mortalities and serious injuries cannot be assigned directly to a stock and available information is not sufficient to support partitioning those deaths and serious injuries among stocks, the proposed guidelines instruct that the total unassigned mortality and serious injuries should be assigned to each stock within the appropriate geographic area. When deaths and serious injuries are assigned to each overlapping stock in this manner, the Reports should discuss the potential for over-estimating stock-specific mortality and serious injury. NMFS has incorporated this language into the revised guidelines.

Transboundary stocks: The proposed guidelines strengthen the language regarding transboundary stocks, cautioning against extrapolating abundance estimates from one surveyed area to another unsurveyed area to estimate range-wide PBR. They state that informed interpolation (e.g., based on habitat associations) may be used, as appropriate and supported by existing data, to fill gaps in survey coverage and estimate abundance and PBR over broader areas. If estimates of mortality or abundance from outside the U.S. EEZ cannot be determined, PBR calculations should be based on abundance in the EEZ and compared to mortality within the EEZ. NMFS has incorporated this language into the revised guidelines and has provided a footnote defining informed interpolation.

Topic 5: Clarifying reporting of mortality and serious injury incidental to commercial fishing. Currently, SARs do not consistently summarize mortality and serious injury incidental to commercial fishing. The proposed guidelines specified that SARs should

include a summary of all human-caused mortality and serious injury including information on all sources of mortality and serious injury. Additionally, a summary of mortality and serious injury incidental to U.S. commercial fisheries should be presented in a table, while mortality and serious injury from other sources (e.g., recreational fisheries, other sources of human-caused mortality and serious injury within the U.S. EEZ, foreign fisheries on the high seas) should be clearly distinguished from U.S. commercial fishery-related mortality. Finally, the proposed guidelines contained the addition of a subsection summarizing the most prevalent potential human-caused mortality and serious injury threats that are unquantified in the SARs, and the SARs should also indicate if there are no known major sources of unquantifiable human-caused mortality and serious injury. NMFS has incorporated this language into the revised guidelines.

Topic 6: When stock declines are sufficient for a strategic designation. The proposed guidelines included the following: "Stocks that have evidence suggesting at least a 50 percent decline, either based on previous abundance estimates or historical abundance estimated by back-calculation, should be noted in the Status of Stocks section as likely to be below OSP. The choice of 50 percent does not mean that OSP is at 50 percent of historical numbers, but rather that a population below this level would be below OSP with high probability. Similarly, a stock that has increased back to levels pre-dating the known decline may be within OSP; however, additional analyses may determine a population is within OSP prior to reaching historical levels." NMFS has incorporated this language into the revised guidelines.

Additionally, the workshop participants recommended and the proposed guidelines included the following interpretation of the definition of a strategic stock: "A stock shall be designated as strategic if it is declining and has a greater than 50 percent probability of a continuing decline of at least five percent per year. Such a decline, if not stopped, would result in a 50 percent decline in 15 years and would likely lead to the stock being listed as threatened. The estimate of trend should be based on data spanning at least eight years. Alternative thresholds for decline rates and duration, as well as alternative data criteria, may also be used if sufficient rationale is provided to indicate that the decline is likely to result in the stock being listed as threatened within the

foreseeable future. Stocks that have been designated as strategic due to a population decline may be designated as non-strategic if the decline is stopped and the stock is not otherwise strategic." NMFS received comments expressing concern with the proposed interpretation of "likely to be listed as a threatened species under the ESA within the foreseeable future" (sec. 3(19)(B) of the MMPA). NMFS is not finalizing the proposed changes related to this topic at this time. Rather, we will further analyze this issue. Should we contemplate changes to the guidelines regarding this topic, NMFS will propose them and solicit public comment in a separate action.

The proposed guidelines included the following direction regarding recovery factors for declining stocks: "A stock that is strategic because, based on the best available scientific information, it is declining and is likely to be listed as a threatened species under the ESA within the foreseeable future (sec. 3(19)(B) of the MMPA) should use a recovery factor between 0.1 and 0.5." As we are not finalizing the recommended changes regarding strategic stock designation (sec. 3(19)(B) of the MMPA), above, we have decided not to revise the guidelines regarding recovery factors under such situations at this time. Should changes to the guidelines regarding the above be contemplated, NMFS will include the recommended recovery factors when we solicit public comment on that action. Therefore, NMFS is not finalizing the recommended change related to this paragraph at this time.

Topic 7: Assessing stocks without abundance estimates or PBR. For many stocks, data are so sparse that it is not possible to produce an N_{min} and not possible to estimate PBR. When mortality and/or population abundance estimates are unavailable, the PBR approach cannot be used to assess populations, in spite of a statutory mandate to do so. The proposed guidelines included the following addition to the Status of Stocks section: "Likewise, trend monitoring can help inform the process of determining strategic status." NMFS has incorporated this language into the revised guidelines.

Topic 8: Characterizing uncertainty in key SAR elements. It is difficult to infer the overall uncertainty for key parameters as they are currently reported in the SARs. The proposed guidelines direct that the Stock Definition and Geographic Range, Elements of the PBR Formula, Population Trend, Annual Human-Caused Mortality and Serious Injury,

and Status of the Stock sections include a description of key uncertainties associated with parameters in these sections and an evaluation of the effects of these uncertainties associated with parameters in these sections. NMFS has incorporated this language into the revised guidelines with some minor revisions.

Topic 9: Including non-serious injuries and disturbance in SARs. Currently, many Reports include information on human-related mortality and serious injury from all known sources (not just from commercial fisheries) but do not include information on human-related non-serious injury or disturbance. The workshop participants concluded that the guidelines, with respect to the scope of content considered by the SARs, could be retained as they currently stand. However, they encouraged authors to routinely consider including information in the Reports about what “other factors” may cause a decline or impede recovery of a particular stock. A final recommended revision to the guidelines was the addition of the following italicized text: “The MMPA requires for strategic stocks a consideration of other factors that may be causing a decline or impeding recovery of the stock, including effects on marine mammal habitat and prey, or other lethal or non-lethal factors.” However, this italicized text is not contained in the MMPA, and therefore, as proposed could be misconstrued as being required by the MMPA. Therefore, the revision to the guidelines has been reworded for clarity.

Comments and Responses

NMFS solicited public comments on the proposed revisions to the guidelines (January 24, 2012, 77 FR 3450), contained in Appendix IV of the GAMMS III workshop report. NMFS received comments from the Commission, the three regional SRGs, two non-governmental environmental organizations (Humane Society of the United States and Center for Biological Diversity), representatives from the fishing industry (Western Pacific Regional Fishery Management Council, Garden State Seafood Association, Maine Lobstermen's Association, Hawaii Longline Association, Cape Cod Hook Fishermen's Association, and two individuals), the American Veterinary Medical Association, the States of Maine and Massachusetts, the Makah Indian Tribe, the Center for Regulatory Effectiveness, representatives from the oil and gas industry (American Petroleum Institute, International Association of Geophysical Contractors,

and Alaska Oil and Gas Association), and one individual.

NMFS received a number of comments supporting its efforts to improve stock identification (topic 2). Many commenters urged NMFS to prioritize conducting regular surveys for those species with the greatest human-caused mortality or oldest survey data. Many commenters disagreed with NMFS' proposals to use a precautionary approach with aging abundance estimates (topic 1) and apportion PBR and serious injuries and mortalities (topic 4). Comments on actions not related to the GAMMS (*e.g.*, convening a Take Reduction Team or listing a marine mammal species under the Endangered Species Act (ESA)), or on items not related to portions of the guidelines finalized in this action, are not included below. Comments and responses are organized below according to the relevant workshop topics outlined in Appendix IV of the report.

Comments on General Issues

Comment 1: The Commission recommended that NMFS continue to encourage more exchange between regional SRGs to ensure consistency where needed and to promote useful and informative exchange among them.

Response: NMFS acknowledges this comment and will continue to encourage exchange between SRGs and strive to ensure consistency among the groups and among the SARs. To that end, we are convening a joint meeting of the three SRGs in February 2016, in addition to individual SRG meetings.

Comment 2: The Commission recommended that NMFS consider requiring a brief summary paragraph or table on the historical trend of each stock in the SARs, where appropriate, to combat the tendency to exclude important stock dynamics or allow for the shifting baselines phenomenon.

Response: It is unclear from the comment what historical trend information, specifically, the Commission is referencing that is not already provided in the SARs. Where able, we provide historical abundance data and estimate trends in abundance (see for example, the California sea lion SAR, which provides abundance data for the prior four decades). With respect to bycatch, we do not think it is feasible or appropriate to provide trends in bycatch rates over decades, as fisheries and monitoring programs change too frequently. The status of each stock is informed by current parameters, such as ESA listing status and relationship to OSP and PBR. Additionally, the statute specifies that the SARs provide current

population trend information. We will continue to endeavor to provide as much historical abundance, trend, and human-related removal information (for example, historical whaling data as it relates to stock recovery and OSP, see Eastern North Pacific blue whale report) as possible, but at this time will not require a summary table or paragraph in each SAR.

Comment 3: NMFS should secure adequate support and funding to conduct marine mammal abundance surveys in the region at least every five years. Alternative cost-effective approaches to determining N_{min} , such as trend data from index sites, should be developed and specified as acceptable methods in the guidelines.

Response: NMFS agrees that such a schedule would be ideal, but we do not currently have the resources to accomplish this. We continue to develop and implement strategies to support more efficient use of ship time through multi-species ecosystem studies, better survey designs and sampling technologies, and leveraging inter- and intra-agency resources. NMFS is also exploring alternative approaches for assessing stock status (*e.g.*, through use of unmanned systems and acoustic technologies) apart from reliance on abundance survey data, in regions where regular surveys are cost-prohibitive. As noted in the workshop report, such approaches could include trend monitoring at index sites. Developing guidelines for alternative assessment methods was not a focus of the GAMMS III workshop, and so this does not appear in the revisions finalized here. However, NMFS will make efforts to consider how alternative sets of information could be used to aid its marine mammal stock assessments.

Comment 4: The effective management of marine mammals requires timely and accurate stock status information that is currently lacking. The proposed assumption that the existing measures protecting marine mammal species are failing to achieve management objectives and the continued use of old data to assess the status of stocks are unacceptable and fail to acknowledge collective efforts to reconcile marine mammal protection with varied ocean uses. NMFS should more frequently assess the status of marine mammal stocks and incorporate this new information into management actions.

Response: NMFS agrees that management of marine mammal stocks depends on timely and accurate stock information, and in many cases up-to-date stock assessments are not available, nor are the resources necessary to

conduct the assessment. NMFS acknowledges that the reliability of abundance estimates for calculating PBR is reduced over time. The proposed approach to calculating PBR with outdated abundance information assumed the worst-case scenario, but we are not finalizing that approach at this time. Accordingly, NMFS is analyzing methods to calculate PBRs for stocks with outdated abundance information as well as developing methods to collect data more efficiently and cost effectively. See response to Comment 3.

Comment 5: The Alaska SRG expressed concern that very different approaches are taken for PBR and mortality components of SARs. A great deal of modeling effort and simulations has gone into making the PBR calculations conservative, but there is no similar concern for the mortality and serious injury data. In some of the Alaska SARs, 20+ year-old observer data are the only mortality data for a particular fishery. The nature of Alaska fisheries can change quite quickly, so Alaska SRG members strongly object to using such old data. The reliability of removals data is just as important as population data when assessing stock status. This issue merits serious attention, and as a first step, the quality of removals data should be thoroughly and explicitly evaluated when uncertainty in SARs is evaluated.

Response: NMFS acknowledges that many of the data related to Alaska marine mammal stocks are dated. NMFS continues to rely upon and incorporate the best available data in the SARs, but in some cases these data are many years old. The revised guidelines instruct SAR authors to describe uncertainties in key factors, including human-caused mortality and serious injury, and to evaluate the effects of those uncertainties.

Comment 6: The proposed changes do not reflect an agency commitment to generating best available science upon which to base its decisions. In fact, this rule contains no statements as to what the agency intends to do with respect to old or non-existent assessments other than to reduce PBR. We request the agency comment for the record specifically how NOAA intends to address the GAMMS III stated need for accurate and timely census data.

Response: The MMPA requires that NMFS and FWS use the best available scientific information in its assessment and management of marine mammal stocks. NMFS strives to collect the data necessary for timely stock assessments in a cost-efficient manner, but agency resources are limited, and there are instances where data are either too old

or non-existent. We are currently analyzing how to calculate PBR when data are outdated.

Comment 7: We appreciate NMFS' efforts to improve stock identification, small stock biases, non-serious injuries, and institute other SAR enhancements, and encourage NMFS to incorporate veterinary expertise relative to marine mammal population, health, and ecosystem conservation status.

Response: NMFS acknowledges this comment. NMFS continues to incorporate and rely upon veterinary expertise in activities related to stock assessment; for example, the development of the serious injury determination policy and procedures, and response to stranded animals and UMEs.

Comment 8: Several of the GAMMS III recommendations require more explanations and verbiage to be added to the SARs (e.g., Topics 2, 5, 8, and 9).

Response: NMFS recognizes that the recommendations require additional text to be added to the SARs. We strive to maintain the conciseness of the SARs while providing best available science and meeting the directive of MMPA section 117(a).

Comment 9: NMFS should produce a record showing that the guidelines and GAMMS Report comply with the Information Quality Act (IQA) Pre-dissemination review requirements as follows: (1) All models that the guidelines or GAMMS Report use should be peer reviewed in order to determine their compliance with Council for Regulatory Environmental Modeling Guidance; (2) the method used by the guidelines and GAMMS Report to estimate population uncertainty violates the IQA accuracy and reliability requirement; and (3) the guidelines and GAMMS Report violate the IQA accuracy and reliability requirements by telling staff to make up abundance data and PBR when measured data do not exist ("informed interpolation"). In addition, NMFS should revise the guidelines and GAMMS Report to delete any suggestion that marine mammal SARs should discuss oil and gas seismic effects, as oil and gas seismic operations do not cause mortality or serious injury to marine mammals and do not cause a decline or impede recovery of any strategic stock.

Response: The GAMMS report referenced by the commenter is a summary of the proceedings of a workshop and was reviewed for accuracy prior to dissemination. We did not solicit comments nor are we responding to comments on the workshop report itself. The guidelines also underwent IQA pre-dissemination

review prior to being finalized and released to the public. There is no requirement under the NOAA or OMB Information Quality Guidance to explain within the guidelines themselves how they have met IQA requirements.

The marine mammal SARs are based on the best available science. NMFS strives to use peer-reviewed data as the basis for reports. However, in some cases, the best available science may not have been published or subjected to a juried professional journal review, as this process can take months or years to complete. In other cases, data pertinent to assessments of stocks are routinely collected and analyzed but are not suitable for a stand-alone external peer-reviewed publication. Therefore, NMFS often relies on science that has been through a NMFS Science Center's internal expert review process and/or has been subjected to other internal or external expert review to ensure that information is not only high quality but is available for management decisions in a timely fashion. In these cases, all NOAA-authored literature should meet, at the least, the standards for Fundamental Research Communications established by the NOAA Research Council and by NMFS. NMFS may rely on the SRGs to provide independent expert reviews of particular components of new science to be incorporated into the SARs to ensure that these components constitute the best available scientific information. Likewise, upon SRG review of these components and the draft SARs themselves, NMFS considers the SRG review of the draft SARs to constitute peer review and to meet the requirements of the OMB Peer Review Bulletin and the Information Quality Act.

The proposed method for projecting uncertainty in abundance estimates (topic 1) is not being finalized at this time (see below). Any models that are employed in the SARs have been peer reviewed, as is their specific application to the SARs, and therefore meet the requirements of the IQA. Regarding the use of informed interpolation to estimate abundance within a study area based on habitat modeling or similar approaches (i.e., model-based abundance estimation), this approach is commonly applied in ecology. The International Whaling Commission Scientific Committee recently acknowledged the strength and utility of model-based abundance estimation methods and is planning a workshop to formulate revisions to its guidelines for conducting surveys and analyzing data to include guidance on the use of these methods in management (IWC, 2015).

Model-based estimation of density is based on survey data and habitat or other covariates, which is entirely science based. To suggest we are directing staff to “make up abundance data and PBR” is a mischaracterization of what is contained in the revised guidelines. We have added a footnote to the guidelines to clarify the definition of “informed interpolation.”

Regarding oil and gas activities, nowhere in the proposed guidelines are oil and gas or seismic activities specifically discussed. The guidelines do not direct the inclusion of oil and gas activities in the SARs; however, if oil and gas activities are found to be having a detrimental effect on a stock or its habitat, we would include it in the report, as we would with any other activity. The final revised guidelines (very slightly revised from the proposed guidelines) state: “The MMPA requires for strategic stocks a consideration of other factors that may be causing a decline or impeding recovery of the stock, including effects on marine mammal habitat and prey. In practice, interpretation of “other factors” may include lethal or non-lethal factors other than effects on habitat and prey. Therefore, such issues should be summarized in the Status of the Stock section for all strategic stocks. If substantial issues regarding the habitat of the stock are important, a separate section titled “Habitat Issues” should be used. If data exist that indicate a problem, they should be summarized and included in the Report. If there are no known habitat issues or other factors causing a decline or impeding recovery, this should be stated in the Status of the Stock section.”

Comments on Topic 1: Assessing Stocks With Outdated Abundance Estimates

NMFS received a number of comments expressing strenuous objection to/concern with the proposed framework for stocks with outdated abundance estimates. As such, NMFS is not finalizing the proposed revisions related to Topic 1 at this time. Rather, we will further analyze this issue. Should we contemplate changes to the guidelines regarding this topic, NMFS will propose them and solicit public comment in a separate action.

Comments on Topic 2: Improving Stock Identification

Comment 10: The Commission recommended that NMFS convene a national workshop to systematically review the status of stock identification efforts and to identify and prioritize the information needed to improve stock identification.

Response: In August 2014, NMFS convened a workshop on the use of multiple lines of evidence to delineate demographically independent populations (Martien et al., 2015). The meeting participants agreed that the best way to provide guidance on the use of multiple lines of evidence when delineating demographically independent populations for marine mammals was to produce a Stock Delineation Handbook that can serve as a guide for future demographically-independent population delineation efforts. Development of the handbook is currently underway. Subsequent to the 2014 workshop, NMFS began developing an internal procedure for identifying and prioritizing stocks in need of examination for potential revisions that would complement and be integrated into the stock delineation workshop outputs and the existing SAR process.

Comment 11: The GAMMS III workshop report makes several very good recommendations for improving stock identification, and the Alaska SRG and the Humane Society of the United States agree with all of them.

Response: NMFS acknowledges this comment.

Comment 12: The Pacific SRG recommends that NMFS focus on the role of genetics in determining marine mammal stock structure and in defining the terms “stock” and “population.”

Response: Although the guidelines are clear that genetic evidence is not the sole evidence that could be used to define stocks, changes in stock definition have relied on genetic data as the primary line of evidence, and species for which genetic evidence are not available have not had new stocks defined. The MMPA uses the term “population stock.” The guidelines have a lengthy section on “Definition of stock” that has been discussed in each of the GAMMS workshops and in a special workshop devoted to stock definition (see response to Comment (10). The language that interprets “population stock” has remained largely unchanged since the first set of guidelines despite much discussion.

Comment 13: The Pacific SRG would like to have the following questions addressed: How do we integrate the MMPA’s goal of maintaining a population as a functioning part of the ecosystem with the statute’s definition of a stock (that emphasizes breeding interchange)? In a continuum of levels of genetic exchange, where does one draw the line between what is a stock and what is not? How will the proposed use of eco-regions be practically implemented in stock determination

and how will migratory stocks that feed in one region and breed in another be treated under this proposal? How do we balance the conservation concerns resulting from stocks being defined very broadly versus the costs and management concerns resulting from stocks being defined very finely?

Response: The definition of “population stock” as “a group of marine mammals of the same species or smaller taxa in a common spatial arrangement, that interbreed when mature” is vague from a biological perspective. To some degree, all “groups” within a species interbreed when mature or else they would be considered different species according to the biological species concept. Clearly, population stock was intended to mean interbreeding at some greater level but that level is not specified. Interpretation becomes more difficult when considering known cases of migratory species with strong fidelity to both feeding and breeding grounds. Consider, for example, humpback whales that feed in Southeast Alaska and breed in Hawaii. These individuals can interbreed when mature but can (and do) interbreed with individuals that feed in other areas. If a threat occurred within Southeast Alaska that resulted in unsustainable deaths in that area, then if the “Southeast Alaska whales” were a stock, that stock’s PBR could be used as an indicator that management efforts to mitigate that threat were warranted. In contrast, if “interbreed when mature” considered all the whales in Hawaii, then the human-caused mortality in Southeast Alaska may never exceed the PBR based on Hawaii, and eventually the ecosystem in Southeast Alaska would cease to have humpback whales as a functioning part. Such cases result in an apparent conflict between the words “interbreed when mature” and the goal to maintain population stocks as functioning elements of their ecosystem.

Often, changes to stock delineations in the SARs have relied on interpretation of genetic data. The Pacific SRG asks where one draws the line on what level of genetic exchange suffices to qualify as a stock. Interpretation has been based on the guidelines:

“Demographic independence means that the population dynamics of the affected group is more a consequence of births and deaths within the group (internal dynamics) rather than immigration or emigration (external dynamics). Thus, the exchange of individuals between population stocks is not great enough to prevent the depletion of one of the populations as

a result of increased mortality or lower birth rates.”

To date, accepted “new” stocks have been strongly differentiated, indicating such low levels of exchange that immigration is relatively trivial. There will be, however, borderline cases. Such is the nature of imposing discrete categories on continuous processes.

The recommendations from the GAMMS III workshop do not propose basing stocks on eco-regions. Eco-regions were discussed during the workshop in two contexts: (1) In a working paper that demonstrated that most stocks are currently defined at a very large scale often encompassing several eco-regions, and (2) that eco-regions may highlight stocks that may deserve consideration in a stock definition meeting because that stock may be at too large a scale and could encompass multiple demographically independent populations.

Comment 14: In the SARs, a concise statement concerning uncertainty in stock structure could be included in the section on uncertainty discussed under Topic 8. Details should be provided only when publications are not yet available. The Pacific SRG questions the usefulness of repeating in nearly every SAR the sentence “It is plausible that there are multiple demographically-independent populations within this stock.”

Response: The Pacific SRG requested that the reader of a SAR be able to readily assess the level of confidence that can be ascribed to the PBR calculation. A critical part of that calculation is abundance, which can be severely biased if stock definition is incorrect. We recognize that many SARs will include the same statement about the plausibility of multiple demographically independent populations within the stock, but we consider it necessary to better inform the reader's understanding of areas of uncertainty.

Comment 15: NMFS received a number of comments related to stock definition and stock delineation based on feeding aggregations. Such as: The revised guidelines should address whether, and under what circumstances, a feeding aggregation can be identified as a stock consistently with the MMPA's statutory definition of a stock. One commenter stated that it is not clear whether or how the definition of a stock in the proposed guidelines relates to the definition of a stock in the MMPA. One commenter suggested that the revised guidelines should clarify the meaning of “internal dynamics” and explain how it relates to the statutory interbreeding requirement. Another

suggestion was that the revised guidelines should address the workshop participants' suggestion “that human-caused mortality on the feeding grounds be monitored and evaluated against a PBR calculation made for the feeding aggregation and that the feeding-ground PBR, mortality, and evaluation results be reported in the SARs, as is currently done for Pacific humpback stocks.”

Response: The workshop participants discussed the possibility of basing stocks on feeding aggregations. Although workshop participants considered this approach to be feasible, they believed it added significant complexity without providing substantial management advantages, and did not recommend revisions to the guidelines at this time. Therefore, this revision of the guidelines does not specifically discuss identification of stocks based on feeding aggregations. We recognize and acknowledge these comments related to feeding aggregations and stock definition, but as they do not relate to the current revisions to the guidelines, we are not addressing them in this action. If the issue is further considered by the agency in a separate action, we will address those comments in the development of that action.

Comment 16: In the proposed guidelines, NMFS suggests that it may delineate marine mammal stocks based upon human factors such as incidental take as a result of human-caused mortality. However, the MMPA does not permit the determination of stock status based on human-related factors. Accordingly, when delineating stocks, NMFS can only consider the demographic and biological characteristics of the species at issue. Carving out stocks in areas where human-caused mortality is high, as NMFS proposes, would violate the MMPA.

Response: The guidelines state: “For example, it is common to have human-caused mortality restricted to a portion of a species' range. Such concentrated mortality (if of a large magnitude) could lead to population fragmentation, a reduction in range, or even the loss of undetected populations, and would only be mitigated by high immigration rates from adjacent areas.” They caution that serious consideration should be given to areas with concentrated high human-caused mortality, but that actual stock definition should be based on biological considerations. In other words, high-localized human-caused mortality should highlight the need for stock identification scrutiny but not the lines of evidence used.

Comment 17: If it cannot be demonstrated with normal genetic analysis, then it is unwarranted to establish populations or subpopulations based on behavior or distribution. To split existing populations into smaller units only invites the development of fragmented PBRs with an aggregate value that will likely be lower than that of the whole population.

Response: Genetic data are certainly useful when attainable, but in many cases genetic samples (of sufficient quantity to draw sound inferences) cannot be obtained. There are many other lines of evidence that can be informative to determining stock structure, including behavior and distribution and also movement data from photographic identification or tagging. Genetic data are sometimes sufficient but are not exclusively needed to make sound inferences concerning stock structure. In 2014, NMFS convened a workshop to review the use of other lines of evidence, as consistency and accuracy in delineating stocks for species with limited data would be improved if guidelines were available on both the strengths of different lines of evidence and how to evaluate multiple lines together (Martien *et al.*, 2015). As a result of this workshop, NMFS is developing a handbook for identification of demographically independent populations, which includes genetic information as well as other lines of evidence.

Comment 18: The revised guidelines should acknowledge that factors other than demographic independence, such as a localized disease or a localized change in prey availability, might cause different population responses between geographic regions. In light of such factors, the revised guidelines should discuss under what circumstances it is appropriate to designate stocks solely on the basis of different population responses between geographic regions.

Response: Demographic independence is defined in terms of birth and death rates within the population and immigrations from outside the population. Presumably, the response of a population to ‘localized disease or localized change in prey availability’ would be changes in the birth and/or death rates. Thus, it would seem that the concern above is already accounted for in the guidelines.

Comment 19: If the revised guidelines continue to define a stock as a demographically-independent biological population, they should explain more clearly the circumstances under which a group of marine mammals can be designated as a stock even in the

absence of evidence that the group comprises a demographically independent biological population. Are such circumstances limited to those in which "mortality is greater than a PBR calculated from the abundance just within the oceanographic region where the human-caused mortality occurs," as suggested in the GAMMS III Report? Or can stocks be designated in other circumstances in the absence of evidence of demographic independence? If so, what other circumstances are contemplated?

Response: The section on definition of stocks in the guidelines seeks to clarify the practical process of definition given biological complexity and different types and qualities of available data. This section was contained in GAMMS II (NMFS 2005) and was not revised in this current revision of the guidelines. The guidelines note that particular attention should be given to areas where mortality is greater than PBR but do not limit stock definition to those circumstances. The stock definition workshop (see above) was suggested as a forum to improve stock definition in data-poor cases.

Comments on Topic 3: Assessment of Small and Endangered Stocks

Comment 20: The Commission recommends that NMFS adopt the workshop recommendation to include, when appropriate, a statement in each assessment explaining that bycatch data are not sufficient to estimate the bycatch rate with acceptable precision. The Commission and another commenter recommended NMFS treat each such stock as strategic unless and until the data are sufficient to demonstrate that it is not.

Response: NMFS agrees with the importance of including a statement in each stock assessment to indicate when bycatch estimates are prone to small-sample bias, though it should be noted that bias and precision are different issues. The guidelines recommend pooling years of information as necessary to achieve precision levels of CV less than 0.3.

At this point, NMFS does not make the default assumption that a stock is strategic until demonstrated otherwise. The MMPA requires a determination of a stock's status as being either strategic or non-strategic and does not include a category of unknown. The revised guidelines state, for non-ESA listed and/or non-depleted stocks, "if abundance or human-related mortality levels are truly unknown (or if the fishery-related mortality level is only available from self-reported data), some judgment will be required to make this determination.

If the human-caused mortality is believed to be small relative to the stock size based on the best scientific judgment, the stock could be considered as non-strategic. If human-caused mortality is likely to be significant relative to stock size (e.g., greater than the annual production increment) the stock could be considered as strategic."

Comment 21: When calculating PBR, NMFS should err on the side of caution rather than allowing loosely defined flexibility that may be used to the detriment of the stock. With stocks such as the Cook Inlet belugas or Hawaiian monk seals, the documented decline in abundance would seem to challenge the assumption that net productivity occurs. Therefore, a PBR of zero is appropriate and would promote regional consistency.

Response: NMFS recognizes that in some cases the dynamics of a stock do not comport with the underlying assumptions of the PBR framework. Given that Section 117 directs the agency to calculate PBR, the revised guidelines direct authors to calculate PBR but in such instances to qualify the calculation in the PBR section of the Report.

Comment 22: We support the calculation of PBR even for small stocks with little human-caused mortality to comply with the MMPA. However, we do not support the exception to depart from the PBR requirement.

Response: NMFS recognizes that, pursuant to Sec. 117 of the MMPA, each stock assessment report should include an estimate of the PBR for the stock. However, PBR is not always estimable. Most obviously, we lack abundance estimates for some stocks. Less obviously, the equation for estimating PBR makes assumptions about the underlying population growth model for marine mammals, and for stocks whose population dynamics do not appear to conform to these assumptions, the calculated PBR is considered unreliable as an estimate of the true potential biological removal. The revisions to the guidelines encourage reporting PBR for all stocks possible and qualifying in the SAR when the reported value is not considered reliable. Departure from this suggestion must be discussed fully within any affected report.

Comment 23: The Commission recommends that NMFS require stock assessment authors to set PBR to zero in those cases that are not in accord with the commonly assumed PBR framework and involve stocks with no tolerance for additional human-related removals.

Response: The revisions to the guidelines encourage reporting PBR for all stocks possible and qualifying in the

stock assessment report when the reported value is not considered reliable or in cases where a stock's dynamics do not conform to the underlying model for calculating PBR. At this point, the guidelines are not instructing authors to set PBR to zero.

Comment 24: The Pacific SRG continues to support a decision not to report a PBR in the monk seal SAR.

Response: By ecological theory, i.e., when the assumption of simple logistic population growth is reasonable and when a stock's status can be attributed to direct anthropogenic impacts, a non-zero estimate of PBR is not unreasonable. In the case of Hawaiian monk seal, however, it is not apparent that these model assumptions hold. See response to Comment 22.

Comment 25: The Alaska SRG preference would be to have an undetermined PBR when assessing endangered stocks. If numerical estimates of PBR are to be given in SARs, we recommend that language be included clarifying whether negligible impact determinations have been made, what they are, and if not, stating that no human-caused takes are authorized. We do not agree that this topic is beyond the scope of SARs and rather believe that inclusion of such information would help readers understand the actual meaning of PBR in this case.

Response: NMFS disagrees with including negligible impact determinations (NIDs) under section 101(a)(5)(E) of the MMPA in the SARs. The five criteria (64 FR 28800, May 27, 1999) that NMFS may use for making a final determination and issuing 3-year incidental take authorizations to Category I and II fisheries are complex and may be difficult to relate to the data contained in the SARs, which often change on an annual basis. Furthermore, while some NIDs may use fisheries bycatch data from the past five years in making an assessment, other NID analyses may contain bycatch data from more than five years, depending on changes in fisheries, particularly regulatory changes such as time/area closures or mandatory bycatch reduction methods. In addition, NMFS may use the more recent observer data or stranding data, which may not yet be included in the most recent SARs, which may also confuse readers. Further, NMFS does not authorize (or prohibit) incidental mortalities through the SAR process.

Comments on Topic 4: Apportioning PBR, Allocating Mortality, and Estimating PBR for Transboundary Stocks

Comment 26: The Commission recommends that NMFS include in their stock assessments comparisons of PBR for feeding aggregations, and estimate or apportion mortality and serious injury levels for each aggregation.

Response: The workshop participants discussed how feeding ground PBRs should be calculated for stocks where there was a desire to monitor potential risks to feeding aggregations; however, this was not reflected in the recommended revised text for the guidelines nor were comments solicited on this issue. NMFS is not including text regarding apportioning PBR among feeding aggregations in this revision of the guidelines.

Comment 27: The Commission recommends that NMFS apply the total unassigned mortality and serious injury to each affected stock in both data-rich and data-poor cases involving taking of mixed stocks that cannot be or are not identified in the field. Doing so is the only way to be precautionary and also provides the appropriate incentive to develop better information about the affected stocks.

Response: NMFS disagrees and believes that the guidelines are sufficiently conservative at this time.

Comment 28: The Commission recommends that NMFS discourage the use of informed interpolation, require strong justification where it is used, and require that it be accompanied by reasonable measures of uncertainty associated with the interpolation.

Response: The revised guidelines allow for the use of informed interpolation (*i.e.*, model-based abundance estimation) as appropriate and supported by existing data. NMFS has added text to the guidelines specifying that when informed interpolation is employed, the Report should provide justification for its use and associated measure of uncertainty. As a point of clarification, informed interpolation is not a person making an informed judgement; it is a model that is informed by the covariation between habitat or other variables and density that is making the "judgement."

Comment 29: We support the recommendation of assigning the total unassigned mortalities and serious injuries to each stock within the appropriate geographic area.

Response: NMFS acknowledges this comment.

Comment 30: NMFS should not assign the "unassigned mortality and serious

injury" to each stock within the affected geographic area as it would effectively double count these human interactions and affect the PBR of multiple stocks. Instead, NMFS should develop methodology based on the best available data to assign the serious injury and mortality according to the relative abundance of the stocks. When this is not possible, serious injury and mortality should remain unassigned to avoid arbitrary determinations.

Response: The revised guidelines direct that in data poor situations with mixed stocks, when relative abundances are unknown, the total unassigned mortality and serious injuries should be assigned to each stock within the appropriate geographic area. NMFS and workshop participants recognize that this approach effectively would repeatedly "count" the same deaths and serious injuries against multiple stocks. However, this approach is considered to be the most conservative in terms of ensuring that the most severe possible impacts were considered for each stock. The revised guidelines instruct that when deaths and serious injuries are assigned to each overlapping stock in this manner, the Reports will contain a discussion of the potential for over-estimating stock-specific mortality and serious injury.

Comment 31: NMFS's proposal to identify transboundary or high seas stocks with no available population data is contrary to the MMPA.

Response: NMFS did not propose to identify transboundary or high seas stocks with no available population data. Rather, the workshop discussions involved estimating range-wide abundance and PBR for transboundary stocks, and specifically, addressing the problem of managing transboundary marine mammal stocks for which PBR is estimated based on abundance from only a portion of each stock's range (for example, PBR levels for transboundary stocks being estimated based on abundance surveys that occur only within the U.S. EEZ). Although it is inappropriate to simply extrapolate abundance estimates to an unsurveyed area, the revised guidelines allow for the use of model-based density estimation to fill gaps in survey coverage and estimate abundance and PBR over broader areas as appropriate and supported by existing data. In such cases, the Report should provide justification for use of interpolation and associated measure of uncertainty.

Comment 32: NMFS must ensure that it prioritizes collection of data necessary to support interpolations when full assessments are not possible. In cases where a partial survey is conducted and

methods of interpolation or modeling are not incorporated, serious injuries and mortalities should only be counted if they occur in the portion of the stock that was surveyed.

Response: NMFS agrees surveys should ideally cover the entirety of the stock range. When this is not possible, N_{min} is defined under the MMPA as an estimate of the number of animals in a stock that provides reasonable assurance that the stock size is equal to or greater than the estimate, so a partial survey can be used to calculate N_{min} and PBR. All human-caused mortality and serious injury needs to be accounted for under the MMPA, so injuries or deaths that are known to come from a stock must be apportioned to that stock even if the abundance is underestimated. The solution to this mismatch is not to ignore human-caused mortality and serious injury (which is contrary to the MMPA), but to conduct adequate surveys or develop models to obtain complete abundance estimates.

Comment 33: The apportionment of PBR to foraging grounds between surveyed and un-surveyed areas appears to be a significant problem in the absence of data and lacks scientific justification. It appears that this will be based on untested assumptions regarding stock distributions. Assuming uniform distribution will have animals present where they may not exist or exist only seasonally.

Response: NMFS agrees that it is not appropriate to assume uniform distribution between surveyed and unsurveyed areas, and as such discourages the use of extrapolation. The workshop participants discussed this issue, and the background paper on this topic suggested that informed modeling exercises may sometimes be appropriate or necessary for management decisions and to ensure that stocks remain as functioning elements of the ecosystem. Therefore, the revised guidelines state, "abundance or density estimates from one area should not be extrapolated to unsurveyed areas to estimate range-wide abundance (and PBR). But, informed interpolation (*e.g.*, based on habitat associations) may be used to fill gaps in survey coverage and estimate abundance and PBR over broader areas as appropriate and supported by existing data."

Comment 34: Given the known lack of general data and uncertainty of existing data, it appears that it will be difficult to accurately use separate PBRs for marine mammal populations with multiple feeding grounds. To the extent that this is understood, information pertaining to separate feeding

aggregations should be noted in the stock assessment reports, but separate PBRs should not be used for stocks with multiple feeding grounds. There is a significant risk that “unassigned mortality and serious injury” could be wrongly assigned and result in erroneous estimates to one or more populations. To avoid arbitrary assignments, when this is not possible, serious injury and mortality should remain unassigned.

Response: See response to Comment 26.

Comment 35: The section on apportioning PBR among feeding aggregations does not provide clear guidance for cases like eastern Pacific gray whales and whether the Pacific Coast Feeding Group is a stock or not, a case where there may be mitochondrial differences between feeding areas but all animals go to a common breeding area.

Response: The current Guideline revisions do not address apportioning PBR among feeding aggregations. See response to Comment 26.

Comment 36: Separate PBRs for stocks with multiple feeding grounds should not be used. Separating PBR among feeding stocks is complicated and data-intensive, and is unlikely to improve management. NMFS is rarely able to adequately determine which portion of the stock was involved in a human interaction.

Response: See response to Comment 26.

Comment 37: There is concern that failure to estimate a population-wide PBR in the assessments will lead to the reliance on the proposed default of assuming the population is in decline. The agency should develop an assessment methodology based on the best available data and devise a statistically sound interpolation algorithm to fill in gaps in survey coverage and estimate abundance over the range of the population. If this is not developed then there is a very strong possibility that assessment scientists will discount or not utilize historical estimates derived from multiple surveys spanning multiple geographic regions in one year, and/or limited surveys the following year.

Response: NMFS recognizes the need to estimate population-wide PBR for marine mammal stocks, which is why the revised guidelines allow for the use of informed interpolation (*i.e.*, model-based abundance estimation) to fill gaps in geographical survey coverage. Where interpolation is employed, the Reports should include a statement about the level of uncertainty surrounding the estimates.

Comment 38: Priority for research should be given to stocks for which serious injury and mortality exceeds PBR and for which additional management action is required under take reduction plans. In cases where this is not possible, NMFS must consider the availability of data for interpolation or informed modeling exercises to obtain abundance estimates for the full range of the stock. This strategy requires careful coordination with Canada for transboundary stocks. If timely and robust data are not available, NMFS should not make stock assessment determinations.

Response: Staffs from NMFS Science Centers, Regional Offices, and Headquarters Offices communicate regularly to discuss science needed to support management and to help prioritize research efforts. This includes discussion of stocks for which human-caused mortality and serious injury exceed PBR and take reduction planning needs. The revised guidelines allow for the use of informed interpolation (*e.g.*, based on habitat associations) to fill gaps in survey coverage and estimate abundance and PBR, as appropriate and when supported by existing data.

Comments on Topic 5: Reporting of Mortality and Serious Injury

Comment 39: The Commission recommends that NMFS require a summary of all human-caused mortality and serious injury in each stock assessment report. Efforts to meet that requirement will almost certainly vary, perhaps markedly. With that in mind, the Commission encourages NMFS to re-examine those report sections after one to two years to identify the most effective reporting strategies that could then be used to develop a consistent and informative reporting approach.

Response: Section 117 of the MMPA requires that all sources of human-caused mortality and serious injury be included in stock assessments. NMFS makes every effort to include these sources of anthropogenic mortality and serious injury in each stock assessment, whether the mortality or serious injury is systematically recorded by fishery observer programs or through opportunistic records, such as strandings, where the cause of death or serious injury can be linked to human-related causes. NMFS understands that clearly presenting these mortality and serious injury data in the SARs is an important part of allowing the public to interpret the status of marine mammal stocks. Every effort will be made to continue to improve the way in which mortality and serious injury are reported in the SARs.

Comment 40: The Alaska SRG believes that extensive tabling of interactions between marine mammals and commercial fisheries should be confined to an Appendix, with only a summary table that includes mortality in the various Federal groundfish fisheries, state water fisheries, and international transboundary fisheries included in the body of the assessment. The strategy of summarizing fishery interactions should lead to a single clearly-documented estimate of mortality and associated variance for all fisheries combined with easy access to details available preferably in an online appendix.

Response: NMFS makes every effort to present fishery interaction data simply in the body of each SAR, whether in the text, tabular form, or both. The agency feels that it is valuable to have all interaction data appear within the SAR itself (although some regions also currently include a separate Appendix describing those fisheries that interact with marine mammals). NMFS also produces stand-alone injury determination and bycatch papers by region, which has reduced the amount of information that needs to go into the SARs, as they are incorporated by reference. The agency will continue to improve the clarity of how interaction data are presented within the SARs.

Comment 41: The SARs tend to lag approximately two years behind in incorporating available observer bycatch data. For some fisheries that have 100-percent observer coverage such as the Hawaii-based swordfish fishery, such bycatch data are available in near real-time. Review of new data should be conducted promptly given that PBR, the zero mortality rate goal, and strategic status for stocks are all based on the most recent SAR.

Response: Bycatch data for most fisheries are not available in real-time and every effort is made to produce and incorporate new bycatch estimates from observer data in a timely manner into the draft SARs. SARs are typically drafted in the autumn of each year, with previous calendar year observer data representing the most up-to-date full-year information. For example, draft 2016 SARs will be prepared in the autumn of 2015 for review by regional Scientific Review Groups in early 2016. These draft 2016 reports will utilize bycatch data from calendar year 2014 if available, thus the 2-year time lag between the year the reports are published and the year of the most recent bycatch data.

Comments on Topic 6: Determining When Stock Declines Warrant a Strategic Designation

Comment 42: In an apparent attempt to interpret the MMPA definition of strategic stock, the proposed guidelines suggest that a “strategic stock” is a stock that “is declining and has a greater than 50 percent probability of a continuing decline of at least five percent per year.” However, in reality, a stock that “has a greater than 50 percent probability of a continuing decline of at least five percent per year” would not necessarily qualify as “threatened” in all cases. Rather, the determination of “threatened” status under the ESA requires a species-specific analysis of specific factors that are expressly set forth in the ESA. While NMFS may have the discretion to develop a general guideline for determining “strategic” status, NMFS may not mechanically apply the “strategic stock” definition set forth in the proposed guidelines.

Response: NMFS acknowledges this comment and has not made this revision to the guidelines. See Response to Comment 43.

Comment 43: The Commission recommends that NMFS consider any marine mammal stock that has declined by 40 percent or more to be strategic. Additionally, the Commission and the Humane Society of the United States recommend that stocks declining with more than 50 percent probability of continuing decline (by at least five percent/year) should be treated as strategic with the aim of reducing and reversing the stock’s decline before a depleted designation is required.

Response: Section 3(19) of the MMPA defines a “strategic stock,” as one: “(A) for which the level of direct human-caused mortality exceeds the potential biological removal level; (B) which, based on the best available scientific information, is declining and is likely to be listed as a threatened species under the Endangered Species Act of 1973 within the foreseeable future; or (C) which is listed as a threatened species or endangered species under the Endangered Species Act of 1973 (16 U.S.C. 1531 *et seq.*), or is designated as depleted under this Act.” NMFS has not adopted the workshop-recommended revisions regarding a quantitative interpretation of strategic status per section 3(19)(B) but will continue to analyze how to interpret “likely to be listed as a threatened species under the (ESA) within the foreseeable future.” However, NMFS has finalized the revision regarding declines in abundance: “Stocks that have evidence suggesting at least a 50 percent decline,

either based on previous abundance estimates or historical abundance estimated by back-calculation, should be noted in the Status of Stocks section as likely to be below OSP. The choice of 50 percent does not mean that OSP is at 50 percent of historical numbers, but rather that a population below this level would be below OSP with high probability.”

Comment 44: The Alaska SRG supports the quantitative recommendations for determining when non-ESA listed stocks should be considered as “strategic.” We also find the rationale for using 15 years as “the foreseeable future” a reasonable default because it is based on a five percent decrease over a 15-year period resulting in a 50 percent decline.

Response: At this time, NMFS is not adopting the recommended changes related to strategic status of stocks that are declining and likely to be listed as a threatened species under the ESA within the foreseeable future.

Comment 45: The Alaska SRG agrees with the working group’s recommendation that a Recovery Factor scaled from 0.1 to 0.5 be associated with stocks that are declining and likely to be listed as a threatened species under the ESA within the foreseeable future. In some cases where a decline is steep and ongoing or where the uncertainty about the population or causes of the decline are high a lower recovery factor could be warranted. We also recommend that there be a more formal process for NMFS to regularly review non-ESA listed stocks of concern to determine their status.

Response: As we are not finalizing the recommended changes regarding strategic stock designation (sec. 3(19)(B) of the MMPA), above, we have decided not to revise the guidelines regarding recovery factors under such situations at this time. Each time a SAR is reviewed, the status of the stock is evaluated.

Comment 46: While the revisions in the guidelines are a step toward developing criteria for a strategic designation, and using the threatened species recovery factors seems prudent, this revision falls short of setting timeframes to evaluate whether a stock should be reclassified.

Response: It is unclear whether the commenter is referencing evaluation timeframes under the MMPA (sec. 117(c)(1)) or the ESA (relative to the interpretation of sec. 3(19)(B) of the MMPA). Stock assessments are reviewed by NMFS every three years for non-strategic stocks or every year for strategic stocks. This sets the timeframe for evaluating whether a stock’s status should be revised. See response to

Comment 45 regarding MMPA sec. 3(19)(B).

Comment 47: The Pacific SRG supports the revision of when stock declines merit a strategic designation but suggests wording changes that give NMFS more flexibility surrounding the obligation to determine when a stock is depleted prior to classifying it as strategic. The SRG recommends that the NMFS regularly review whether a “depleted” status is warranted for (1) unlisted stocks of marine mammals that are declining and (2) stocks listed as depleted that are recovering.

Response: NMFS acknowledges this comment, and agrees that the depleted status of marine mammal stocks should be reviewed periodically to ensure that designations are appropriate. We are currently evaluating information contained within a review of the SARs conducted by the Commission and will, as a part of this evaluation, consider whether there is more that NMFS should do to enhance consistency and accuracy with regard to depleted status of marine mammal stocks on a more regular basis.

Comment 48: Given the challenges facing NMFS to collect timely data covering the full range of stocks already designated as strategic, NMFS should not adopt new guidelines to take on the responsibility of delineating strategic stocks that are not designated under the ESA. There is already an acceptable federal process under the ESA to designate strategic stocks.

Response: The ESA does not designate stocks as strategic or non-strategic. Rather, the MMPA directs stocks be considered strategic if ESA-listed (*i.e.*, threatened or endangered), depleted, or human-caused mortality exceeds PBR. Additionally section 3(19)(B) allows for strategic designations of a stock that is declining and is likely to be listed as a threatened species under the Endangered Species Act of 1973 within the foreseeable future. At this time, we are not finalizing the recommended changes regarding strategic stock designation (sec. 3(19)(B) of the MMPA).

Comments on Topic 7: Assessing Stocks Without Abundance Estimates or PBR

Comment 49: The Alaska SRG supports the suggested guideline modifications relating to the use of trend monitoring. However, small changes to the guidelines will do very little to improve the situation. More substantive changes and new approaches are needed and have been described.

Response: NMFS agrees that it would be valuable to identify alternative

approaches for assessing stock status, apart from reliance on abundance survey data, in regions where regular surveys are cost-prohibitive. As noted in the guidelines, such approaches could include trend monitoring at index sites. However, developing guidelines for alternative assessment methods was not a focus of the GAMMS III workshop. NMFS will make efforts to consider how alternative sets of information could be used to aid its marine mammal stock assessments. See responses to Comment 3 and Comment 4.

Comment 50: Based on the statutory mandate to use the PBR formula, NMFS should prioritize gathering data for any stocks with insufficient information to calculate levels of abundance, trends, or mortality. NMFS should not consider approaches other than those that are mandated and should provide admonition that stocks should not automatically be determined to be non-strategic in the absence of information. Absence of data on the degree of impact to stocks is not the same as data on the absence of impacts to stocks.

Response: NMFS does prioritize its data collection based upon what it perceives to be the most critical information gaps. NMFS does not make the default assumption that a stock is strategic or non-strategic until demonstrated otherwise. See response to Comment 20.

Comment 51: If a significant data shortage makes it difficult to identify unit stocks, then NMFS should make it a high priority to remedy this uncertainty that seems crucial to determine "population status." What has NMFS done to improve "best available science" on marine mammal abundance and stock structure?

Response: NMFS agrees that it is a high priority to improve the identification of unit stocks. Consistent with this, the GAMMS III workshop participants recommended a national workshop be held to review and summarize information that is relevant to population structure. NMFS convened such a workshop and has begun developing an internal procedure for identifying and prioritizing stocks in need of examination for potential revisions that would complement and be integrated into the stock delineation workshop outputs and the existing SAR process.

Comment 52: Given that the MMPA provides significant latitude in data sources for affected species and to the extent that "anecdotal information" and "unpublished information" are used, "trend monitoring" information from the fishermen who are out there every

day should be used in stock assessments.

Response: Various sources of information could be used to estimate trends as long as the information is credible and compatible with existing statistical or modeling frameworks.

Comments on Topic 8: Characterizing Uncertainty

Comment 53: The Commission recommends that NMFS include all relevant sources or measures of uncertainty in stock assessment documents. Such indicators of uncertainty are essential for readers to form reliable conclusions regarding the status of the affected stocks and the factors affecting them.

Response: NMFS agrees that information on key sources of uncertainty should be made explicit in the Reports, and this has been added to the revised guidelines.

Comment 54: The Pacific SRG has strived over the years to make the SARs models of conciseness, and the proposed guidelines could reverse these efforts. SARs should be summaries of significant results and conclusions and not lengthy discussions including detailed descriptions of methods and repetitive caveats. The recommendation to include statements regarding uncertainty about parameters affecting PBR has been made by the Pacific SRG previously, which envisioned a brief separate "Uncertainties" section summarizing significant sources of uncertainty in the stock assessment. Lengthy discussions of uncertainty embedded in each SAR section reduce clarity and readability. Additions such as points of contact could be placed in an appendix to each set of SARs, but not be placed in each individual SAR.

Response: NMFS agrees that discussions of uncertainty should be added in a way that will not detract from the clarity and readability of the stock assessment reports and will not add appreciably to the length of those reports. The workshop participants' recommended addition of providing a point of contact has not been incorporated.

Comment 55: The Alaska SRG supports changes to guidelines that would help ensure that SARs provide adequate evaluations of uncertainty. We recommend a 'report card' format as suggested by workshop attendees that will likely be more user-friendly and promote consistency between regional SARs. Additionally, this format would be more concise than the text additions recommended in the GAMMS III proposed guidelines. This report card could include the proportion of fisheries

monitored within the last five years that might be interacting with strategic stocks.

Response: NMFS agrees that quantitative criteria should be used to evaluate the uncertainty in marine mammal stock assessment reports and that a "report card" may be a good format for presenting this information. The quantitative criteria and format for this has not yet been finalized and is not specified in the revised guidelines. The workshop participants also saw merit to the report card, but there was general agreement that such information would be better conveyed as a periodic publication, such as in a NOAA Technical Memorandum, which could be considered by the SRGs.

Comment 56: The Alaska SRG supports including a characterization of uncertainty in the Status of Stocks section, and recommends that it be described as "reliable," "moderately reliable," or "unreliable" as a clear way to characterize the overall utility of the status determination. We also support the suggestion that an overall assessment of the quality of SARs be conducted periodically and reported as Tech Memos, but not as a substitute for the "report cards" in the individual SARs.

Response: Uncertainty comes in many gradations, and the method of determining PBR for human-caused mortality and serious injury was specifically designed to be effective at achieving management objectives in the face of many sources and levels of uncertainty. Furthermore, the revised guidelines recommend that the most prevalent sources of uncertainty in determining stock status and PBR levels be identified so that future research can be better directed at reducing these sources of uncertainty.

Comments on Topic 9: Expanding SARs To Include Non-Serious Injury and Disturbance

Comment 57: The Commission recommends that NMFS require sections in stock assessment reports that identify and characterize non-lethal factors that may affect population status.

Response: Section 117(a)(3) requires NMFS, in consultation with the appropriate regional scientific review group, to include other factors that might be causing a decline or impeding recovery of a strategic stock, including effects on marine mammal habitat and prey. While inclusion of non-lethal factors may be a useful qualitative approach, such factors cannot be compared to PBR to assess population status. Furthermore, other environmental documents such as

environmental assessments or impact statements required under the National Environmental Policy Act would contain that information, where known. Consistent with SRG recommendations, NMFS is trying to keep the SARs concise.

Comment 58: NMFS should revise the guidelines to delete any suggestion that a mere “disturbance” or “non-serious injury” is sufficient to be included in SARs. SARs should only include events—in particular commercial fishing events—which cause mortality or serious injury, or which can be shown to cause the decline or impede the recovery of a strategic stock. This has been NMFS’ position in the past, it is correct, and it should not be changed.

Response: The MMPA requires SARs to include an estimate of all sources of human-caused mortality and serious injury, not just an estimate of commercial fisheries mortality. See response to Comment 57.

Comment 59: The Alaska SRG agrees that SARs should include the annual levels of mortality and serious injury reported through take authorizations and research permits in the “Other Mortality” section.

Response: NMFS acknowledges this and is finalizing this text within the revised guidelines under the Annual Human-caused Mortality and Serious Injury section.

Comment 60: The MMPA allows for SAR comments on non-lethal factors affecting recovery for strategic stocks, and it seems reasonable that SARs for non-strategic stocks should also evaluate such factors. However, because there is a high degree of uncertainty regarding population-level effects of non-lethal injury and disturbance, it is inappropriate to include estimates of those takes in the SARs unless there is evidence they are affecting stock recovery. Disturbance and non-serious injury do not constitute “Potential Biological Removal.” While it may be useful for NMFS permit users or others to compare their potential for disturbance/injury to a stock’s PBR, this falls outside the intent of the MMPA-mandated PBR process for managing interactions with commercial fisheries.

Response: The revised GAMMS specify that SARs contain information on other factors that may be causing a decline or impeding recovery strategic stocks, which we have interpreted as including non-lethal effects. As discussed in response to Comment 9, we would report on all activities found to be having a detrimental effect on a stock or its habitat. Within the SARs, PBR is only compared to takes that are

determined to be serious injuries or mortalities.

Comment 61: The guidelines should require a “Habitat Concerns” section in all new stock assessments. If there are no known habitat issues, this should be stated.

Response: The previous (2005) guidelines direct that if substantial issues regarding the habitat of the stock are important, a separate section titled “Habitat Issues” should be used. Specifically, “If data exist that indicate a problem, they should be summarized and included in the Report. If there are no known habitat issues or other factors causing a decline or impeding recovery, this should be stated in the Status of the Stock section.” This section of the guidelines was not changed in this revision.

Dated: February 26, 2016.

Perry F. Gayaldo,

Deputy Director, Office of Protected Resources, National Marine Fisheries Service.

BILLING CODE 3510-22-P

DEPARTMENT OF COMMERCE

National Oceanic and Atmospheric Administration

Submission for OMB Review; Comment Request

The Department of Commerce will submit to the Office of Management and Budget (OMB) for clearance the following proposal for collection of information under the provisions of the Paperwork Reduction Act (44 U.S.C. Chapter 35).

Agency: National Oceanic and Atmospheric Administration (NOAA).

Title: Greater Atlantic Region Logbook Family of Forms.

OMB Control Number: 0648-0212.

Form Number(s): NOAA 88-30 and 88-140.

Type of Request: Regular (extension of a currently approved information collection).

Number of Respondents: 4,337.

Average Hours per Response: 5 minutes per Fishing Vessel Trip Report page (FVTR); 12.5 minutes per response for the Shellfish Log; 4 minutes for a herring or red crab report to the IVR system; 2 minutes for a tilefish report to the Interactive Voice Response (IVR) system; 30 seconds for voluntary additional halibut information; and 5 minutes for each Days at Sea (DAS) credit request.

Burden Hours: 11,508.

Needs and Uses: This request is for an extension of a currently approved information collection.

Under the Magnuson-Stevens Fishery Conservation and Management Act, the Secretary of Commerce (Secretary) has the responsibility for the conservation and management of marine fishery resources. Much of this responsibility has been delegated to the National Oceanic and Atmospheric Administration (NOAA)/National Marine Fisheries Service (NMFS). Under this stewardship role, the Secretary was given certain regulatory authorities to ensure the most beneficial uses of these resources. One of the regulatory steps taken to carry out the conservation and management objectives is to collect data from users of the resource. Thus, as regional Fishery Management Councils develop specific Fishery Management Plans (FMP), the Secretary has promulgated rules for the issuance and use of a vessel Interactive Voice Response (IVR) system, a Vessel Monitoring System (VMS) and vessel logbooks (VTR) to obtain fishery-dependent data to monitor, evaluate, and enforce fishery regulations.

Fishing vessels permitted to participate in Federally-permitted fisheries in the Northeast are required to submit logbooks containing catch and effort information about their fishing trips. Participants in the herring, tilefish and red crab fisheries are also required to make weekly reports on their catch through IVR. In addition, vessels fishing under a days-at sea (DAS) management system can use the IVR system to request a DAS credit when they have canceled a trip for unforeseen circumstances. The information submitted is needed for the management of the fisheries.

Affected Public: Business or other for-profit organizations.

Frequency: Weekly, monthly and on occasion.

Respondent's Obligation: Mandatory.

This information collection request may be viewed at reginfo.gov. Follow the instructions to view Department of Commerce collections currently under review by OMB.

Written comments and recommendations for the proposed information collection should be sent within 30 days of publication of this notice to OIRA_Submission@omb.eop.gov or fax to (202) 395-5806.

Dated: February 25, 2016.

Sarah Brabson,

NOAA PRA Clearance Officer.

BILLING CODE 3510-22-P

POSSIBLE MIGRATION ROUTE OF THE GRAY WHALE ON THE COAST OF JAPAN

HIDEO OMURA

Whales Research Institute, Tokyo.

ABSTRACT

The gray whale occurred on the south coast of Wakayama and Kochi prior to the turn of the century. The calving ground of this stock was possibly in the Seto Inland Sea. It migrated to and from the feeding ground in the Okhotsk Sea, along the east coast of Japan. With the increasing industrial development and boat and ship traffic this stock of the gray whale was driven from the Inland Sea and probably joined to the Korean stock or even to the California stock. A case of stranding of the blue whale is also reported.

INTRODUCTION

Occurrence of the gray whale on the coast of Japan is described by many authors of old Japanese books and picture scrolls of whales. In *Geishi* (The treatise of the whale), written by Jiemon Kandoriya of the castellany of Wakayama in 1758 and printed in 1760, which is the earliest printed monograph of the cetacea in Japan, is shown a drawing of Kokujira with a brief description (Fig. 1). This whale is drawn rather slender, but it has a series of knobs instead of a dorsal fin and bears many circular and semicircular scars on the surface of the body and tail flukes. It has bristles spreading over the entire head. He also describes that this species is the smallest among whales. He has a reason because the minke whale was not taken in these days (see Table 1).

Kiyonori Otsuki (1773-1850), a famous scholar in the Tokugawa era, left an undated manuscript on whales and whaling, entitled *Geishiko* (A draft of a history of the whale). It remained unpublished till 1925, when it was printed in a series of various collections in Sendai. It is by far the most systematic survey of whales and whaling that was written in the Tokugawa period (Hawley, 1958). In this book he notes that Kokujira has baleen plates of white in color. Other descriptions agree in general with those in *Geishi*, but he mentions the body form of Kokujira is more fat than the drawing in *Geishi* and gives two figures of Kokujira which resemble more to the gray whale (Fig. 2).

From the above it may safely be concluded that Kokujira is identical with the gray whale (*Eschrichtius robustus*) and it had occurred in the past at least on the coast of Wakayama. Further there remains some statistical data which show Kokujira or the gray whales were taken on the coast of Kochi, southern part of Shikoku, by the so-called net whaling prior to this century.

Modern whaling was introduced to Japan in 1897. Operation of this type

of whaling was firstly conducted on the east coast of Korea under the permission of the said government. After several years it was introduced to the coast of Kyushu, Kochi and Wakayama, gradually replacing the net whaling, and then to the northeast coast of Japan and off Hokkaido. But there is no record of the gray whale taken by modern whaling on the coast of Kochi and Wakayama, except one reported by Andrews (1914), referred from records of whaling company. This whale, a male of 40 feet long, was taken at Oshima, Wakayama, on 9 February 1910.

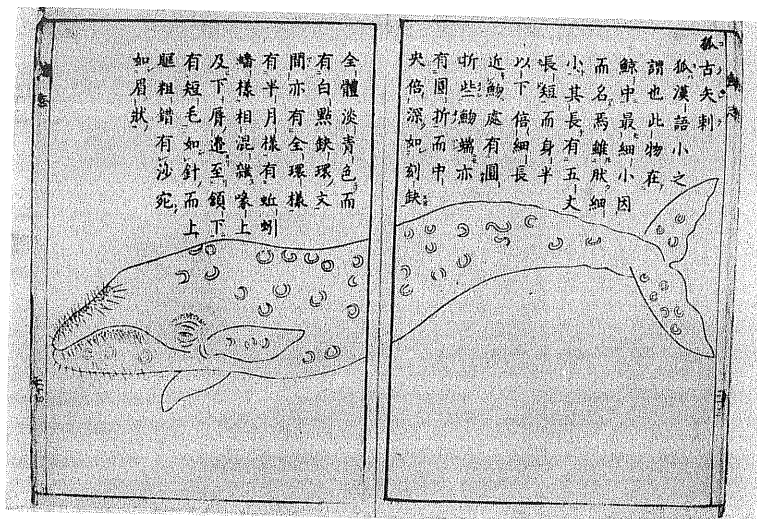

Fig. 1. Kokujira in Geishi, 1760. Cited from Hawley, 1958.

Fig. 2. Kokujira in Geishiko (Share).

In April of the year he stayed at Oshima, but no gray whale was observed at this landstation by him (Andrews, 1916). On the other coast of Japan the gray whale was taken rarely, as reported by Mizue (1951). What happened with the gray whale on the coast of Japan? This problem is discussed in this paper in relation to the supposed calving ground of this species.

*Sci. Rep. Whales Res. Inst.,
No. 26, 1974*

CATCH OF THE GRAY WHALE IN THE DAYS OF NET WHALING

The method of taking whales by net was invented by Kakuemon Taiji in 1677 at Taiji of the castellany of Wakayama (now Wakayama-ken), and then it spread to fishing villages on the south and west coast of Japan, including Shikoku and Kyushu, where whales came in shore in winter.

This method is a combined method of driving, netting and harpooning. When a whale was sighted by Yamami (watch on the hill), they make a signal informing species, position and swimming direction of the whale with flags or rockets. Various kinds of boats waited and went into action in orderly fashion as soon as the commander gave the order. The basic organization of whaling fleet was as follow.

Sekobune (for driving and killing whales). One group of about ten boats or more, 13 m long and 2.2 m wide with 8 oars, occasionally with sail. Crew consists of 15 men.

Amibune (netting boats). One group of about 6 boats, 13 m long and 3.5 m wide with 8 oars. Crew of 10 men.

Mossobune (tug boats). A group of 4 boats, nearly same as Sekobune but with a little broader beam. Crew of 13 men.

Sekobunes drive the whale to the place called Amiba (netting place) near the shore, producing underwater sounds with wooden hammer, where Amibunes are waiting to set the nets. Net is set sometimes two or three-fold in order to prevent the whale's escape and to check its action by entanglement.

Various kinds of harpoons, made of iron, were used. Their weights are not heavy and usually 1.0-2.0 kg in weight. Attached with harpoon a slender wooden pole and a rope with float at its end. Harpoons are thrown high up in the air so that they drop on the back of the whale from the air. When the whale has been sufficiently weakened by a number of harpoons, and later by the help of heavy swords thrown to the thorax, a sailor swims and climbs up on it and makes a hole at the blowholes with his knife in order to pass a rope through it. Then the whale is wound by several strands of rope around the body in order to tie the whale body between two Mossobunes before the whale was finally killed. Then it is stabbed at the heart with long swords.

In this way not only the right whale but also the balaenopterid whales were taken by the net whaling. This type of whaling was conducted by villagers forming groups. In these days two groups were in operation on the coast of Kochi and four groups in Wakayama. Shibusawa (1930) gives catch statistics of Ukitsugumi, one of these groups in Kochi, during 22 years from 1875 to 1896, by species of whales (Table 1). As seen in this table 64 whales or 17 percent among the total of 370 whales taken during this period were gray whales. From this table it is clear that the gray whale was hunted regularly at least until 1896 in these regions, as stated briefly by Nishiwaki and Kasuya (1970).

Further Hattori (1888) presents some data on details of operation and sighting of whales by the same whaling group in three years of 1880, 1882, and 1883 (Table

2). A total of 43 gray whales were sighted in these years, in which 12 were taken, 24 escaped from taking and 7 were not pursued due to unfavorable weather.

In general the rate of the catch against total whales sighted is very low and this is thought to be the main reason why the net whaling could survive more than 200 years. Among whale species other than the gray in Table 1 were also taken later by the modern whaling on the coast of Kochi and Wakayama.

TABLE 1. CATCH OF WHALES BY UKITSU WHALING GROUP, 1875-1896.
(Cited from Shibusawa, 1939)

Year	Blue	Fin	Bryde's	Humpback	Right	Gray	Total
1875	3	—	4	2	1	1	11
1876	2	2	5	6	—	2	17
1877	—	—	3	19	—	11	33
1878	3	—	4	4	6	1	18
1879	1	—	2	9	3	7	22
1880	5	1	8	2	1	6	23
1881	1	—	5	10	2	5	23
1882	3	—	2	4	—	3	12
1883	—	—	3	7	1	3	14
1884	5	1	2	1	2	1	12
1885	4	1	4	5	2	3	19
1886	1	9	3	6	—	1	20
1887	5	—	4	13	—	4	26
1888	1	3	4	6	—	1	15
1889	2	—	7	4	—	2	15
1890	—	3	4	—	—	1	8
1891	5	—	—	9	—	1	15
1892	2	—	3	1	1	1	8
1893	4	—	1	3	1	4	13
1894	1	—	4	3	1	1	10
1895	2	1	5	6	—	3	17
1896	5	2	4	6	—	2	19
Total	55	23	81	126	21	64	370

Note: Japanese name of the above whale species in these days are:

Blue whale—Nagasukujira, Fin—Nosokujira, Bryde's—Iwashi or Katsuokujira,
Humpback—Zatokujira, Right—Semikujira, Gray—Kokujira.

But now the blue whale is called Shironagasukujira, and the fin Nagasukujira. Iwashikujira means usually the sei whale, but Iwashikujira in these districts is possibly the Bryde's whale.

SUPPOSED CALVING GROUND IN THE SETO INLAND SEA

Shindo (1970) proposes the "east Kyushu migration route" of whales. He is a clinical doctor, but concurrently a historian and has much interest on whales and whaling, especially on whales in the Seto Inland Sea. His conclusion is based upon his study of tombs and memorials of whales and old documents concerning these whales. He also visited villages and made interviews with people concerned.

*Sci. Rep. Whales Res. Inst.,
No. 26, 1974*

In old days it was a general custom to erect a tomb or a memorial when a whale stranded on the beach or occasionally killed by fishermen, like human being following after buddhism. These tombs or memorials are most abundantly remaining on the northeast coast of Kyushu and west coast of Shikoku (Fig. 10). Among 34 tombs or memorials, he investigated all over Japan, 15 are situated in these districts. They were erected within a period of about 100 years from 1809 to 1907. It is suggested from these facts that whales have passed frequently this strait and some of them were killed occasionally or stranded.

* One whale difference from Table 1.

Escaped, A—breaking net, B—beneath net, C—round net.

Not operated, D—due to rough weather, E—offshore.

He (1968) also ascertained that Beppu-wan, a small bay on the northeast coast of Kyushu, was a calving ground of whales. Fishermen applied in vain several times for permission of whaling to the local government. These documents are remaining, but the reason of the rejection has not been made clear. Coming of whales to this bay has lasted until about 1887. With regard to the whale species he notes as Nagasukujira, mainly based on old papers left in Usuki, a city facing to a small bay next to Beppu-wan, and where a memorial of a stranded whale remaining. The story of this stranding is described later in this report.

Waters around Iwajima, Yamaguchi-ken, was also a calving ground of whales.

Sci. Rep. Whales Res. Inst.,
No. 26, 1974

This is supported by Higashi (1944), who writes "Nearby waters of Iwaijima was a calving ground of Nagasukujira and 60-70 whales have gathered yearly in these waters. Sometimes dead calves were washed ashore". In Onoda, a city located westward of Iwaijima in Yamaguchi-ken, whaling was conducted in small scale in winter with hand harpoons and without using net. The whaling group was consisted of 15-20 fishing vessels. The whale species is not known, but most of them were accompanied by calves. The whaling group was dissolved in some years around 1877.

Fig. 3. Kokujiira in Yakuyoki, Kawanoe. First whale.

Fig. 4. Kokujiira in Yakuyoki, Kawanoe. Second whale (Aosagi).

Above are the basis why Shindo (1970) proposes the "east Kyushu migration route" of whales. He concludes that there are good evidences of whales coming into Beppu-wan and came in shore of the south coast of Yamaguchi-ken and the purpose of this migration was for calving. For the whale species he notes the pos-

*Sci. Rep. Whales Res. Inst.,
No. 26, 1974*

ajjima was
rly in these
city located
small scale
group was
out most of
ed in some

sibility of the balaenopterid whales, but this is hardly be thought. No baleen whales other than the gray whale give birth to a calf in such shallow coastal waters. It is highly possible, therefore, that the Shindo's proposal of migration route is only applied for the gray whale. There is a possibility of other species entering into the Seto Inland Sea through this passage, but it is not for calving. In fact a skull of a balaenopterid whale was dug out from sea bottom off Onoda in 1926. This skull was identified as a minke whale by Dr. T. Ogawa (Shindo, 1968).

Shindo (1968) reports two gray whales were taken at Kawanoe, Ehime-ken, in 1864. The official records or diary of the local government (Yakuyoki) in these days are still being kept at the city library. The first whale was taken on 20 February 1864 by nets and harpoons. This whale came in shore of the city several days before the hunting was done, during which period villagers prepared catching equipment. Shortly after the catch of the first whale the second whale came and this whale was taken on 26 February of the same year.

Attached with the official records there remains sketches of two whales (Figs. 3 and 4). Both are without doubt the gray whale, having several knobs instead of a dorsal fin and the head is small and not arched, unlikely to the right whale. The first whale was marked with white color on the dark gray of the body the infection of barnacles, but lacking the pale patches. The second whale bears pale patches all over the body, in addition to the barnacles. The body length of the first and the second whales were recorded as having 4 Hiro (1 Hiro approximately 1 Fathom) and 6 Hiro respectively. This length does not mean the total length, because it was a custom in Wakayama and Kochi to measure the length of the whale body from the blowholes to the insertion of the tail flukes. In any case the first whale was smaller and younger than the second whale. The first whale is noted as Kokujira, but the second whale as Kokujira or Aosagi. Two types of Kokujira were noted in these days. One is Aosagi and another is Share, but the difference between two types is not clearly described in most of the old books. Should the first whale grouped as Share, then the difference is based on the color pattern of the whale body caused by the infection of barnacles, or it can be said that Share is younger than Aosagi. Both whales are thought to be females, because teats are noted in addition to navel, genital grooves, anus and blow holes in their right positions.

One scapula from one of these whales has been preserved. It has been kept at Hachiman shrine in the city (Fig. 5). There is a custom in Japan to donate Ema to a shrine in memory of big event or from some other reasons. Usually Ema is a painting on a wooden plate. In this case a scapula was used instead of wooden plate. At the center of the scapula a big Japanese (or Chinese) character which means a whale is written with powdered gold. On both sides and below this character a brief descriptions of this whale is also written with paint by small characters. This Ema has been hanged more than a hundred years on the wall of the shrine with other wooden Emas.

These two whales were the only whales taken at Kawanoe in the history, but at Takuma, a small town east of Kawanoe, whaling had been conducted with nets

and harpoons annually, taking about three whales in average, at least in a period from 1889 to 1897. The species of whale are not known, but the size of whales is said to be 5-7 Hiro, which are the comparable size with the Kawanoe whales.

Fig. 5. Left scapula of the Kawanoe whale.

OBSERVATION OF SCAPULAE AND OTHER BONES

Shindo (1970) reports a scapula, a tympanic bulla and one of ribs of the stranded whale at Usuki also have been preserved in the city. These are private possession of persons living there. I had a short trip in April 1974 to Usuki and Kawanoe in order to examine these bones. It may be of some interest to note here the story of the stranded whale briefly. The village of Odomari, now included in Usuki city, constructed fishing harbor (Fig. 6) in 1868, but the cost has remained as a big burden of debt. On 1 February 1870 a big whale came into the harbor and finally stranded. This whale was sold, after being dismembered by all hands of the villagers, and the amount of money earned could cover all of the cost needed for the construction of the harbor. The villagers constructed a memorial (Fig. 7) and on 1 February of the following year they held a buddhistic ceremony for the whale. Since then the ceremony is being held on 1 February every year, including 1974.

On arrival at Odomari, Usuki city, I knew that another scapula has also been preserved at a family. They also said some of the baleen plates of the whale were remained until about five years ago, when they were finally burned, not knowing the value of such precious sample. In Table 3 measurements of the scapulae of the Usuki and Kawanoe whales are shown, together with measurements of other

n a period
of whales
be whales.

authors. The scapula of the Kawanoe whale (Fig. 5) agrees in general with the descriptions by Andrews (1914), being intermediate between the wide, low blade of *Balaenoptera* and the high, narrower and more symmetrically fan-shaped scapula of *Eubalaena*. The superior margin is quite evenly convex and the glenoid border is almost straight except for a short concavity where it rises from the glenoid fossa. The acromion is wide, but it is not expanding towards its distal end, contrarily to the description of Andrews and the photograph shown by Nishiwaki and Kasuya

ents of other

(1970). But this is thought to be caused by abrasion of the extreme end. The coracoid is thick and massive and directed somewhat upward from the margin of the glenoid fossa. The external face of the scapula is quite strongly concave. This scapula is smaller than that reported by Andrews (1914), but larger than those reported by Nishiwaki and Kasuya (1970). The former whale is an old male of 1250 cm long, and the latter is a young female of 900 cm in length. This scapula is thought to be taken from the second whale, and the size of this whale is possibly between the two lengths.

The scapulae of the Usuki whale (Fig. 8) differ from that of the Kawanoe whale, being more broader and less massive, as shown in the table expressed by thickness of the superior margin of the fan. The acromion and the coracoid are shorter than in the Kawanoe whale. The external face is quite different from the Kawanoe whale, having no concavity, a characteristic feature of the gray whale. On the rear surface it has several shallow grooves radiating from the center of the fan. Without doubt these scapulae came from one of the balaenopterid whales. The tympanic bone, 129 mm in length, is broken at its margin, but this also suggest this and the outline of this bone resembles to that of the blue whale from the North Pacific (Fig. 9). The remaining rib is thought to be one of the latter half

ribs. Its head is rounded and it measures 147 cm in straight line, but its distal end was cut off by knife. This bone has lesser value for the identification of the species.

After returning to Tokyo I sent three baleen plates, each one from the blue, fin and Bryde's whales, to Usuki for their identification, not informing them the species. They told me the color of the baleen plates was black, but the scapulae

Fig. 7. Memorial of the big whale at Odomari.

are without doubt not from a right nor a humpback whale, and there is less possibility of the sei whale in these regions. The reply was that the whale was a blue whale. Tomilin (1957) describes the ratio of breadth of the scapula against the height is 1.5–1.6 in the blue, 1.65 in the fin, and 2.0 in the sei whale. This value of the Usuki whale is around 1.6 and very close to the value for both blue and fin whales.

In conclusion above the Usuki whale was possibly a blue whale and this was a rare case of the stranding of this species. The size of the scapulae are relatively small. The body length of this whale was recorded as having 15 Hiro which means roughly 75 feet (2250 cm.). This is clearly too big, even if this means the total length. Possibly the size of this whale was smaller than 20 m and probably around 17 m. The sex of this whale was male, because there remains a record that both

*Sci. Rep. Whales Res. Inst.,
No. 26, 1974*

eyes, penis, and bones in the loin (pelvic bones?) were buried beneath the memorial, sealed in a pot.

DISCUSSION

Although practically nothing was described by Andrews (1914), Mizue (1951) and Rice and Wolman (1971), the gray whale occurred on the coast of Wakayama and Kochi in the days of the net whaling as already stated. It is possible that they

Sci. Rep. Whales Res. Inst.,
No. 26, 1974

Sci. Rep. Whales Res. Inst.,
No. 26, 1974

entered into the Seto Inland Sea for calving, along the west coast of Shikoku. Their calving grounds were at least in the Beppu-wan and on the south coast of Yamaguchi. Possibly some of them then turned to east and reached as far as Kawanoe and Takuma. There is less possibility that the whale entered into the Seto Inland Sea along the west coast of Wakayama. One reason for this is the

Fig. 9. Tympanic bulla of the Usuki whale.

fact that no tomb or memorial is remaining on the west coast of Wakayama and east coast of Shikoku. Fishermen who engaged in the net whaling believed that whales come straight from off Shionomisaki, the southmost point of Wakayama, to the coast of Shikoku. Supposed migration route is shown in Fig. 10.

With the increasing of industrial development along the coast of the Seto Inland Sea and boat and ship traffic the species has been driven from there since some time prior to this century. This might be the most possible explanation why practically no gray whale has been taken by modern whaling on the coast of Japan. Mizue (1951) reports, after investigating available catch records of whaling companies in seven years from 1911 to 1932, three were taken at Ayukawa and one at Nemuro, Hokkaido. Nishiwaki and Kasuya (1970) describe two recent occurrences off Wakayama.

The feeding ground of the Japanese stock of the gray whale was probably in the Okhotsk Sea as in the case of the Korean stock (Rice and Wolman, 1971). The migration route to and from the feeding ground was possibly on the east coast of Japan, as already stated by Nishiwaki and Kasuya (1970). After driven from the calving ground in the Seto Inland Sea it probably has joined to the Korean stock. Further a possibility of joining to the California stock in the Bering Sea can not be denied. The original size of this stock is thought to be small and less than a thousand at the largest.

At Omijima, a small island on the north coast of Yamaguchi, or in the Sea of Japan, the gray whale was also taken in the days of the net whaling (Kimura, 1956). There remains catch records during a period from 1802 to 1850, by species. Annual catch, inclusive of all species, was fluctuated from one to fifteen whales.

st of Shikoku.
south coast of
hed as far as
tered into the
for this is the

The total catch during this period was consisted of the fin (38%), the humpback (34%), the right (19%), and the gray whale (9%). The catch of the gray whale has decreased since 1812. A question remains whether these gray whales belong to the Korean stock or they are stragglers from the Japanese stock.

ACKNOWLEDGEMENTS

Sincere thanks are due to Dr. N. Shindo who helped me greatly in this study. He joined my trip to Usuki and Kawanoe and made all possible arrangements for me. My thanks are also due to Mr. S. G. Brown of the Institute of Oceanographic Sciences, England. He gave me the old Japanese book, he found at an old book store in London, and from which Table 2 in the text was referred.

POSTSCRIPT

After completion of the manuscript I read a paper on the Korean stock of the gray whale by Bowen (1974). The author states that the 1968 specimen (Nishiwaki and Kasuya, 1970) resembled members of the California stock in morphological features, without mentioning the character in question. As seen in Table 3 the ratios of breadth against height of scapulae in three specimens of the gray whale are: the Kawanoe whale 1.34, Gray A (Nishiwaki and Kasuya, 1970) 1.48-1.53, and Gray B (Andrews, 1914, Korean stock) 1.31. Thus in this respect the Kawanoe whale resembles more to the member of the Korean stock than the whale reported from the coast of Japan. But the latter whale is a young female and this is thought to be a difference due to the growth.

As regards the distribution of the Korean stock Dr. K. Uchida (1964) describes a gray whale sighted by him towards the end of May 1930 on the west coast of Korea, in the Yellow Sea, at a position close to 38°N.

Introduction

The occurrence of gray whales in the coastal waters of Japan prior to the turn of the century was described by Omura (1974). He referred to a population occurring in the south of Wakayama and Kochi prefectures and very briefly to the presence of another population occurring off the north coast of Yamaguchi prefecture, in the Sea of Japan, and off the west coast of Kyushu, in the East China Sea. Catches were made from both populations in the days of net whaling (1675–1890).

The Wakayama/Kochi population is thought to have followed a migration route along the east coast of Japan (Nishiwaki and Kasuya, 1970; Omura, 1974). The Yamaguchi/Kyushu population is thought to have been a portion of the Korean stock. This stock migrated down the east coast of Korea in winter. The majority turned west along the south coast of Korea (Andrews, 1914) but a fraction is assumed to have continued southward until they reached the north coast of Yamaguchi prefecture (near Kayoi, a present Nagato city) and then to have turned along the west coast of Kyushu.

Subfossil mandibles excavated some years ago from the city of Ichikawa were recently identified as belonging to a gray whale. This further supports the contention that this species occurred in coastal waters of Japan.

Brief History of Old Whaling in Japan

Whaling off Japan appears to have a very long history. A poem describing the catching of whales by a small boat is dated prior to the tenth century. Nothing is known, however, about the method and gear used or about the species of whales taken.

In the years of Genki (1570–1573), whaling in Mikawa and Qwari districts (now Aichi prefecture) facing Ise Bay was conducted by villagers who formed teams of 7–8 vessels and used hand harpoons (Otsuki, 1808; Fukumoto, 1960; Hashiura, 1969; Nagasaki, 1981). It can be assumed this whaling began as bay whaling and its center was Morosaki (see Fig. 7). Nothing is known about the species of whales taken, but there is a possibility that gray whales were the target. In the Edo era (1603–1867), gray whales en route to the Seto Inland Sea were thought to enter Ise Bay, passing sufficiently close to shore to become accessible to fishermen.

In years of the Bunroku (1592–1595), a skilled harpooner from Morosaki named Sukebei Mase came to Misaki (now in Kanagawa prefecture) and began whaling (Hashiura, 1969). The species of whales taken are not known, but a considerable number of whales was taken and local fishermen were stimulated to begin whaling with the same technique. It was reported this period did not last more than 20 years, because of a scarcity of whales.

There are grounds to believe that the harpoon method of whaling was transferred to Katsuyama, the village opposite Misaki across Tokyo Bay in Chiba prefecture. According to Yoshihara (1976a), new whaling started there in the years of the Keicho (1596–1603). This was the origin of the small cetacean whaling now in operation in Chiba prefecture, which takes mainly Baird's beaked whales (*Berardius bairdii*) and some other small toothed whales but no gray whales. Hand harpoons, and after 1907 small harpoon guns, were used for killing whales. Nets were not used at all in this fishery, contrary to the practice in other whaling sites in western Japan. The whaling grounds were later shifted to the east coast of Chiba prefecture.

Hand-harpoon whaling originated in Morosaki and spread to the south along the coast of Ise and Kumano districts (present Mie and Wakayama prefecture). In the eleventh year of Keicho (1606), Yorimoto, head of the then powerful Wada clan, established five whaling groups at Taiji, Kumano. He took command of the operation in the Taiji area, consulting with two fishermen, Denji from Morosaki and Jiemon from Sakai near Osaka (Hashiura, 1969). It is thought Denji, possibly a harpooner, assisted Yorimoto with the technical aspects and that Jiemon handled the commercial aspects of whaling. In 1618 a skillful harpooner named Yoheiji, from Onoura, near Morosaki, was employed at Taiji and given the name of Hazashi (chief harpooner), showing superior status to that of any other whaling crew.

In 1675, Yoriharu Wada, a grandson of Yorimoto later renamed Kakuemon Taiji, invented a new method of whaling using nets. Whales trapped and entangled by many folds of nets were easily harpooned. Straw nets were used at first, but they were too weak and were replaced in following years by hemp.

The use of nets was a revolutionary event in the history of whaling in Japan, allowing takes of humpback whales, other balaenopterid whales, and right whales, none of which could have been taken by hand harpoon previously. This method, however, required more fishing boats, more manpower, and a coordinated cooperative operation. At Taiji, five whaling groups were reorganized into one and Yoriharu Wada took the command.

The basic organization of the net-whaling fleet consisted of the following groups:

1. Seko-bune or beater boats (for driving and killing whales), one group of about 15–20 boats, 13 m long and 2.3 m wide, with eight oars. The crew of each boat consisted of 15 men, namely 1 captain, 13 sailors, and 1 apprentice.
2. Ami-bune or netting boats, one group of 6 boats, 13 m long and 3.5 m wide, with eight oars and a crew of 10 men.
3. Mosso-bune or tug boats, a group of 4 boats, nearly the same as beater boats but with a broader beam, and a crew of 1 captain and 12 sailors.

From a hillside hut commanding a wide view, watchmen scanned the sea surface for whale blows. When a whale was sighted within range, the watchmen sent signals with flags or rockets informing the boat crews of the species, position, and swimming direction of the whale. The boats described above waited in scattered positions and moved into action in an orderly fashion when the commander gave the order.

The beater boats surrounded the whale from a distance and drove it toward the netting boats which moved into proper position to set their nets. Nets were sometimes set two or three deep to prevent the whale's escape and to reduce its struggle. The netted whale was harpooned from the beater boats. When the whale was sufficiently weakened by a number of harpoons, a sailor jumped into the water and climbed onto the head of the whale with his knife to make a hole on the septum of the blowholes through which a rope was passed. Another hole was made in a similar way near the dorsal hump. In both cases the sailor stayed on the slippery surface of the whale body by grasping the handle of a struck harpoon. These harpoons also prevented the nets from slipping off.

The invention of net whaling was a major event in the economy of Japanese fishing villages. Whaling supported many hundreds of people, including workers processing the whale carcass, making nets, or engaged in other related activities, as well as sailors at sea.

Net whaling was soon introduced at Koza, a town close to Taiji, and at other places in Kumano district (part of the present Mie and Wakayama prefectures). In 1683 this method was transferred to Tosa (in the present Kochi prefecture), where the two whaling groups of Ukitsu and Tsuru were already in operation. In the following year a whaling boss named Gidayu Fukazawa from Omura, west Kyushu, came to Taiji and learned this method from Yoriharu (Hashiura, 1969). When Fukazawa returned to Kyushu, net whaling soon spread over the west coast of Kyushu and the north coast of Yamaguchi prefecture.

Descriptions of Gray Whales in Old Literature

Old Japanese whaling flourished in the Edo or Tokugawa era (1603–1867). Several books and picture scrolls of whales and whaling published during this period are useful because they contain such information on the whales migrating to Japanese waters as their species composition, migratory pattern, and catch statistics.

"Geishi" (the Treatise of the Whale), written in 1758 and printed in 1760 by Jiemon Kandoriya, the castellany of Wakayama, is the earliest printed monograph of the cetacea of Japan. It contains a drawing and brief description of the gray whale (Fig. 1), named Kokujira from *ko* meaning small and *kujira* meaning whale. The gray whale was so called because it was thought to be the smallest species among whales. There is evidence to suggest that at that time the minke whale was not identified as an independent species of baleen whale.

Kokujira had no dorsal fin but was illustrated as having several knobs in the posterior portion of the back. On both upper and lower jaws there were many hairs that spread over the entire head. This agrees with the description by Andrews (1914) who states "they (hairs) are more widely and more uniformly spread over the entire head, than in any other baleen whales."

The body color of Kokujira is described as pale blue, and there are many circular or

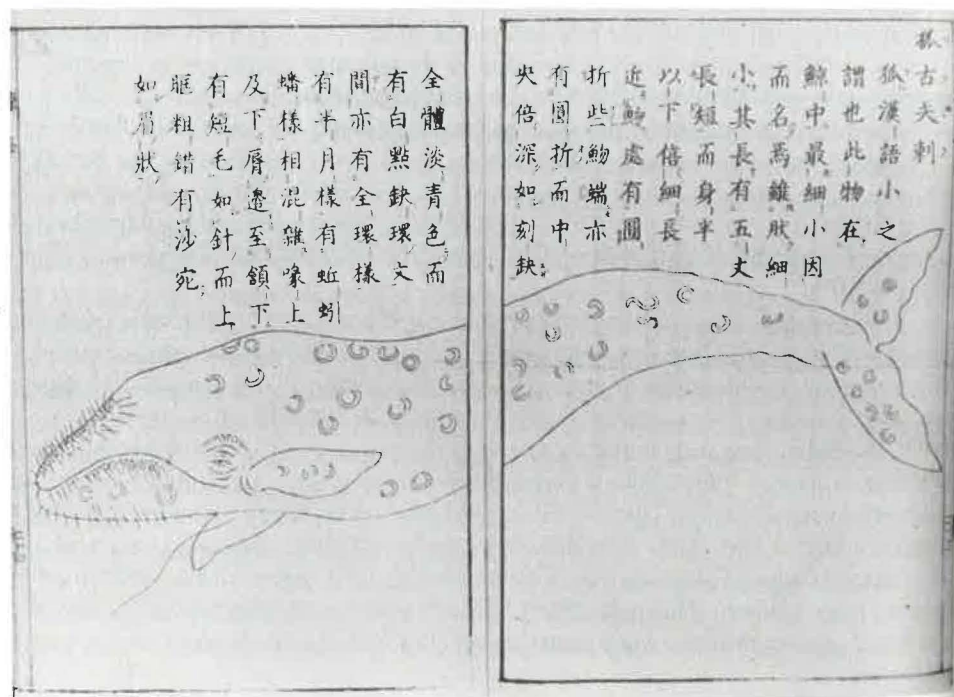

Fig. 1. Kokujira in *Geishi*, 1760 (from Hawley, 1958).

e many circular or

The author of the “Geishiko” refers to various books on whales and whaling which

Ex. M-0456

were then available to him. Kokujira was also called Chikokujira, *chiko* also meaning small. The baleen plates of Chikokujira were described as being white. Two kinds of Kokujira were reported, one called *Aosagi* and the other *Share*. *Aosagi* was preferred to *Share* because its oil was white. However, interpretation of this old description became somewhat confused in later years. Andrews (1914) states

The blubber is thick and fat, and varies in color from red to flesh pink. Because of this the Japanese recognized two kinds of gray whale, the 'Aosaki' (red blubber) and the 'Shirasaki' (white blubber). Although specimens with blubber strongly red, almost white, and of every intermediate shade, were taken during my stay at Ulsan, I could detect no difference, other than those purely individual, between them.

In Andrews' description, *Aosaki* is the same as *Aosagi*. There is only a slight difference in pronunciation of the two words, and *Aosagi* means blue heron.

I have been unable to find the names of *Shirasaki* or *Shirasagi* in any of the old books on whales and whaling. The only two kinds of Kokujira named are "*Aosagi*" and "*Share*." And, contrary to the above description, the color of blubber in *Aosagi* is said to be white. Hattori (1887-1888) thought that *Share* were young animals and *Aosagi* full-grown adults. This may be the correct interpretation. The individual differences in color of the blubber may be due to the different foods they took, as suggested by Andrews (1914). There is a description (Anonymous, 1890) in which the bigger whales which come from the west are called *Aosagi* (at Kawajiri). If this statement is correct, *Aosagi* referred to whales that were migrating from the calving ground to feeding grounds.

Biological Evidence of Occurrences

SUBFOSSIL EVIDENCE

In 1966, both mandibles, some vertebrae, and ribs of a whale were excavated from a depth of 4 m in a sand stratum in Ichikawa city, a neighboring city of Tokyo, during construction of the Ichikawa Telegram and Telephone Office. This stratum contained fossil shells, which were radiocarbon dated to 6000 years BP, or the time of the Jomon Sea Regression. The whale was erroneously identified as the sei whale, *Balaenoptera borealis*. The skeleton was then mounted with an artificial skull, vertebrae, and ribs, and exhibited in the main hall of the Ichikawa Municipal Museum.

In March, 1982 I visited the museum, with Dr. T. Kasuya of the Ocean Research Institute, University of Tokyo, and Mr. H. Kato of the Whales Research Institute and positively identified the specimen to be a gray whale. In gray whales the "lower jaws are massive, wide, and without coronoid processes: their inner surface somewhat concave at the proximal part" (Tomilin, 1967). There was no difficulty with the identification, because these features are very prominent even at a glance (Fig. 3).

Both mandibles of the Ichikawa whale have been broken anteriorly. The straight-line length of the right bone from broken tip to posterior end is 2.22 m. The height is 35

Fig. 3. Mandibles of the Ichikawa whale (courtesy of the Ichikawa Municipal Museum).

cm at the articulation, 21.5 cm at the lowest part just in front of articulation, and 29.7 cm at the top of the remaining part. Total length of this mandible is estimated to have been about 2.5 m and the body length of the whale approximately 12 m.

Ichikawa city is situated at the innermost part of the Tokyo Bay. The positive identification of this specimen is direct evidence that gray whales once occurred in the eastern coastal waters of Japan.

RECENT HISTORICAL EVIDENCE

In 1864 two gray whales were taken in the Seto Inland Sea, at Kawanoe, Ehime prefecture, the first on February 20 and the second on February 26. These whales were reported first by Shindo (1968) and then by Omura (1974). It is not necessary to describe them here in detail, but I wish to mention briefly their relationships to Aosagi and Share. Drawings of these whales are kept at the Kawanoe City Library (Figs. 4 and 5).

The first whale is smaller than the second and possibly would have been referred to as Share, although nothing was noted on the drawing (Fig. 4); the second whale (Fig. 5) was labeled as Aosagi. The body surface of the first whale was slightly infested with barnacles. The second whale bears heavy white markings of barnacle infestation, suggesting it was older than the first. A left scapula, possibly from the second whale, has been preserved at Hachiman shrine in the city, presented as Ema in memory of the whaling event (Fig. 6). The scapula of *Rhachianectes* (*Eschrichtius*) is distinctive in being intermediate between the wide, low scapula of *Balaenoptera* and the high, narrower, and more symmetrically fan-shaped scapula of *Eubalaena* (Andrews, 1914). Measurements of

Fig. 4. Kawano whale—first whale (from Omura, 1974).

the at Hachiman shrine scapula were given by Omura (1974). Greatest breadth and greatest height are 99 and 74 cm, respectively, and the ratio of breadth to height is 1.34.

Omura (1974) thought the nearby waters of Iwajima in the Seto Inland Sea was a calving ground of the gray whales, which occurred on the south coast of Japan. According to Saito (1977), Engelbert Kaempfer, a German traveler and physician, sighted small whales in the waters near Mitajiri on April 30, 1691, while he was returning from a visit to the Shogun's capital of Edo (Tokyo). Mitajiri is close to Iwajima and not far from Shimonoseki, the western entrance to the Inland Sea. Kaempfer referred to these

Fig. 5. Kawano whale—second whale (from Omura, 1974).

Fig. 6. Left scapula of the Kawano whale (from Omura, 1974).

whales as "Nordcaper," which means right whale, a species not reported from the Inland Sea; he further describes them as small whales. It is possible the whales he sighted were in fact gray whales. Gray whales and right whales have often been confused, even by gunners of modern whale catcher boats.

Nishiwaki and Kasuya (1970) report the accidental catch of a young female gray whale in 1968 at Shingu, Wakayama prefecture (the skeleton of this whale is maintained at Taiji Whale Museum). They also reported the sighting, by a skillful gunner of long experience, of a gray whale in nearby waters around 1959.

Catches of Gray Whales

Net whaling flourished nearly 200 years in the Edo era (1603–1867), during which time gray, right, humpback, and other species of whales were taken. The gray whales were usually taken without nets, because of their relatively smaller size (Taiji, 1937).

Practically no catch statistics exist for Wakayama and Mie prefectures. At Taiji, whaling continued after the Meiji Revolution (1868) until a tragedy occurred in 1878. In

that year more than 100 people were killed by a heavy storm while they pursued a right whale accompanied by a calf. This incident was practically the end of old whaling at Taiji.

There remain at Taiji some fragmentary records of the catch. For example, from December 24, 1799 to January 15, 1800, a total of 9 whales was taken, including 1 right, 6 humpback, and 2 gray whales. However, because most of the records were lost by fire or during several floods, it is not clear whether this was an exceptionally good season. This seems to have been a good catch, but further comparison of catch records is not possible.

Whaling on the coast of the Sea of Japan, at Ine, Kyoto prefecture, had been conducted since very ancient times, probably as early as Tenmon (1532-1554). The methods were somewhat different from those used in other places. The village of Ine is located on a small inlet, called Inewan, into which whales occasionally swam. When this happened the fishermen of Ine blocked the entrance of the inlet with nets and then caught the whale using hand harpoons and nets. Catch records of the Ine whaling operation during a period from 1656 to 1913 are available by species (Yoshihara, 1976b). During this time a total of 357 whales, including 167 humpback, 149 "fin" (including minke), and 41 right whales, was taken. No gray whales were taken, evidence that gray whales did not occur on the east side of the Sea of Japan at that time.

Whaling was conducted, however, in several villages on the north coast of Yamaguchi prefecture, including Kayoi in the east and Kawajiri in the west (Tokumi, 1957; Tada, 1978). At Kayoi, at present Nagato city, there is a temple named Koganji where notes are preserved which contain the Buddhist names of each whale taken and from which catches of species have been summarized (Kimura, 1956). Japanese people were given special names from a Buddhist priest when they died, and in this respect the whales were treated somewhat like human beings. The first volume of the Koganji notes is missing, but from remaining volumes catch figures are available for about 50 years, from 1802 to 1850. During this period a total of 308 whales, including 116 fin, 105 humpback, 59 right, and 28 gray whales, was taken. The average catch per year was 6.3 animals; gray whales comprised 9% of the catch.

For Kawajiri, catch statistics arranged by species and by 10-year increments are available from 1699, when whaling was started, until 1888 (Anonymous, 1890). Yearly figures for the 8 years from 1894 to 1901 were given by Tada (1978) (Table I). For a period of 50 years, from 1769 to 1818, only the total number of catches was reported, but catches by species can be compared for the periods 1699 to 1768 and 1819 to 1888. Catches of gray whales increased from 12% in the former period to 16% in the latter. Both figures are greater than proportions of gray whales in catches at Kayoi. Catches of right and humpback whales decreased as those of "fin" whales (again possibly including minke whales) increased, possibly due to decrease of the former two species. Tada (1978) states that no right whales were taken after 1884. Catch statistics at Kawajiri in the later years are given by Tada (1978) for a period from 1894 to 1901. The decline of gray whale catches and the increase of "fin" whale catches during this period are remarkable. Whaling at Kawajiri was virtually terminated in 1902.

In addition to Kayoi and Kawajiri, whaling was conducted at several villages including Mishima (Tada, 1968), a small island about 45 km northwest of Hagi city. Whaling in

these villages began around 1680 and lasted until near the end of the nineteenth century. Unfortunately, details of the catches are not available.

On the west coast of Kyushu, whaling was conducted at various places. Otsuki (1808), for example, listed 68 localities. This does not mean, however, that 68 whaling groups existed in Kyushu; rather, it represents the total number of places where whales,

^aTada (1978).

especially right whales, were taken. These numbers were reduced to only 3 a few years before the turn of the century, due to heavy reduction in numbers of right whales migrating there (Takahashi, 1899).

Whaling in Kyushu also started as a small enterprise using hand harpoons. After the invention of net whaling, this method spread over the west coast of Kyushu, and whaling flourished there more than in any other place (Anonymous, 1980). Whaling in Kyushu was operated by several groups, such as the Nakao group of Yobuko and Ogawajima (Saga prefecture), the Toi group of Iki Island (Nagasaki prefecture), and the Masutomi group of Hirado and Ikitsuki (Nagasaki prefecture). Among them the Masutomi group was the largest. From 1725, the year when the group was formed by Matazaemon Masutomi, to 1874, a total of 21,790 whales was taken (Yoshihara, 1977), a yearly average of 150 whales for all locations combined. The group operated at several locations in Kyushu, and sometimes at Mishima and Kayoi (both in Yamaguchi prefecture) as well. It was said this whaling group employed 3,000 people and about 200 fishing vessels when in operation.

Whaling at Ogawajima survived long after the introduction of modern whaling (Anonymous, 1980). A hut called Yamami, or lookout, was built on the top of a hill. When the watchmen sighted a whale he telephoned to a modern catcher waiting in the port of Yobuko. The catcher then pursued and killed the whale and returned it to the village, where it was processed by the villagers using traditional methods. This type of whaling lasted until 1948.

It is possible that gray whales were also taken in the waters west of Kyushu, but there are no catch statistics by species. Catch figures of whales at Iki Island in the 16 years from 1845 to 1860 are shown in Table II. Whaling from Iki Island was conducted by two whaling groups, Masutomi and Kuramitsu, operating at Katsumoto one season and

Maeme the next. The catches of whales at Iki decreased after 1849, probably because of the decrease of right whales.

In Tosa (present Kochi prefecture) whaling with hand harpoons dates from the years of Kanei (1624–1643) (Izukawa, 1943), and net whaling from 1683 when it was introduced from Taiji. Two groups of whalers, Ukitsu and Tsuro, operated on the coast of Tosa, splitting their activities between an east and a west whaling ground. There are two peninsulas in Kochi, the Muroto Peninsula in the east and the Ashizuri Peninsula in the west. The east whaling grounds were on the east side (in winter), and west side (in spring) of the Muroto Peninsula. The west ground was on the east side of the Ashizuri Peninsula in both winter and spring.

Each year the Ukitsu whaling group operated in one ground and the Tsuro whaling group on the other, and the two alternated grounds each year. Both groups left good catch records by year, from which general trends of the whaling in Kochi can be detected (Table III).

Table IIIA shows the total catches of whales by the Tsuro group in the years 1693–1712, inclusive. The average catch per year was 20.6 whales, but no species breakdown was available. For the 35 years from 1800 to 1835 (Table IIIB), the Ukitsu group took 959 whales, or 27.4 whales per year. Humpback whales comprise more than one-half of the total catch. In the years 1849 and thereafter (Tables IIIC, D, and E), right whales decreased considerably, while catches of Bryde's, blue, and fin or balaenopterid whales increased. Catches of gray whales appear to have been rather stable.

Discussion and Conclusions

Except for a few stragglers, gray whales do not occur in the coastal waters of Japan at present. Prior to the turn of the century, however, they were found in two regions, one on the Pacific side of Japan, from Tokyo Bay to Kochi prefecture, and the other on the west side of Japan off Kyushu, including the north coast of Yamaguchi prefecture. This conclusion is supported by subfossil mandibles excavated from Ichikawa city, old books on whales and whaling, and catch statistics of old whaling operations in the Edo era (1603–1867). The whales in these two regions may represent different populations of gray whales. The latter (the Kyushu group) is clearly a portion of the Korean stock. Distribution of the two populations in the waters off Japan and Korea is shown in Fig. 7. The two populations may have intermingled in the Seto Inland Sea. If so, then both populations belong to the Korean stock.

In summer, the Korean stock of gray whales occupies, or at least formerly occupied, the northern Okhotsk Sea (Rice and Wolman, 1971). It is not clear whether or not the gray whale population occurring off the south coast of Japan also spends the summer in Okhotsk Sea mingling with the Korean stock. Bowen (1974) states that the young female gray whale accidentally taken in 1968 at Shingu (Nishiwaki and Kasuya, 1970) resembled members of the California stock in morphological features and should be regarded as a stray from the Bering Sea. There still exists the possibility, however, that the two populations occurring in the coastal waters of Japan intermingle with each other in the Seto Inland Sea.

The annual catch of gray whales in Kochi prefecture in the days of net whaling was rather small (Table III). The largest catch was 11 in 1877 by the Ukitsu group; the yearly

Fig. 7. Map showing the distribution of gray whales in the coastal waters of Japan and Korea. Place names appearing in the text are indicated by numerals as follows: (1) Tokyo, (2) Ichikawa, (3) Katsuyama, (4) Misaki, (5) Morosaki, (6) Taiji, (7) Koza, (8) Sakai, (9) Osaka, (10) Ine, (11) Tsuru, (12) Ukitsu, (13) Kawano, (14) Iwajima, (15) Mitajiri, (16) Mishima, (17) Kayoi, (18) Kawajiri, (19) Ulsan, (20) Tsushima, (21) Iki, (22) Ogawajima, (23) Yobuko, (24) Ikitsuki, (25) Hirado. Solid arrow, migration routes and area of distribution of Gray whales; broken arrow, movements uncertain.

average was 2.9–5.9, and there were no remarkable differences between the two whaling groups or among different years. The total yearly catch of gray whales by the two groups in Kochi prefecture is estimated to have been around 10 whales. This suggests gray whales occupied a less important position than right and humpback whales.

Catch figures of gray whales in Wakayama and Mie prefectures are not known. Presumably gray whales were taken in numbers such as in the Kochi prefecture. If one assumes that equal numbers were taken in each of these prefectures, then the total catch of gray whales from the population would have been 30 per year. The catch of gray whales from this population appears to have been rather stable (Table III), suggesting that the catch rate from this population was not high.

The catch of gray whales at Kawajiri, Yamaguchi prefecture during the period of 1699–1768 totaled 110 whales, or an average of 1.6 whales per year (Table I). In the third

period, 1819–1888, the corresponding figures are 170 total and 2.4 whales per year, indicating an average increase in take of 0.8 whales per year. These catches are very low compared with the corresponding figures in Kochi prefecture. For the period 1894–1901, the average catch per year was 0.9, less than in previous years. Kimura (1956) also shows a reduction in gray whale catch at Kayoi after 1831.

It is not known how many gray whales were caught on the west coast of Kyushu. It is assumed, however, these catches were far more dependent on availability of right, humpback, and fin whales, as in Kawajiri and Kayoi, and that gray whales were caught only secondarily to the whaling there. It is assumed as many as 20–30 gray whales were taken per year but the catch of gray whales decreased towards the end of net whaling around 1900 and these stocks were finally extirpated.

This reduction does not necessarily mean a reduction of the Korean stock. Mizue (1951) reports heavy catches of gray whales at Ulsan, Korea after 1910. Therefore, the decrease of gray whales migrating to the coast of Yamaguchi and to the west coast of Kyushu may have resulted in a change in migration route.

Modern-type whaling in Japan commenced in 1898, when the first catcher Hokamaru, built of wood, caught three whales (Akashi, 1910). After that year, whaling operated first on the east coast of Korea, the west coast of Kyushu, and the south coast of Japan, and then shifted to the northeast coasts of Japan and Hokkaido. As pointed out by Mizue (1951), only a few gray whales were taken during modern whaling, except in Korea and Tsushima. Omura (1974) speculated the gray whale population on the Pacific side of Japan was driven from its calving ground in the Seto Inland Sea sometime prior to this century by the increase in boat traffic and industrial development on the coast. It now appears this matter is more complicated and that additional material is needed to support firm conclusions.

Summary

Prior to the turn of the century, two populations of gray whales migrated to the coastal waters of Japan, one to the southern coast of Hokkaido and Honshu and the other to the west coast of Kyushu via the north coast of Yamaguchi prefecture. The former migrated along the east coast of Japan from the north and entered the Seto Inland Sea, the supposed calving ground for this population. The latter, considered to be a portion of the Korean stock, migrated along the east coast of Korea and then to southwest Honshu and northwest Kyushu. Intermingling of the two populations in the Seto Inland Sea cannot be denied.

The annual catch of gray whales in the days of net whaling (1675–1890) was approximately 30 whales from the former population and 20–30 from the latter. Virtually no gray whales, however, have been observed in the waters around Japan since about 1898 when modern-type whaling was introduced.

The southern coast population was probably driven from the Inland Sea sometime

of Korea. Place names

Preface

This volume represents the culmination of over four years work, beginning with the organisation of a Symposium and Workshop held in La Jolla in 1990. It includes the report of that Workshop, the IWC Scientific Committee's report on stocks of small cetaceans that are subjected to 'significant' directed and incidental takes submitted to the 1992 UNCED and over 50 papers either presented to the Workshop, subsequent IWC Scientific Committee meetings or requested to address important relevant issues not covered by the presented papers. The papers herein represent the most complete and current account of a problem that probably represents the most serious threat to cetaceans today. Unfortunately, despite some progress in documenting the problems, we are still a long way from arriving at solutions for many regions and fisheries around the world. I hope that publication of this book stimulates Governments to address the issues highlighted here in a prompt and determined manner. This will involve: encouraging research in the wide range of disciplines necessary, including cetacean biology, fish biology, population dynamics, management science, and fishing gear technology; and, not least, the participation of fishermen in the process.

Introduction

The International Whaling Commission's Scientific Committee first recognised the potential threat to cetacean populations posed by incidental kills in fisheries in 1972, when it

'discussed and expressed concern over the large incidental kill of porpoises and dolphins in the US tuna fishery, reported to be about 250,000 per year' (IWC, 1973, p.37).

In that same year, the Committee recommended that a sub-committee on small cetaceans be established, to improve data collection on world catches and to review species and stock identification and other problems; much of the subsequent review and scientific discussion in the Committee of incidental fishery kills and their impact has taken place in this sub-committee. The founding chairman of the sub-committee was Edward Mitchell, who deserves great credit for bringing the related issues of small cetaceans and incidental kills (of cetaceans both large and small) to the fore in the Committee and the Commission.

In 1972 the Committee also recommended that member nations

'engaged in killing small cetaceans provide information on their controls on these operations and also include information on catch and incidental kills in future progress reports' (IWC, 1973, p.42).

The Commission formally implemented this recommendation in 1976 (IWC, 1977, p.26) and information on incidental kills and associated research began to appear in national progress reports that year (e.g. Anonymous, 1977).

The sub-committee on small cetaceans met for the first time in Montreal in 1974 and conducted a comprehensive review across species, regions, fisheries and problems (Mitchell, 1975). It emerged that cetaceans of many species were being killed incidentally in gillnets, including Dall's porpoises, pilot whales and Baird's beaked whales, all also taken in commercial directed fisheries. The major net fisheries involved were the salmon driftnet fisheries of the North Pacific and North Atlantic, shark gillnet fisheries in several regions and coastal gillnet fisheries in South America. Thousands of Dall's porpoises were being killed in the Japanese salmon driftnet fishery alone (Ohsumi, 1975). The sub-committee recommended that further statistics on these and other kills be collected.

The FAO ACMRR Working Party on Marine Mammals conducted a large international consultation in Bergen, Norway in 1976 (Anonymous, 1978). In their conclusions, they stressed the potential importance of incidental kills and the need to document the distribution of gillnet fisheries relative to that of cetaceans, the extent of the mortality and the impact of this mortality on cetacean populations. They suggested that research on behaviour, particularly with respect to feeding and echolocation, be

undertaken with the goal of modifying fishing gear or practices to reduce entanglements.

The conference that formed the basis for the present volume had its beginnings in 1984, when the sub-committee on small cetaceans proposed that an expanded session of the sub-committee should be convened in 1985 to review new and expanding gillnet fisheries that have or may have an impact on small cetacean populations, with invitations to be extended to outside experts on gillnet fisheries and gillnet fishing gear (IWC, 1985, p.137). Because of budgetary limitations, the review did not occur in 1985, but a workshop separate from the annual IWC meeting and expanded to include the large whales (specifically gray, humpback and right whales) was proposed by the Committee for late 1986 (IWC, 1986, p.37). The Committee stressed that the meeting's scope should be limited to scientific and technical matters related to cetacean entanglement in gillnets. The participation of a behaviourist, a sensory physiologist, a fisheries development officer and a gear expert were to be encouraged. Funds for the meeting were to be sought outside the Commission. Funds were not found and the meeting did not materialise in 1986.

The meeting was subsequently included in the 1988–1992 action plan of the IUCN Cetacean Specialist Group (Perrin, 1988) and an offer to host the meeting was extended to the Commission by the Southwest Fisheries Science Center in La Jolla, California (IWC, 1988, p.123). The invitation was accepted, and in 1988 a Steering Group was established consisting of W.F. Perrin (convener), R.L. Brownell Jr., L. Jones, D.P. DeMaster, J.S. Leatherwood and J. Barlow (IWC, 1989, p.62). The scope of the meeting was extended to include a symposium of contributed papers and consideration of incidental kill in traps and other passive fishing gear, and terms of reference were drawn up (Perrin and Brownell, 1989). The Commission approved the terms of reference but again postponed the meeting because of budgetary constraints. Meanwhile, additional reports of kills in gillnet, driftnet and trap fisheries surfaced: sperm whales, humpbacks, minke whales, gray whales, right whales and many species of small cetaceans in fisheries in the Mediterranean, at the Azores, off California, in the Baltic, in the Northwest Atlantic, off the Pacific coasts of Canada and Alaska, in Japanese waters and in other regions (Perrin, 1990).

In 1989, partial funding was offered by World Wildlife Fund – Sweden. Promises of support soon followed from the United Nations Environmental Programme, the New Zealand Department of Conservation, the US Marine Mammal Commission, the Australian Fisheries Service, the US National Oceanic and Atmospheric Administration, the Southwest Fisheries Science Center and World Wildlife Fund – USA; and the Conference was

set for October 1990 in La Jolla. The support provided by these agencies and NGOs was also sufficient to pay over half of the publication costs of this volume.

The Report of the Workshop was presented to the Scientific Committee and the Commission in 1991. It then became publicly available and was circulated to relevant member and non-member nations of the IWC. Partly in response to the need for the meeting and its subsequent report, the Commission passed two Resolutions requesting the Scientific Committee to draw together available information on the status of those stocks of small cetaceans that are subjected to 'significant' directed and incidental takes (IWC, 1991) and to forward that information to the 1992 United Nations Conference on Environment and Development (IWC, 1992).

We have decided to include both the Report of the Workshop and the Report to UNCED in this volume because the latter places the threat posed by incidental mortality in passive fishing gear into the context of overall threats to small cetaceans throughout the world.

The production of this extensive volume has been a major task. For a number of reasons, including communication with authors and reviewers from every continent (except Antarctica) and a full publication schedule for IWC volumes, production has taken longer than we originally anticipated. For this reason we have taken the opportunity to:

- (1) encourage authors to update their papers to include data and information from after the 1991 IWC meeting when the report first became publicly available;
- (2) include papers that originated in part in response to recommendations made in the Report of the Workshop.

Although this resulted in a slight additional delay to the volume, we believe that this has been worthwhile in that the included papers now represent the most complete and current account of the worldwide situation of a problem that probably represents the most serious threat to cetaceans today – some of the papers include data collected as recently as October 1994.

The contributed papers published in this volume each received at least two anonymous peer reviews. Some of the symposium and workshop papers are not included here because they were not submitted for publication (for various reasons, such as publication elsewhere) or did not pass peer review. Abstracts are included for those papers not published.

Many people made the conference and this volume possible. In particular we would like to thank those scientists who gave up their time to review papers in the volume, including: A. Aguilar, D. Ainley, W. Au, D. Auriol-Gamboa, F. Awbrey, R. Baird, N. Bartoo, H. Benke, P. Berggren, P. Boveng, R.L. Brownell, Jr., J. Calambokidis, M. Cawthorn, I. Christensen, P. Clapham, V. Cockcroft, J.M. Coe, A. Collet, E.A. Crespo, S. Dawson, A. Di Natale, T. Gerrodette, D. Goodson, P. Hammond, D. Hanan, M-P. Heide Jørgensen, J.E. Heyning, A.A. Hohn, T. Jefferson, L. Jones, T. Kasuya, P. Kleiber, S. Kraus, F. Larsen, J.S. Leatherwood, C. Lockyer, J. Maigret, A. Martin, M.K. Marx, N. Miyazaki, K.S. Norris, G. Notarbartolo-di-Sciara, M. Pawson, M.C. Pinedo, T. Polacheck, L. Popov, R. Praderi, J. Prado, A.

Read, R.R. Reeves, G.J.B. Ross, C. Smeenk, T.D. Smith, B. Taylor, A.M. Teixeira, P. Tyack, O. Vidal, G. Waring, W. Watkins, H. Whitehead, B. Würsig and K. Wynne. S. Smith and C. Blair assisted with the initial editing of some of the papers at the Southwest Fisheries Science Center. Special thanks must go to: Helen Coulson who keeps track of the manuscripts and who prepares and types in many of the revised manuscripts; Stella Duff for proof reading; Julie Creek who typesets all the tables; Helen Richardson who prepares the artwork and helps with the proof reading; and the staff of Black Bear Press. Those who helped find and shepherd funds for the meeting included J.R. Twiss, G. Anderson, R. Gambell, A.T. Brough, S.J. Holt, M. Harvey, M. Sutton, M.F. Donoghue, I. Barrett, and T. Arnbo. D.P. DeMaster, J. Sisson, J. Kashiwada, J. Ortiz, B. Remington and C. Ratcliffe assisted with the organisation and logistics of the meeting. We thank all of these people and anyone we may have inadvertently missed.

The papers in this volume reveal that some progress has been made towards addressing some of the recommendations coming out of the Conference. We hope that publication here will stimulate scientists, managers and Governments to greater efforts to further address and resolve this most important issue.

W.F. Perrin, G.P. Donovan and J. Barlow
Cambridge, 16 November 1994

REPORTS	
REPORT OF THE WORKSHOP ON MORTALITY OF CETACEANS IN PASSIVE FISHING NETS AND TRAPS	1
REPORT TO THE UNITED NATIONS CONFERENCE ON THE ENVIRONMENT AND DEVELOPMENT (UNCED) ON SIGNIFICANT DIRECT AND INCIDENTAL CATCHES OF SMALL CETACEANS	73
CONTRIBUTED PAPERS	
North Atlantic (including the Baltic and Mediterranean)	
Read, A.J. – Interactions between cetaceans and gillnet and trap fisheries in the Northwest Atlantic	133
Lien, J. – Entrapments of large cetaceans in passive inshore fishing gear in Newfoundland and Labrador (1979–1990)	149
Fontaine, P-M., Barrette, C., Hammill, M.O. and Kingsley, C.S. – Incidental catches of harbour porpoises (<i>Phocoena phocoena</i>) in the Gulf of St. Lawrence and the St. Lawrence River Estuary, Quebec, Canada.	159
Sequeira, M. and Ferreira, C. – Coastal fisheries and cetacean mortality in Portugal.	165
Kinze, C.C. – Incidental catches of harbour porpoises (<i>Phocoena phocoena</i>) in Danish waters, 1986–89	183
Di Natale, A. and Notobartolo-di-Sciara, G. – A review of the passive fishing nets and trap fisheries in the Mediterranean Sea and of the cetacean bycatch	189
Lowry, N. and Teilmann, J. – Bycatch and bycatch reduction of the harbour porpoise (<i>Phocoena phocoena</i>) in Danish waters	203
Berggren, P. – Bycatches of the harbour porpoise (<i>Phocoena phocoena</i>) in the Swedish Skagerrak, Kattegat and Baltic waters, 1973–93.	211
Benke, H. – A note on cetacean bycatches in German waters	217
Central America and Caribbean	
Vidal, O., Van Waerebeek, K. and Findley, L.T. – Cetaceans and gillnet fisheries in Mexico, Central America and the wider Caribbean: a review	221
Zavala-González, A., Urbán-Ramírez, J. and Esquivel-Macías, C. – A note on artisanal fisheries interactions with small cetaceans in Mexico	235
Western South Atlantic	
Siciliano, S. – Review of small cetaceans and fishery interactions in coastal waters of Brazil	241
Pinedo, M. C. – Review of small cetacean fishery interactions in southern Brazil with special reference to the franciscana, <i>Pontoporia blainvillei</i>	251
Pinedo, M.C. – Impact of incidental fishery mortality on the age structure of <i>Pontoporia blainvillei</i> in southern Brazil and Uruguay.	261
Barros, N.B. and Teixeira, R.L. – Incidental catch of marine tucuxi, <i>Sotalia fluviatilis</i> , in Alagoas, northeastern Brazil.	265
Crespo, E. A., Corcuera, J. F. and Cazorla, A. L. – Interactions between marine mammals and fisheries in some coastal fishing areas of Argentina	269
Corcuera, J., Monzon, F., Crespo, E.A., Aguilar, A. and Raga, J.A. – Interactions between marine mammals and the coastal fisheries of Necochea and Claromecó (Buenos Aires Province, Argentina)	283
Corcuera, J. – Incidental mortality of franciscanas in Argentine waters: the threat of small fishing camps	291
Goodall, R.N.P., Schiavini, A.C.M. and Fermani, C. – Net fisheries and net mortality of small cetaceans off Tierra del Fuego, Argentina	295
Africa and Indian Ocean	
Maigret, L. – Marine mammals and fisheries along the west African coast	307

	<i>Page</i>
Cockcroft, V.G. and Krohn, R. – Passive gear fisheries of the southwestern Indian and southeastern Atlantic Oceans: an assessment of their possible impact on cetaceans.	317
Lal Mohan, R.S. – Review of gillnet fisheries and cetacean bycatches in the northeastern Indian Ocean	329
Asia and North Pacific pelagic	
Zhou, K. and Wang, X. – Brief review of passive fishing gear and incidental catches of small cetaceans in Chinese waters	347
Dolar, M.L.L. – Incidental takes of small cetaceans in fisheries in Palawan, Central Visayas and northern Mindanao in the Philippines.	355
Yatsu, A., Hiramatsu, K. and Hayase, S. – A review of the Japanese squid driftnet fishery with notes on the cetacean bycatch	365
Nagao, K. – Regulation of the Japanese high seas driftnet fisheries	381
Watanabe, Y. – The Japanese large-mesh driftnet fishery in the Pacific Ocean.	385
Perrin, P.M. and Brownell, R.L. – A brief review of stock identity in small marine cetaceans in relation to assessment of driftnet mortality in the North Pacific.	393
Eastern North Pacific	
Barlow, J., Baird, R.W., Heyning, J.E., Wynne, K., Manville, A.M., Lowry, L.F., Hanan, D., Sease, J. and Burkanov, V.N. – A review of cetacean and pinniped mortality in coastal fisheries along the west coast of the USA and Canada and the east coast of the Russian Federation.	405
Gearin, P.J., Melin, S.R., DeLong, R.L., Kajimura, H. and Johnson, M.A. – Harbor porpoise interactions with a Chinook salmon set-net fishery in Washington State	427
Heyning, J.E., Lewis, T.D. and Woodhouse, C.D. – A note on odontocete mortality from fishing gear entanglements off southern California	439
Kornev, S.I. – A note on the death of a right whale (<i>Eubalaena glacialis</i>) off Cape Lopatka (Kamchatka)	443
Jefferson, T.A., Curry, B.E. and Black, N.A. – Harbour porpoise mortality in the Monterey Bay halibut gillnet fishery, 1989	445
Lennert, C., Kruse, S., Beeson, M. and Barlow, J. – Estimates of incidental marine mammal bycatch in California gillnet fisheries for July through December, 1990	449
Southeastern Pacific	
Reyes, J.C. and Oporto, J.A. – Gillnet fisheries and cetaceans in the southeast Pacific	467
Felix, F. and Samaniego, J. – Incidental catches of small cetaceans in the artisanal fisheries of Ecuador	475
Haase, B. and Felix, F. – A note on the incidental mortality of sperm whales (<i>Physeter macrocephalus</i>) in Ecuador.	481
Lescrauwaet, A.C. and Gibbons, J. – Mortality of small cetaceans and the crab bait fishery in the Magallanes area of Chile since 1980.	485
Van Waerebeek, K. and Reyes, J.C. – Interactions between small cetaceans and Peruvian fisheries in 1988/89 and analysis of trends	495
Van Waerebeek, K. and Reyes, J.C. – Post-ban small cetacean takes off Peru: a review	503
Van Waerebeek, K. and Reyes, J.C. – A note on incidental mortality of southern minke whales off western South America	521
Van Waerebeek, K. – A note on the status of the dusky dolphins (<i>Lagenorhynchus obscurus</i>) off Peru	525
Earle, M., Woodley, T.H. and Hagler, M. – An investigation of incidental catches of large-mesh driftnet fisheries from the South Pacific and North Atlantic.	529
Causes and solutions

Report of the Workshop on Mortality of Cetaceans in Passive Fishing Nets and Traps

Contents

	<i>Page</i>
1. WELCOME AND INTRODUCTION	6
2. TERMS OF REFERENCE AND ADOPTION OF AGENDA	6
3. ARRANGEMENTS FOR THE MEETING	6
4. GLOBAL REVIEW OF GILLNET AND TRAP FISHERIES	6
4.1 Mediterranean region	7
4.1.1 Trap net fishery for tuna.	7
4.1.2 Drift gillnet fishery for small pelagic fish	7
4.1.3 Drift gillnet fishery for swordfish and albacore	7
4.1.4 Coastal set gillnet fisheries	7
4.1.5 Recommendations.	7
4.2 Baltic region	7
4.2.1 Coastal set gillnet fishery	8
4.2.2 Pound-net fishery for eels	8
4.2.3 Pelagic driftnet fisheries	8
4.2.4 Recommendations.	8
4.3 Eastern North Atlantic region	8
4.3.1 Portuguese gillnet fisheries	8
4.3.2 Portuguese trap fisheries.	8
4.3.3 Coastal set net fisheries in other western European countries.	8
4.3.4 Irish salmon driftnet fisheries	8
4.3.5 Norwegian salmon driftnet fishery	8
4.3.6 Spanish driftnet fishery.	9
4.3.7 Other driftnet fisheries in northwest Europe	9
4.3.8 Recommendations.	9
4.4 Western North Atlantic region	9
4.4.1 US east coast swordfish drift gillnet fishery.	9
4.4.2 Greenland and eastern Canada surface gillnet fishery for salmon	9
4.4.3 Bay of Fundy and Gulf of Maine herring weirs	9
4.4.4 Atlantic Canada cod traps.	9
4.4.5 Atlantic Canada and Gulf of Maine demersal gillnets	9
4.4.6 Florida shark driftnet fishery	10
4.4.7 US east coast shad gillnets	10
4.4.8 US east coast trap and pound net fisheries	10
4.4.9 Atlantic Canada and US east coast bait gillnets.	10
4.4.10 US east coast mixed species demersal gillnets	10
4.4.11 Recommendations	10
4.5 Mexico, Central America and Caribbean region	11
4.5.1 Pacific small-scale gillnet fisheries.	11
4.5.2 Gulf of Mexico and Caribbean small-scale gillnet fisheries.	11
4.5.3 Small-scale gillnet fisheries in the Amazon and Orinoco rivers	11
4.5.4 Drift gillnet fisheries for pelagic fish in the Caribbean.	11
4.5.6 Recommendations.	11
4.6 Brazil region	11
4.6.1 Net fishery for red porgy and Brazilian shrimp	11
4.6.2 Gillnet fishery for croakers, weakfish and marine catfish	11
4.6.3 Lobster trap fisheries in northeast region	12
4.6.4 Artisanal gillnet fisheries in northeast region	12
4.6.5 Longline fishery in northeast region	12
4.6.6 Gillnet fisheries in southeast region.	12
4.6.7 Gillnet fisheries in southern region	12
4.6.8 Recommendation	12
4.7 Southwest Atlantic region	12
4.7.1 Gillnet fishery for sharks in Uruguay.	12
4.7.2 Gillnet fishery for croaker species in Argentina	12
4.7.3 Gillnet fishery for sharks in Argentina.	12
4.7.4 Other coastal gillnet fisheries.	12
4.7.5 Recommendations.	12
4.8 Western Africa region	13
4.8.1 Drift gillnet fishery for tuna.	13
4.8.2 Western Africa lobster set nets	13

	<i>Page</i>
4.8.3 Western Africa set gillnet fisheries	13
4.8.4 Small-scale drift gillnet fishery for small pelagic fishes	13
4.8.5 Recommendations	13
4.9 Southern Africa and southern Indian Ocean region	13
4.9.1 Shark gillnetting in Natal, South Africa	13
4.9.2 Shrimp set netting in Mozambique	14
4.9.3 Artisanal gillnet fisheries in the Malagasy Republic, Mauritius, Mozambique, Reunion and Seychelles.	14
4.9.4 Recommendations	14
4.10 East Africa, northwestern Indian Ocean and Red Sea region	14
4.10.1 Large pelagic gillnet fishery in Pakistan	14
4.10.2 Bottom set gillnet fishery in Pakistan	14
4.10.3 Artisanal fisheries in Pakistan	14
4.10.4 Fishery for large pelagic species in Oman	14
4.10.5 Driftnet fishery for tuna in Iran	14
4.10.6 Artisanal gillnet fishery in Kenya	15
4.10.7 Artisanal driftnet fishery for sharks and large pelagics in Somalia	15
4.10.8 Artisanal gillnet fisheries in mainland Tanzania	15
4.10.9 Gillnet fisheries for large pelagic fish and sharks in Zanzibar	15
4.10.10 Recommendations	15
4.11 Northeastern Indian Ocean region	15
4.11.1 Small scale artisanal gillnet fisheries of India, Bangladesh and Sri Lanka	15
4.11.2 Recommendations	15
4.12 Southeast Asia region	15
4.12.1 Artisanal fishery for pelagic fish in Thailand	16
4.12.2 Artisanal fisheries in the Philippines	16
4.12.3 Recommendations	16
4.13 Australasia and Melanesia region.	16
4.13.1 Northern drift gillnet fishery for sharks	16
4.13.2 Southern set gillnet fishery for sharks	16
4.13.3 Inshore set gillnet fishery for barramundi	16
4.13.4 Haul-net fishery in Tasmania	16
4.13.5 Taiwanese driftnet fishery for sharks, billfishes and tunas.	16
4.13.6 Indonesian tuna gillnet fishery	16
4.13.7 Recommendations	16
4.14 South Pacific region	17
4.14.1 Set net fisheries in Fiji, Tonga, Samoa, Cooks and French Polynesia	17
4.14.2 Gillnet fisheries in New Zealand.	17
4.14.3 Recommendations	17
4.15 Micronesia and Central Pacific region	18
4.15.1 Artisanal and small-scale fisheries.	18
4.15.2 Surround-net and gillnet fisheries in Hawaii	18
4.15.3 Recommendations	18
4.16 Japan coastal region	18
4.16.1 Japan coastal small-scale trap net fishery	18
4.16.2 Northern Japan coastal large-scale trap net fishery for salmon	18
4.16.3 Japan coastal large-scale trap net fishery	18
4.16.4 Recommendation	18
4.17 Korean coastal region	19
4.18 China, Taiwan Insular region	19
4.19 Mainland China region	19
4.19.1 Drift gillnets	19
4.19.2 Set gillnets	19
4.19.3 Stow nets	19
4.19.4 Fish traps.	19
4.19.5 Recommendations	19
4.20 Eastern North Pacific and Russian Far East region	19
4.20.1 California drift gillnet fishery for swordfish and sharks	19
4.20.2 California set gillnet fishery for halibut and angel sharks	19
4.20.3 Washington bottom-set gillnet fishery for salmon	20
4.20.4 Alaska and British Columbia driftnet fisheries for salmon	20
4.20.5 Alaska set gillnet fisheries for salmon	20
4.20.6 Salmon trap fisheries in the Kamchatka region	20
4.20.7 Bottom long-line fisheries in Kamchatka and Okhotsk Sea.	20
4.20.8 Crab trap fisheries in the Kamchatka region	20
4.20.9 Recommendations	20

	<i>Page</i>
4.21 Southeastern Pacific region	20
4.21.1 Swordfish driftnet fishery	20
4.21.2 Chilean bottom set net fishery	20
4.21.3 Chilean salmon cage fishery	21
4.21.4 Ecuadorian gillnet fisheries	21
4.21.5 Peruvian gillnet fisheries	21
4.21.6 Recommendations	21
4.22 North Pacific Basin (large-scale pelagic driftnet fisheries)	21
4.22.1 Japanese salmon drift gillnet fishery	21
4.22.2 Drift squid gillnet fishery	21
4.22.3 Japanese large mesh drift gillnet fishery	22
4.22.4 China, Taiwanese large mesh drift gillnet fishery	22
4.22.5 Recommendations	22
4.23 South Pacific Basin (large-scale pelagic driftnet fisheries)	22
4.23.1 Large-mesh driftnet fishery	22
4.24 Indian Ocean Basin (large-scale pelagic driftnet fisheries)	22
4.24.1 Large-mesh driftnet fishery	22
4.25 North Atlantic Basin (large-scale pelagic driftnet fisheries)	22
4.25.1 French albacore driftnet fishery	23
4.25.2 China, Taiwanese tuna/squid driftnet fishery	23
4.26 South Atlantic Basin (large-scale pelagic driftnet fisheries)	23
4.26.1 China, Taiwanese albacore driftnet fishery	23
5. IMPACTS ON SPECIES AND POPULATIONS	23
5.1 Definitions	23
5.2 Populations experiencing levels of mortality that are not sustainable	28
5.3 Explanation of Table 1 summarising impacts on species and populations	28
5.4 Annotations to Table 1	29
5.4.1 Regional or fishery-specific general notes	29
5.4.2 Species/population/region-specific notes	29
6. CAUSES AND SOLUTIONS	38
6.1 Sensory abilities – thresholds and detection	38
6.1.1 Acoustics	38
6.1.2 Prey size/target strength	39
6.1.3 Vision	39
6.1.4 Other	40
6.2 Environmental/ecological correlates	41
6.2.1 Food	41
6.2.2 Physical conditions	41
6.3 Behaviour	42
6.3.1 Curiosity, exploration	42
6.3.2 Attention and perception	43
6.3.3 Orientation	43
6.3.4 Escape patterns	43
6.3.5 Social patterns	43
6.3.6 Feeding behaviour	43
6.4 Morphology: anatomy of entrapment	44
6.5 Types of gillnet and marine mammal bycatch risk	44
6.5.1 Bottom gillnets	45
6.5.2 Bottom driftnets	45
6.5.3 Coastal drifting midwater or surface gillnets	45
6.5.4 Large-mesh pelagic driftnets	45
6.5.5 High seas monofilament driftnets	46
6.5.6 Traps and weirs	46
6.6 Technical aspects of modifying gillnets	46
6.6.1 Types of modifications	46
6.6.2 Summary and conclusions	47
6.7 Alternative technologies	47
6.7.1 Industry involvement	47
6.7.2 Understanding why a fishery uses gillnets	47
6.8 Disentanglement technology and resources	48
6.9 Management	48
6.9.1 Time and area restrictions	49
6.9.2 Bycatch quotas	49

	<i>Page</i>
6.9.3 Effort and access limitations	49
6.9.4 Bans on practices and technologies	49
6.9.5 Individual or fleet performance criteria	49
6.9.6 Retention of all catch – the ‘no bycatch’ option	49
6.9.7 Limitations on non-marine mammal bycatch levels	49
6.9.8 Stipulations on gear and procedures	49
6.9.9 Economic assistance and subsidies	49
6.9.10 Conclusions	50
7. CONCLUSIONS AND RECOMMENDATIONS	50
7.1 Global review of fisheries	50
7.1.1 General	50
7.1.2 High priority recommendations relating to specific regions	51
7.2 Impacts on species and populations	51
7.2.1 Conclusions	51
7.2.2 Recommendations	51
7.3 Causes and solutions	53
7.3.1 Conclusions	53
7.3.2 Recommendations	53
REFERENCES	53
Annex A – List of participants	58
Annex B – List of documents	62
Annex C – Agenda	63
Annex D – Re-estimation of incidental cetacean catches in Sri Lanka	64
Annex E – Guidelines for the correct description of a gillnet	66
Annex F – A review of modifications to the webbing and setting strategies of passive fishing gear to reduce incidental bycatch of cetaceans	67
Annex G – List of cetacean species	70

Report of the Workshop on Mortality of Cetaceans in Passive Fishing Nets and Traps

The Workshop was held in La Jolla, California, USA from 22 to 25 October 1990. Plenary sessions were held in the La Jolla Village Inn and sub-groups met at the Southwest Fisheries Science Center. A list of participants is given in Annex A. Perrin convened and chaired the Workshop.

1. WELCOME AND INTRODUCTION

Gambell outlined the background to the Workshop and stressed the importance of its findings, which would not only provide advice to member governments of the IWC but would also form a major part of the IWC's contribution to UN deliberations on the impacts of driftnetting (IWC, 1991a).

2. TERMS OF REFERENCE AND ADOPTION OF AGENDA

The Scientific Committee adopted terms of reference for the Workshop at its annual meeting in 1988 (Perrin and Brownell, 1989). It was stressed by the Committee that the meeting's scope should be limited to scientific and other technical matters related to cetacean entanglement in gillnets and other static fishing gear. The main charges were:

- (1) to identify and describe new and expanding net and trap fisheries which take cetaceans;
- (2) to investigate how and why entanglement occurs;
- (3) to the extent possible, to estimate mortality and assess its impact on cetacean populations; and
- (4) to consider possible ways of reducing levels of net-caused mortality.

The resultant report was to include:

- (1) a list and summary descriptions of gillnet and trap fisheries that take or potentially could take cetaceans, with lists of the species involved;
- (2) a species-by-species summary, listing cetacean takes by population and fishery and assessing the impacts of the takes;
- (3) an analysis of the causes of entanglement and assessment of technology and alternatives for reducing the incidental takes; and
- (4) recommendations for (a) documentation of takes, (b) research to develop methods for reducing takes and (c) management actions.

Invited and selected unsolicited papers were presented at a two-day open symposium immediately preceding the Workshop. Abstracts of the symposium papers are available from the Secretariat. Working papers for the Workshop are listed in Annex B.

The Agenda adopted is given as Annex C.

3. ARRANGEMENTS FOR THE MEETING

Donovan served as rapporteur for the plenary sessions.

The Workshop agreed to form three sub-groups (see Annex A) assigned the tasks of: conducting a global review of fisheries; assessing impacts; and reviewing causes and solutions. The Workshop agreed to reconvene in a plenary session on the last day, to review the reports of the sub-groups and reach agreement on conclusions and recommendations. It was agreed that the sub-group reports would form the body of the Workshop report. The sub-groups met at the Southwest Fisheries Science Center the afternoon of 22 October and all day on 23 and 24 October. Compilation of the final report was co-ordinated by Donovan and Perrin and agreed by the participants by post.

The report was submitted to the full Scientific Committee at its 1991 Annual Meeting. The Committee approved the Report and its Recommendations (IWC, 1992, p.53) after which the Report became publicly available and was circulated to relevant Governments and organisations. As this is an agreed report it has been left unaltered. Developments since its adoption by the IWC in 1991 are discussed by Donovan (this volume, pp.609–614) and in many of the published papers.

4. GLOBAL REVIEW OF GILLNET AND TRAP FISHERIES

Perrin chaired the sub-group conducting a global review of passive net and trap fisheries which take marine mammals. Barlow, Northridge and Read served as rapporteurs, and Sisson assisted with preparation of this section of the workshop report.

In addition to the terms of reference given above to identify and describe new and expanding net and trap fisheries which take marine mammals, the sub-group further agreed to provide quantitative estimates of cetacean and other marine mammal mortality where available. In the discussions of the sub-group, the world's oceans were divided into 21 coastal regions and 5 major ocean basins. The discussions and conclusions are summarised below. The sub-group agreed on the most important items to include in the summaries.

Most of the information is taken from the regional review documents, although some is from responses to a questionnaire circulated by Lien to national fishery agencies before the meeting or from other personal communications to members of the group. Where necessary, additional information from the literature and from unpublished sources was added during the editing of the report, but time did not allow an exhaustive review of the very large 'grey' fishery literature. Unless otherwise

noted, fish landings are in metric tonnes and their values are based on the price paid to fishermen, converted to US dollars. Effort is expressed as kilometres of net per day (KND). Common names are used throughout the Report. Latin names are given in Annex G.

4.1 Mediterranean region

The Mediterranean and Black Seas are bordered by 28 countries: Albania, Algeria, Bulgaria, Cyprus, Egypt, France (Mediterranean coast and Corsica), Gibraltar, Greece, Israel, Italy, Lebanon, Libya, Malta, Monaco, Morocco, Rumania, Spain, Syria, Tunisia, Turkey, the former USSR (now Russian Federation, Ukraine and Georgia) and the former Yugoslavia (now Slovenia, Croatia, Serbia, Bosnia Herzegovina and Montenegro). Available fishery information varies considerably among these. Passive net fisheries in this region are of four basic types: a trap net fishery for tuna in shallow coastal waters; a drift gillnet fishery for small pelagic fish; a pelagic driftnet fishery for swordfish and tuna; and a coastal set net fishery. Significant marine mammal mortality is primarily limited to the pelagic driftnet fishery. Summaries of these four fisheries are given below. Additional information on Black Sea fisheries may be available in older FAO reports not consulted at the meeting. Detailed information on the Mediterranean is given by di Natale and Notarbartolo-di-Sciara (SC/O90/G34).

4.1.1 Trap net fishery for tuna

Trap nets for bluefin tuna are found in coastal waters in several localised areas of the Mediterranean. These anchored nets are made of natural or artificial fibres. The effort is not well quantified, but there are believed to be more than 10 traps and less than 1,000 participating fishermen. The fishery is believed to be stable in size. Fishing occurs approximately 60 days per year. Catches are greater than 1,000 tonnes for bluefin tuna and greater than 50 tonnes for swordfish; the value of these catches is approximately \$4m and \$0.7m, respectively. Ranges of annual cetacean catches are 0–1 minke whales, 0–1 killer whales, 0–5 bottlenose dolphins and 0–1 common dolphins.

4.1.2 Drift gillnet fishery for small pelagic fish

This fishery is found in coastal waters around the Mediterranean basin. Target species include bullet tuna, little tuna, skipjack tuna, Atlantic bonito, chub mackerel and Atlantic mackerel. Typically nets are multifilament nylon or monofilament with mesh sizes of 4–9cm and lengths of 0.2–1.5km. Vessels range from 4–14m. There are about 100–1,000 vessels and 250–3,000 fishermen operating in this fishery. The fishing season is not known, but is likely to range from 10–100 days per year. Based on this, estimates of 100–1,000 nets and a mean net length of 850m, total effort is likely to be between 850–85,000KND per year. Ranges of annual cetacean catches are 1–10 Risso's dolphins, 10–50 bottlenose dolphins, 0–2 common dolphins and 0–5 striped dolphins.

4.1.3 Drift gillnet fishery for swordfish and albacore

Vessels are from Italy, Spain, Morocco, France, Greece, Turkey, Malta and Algeria. Some countries fish in localised areas and others cover the entire Mediterranean. Multifilament nylon nets for swordfish have 36–52cm mesh and are 2–40km length, with a typical length of 12–15km. Similar nets are used for albacore, with a mesh size of 16–20cm and a total length of 9–15km. Vessels are

approximately 7–26m long. The number of vessels rapidly increased to over 1,020 by July 1990. After an offshore drift gillnetting ban by Italy, this number dropped to 120 vessels in August 1990. Approximately 4,000 people fished prior to the ban and approximately 300 after the ban. Based on a mean net length of 12.6km, 1,020 vessels and a fishing season of 57 days, the total effort would have been approximately 750,000KND prior to the Italian ban. The most recent annual landings were about 9,000 tonnes for swordfish and 1,500 tonnes for albacore and were worth \$130m and \$8m, respectively. Prior to the Italian ban, annual catches of cetaceans were 0–1 fin, 0–1 minke, sperm 20–30, Cuvier's beaked <10 and long-finned pilot whales 50–150, and Risso's 30–80, bottlenose 50–200, striped 5,000–10,000, common 1–30 and rough-toothed dolphins 0–10. These estimates were based on specimens stranded on Italian beaches showing evidence of net entanglement. Di Natale reported that R. Ktari-Chakroun obtained observations of four of a group of 10 minke whales off North Africa entangled in driftnets.

4.1.4 Coastal set gillnet fisheries

This fishery is found all around the Mediterranean over coastal shelf regions. Target species include benthic fish, lobsters and small pelagic schooling fish. Vessels are small, typically 4–16m in length. There are approximately 50,000–100,000 such vessels fishing in the Mediterranean and approximately twice that number of fishermen. There are no data on fishing effort or the economic value of the fishery. It is thought that the fishery may be increasing moderately. Likely annual ranges of marine mammal mortality are 0–2 minke whales, 0–1 sperm whales, 1–10 Risso's dolphins, 0–5 common dolphins, 50–200 bottlenose dolphins, 1–20 striped dolphins, 0–1 rough-toothed dolphins and 0–5 Mediterranean monk seals.

4.1.5 Recommendations

- (1) It is **recommended** that actions similar to the ban instituted by Italy are encouraged elsewhere. International co-operation and action by the General Council for Mediterranean Fisheries (CGPM) are required to ensure that large scale driftnet fisheries do not restart from other nations, or that reflagging for the purpose of continuing the fishery does not occur.
- (2) There is little information on set gillnet and small pelagic driftnet fisheries in the Mediterranean. It is therefore **recommended** that further efforts be made to investigate the nature and extent of these fisheries and their impacts on marine mammals of the region.
- (3) The action of Italy in banning driftnets has had an immediate impact on several thousand fishermen. It is **recommended** that wherever possible the consequences of such actions are studied, the economic impacts on the fishing community are appraised and the subsequent development of alternative fishing methods are monitored.
- (4) It is **recommended** that information on gillnet and trap fisheries be collected for the Black Sea, including information on incidental catches of small cetaceans.

4.2 Baltic region

This region is taken to include what are commonly referred to as the Baltic and Kattegat Seas. Coastal states include Denmark, Estonia, Finland, Germany, Latvia, Lithuania, Poland, Sweden and the Russian Federation. In this region, cetaceans are commonly found only in the Kattegat and the only common species is the harbour porpoise.

Cetacean mortality presently occurs mostly in bottom set net fisheries and pound-net fisheries. Both are described below, along with a pelagic driftnet fishery in the central Baltic. Burkanov reported that information also exists on fisheries and their bycatch of seals in Latvia, Lithuania, Estonia and the western USSR. Detailed information is given by Kinze (SC/O90/G25). Estimates of total cetacean mortality do not exist.

4.2.1 Coastal set gillnet fishery

Vessels from Denmark, Sweden and Germany participate in a bottom set net fishery for cod and (secondarily) plaice. Vessels are typically 5–20m long. Gillnets are typically 6–17cm in mesh size and are set in water depths of less than 40m; mean net lengths were not available at the meeting. The number of vessels fishing by this method is 750 for Denmark and 565 for Germany; the number for Sweden is not known. The amount of fishing effort for Denmark is stable or decreasing slightly. Harbour porpoise mortality is largely limited to the Kattegat Sea and is probably less than 500 animals per year. Harbour seal mortality is limited to the Kattegat and the southern Baltic; no estimates of seal mortality are available.

4.2.2 Pound-net fishery for eels

A small-scale pound-net fishery for eels is found along the eastern coast of Denmark. These nets are in shallow waters of less than 15m depth. Little information is available on the level of effort in this fishery, but effort is believed to have been decreasing in recent years. Harbour porpoises are occasionally captured in these traps, but are usually released alive.

4.2.3 Pelagic driftnet fisheries

Pelagic drift gillnets are used in the central Baltic by fishermen from Denmark, Estonia, Finland, Germany, Latvia, Lithuania, Poland, Sweden and the Russian Federation. No details about this fishery were presented at the meeting. Nets are likely to take harbour, ringed and gray seals. Harbour porpoise mortality is likely to be uncommon because the species is very rare in the area of the fishery. This fishery mortality may, however, be sufficient to affect harbour porpoise recovery in the Baltic.

4.2.4 Recommendations

- (1) It is **recommended** that captures of marine mammals in Baltic fisheries be monitored at an international level, as it is likely that a single harbour porpoise population is being impacted by the fisheries of several nations in this area.
- (2) In this connection it is **recommended** that further research be carried out to improve understanding of harbour porpoise stock identities in the Baltic and North Seas.

4.3 Eastern North Atlantic region

Thirteen coastal states are included in the eastern North Atlantic region, including Belgium, Denmark (west coast), the Faroe Islands, France (north coast), Germany (North Sea coast), Iceland, Ireland, Netherlands, Norway, Portugal, Spain (Atlantic coast), United Kingdom and the Russian Federation (western Arctic). There is a long tradition of fishing in this entire area and much large- and small-scale fishing occurs there. In Norwegian coastal waters, set gillnets are used for migrating cod and drift gillnets for salmon. Although gillnets are used in Iceland,

no information was available during the meeting. Detailed information is given by Northridge (SC/O90/G35) and Sequeira *et al.* (SC/O90/G47).

4.3.1 Portuguese gillnet fisheries

Around 3,300 Portuguese vessels are licensed to use gillnets for hake, other gadoids and demersal species along the Portuguese continental shelf. The mean length of nets and type of netting material varies considerably among vessels. Incidental catches of some tens of cetaceans, mainly common dolphins, harbour porpoises, striped dolphins and possibly bottlenose dolphins, are recorded.

4.3.2 Portuguese trap fisheries

Over 1,300 vessels are licensed to fish for octopus, crustaceans and some fish with basket traps and pots. There are no data on the numbers of fishermen involved, nor on the value of the catch or total landings. There are records of three minke whales having drowned in such fisheries.

4.3.3 Coastal set net fisheries in other western European countries

Set nets are used throughout European waters by a large proportion of inshore boats. Statistics on the activities and dimensions of this fleet are largely unavailable. There are over 5,500 fishing vessels of less than 16m registered in French Atlantic ports. There are more than 5,000 vessels working in British coastal waters, more than 3,000 in Norwegian waters and around 750 working in Danish North Sea coastal waters. Numbers in Spain, Iceland, Ireland, Belgium, the Netherlands and Germany are not available. The total number of coastal vessels (<20m) in western European waters is likely to be between 15–20,000 and perhaps more. An unknown but significant proportion of these are using gillnets for at least part of the year. Mesh sizes vary depending on the target species and net lengths are highly variable, from a few tens of metres for some small boats to several tens of kilometres. In some areas, notably the North Sea and English Channel, there are large amounts of netting set by fleets of vessels more or less dedicated to net fishing. In the southwest of England some of these vessels may set nets of 80km or more and increasingly large vessels have been used in recent years.

In Norway, coastal set net fisheries regularly take harp seals. Around 10,000 were caught annually for the period 1978–1981, but by the winter of 1987/88 this had reached 60,000. Harbour porpoises are taken in set gillnets throughout their range, but apparently most frequently in the North Sea. Common dolphins are also taken, notably in the English Channel. These fisheries are complex and few reliable statistics are available on effort.

4.3.4 Irish salmon driftnet fisheries

More than 700 salmon licenses were issued in Ireland in 1988, but the actual number of vessels using driftnets for salmon is unknown, as there is also a large illegal driftnet fishery. Cetaceans reported taken include common dolphins and harbour porpoises. No further details were available at the meeting.

4.3.5 Norwegian salmon driftnet fishery

In 1988 there were 582 vessels (5–12m) licensed to fish for salmon in Norwegian coastal waters. The total fishing period was about 12 weeks in 1988. During this period, 96 harbour porpoises were recorded caught in salmon nets. The fishery is now banned.

4.3.6 Spanish driftnet fishery

Approximately 40 vessels from Spain have fished for tuna and billfish in the area around the Straits of Gibraltar since 1988, under a Moroccan/EEC fishing agreement. Most of these fish in the Atlantic area, although an unknown number occasionally also fish in Mediterranean waters (Aguilar, 1990). Information on bycatches was not available to the meeting.

4.3.7 Other driftnet fisheries in northwest Europe

Small driftnet fisheries exist in a number of other locations, but information was not available to the meeting. These include driftnet fisheries for salmon and for bass in the UK, for herring in England and Wales and for mackerel in southern Norway.

4.3.8 Recommendations

- (1) There is little information on the nature and extent of numerous coastal gillnet fisheries in this area. It is **recommended** that the collection of statistics on gillnet fisheries should be improved in all countries of the region and that the European Community and the International Council for the Exploration of the Sea (ICES) also give increased attention to the collection of statistics on gillnet fishing activities.
- (2) There are inadequate data to assess the impact of incidental catches of cetaceans in this area. It is **recommended** that the collection of data be improved and co-ordinated. Countries that do not yet have adequate systems for recording incidental catches are urged to implement them. Again, ICES and the European Community should play important roles in facilitating these activities. Several fisheries should receive a high priority. These include the Irish salmon driftnet fishery, the Danish set net fishery in the North Sea, the English and French set net fisheries in the western English Channel, the French albacore driftnet fishery and Portuguese coastal gillnet fisheries.

4.4 Western North Atlantic region

The western North Atlantic region includes Bermuda, Canada (Atlantic provinces), Greenland (Denmark), St. Pierre and Miquelon (France) and the USA (Atlantic and Gulf states). Ten distinct fisheries have been shown to result in at least some cetacean mortality. These are summarised below. Of particular concern with regard to cetacean mortality are the several fisheries which each take hundreds to thousands of harbour porpoises per year from Greenland to the Gulf of Maine, the large-mesh drift gillnet for swordfish along the US coast and the gillnet and trap fisheries which entangle right and humpback whales. Detailed information is given by Read (SC/O90/G6), Earle (SC/O90/G42), Drew (SC/O90/G38) and Payne (SC/O90/G41).

4.4.1 US east coast swordfish drift gillnet fishery

This fishery is found along the continental shelf break from north of Cape Hatteras to Block Island. The target species are swordfish and other large pelagic fish. The 1–1.5 mile (1.6–2.4km) nets have an 18–24" (46–61cm) mesh and are set 2–6m below the surface. Approximately 10–15 vessels participate in this fishery and fishing effort has been increasing rapidly. An observer programme has determined that the incidental catches include (in order of importance) common dolphins, bottlenose dolphins, Risso's dolphins, beaked whales, pilot whales, Atlantic spotted dolphins and striped dolphins.

4.4.2 Greenland and eastern Canada surface gillnet fishery for salmon

This fishery is primarily in the inshore waters of western Greenland, Labrador, Newfoundland and the Gulf of St. Lawrence. The target species is *Salmo salar*. Nets are either anchored or (in Greenland only) drifting. A mesh size of approximately 5" (13cm) is used in Canada and 13–15cm in Greenland. There are approximately 549 fishermen in Newfoundland and Labrador and approximately 2,196 nets in Newfoundland. Mean net length is approximately 100m in Newfoundland. The level of effort may be decreasing. Total salmon landings in 1987 were 963 tonnes in Greenland, 481 tonnes in Labrador, 794 tonnes in Newfoundland and 306 tonnes in the Gulf of St. Lawrence. Incidentally caught cetaceans include harbour porpoises (probably several thousands per year), long-finned pilot whales, humpback whales and minke whales.

4.4.3 Bay of Fundy and Gulf of Maine herring weirs

Herring weirs are large fish traps designed to catch schools of pelagic fishes moving parallel to the shoreline. Weirs are found primarily in the Bay of Fundy and northern Gulf of Maine, although a few are scattered along southern New England shores. The target species are Atlantic herring and mackerel. There are more than 250 active weirs at present, but this number is slowly decreasing. Harbour porpoises and humpback, minke and right whales have been reported trapped inside weirs. Large whales are almost always removed alive, but some harbour porpoises are either shot or die during seining. Approximately 70 porpoises become trapped each year and, on average, 27 die as a result of the entrapment.

4.4.4 Atlantic Canada cod traps

Cod traps are found scattered along the shores of southern Labrador, Newfoundland and the Gulf of St. Lawrence. There are also a few cod traps in operation along the coast of western Greenland. Atlantic cod are captured as they move into inshore waters during the summer. The traps are essentially rectangular boxes of net, with a leader extending from the mouth to the shoreline. There were approximately 3,121 cod traps operating in Newfoundland alone during 1979. Harbour porpoises and white, long-finned pilot, humpback, right and minke whales all become entangled in cod traps, more often with the leader than with the trap itself. Mortality rates of large whales in this gear are fairly low, at least in Newfoundland waters, largely due to the efforts of the entrapment assistance programme run by Memorial University. In 1989, there were reports of 22 humpbacks and six minke whales entangled with Newfoundland cod traps, although a much larger number of collisions go unreported.

4.4.5 Atlantic Canada and Gulf of Maine demersal gillnets

This fishery operates throughout the inshore waters of southern Labrador, Newfoundland, the Gulf of St. Lawrence, the Bay of Fundy and Gulf of Maine. The target species are primarily Atlantic cod, pollock and hake. Gill nets are constructed of 14–23cm monofilament mesh, are between three and four metres deep and vary in length from 450 to 2,000m. Each vessel sets between four and six nets each day. The nets are anchored on the bottom in depths of 30 to 100m. The fishery operates year-round in the southern Gulf of Maine, but is highly seasonal in more northerly waters. In 1989, there were 325 vessels operating in US waters. The number of active vessels in Canadian waters is not known, but is in the thousands. Effort data are

being collected by the National Marine Fisheries Service (NMFS) in US waters; preliminary data suggest that gillnet vessels made over 14,000 day trips in 1989. Assuming 5 net sets per day trip of 1km each, total fishing effort would be approximately 70,000KND. Fishing effort is increasing, at least in US waters. There are no data on fishing effort in Canada.

A large number of cetacean species are entangled in these demersal gillnets, including harbour porpoises, white-sided and white-beaked dolphins and long-finned pilot, white, humpback, minke, fin and right whales. Many large whales survive entanglement, although they may carry off portions of gear. Entanglement is almost always fatal for smaller cetaceans. Harbour porpoises are the most frequently killed cetacean in these nets and annual mortality estimates are: Bay of Fundy – approximately 100; Gulf of Maine – 600 to 1,000; Gulf of St. Lawrence – approximately 1,500. There is no estimate from Newfoundland, although large numbers of porpoises are known to be taken in that area. The demersal fishery in the Gulf of Maine has been classified as Category I under 1988 amendments to the US Marine Mammal Protection Act. Observers placed on gillnet vessels in 1989 and 1990 witnessed 15 harbour porpoises killed in 247 fishing days, believed to represent between 1 and 3% of total effort. Sampling effort for this observer programme was not proportional to fishing effort or corrected for seasonal movements of porpoises.

4.4.6 Florida shark driftnet fishery

This is a small and poorly documented fishery operating along the northeastern coast of Florida. Nets are constructed from 8 – 12" (20–30cm) mesh and allowed to drift within 10 miles offshore. The primary target species is blacktip shark, although a variety of pelagic species are taken. There is no information on incidental catches of cetaceans in this fishery, although it is likely that bottlenose dolphins are taken. The fishery operates within the winter range of the endangered northern right whale population.

4.4.7 US east coast shad gillnets

These gillnets are set in estuarine and coastal waters to intercept anadromous movements of shad. Most nets employ 13–15cm mesh and vary from approximately 100–1,000m in length, depending on local regulations. Several thousand nets are used each spring, but the fishery is in gradual decline. Bottlenose dolphins and harbour porpoises are occasionally taken and there are two records of humpback whale mortality in these nets.

4.4.8 US east coast trap and pound net fisheries

A variety of pound, fyke and trap nets are used in coastal areas from Massachusetts to North Carolina. The nets are anchored near shore and are usually constructed of fine mesh, designed to capture a variety of coastal species including striped bass, tautog, bluefish and mackerel. The only reported cetacean entanglement was of a minke whale killed in a Rhode Island fish trap during 1976.

4.4.9 Atlantic Canada and US east coast bait gillnets

A large number of gillnets are used to take small pelagic fish in the waters of eastern Canada and the northeastern USA. Target species include Atlantic herring, mackerel and menhaden. The nets are usually constructed of fine mesh (2–3", 5–8cm) and are no more than 100–200m in

length. These nets are either allowed to drift or are anchored, but all fish at the surface. The fish are used variously for direct consumption, roe, or bait for lobster or crab traps. Harbour porpoises, white-sided dolphins, short-finned pilot whales, humpback whales and fin whales are occasionally entangled in these nets. The only fishery that takes significant numbers of cetaceans is a small driftnet fishery for mackerel in Cape Cod Bay. Most porpoises and dolphins entangled in this fishery, however, are released alive.

4.4.10 US east coast mixed species demersal gillnets

A large number of fisheries utilise demersal gillnets along the US coast from Rhode Island to Louisiana. Coastal gillnets have been banned in South Carolina, Georgia and Texas waters for fisheries conservation reasons. These fisheries use a variety of mesh sizes, from 9–35cm, depending on the target species. Most nets are fairly short, less than 1km in length, although individual fishermen may set several at a time. Harbour porpoises and bottlenose dolphins are occasionally taken, although incidental catches have not been systematically examined.

4.4.11 Recommendations

- (1) It is **recommended** that estimation of incidental catches of harbour porpoise made by groundfish gillnets in (i) Newfoundland and Labrador and (ii) the Gulf of St. Lawrence be undertaken. Such estimates will require an on-board observation programme, if accurate data on catch rates are to be obtained. An observer programme should be formulated as soon as possible, even with very low sampling intensity, to provide rough estimates of the magnitude of mortality. In addition, attempts should be made to improve the reporting of fishing effort.
- (2) It is **recommended** that estimates be made of the magnitude of incidental mortality of harbour porpoises in the Greenland salmon driftnet fishery. As noted for (1) above, this will require accurate information on both catch rates and total effort.
- (3) It is **recommended** that efforts to estimate incidental catch of harbour porpoise and fishing effort for the Gulf of Maine/Bay of Fundy groundfish gillnet fishery be continued. These efforts should ensure that future sampling intensity is statistically adequate and should explore the effects of variation in gear type and mode of operation on mortality rates. In addition, the level of incidental mortality should be assessed and data collected in previously unstudied areas, such as southwestern Nova Scotia.
- (4) It is **recommended** that onboard observations of the swordfish driftnet fishery be continued at a level which is proportional to fishing effort. Consideration should be given to increasing sampling intensity because of (i) the large number of cetaceans killed and (ii) the relatively small size of the fishery in relation to other driftnet fisheries. It should be possible to sample a large proportion of all sets made, increasing the reliability of estimates of total mortality. Data on fishing effort should be obtained from ICCAT (International Convention for the Conservation of Atlantic Tuna).
- (5) It is **recommended** that the magnitude of incidental mortality of cetaceans be assessed for several US east coast gillnet fisheries, including the Florida east coast shark driftnet fishery and the North Carolina sink net

fishery. A small observer programme would suffice to determine whether or not substantial incidental catches are incurred by these fisheries.

- (6) The threat of gear damage is an excellent incentive to persuade fishermen to cooperate in programmes that release entangled large whales. It is **strongly recommended** that projects such as Memorial University's entrapment assistance programme be encouraged and supported.

4.5 Mexico, Central America and Caribbean region

This region is defined to include Anguilla, Antigua & Barbuda, Bahamas, Barbados, Belize, British Virgin Islands, Cayman Islands, Colombia, Costa Rica, Cuba, Dominica, Dominican Republic, El Salvador, French Guiana, Grenada, Guadeloupe, Guatemala, Guyana, Haiti, Honduras, Jamaica, Martinique, Mexico, Montserrat, Netherlands Antilles, Nicaragua, Panama, Puerto Rico (US), St. Christopher & Nevis, St. Lucia, St. Vincent & The Grenadines, Surinam, Trinidad & Tobago, Turks & Caicos Islands, Virgin Islands (US) and Venezuela. Very little information is available on fisheries and their incidental catches in this large area. Most passive gear fisheries are based on small-scale coastal gillnets. These fisheries are divided into Pacific, Gulf/Caribbean and Amazon/Orinoco regions and are summarised below. Also included is limited information on large-scale driftnet fisheries operating in the Caribbean. Detailed information is given by Vidal *et al.* (SC/O90/G7).

4.5.1 Pacific small-scale gillnet fisheries

Small-scale and subsistence fisheries occur along the entire west coasts of Mexico, Central America and Colombia. The fisheries take a large number of fish species, including elasmobranchs, usually within a very short distance from shore. Gillnets range in length from 30–700m and from 8–30cm mesh sizes. Vessels are typically 4–12m in length. The number of vessels is available only for a few of the countries. Based on data from those countries, we know that the minimum number of boats is 7,550–8,550 and the minimum number of fishermen using gillnets is 5,500–12,000. The actual number is likely to be much greater and increasing. Cetacean species taken in these fisheries include the vaquita (at least 30–40 per year), common dolphins, bottlenose dolphins and gray whales. No estimates are available for the take of the latter three.

4.5.2 Gulf of Mexico and Caribbean small-scale gillnet fisheries

Small-scale and subsistence fisheries occur along the entire Gulf of Mexico and the Caribbean. The fisheries take a large number of fish, turtles and elasmobranch species. Gillnets range in length from 30–2,000m and from 4–40cm in mesh size. Vessels are typically 4–15m in length. Based on data from a few countries, we know that the minimum number of boats is 732 and the minimum number of fishermen using gillnets is 1,600. Fishing effort in these fisheries is generally increasing. Based on the few countries which report catch statistics, the minimum catch is 420 tonnes per year. Cetacean species taken include pygmy sperm whales, tucuxi, Risso's dolphin, bottlenose dolphins, Atlantic spotted dolphins, killer whales, clymene dolphins, spinner dolphins, rorquals and humpback whales. The annual take of cetaceans has not been estimated for any species or fishery.

4.5.3 Small-scale gillnet fisheries in the Amazon and Orinoco rivers

In the Colombian Amazon and in the Orinoco River basin, gillnets are used in artisanal fisheries. Target species include mainly pimelodid catfishes and characids but also other species. Vessels are typically 3–10m. Cetaceans killed include the boto (in the Amazon).

4.5.4 Drift gillnet fisheries for pelagic fish in the Caribbean

Gillnets are used to catch pelagic fishes in the vicinity of Trinidad & Tobago, Barbados, Grenada and along parts of the coast of Mexico. Target species include *Scomberomorus* spp., flying fish, large pelagic fishes (possibly including tuna) and possibly flying squid. Detailed information is only available for Trinidad. Driftnets with lengths of 100–150m and mesh sizes of 10–11cm are set from 10m vessels. There are 100–150 such vessels in Trinidad. The total catch of *Scomberomorus* in Trinidad is approximately 2,000 tonnes (including some other gear types). Marine mammal mortality has included killer whales and unidentified dolphins.

4.5.6 Recommendations

- (1) It is **urgently recommended** that the incidental mortality of the vaquita be urgently addressed by (i) fully enforcing the ban on the totoaba gillnet fishery, (ii) reconsidering the issuance of experimental totoaba gillnet fishing permits and (iii) monitoring and evaluating the incidental mortality of the vaquita in the shark gillnet fishery.
- (2) It is **recommended** that new and expanding driftnet fisheries in this area be identified and the occurrence and magnitude of cetacean bycatch determined. This should be accomplished through national and regional international programmes.
- (3) It is **recommended** that education programmes be designed and implemented to increase the awareness of fishermen and the general public to the problems faced by cetacean populations interacting with gillnet fisheries.
- (4) The tucuxi is especially vulnerable to population depletion because of its restricted coastal and riverine habitats and the possible existence of isolated and locally adapted populations. It is **recommended** that incidental mortality of this species receives particular attention in the Caribbean.

4.6 Brazil region

For discussion in this report, Brazil is divided into five regions: the north coast (2°33'S to 4°52'S); the northeast coast (4°52'S to 18°20'S); the southeast coast (18°20'S to 23°16'S); the south coast (23°16'S to 33°45'S); and the Amazon. Detailed information is given by Pinedo (SC/O90/G3), Cannella and Ximenez (SC/O90/G26) and da Silva and Best (SC/O90/G27).

4.6.1 Net fishery for red porgy and Brazilian shrimp

No details about this northern region fishery were available at the meeting, but Lodi *et al.* (1990) noted the take of tucuxi in this fishery.

4.6.2 Gillnet fishery for croakers, weakfish and marine catfish

This fishery is found in the north, northeast and southeast. At least 83 fishing villages operate gillnets year round (Lodi *et al.*, 1990). No additional information was available about the fishery, but recorded marine mammal takes

include approximately 90 tucuxi, 29 franciscana, 3 rough-toothed dolphins, 2 common dolphins, 1 false killer whale and 1 Atlantic spotted dolphin.

4.6.3 Lobster trap fisheries in northeast region

Baited traps are used to catch lobsters in northeast Brazil. No marine mammal mortality has been reported, but in other parts of the world, large whales have been entangled in crustacean trap lines.

4.6.4 Artisanal gillnet fisheries in northeast region

Gillnets are used (along with other gear) to catch a variety of coastal fishes in northeast Brazil. Nets are typically set from small (4–8m) sail-rigged open boats called *jangadas* or *saveiros*. Data are not available on effort for these fisheries. Tucuxi are occasionally caught in gillnets (Barros and Teixeira, 1994). These dolphins are used as bait and for human consumption (Capistrano *et al.*, 1990; Taveres de Almeida, pers. comm. to Ximenez; Nerees do Reis, pers. comm. to Ximenez).

4.6.5 Longline fishery in northeast region

Longlines are used to catch tuna, marine catfish, half beaks, ballyhoo, tarpon and other species in coastal areas of northwest Brazil. There are approximately 30,000 small boats. Other small vessels carry iced fish between the fishing vessels on the open sea and the home ports. At least 275 tonnes of fish product are landed in Maranhão state alone. No information is available regarding marine mammal mortality.

4.6.6 Gillnet fisheries in southeast region

Gillnets and trap fisheries are used to catch a variety of fish species in southeastern Brazil. Gillnets are 146–2,000m long with mesh sizes of 3–20cm (Capistrano *et al.*, 1990). No additional information is available about the fishery operation. Reported cetacean bycatch in gillnets has included 17 tucuxi, 7 franciscana and one unidentified dolphin (Capistrano *et al.*, 1990). Three dolphins have also been reported taken in trap fisheries (Monteiro Filho, 1990). Tucuxi have been reported to be used for bait and human consumption (Lodi, pers. comm.).

4.6.7 Gillnet fisheries in southern region

Gillnets are used to catch a variety of fish species in southern Brazil. Nets are fished up to 30 n.miles offshore. Approximately 1,600 vessels are licensed to fish in the Rio Grande area. Each vessel fishes up to 3km of net each day for a total of 300 days per year. If all vessels are fishing, total effort is approximately 1,500,000KND. Records of marine mammal mortality include 867 franciscana, 1 tucuxi, 3 rough-toothed, 4 bottlenose, 5 Atlantic spotted and 2 common dolphins, and 1 false killer and 1 minke whale.

4.6.8 Recommendation

All the gillnet fisheries of Brazil require systematic monitoring in order to assess the level of incidental catches of small cetaceans, especially those from the north, northeast and southwest and it is **recommended** that this be initiated as soon as possible. Mortality of the tucuxi and the franciscana urgently requires monitoring.

4.7 Southwest Atlantic region

The Southwest Atlantic region consists of Argentina, the Falkland Islands/Islas Malvinas and Uruguay. Gillnet fisheries include shark fisheries in both Uruguay and

Argentina, a croaker fishery in Argentina and a mixed-species trammel net fishery in Argentina. These are summarised below. Detailed accounts are given by Crespo (SC/O90/G2) and Praderi (SC/O90/G1).

4.7.1 Gillnet fishery for sharks in Uruguay

Bottom-set gillnets are used to catch soupfin sharks, other shark species and bony fish along the coast of Uruguay. Twenty vessels (each approximately 8m long) fish out of five fishing villages along the Uruguay coast. Approximately 80 fishermen are employed in this fishery. Gillnets are approximately 1,200m long and have mesh sizes of 10cm, 20–22cm and 32–34cm. Based on an estimated 72km of net being used in 1989 and a fishing season of 60 days, total effort was approximately 4,356KND. Effort is currently estimated to be decreasing. The total annual value of the catch is approximately \$200,000. Marine mammals killed incidentally include franciscanas (more than 100 per year) and, to a much lesser extent, bottlenose dolphins and Burmeister's porpoises.

4.7.2 Gillnet fishery for croaker species in Argentina

Gillnets are set on the bottom to catch several species of croaker (Sciaenidae) in the Samborombon Bay and Bahía Blanca regions of Argentina. Vessel sizes in these regions are 8–10m and 13–15m, respectively, and the number of vessels fishing gillnets 7–8 and 15–16, respectively. Gillnets in Samborombon Bay are typically 200m long and have mesh sizes of 10–30cm. For Bahía Blanca three types of nets are used with mesh sizes ranging from 2cm to 10cm. Given 8 vessels fishing 200m of net over a 60-day fishing season, total annual effort in Samborombon Bay is approximately 100KND. There are no effort data for the Bahía Blanca area. Effort is stable or increasing slightly. Cetacean mortality at Samborombon Bay includes approximately 50 franciscanas per year. No information on cetacean mortality is available for Bahía Blanca.

4.7.3 Gillnet fishery for sharks in Argentina

Set gillnets are used to catch soupfin and other shark species in the Necochea and Claromecó areas of Argentina. There were 21 vessels fishing in 1989 and 17 in 1988. Vessels are 8–45m in length and typically fish 1–4km of 19–21cm mesh gillnet. Approximately 150 fishermen are employed in this fishery. Total effort is approximately 6,700KND and is increasing. The catch is approximately 500 tonnes per year and is worth approximately \$2 million. The annual cetacean catch includes franciscanas (approximately 70–80), Burmeister's porpoises (approximately 20) and common and dusky dolphins.

4.7.4 Other coastal gillnet fisheries

Gillnets are used to catch a variety of fish species, including robalo, silverside and hake, in the region of southern Patagonia and Tierra del Fuego. Nets include single-panel gillnets and 3-walled trammel nets with mesh sizes of 3, 12 and 30cm. Nets are set from shore with and without vessels. Little is known about the level of fishing effort, but it is believed to be increasing. Incidental cetacean catch has not been quantified, but includes Commerson's dolphins, spectacled porpoises, Peale's dolphins and Burmeister's porpoises.

4.7.5 Recommendations

- (1) It is **recommended** that age and reproductive parameters of the franciscana continue to be monitored and that they be compared with those found

by Kasuya and Brownell during the 1970s (Kasuya and Brownell, 1979) and between populations within the area.

- (2) It is **recommended** that Punta del Diablo be used as a location to estimate the size of the franciscana population off Uruguay. In Argentina, incidental mortality and abundance should be assessed at San Clemente del Tuyu, Nocochea, Claromecó and Bahía Blanca.
- (3) It is **recommended** that samples be collected and analysed to examine genetic variability and stock structure in the franciscana.
- (4) It is **recommended** that the purse-seine fishery in Buenos Aires Province be assessed for its impact on dusky and common dolphins.
- (5) It is **recommended** that mortality rates and population sizes of cetaceans impacted by trawl fisheries in northern Patagonia be assessed.
- (6) In southern Patagonia and Tierra del Fuego, the fisheries require further documentation, in terms of gears used and the amount of effort expended. It is **recommended** that such research begin. Mortality to cetaceans and population sizes of those species affected also need to be assessed in this region. A co-operative research programme should be established between Argentina and Chile for the Tierra del Fuego region.

4.8 Western Africa region

The western Africa region includes 22 coastal states, including Angola, Benin, Cameroon, Cape Verde, Congo, Equatorial Guinea, Gabon, Gambia, Ghana, Guinea, Guinea-Bissau, Ivory Coast, Liberia, Mauritania, Morocco (Atlantic coast), Nigeria, Sao Tome & Principe, Senegal, Sierra Leone, Togo, Western Sahara and Zaire. Most of the gillnet fishing in this area is conducted from small vessels. Little information is available on catch, effort or bycatch. Summaries are provided for four such fisheries. More detailed information is given by Maigret (SC/O90/G5).

4.8.1 Drift gillnet fishery for tuna

A drift gillnet fishery for tuna and billfish is found off the Ivory Coast and the Moroccan coast. In Morocco, vessels are primarily small boats which previously fished with seines or hook and line. In the Ivory Coast and Ghana, small vessels called *pirogues* (10–15m long) fish with approximately 450m of 40–60cm mesh gillnet. There are approximately 30 vessels in the Ivory Coast. No information is available on the level of effort in Morocco, other than the fact that the number of vessels is rapidly increasing. The annual catch of tuna by all gear types is approximately 3,000 tonnes per year in Morocco. The gillnet catch in the Ivory Coast is approximately 200 tonnes and is sold in local markets. Approximately 100 ‘dolphins’ are estimated to be caught per year in the Ivory Coast fishery. No information was available for Morocco.

4.8.2 Western Africa lobster set nets

Spiny lobsters (*Panulirus regius*) are taken in set nets from the Western Sahara to the Congo. Bottom entangling nets are set with small boats (8–12m). The fishery appears to be stable. Lobsters are sold domestically and are exported to Spain and France. No information is available on marine mammal mortality in most areas, but in the north

approximately 10 dolphins and harbour porpoises are believed to be caught each year. Monk seals are also found in the area and may be caught.

4.8.3 Western Africa set gillnet fisheries

Bottom-set gillnets are used for a variety of fish species from Mauritania to Angola. Nets are set from small boats, with or without engines. A variety of sizes and types of gillnets are used, all of relatively short length. No quantitative estimates of effort are available, but this type of fishing is generally increasing in all countries. No information is available on marine mammal mortality, but these nets may occasionally capture Atlantic hump-backed dolphins and (in lagoons) manatees.

4.8.4 Small-scale drift gillnet fishery for small pelagic fishes

This fishery occurs along the coasts of Nigeria, Benin and Gabon. Small pelagic species (e.g., *Sardinella*) are taken with short (65–70m), small-mesh (5–6cm) gillnets which are deployed from small boats (only 10% of which may have outboard engines in Nigeria). There is no information on the effort or the catch. The catch is sold in local markets. There has been some documentation of the catch of unidentified ‘dolphins’.

4.8.5 Recommendations

- (1) There is very little or no expertise on marine mammals in the West African nations. It is **recommended** that a training programme for African scientists be implemented in order to facilitate the formation of a local network to study the problems of incidental catches in West African waters.
- (2) More information on gillnet fisheries in this area is required than was available to the Workshop and it is **recommended** that this be collected and reviewed.
- (3) The identity, size and status of cetacean populations in the eastern tropical Atlantic is unknown. It is **recommended** that these be investigated.

4.9 Southern Africa and southern Indian Ocean region

The southern Africa and southern Indian Ocean region includes the coastal waters of British Indian Ocean Territory, Comoros, Kerguelen (France), Malagasy Republic, Mauritius, Mozambique, Namibia, Reunion (France), Seychelles, South Africa and St. Helena (and dependencies Ascension Island and Tristan da Cunha, UK). Most of the coastal gillnet fishing in this area is artisanal and subsistence-type fishing. Data are completely lacking on most of the fisheries. Some information is summarised below for three fisheries. A small gillnet fishery for tunas is known to exist in the Seychelles, but no information is available on bycatches (Indo-Pacific Tuna Development and Management Programme, 1987). More detailed information is presented by Cockcroft (SC/O90/G20).

4.9.1 Shark gillnetting in Natal, South Africa

Gillnets are used to catch sharks (and presumably protect bathers) along beaches in Natal, South Africa. Nets are set along popular beaches within 500m of shore. Nets are constructed of multifilament nylon with stretched-mesh size of 34cm. There are 416 such nets which are left in a fixed position for most of the year apart from mid-winter when some may deliberately be lifted to avoid major entanglements of predators associated with the sardine run. Each net is 110m long. Total effort is 16,702KND per year and is stable. Shark catch and bycatch in the nets is

carefully monitored. The cetacean species most commonly caught include bottlenose, Indo-Pacific hump-backed and common dolphins. Bottlenose and hump-backed dolphin populations appear to be declining in this area.

4.9.2 Shrimp set netting in Mozambique

Very small mesh (1cm) gillnets are used to catch shrimp in an artisanal fishery in Mozambique and probably some areas of Madagascar. Almost nothing is known about this fishing method. Shore-based dugouts less than 8m long are used. Incidental cetacean catch is not known, but is probably marginal due to the small size of the nets and the small mesh size.

4.9.3 Artisanal gillnet fisheries in the Malagasy Republic, Mauritius, Mozambique, Reunion and Seychelles

Gillnets are used to take a variety of benthic and neritic fish species in coastal areas throughout the southwestern Indian Ocean and southeastern Atlantic. Nets may be set or drift types and may be fished at either the surface or the bottom. Mesh sizes vary between 5–15cm. Vessels range in size from dugouts to 10m sail or motorised boats. There are a minimum of 15,404 such vessels and more probably 20,000. There are more than 20,000 fishermen using these methods and possibly 40–50,000. Total effort is likely to be greater than 450,000KND days per year. Effort is probably increasing with population size. Such fisheries probably also exist in the other nations in the region, with the possible exception of the Comoros. There is no information available on cetacean bycatches.

4.9.4 Recommendations

- (1) Where aid agencies have provided gillnets as part of development assistance programmes, it is **recommended** that the donors be encouraged to obtain information on the impacts of these gears on non-target species.
- (2) In order to encourage fishermen to report incidental catches, it is **recommended** that regulations concerning marine mammals be devised which encourage rather than discourage reporting.
- (3) It is **recommended** that the UN and other aid agencies be made aware of the potential effects of the development of gillnet fisheries.
- (4) It is recommended that Regional fishery bodies be encouraged to place observers on board high seas driftnet vessels to collect information on incidental catches.
- (5) In view of the mortality and depletion of Indo-Pacific hump-backed and bottlenose dolphins by incidental capture in shark nets, it is **urgently recommended** that an immediate reassessment of existing deployment of these nets be carried out.

4.10 East Africa, northwestern Indian Ocean and Red Sea region

This region includes Bahrain, Djibouti, Egypt (Red Sea coast), Ethiopia, Iran, Iraq, Israel (Red Sea coast), Kenya, Kuwait, Oman, Pakistan, Qatar, Saudi Arabia, Somalia, Sudan, Tanzania, United Arab Emirates and Yemen. Information from the region presented to the meeting was limited to a review of the fisheries of Pakistan by Niazi (SC/O90/G30). There are several important marine fisheries in the waters of Pakistan that are known to take cetaceans, although the magnitude of this problem has received little

study to date. It is known that many fishermen attempt to avoid entangling dolphins and attempt to release them alive whenever possible. Of particular concern in Pakistan is a proposed refitting of 1,800 trawlers with gillnet gear. Such an expansion of existing gillnet fisheries could have a serious impact on coastal cetacean populations.

A shark gillnet fishery in the Gulf of Oman is known to take at least common dolphins and humpbacked whales (Papastavrou, 1990), but no further information was available to the meeting. A gillnet fishery for large pelagic species, mainly tuna, is described below; the information comes from Dudley (1989).

Information from the literature on gillnet fisheries of Iran, Kenya, Somalia, Tanzania and Zanzibar is also summarised below.

4.10.1 Large pelagic gillnet fishery in Pakistan

This fishery is conducted in offshore waters along the Sind and Baluchistan coasts and as far away as Oman, in depths of 25–100m. A variety of sharks, tuna and seerfish are taken by drift gillnets that are as long as 10km (Indo-Pacific Tuna Development and Management Programme, 1987). The mesh size of these nets varies between 15 and 25cm. Approximately 500 vessels are active in the fishery, each setting two nets. Assuming a 200-day fishing season, these 500 vessels each setting two 3km nets each day would have a combined effort of 600,000KND per year. Indo-Pacific hump-backed, bottlenose, spinner and spotted dolphins are among the cetacean species taken in unknown numbers by this growing fishery.

4.10.2 Bottom set gillnet fishery in Pakistan

These nets are used in coastal waters in Sind and Baluchistan in depths of 10–30m. A variety of groupers, grunts, croakers and other demersal species are taken in these set nets using mesh sizes of 10–12cm. A total of 2,500 vessels each set one to three nets of between 500 and 1,200m in length. Total fishing effort would be approximately 500,000KND based on each vessel setting 1km of net each day during a 200-day fishing season. This fishery is also growing and is known to take Indo-Pacific hump-backed dolphins, bottlenose dolphins, spotted dolphins and finless porpoises.

4.10.3 Artisanal fisheries in Pakistan

This category includes a large number of small-scale fisheries that employ a variety of gear, including fine mesh gillnets and stake nets. These fisheries operate year round and take most coastal shallow water fish species. More than 20,000 artisanal vessels are in operation in Pakistan around the year. Only the finless porpoise is known to be taken by these small scale fisheries.

4.10.4 Fishery for large pelagic species in Oman

The primary target species are *Scomberomorus commerson* (about 27,581 tonnes landed in 1988), *Thunnus tonggol* (15,669 tonnes in 1988) and other small tunas. Both set nets (some configured as traps) and driftnets of 1–2,000m are used. The fleet consists of a variety of vessels ranging from small fibreglass boats of less than 10m to large dhows. No information is available on effort or bycatches.

4.10.5 Driftnet fishery for tuna in Iran

Iran operates a gillnet fishery for tunas in the Indian Ocean, with total catches in 1986 of 5,071 tonnes (Indo-Pacific Tuna Development and Management Programme,

1987; Indian Ocean Fishery Commission, 1990). There are about 2,500 multipurpose artisanal vessels engaged in the fishery; most are wooden and range from 5 to 100 GRT. Some are fibreglass and range from 12 to 27ft (3.7–8.2m). The nets range in length from 0.5 to 7–8km; mesh size is 14–16cm. There is no information on incidental catches.

4.10.6 Artisanal gillnet fishery in Kenya

In 1987, 404 vessels (most less than 10m) operated bottom and surface gillnets, targeting sharks, rays, tunas and over 100 other species including needlefish, jacks, parrotfish, kingfish and rabbitfish; 2,288 tonnes of all species were landed in that year (de Sousa, 1988). Nets are 90m by 26 meshes; three are usually fished together by one boat. There is no information on incidental catches of cetaceans.

4.10.7 Artisanal driftnet fishery for sharks and large pelagics in Somalia

'Mesh nets' are employed in Somalian fisheries (Van Zelling, 1988). Reported data on vessels and catches have not been broken down by gear type. No data are available on incidental catches.

4.10.8 Artisanal gillnet fisheries in mainland Tanzania

In 1986, a reported 8,842 'gillnets' and 3,590 'shark gillnets' were in use in mainland Tanzania (Nhwani, 1988). The reported data are not broken down by gear type. There is no information on incidental catches.

4.10.9 Gillnet fisheries for large pelagic fish and sharks in Zanzibar

Two vessels engaged in driftnetting for large pelagic fish in 1986 (Jiddawi and Pandu, 1988). The fleet in that year fished 5,622 gillnets for sharks and large pelagics. For the period 1974–76, 91,375 tonnes were landed from gillnets. Again, there is no information available on incidental catches of cetaceans.

4.10.10 Recommendations

- (1) Further research effort into cetaceans in the region is required. In particular, the population status of the finless porpoise and factors controlling it need urgent attention; it is **recommended** that this begin as soon as possible. The causes of the decline in this species should be identified and steps taken to reverse the decline.
- (2) Gillnet fisheries continue to be developed in Pakistan and elsewhere throughout the region. It is **recommended** that these fisheries not be further developed until evaluation of their effects on non-target species has been conducted.
- (3) It is **strongly recommended** that distant water large mesh driftnet fleets operating in the Indian Ocean either be closely monitored or stopped.

4.11 Northeastern Indian Ocean region

This region includes Bangladesh, Myanmar, India, Maldives and Sri Lanka. Within this region, with the exception of the Maldives (Anderson, 1990), gillnets are the most common passive fishing gear. Literally millions of fishermen use this method. The vast majority of the effort is in small-scale artisanal or subsistence fisheries. For purposes of summary, all of these fisheries are considered

collectively below. Details are given by Mohan (SC/O90/G22), Dayaratne and de Silva (1990) and Leatherwood and Reeves (1989).

4.11.1 Small scale artisanal gillnet fisheries of India, Bangladesh and Sri Lanka

Target species in these fisheries include many marine fish and elasmobranchs and freshwater catfish. Almost all coastal areas are fished. Nets include both drift and set type gillnets. Most vessels are small (5–15m). Of approximately 289,000 vessels, only about 8% are motorised. Approximately 2,500,000 fishermen are found in this region, most of whom fish with gillnets at least some of the time. There are estimated to be 216,000 gillnets in India. Although data are not available for the rest of the countries, the total number of nets is likely to be close to 350,000. Mean net length is approximately 400m and mesh sizes range between 2–30cm. Assuming each net is fished 150 days per year, the total effort is approximately 21,000,000KND per year in this region. Marine mammal mortality includes spinner, spotted, striped, common, bottlenose, Indo-Pacific hump-backed, Risso's and Ganges river dolphins and false killer, dwarf sperm and pygmy sperm whales. Total mortality has been estimated by statistical sampling in Sri Lanka and by fishery reporting systems in India. Total mortality of all cetacean species in Sri Lanka alone may exceed 40,000 per year, with a minimum additional catch of 2,000 dolphins in other areas of this region. Dolphin catches in portions of Sri Lanka have evolved from being a bycatch to being a directed catch for human consumption and for bait for the long-line fisheries.

4.11.2 Recommendations

- (1) The fisheries of the region are generally poorly documented and it is **recommended** that a comprehensive survey be made of the fisheries of Bangladesh, Burma, Sri Lanka and India which are known or suspected to kill marine mammals.
- (2) It is **recommended** that the nations in the region consider the establishment of marine mammal protection agencies.
- (3) It is **recommended** that education programmes be initiated for fishermen, fishery officials and others to highlight the problems faced by cetacean populations interacting with gillnet fisheries. Cetacean awareness programmes should be instigated at the village level. Fishery co-operatives and local schools and colleges should be involved in the work, and where dolphins are being caught, a local college or school should be identified to protect the dolphins through public contact programmes.
- (4) Because of the vulnerability and general depletion of river dolphins in Asia, it is **recommended** that particular efforts be made to collect information on the gillnet fisheries of the Ganges and Brahmaputra rivers and their involvement in entanglement of the Ganges susu.

4.12 Southeast Asia region

This region includes the coastal areas of Brunei Darussalam, Kampuchea, Malaysia, Philippines, Singapore, Thailand and Vietnam. Most passive net fisheries in all of these countries are small-scale, artisanal type enterprises. Little information is available for some regions; no information is available for most. Malaysia, Thailand and the Philippines operate gillnet fisheries for

tunas, with reported catches in 1986 of 9,751 and 25,154 tonnes in Malaysia and Thailand, respectively, and 25,186 tonnes in the Philippines in 1985 (Indo-Pacific Tuna Development and Management Programme, 1987), but little information on vessels, gear, effort or bycatches was available to the meeting. The limited information available to the meeting on some areas in the Philippines and on Thailand is summarised below. More detailed accounts are given by Dolar (SC/O90/G29) and Sudara (SC/O90/G32).

4.12.1 Artisanal fishery for pelagic fish in Thailand

Gillnets are used to catch skipjack, Spanish mackerel and longtail tuna in the Gulf of Thailand and in the Andaman Sea. According to Bhatia *et al.* (1989), driftnetting accounted for about 1/3 of the catch of 95,679 tonnes in the Gulf of Thailand in 1987. There are approximately 10,000 small (6–8m) vessels in this fishery. Nets are typically less than 1km, but some are up to 5km long. Nets are either anchored or are allowed to drift. Marine mammals taken in these nets include dwarf spinner dolphins, Indo-Pacific hump-backed dolphins, Irrawaddy dolphins and dugongs.

4.12.2 Artisanal fisheries in the Philippines

Gillnets are used to catch a wide variety of small fish throughout the coastal waters of the Philippines. Boats are small, typically 3–6m in length. There are approximately 3–15,000 such vessels fishing with small (approx. 300m) gillnets. If fishing is practised 220 days per year, total effort would be in the range of 200,000–1,000,000KND per year. Cetacean mortality includes spinner, spotted and Fraser's dolphins. Based on a small sample observed in the Negros and Bohol Islands, estimated kill rates are 0.66 dolphins/km/year. Based on the above estimate of the number and length of nets, extrapolated cetacean mortality may be in the range of 600–2,000 dolphins per year.

4.12.3 Recommendations

- (1) It is **recommended** that studies of cetacean populations and cetacean mortality in fishing operations should be initiated in Southeast Asia as a priority issue.
- (2) It is **recommended** that national and international organisations develop educational programmes for fishermen, scientists, officials and the general public about cetaceans and their interactions with fisheries.

4.13 Australasia and Melanesia region

This region includes coastal waters of Australia, East Timor, Indonesia, New Caledonia, Papua New Guinea, Solomon Islands and Vanuatu. At this meeting, information on fisheries and marine mammal takes included only Australia. Four important net fisheries of Australia, the Taiwanese fishery operating in the Arafura and Timor Sea and the Indonesian tuna gillnet fishery are summarised below. Detailed information on the Australian fisheries was presented by Anderson.

4.13.1 Northern drift gillnet fishery for sharks

Surface driftnets are used to catch sharks, tuna and gray mackerel, 2–12km offshore along the Arafura Sea. Nets are 2.5km long and have a mesh size of 4–6" (10–15cm). There are 45 permits to fish this area, but only 10–12 vessels (approximately 30 fishermen) are actively fishing. Vessels are 10–17m long. Each vessel makes 5–10 trips of 7–21 days duration. Assuming 5–19 days of actual fishing, 7.5 trips per year and 12 vessels, the total effort is approximately 1–4,000KND per year. Bycatches of bottlenose dolphins, *Stenella* spp. and Indo-Pacific hump-backed dolphins are

most likely. Cetacean catch rates are likely to range from 4–6 dolphins/100KND. Given this and the above effort estimate, total catches may be between 40–240 dolphins per year.

4.13.2 Southern set gillnet fishery for sharks

Bottom-set gillnets are used to catch gummy, whiskey and dusky sharks in Western Australia, South Australia, Tasmania, Victoria and southern New South Wales. Vessels are typically 10–20m long. The number of vessels is 172 in South Australia and 20 in Tasmania and is not known for the other areas. The total number of fishermen is approximately 500. Nets are approximately 2.5km long. Effort is generally increasing. Landings are worth approximately \$20m. Reported dolphin takes are approximately 1–7 per year for the West Australia coast and are probably much lower for other areas. Species taken have not been reported, but they were probably bottlenose or common dolphins.

4.13.3 Inshore set gillnet fishery for barramundi

Set gillnets are used to catch barramundi and threadfin in estuaries and tidal areas of northeast, north and northwest Australia. Vessels include 17m net boats and 3.5m net tenders. There are approximately 23 of the mother vessels in the Northern Territories and 9 in West Australia. The number in Queensland is not known. Maximum net length is 1km and mesh sizes are typically 15–18cm. Total catches are in excess of 850 tonnes and are worth a minimum of \$12m. Marine mammal catches probably occur, but data are not available.

4.13.4 Haul-net fishery in Tasmania

Haul-type nets are used to catch baitfish, arridis and mullet in inshore waters of Tasmania. Sometimes these nets are set to fish passively. Nets are set from small dinghies. There may be approximately 7,100 such nets. Nothing is known about levels of fishing effort. Marine mammal mortality included 6 common dolphins in 1980 and 9 in 1989.

4.13.5 Taiwanese driftnet fishery for sharks, billfishes and tunas

This fishery formerly operated in the 200-mile zone of Australia but was ejected from Australian waters in 1986 because of an unacceptably high dolphin bycatch (Harwood and Hembree, 1987; Anon., 1988). The fishery has continued in other waters to the north off Indonesia and Papua New Guinea (Liu, 1989), but there was no information available to the meeting on recent bycatches. Information is also lacking on bycatches outside Australian waters before 1986.

4.13.6 Indonesian tuna gillnet fishery

Approximately 200 gillnetters of 3–6 GRT with 40 HP engines operated out of Sumatra in 1987 (Uktolseja, 1989). The principal target species are skipjack and yellowfin tuna. Catches of tunas in 1988 totalled 902 tonnes; smaller amounts of sharks and billfish were also landed. Nets consist of 20 units each 60m long and 14m deep (total 1,200m), with mesh size of 4–5" (10–13cm). Vessels typically have a crew of 3–4. No information is available on cetacean bycatches.

4.13.7 Recommendations

- (1) Improved documentation of the nature and extent of bycatch, including marine mammals, in southern and

western Australian shark set net fisheries and in the northern Australian driftnet fishery is required, as is an assessment of the cetacean populations involved. It is **recommended** that programmes to accomplish this be initiated.

- (2) It is **recommended** that an assessment be made of the level of bycatch, including marine mammals, in commercial and other net fisheries for barramundi and threadfin bream in northern Queensland, Northern Territory and Western Australia.
- (3) It is **recommended** that assessments should be made of the status of populations of small cetaceans, particularly Indo-Pacific hump-backed dolphins and Irrawaddy river dolphins, in inshore waters of the area where barramundi fisheries operate in northern Australia and in areas which shark fishing operations occur.
- (4) It is **recommended** that other small scale and recreational gillnet fisheries in Australia which have a potential for impact on inshore cetacean populations be better documented.
- (5) Throughout Melanesia, improved documentation of the level and distribution of net and trap fisheries and any cetacean catch or bycatch should be obtained and reporting procedures to maintain the flow of information should be developed. It is **recommended** that these begin as soon as possible. An initial assessment of the identity, distribution and abundance of cetacean populations in the Melanesian region should be made.
- (6) Co-operation should be sought between nations of the area, to implement measures designed to increase the awareness of an need to reduce or eliminate incidental catches of cetaceans and other marine mammals and turtles. It is **recommended** that such efforts be initiated through existing regional cooperative bodies.

4.14 South Pacific region

For purposes of this workshop, the South Pacific is defined to include 13 island groups or territories which are loosely combined as follows: Norfolk Island, New Zealand, Fiji Islands, Tonga (including Niue and Tokelau), Western and American Samoa, the Cook Islands, French Polynesia (including Wallis and Uvea) and Pitcairn Island.

The area is predominantly characterised by islands with either fringing reefs or lagoons surrounded by low coral atolls. Two islands, Pitcairn and Norfolk, lack fringing reefs or coastal shelves; passive net or trap fisheries are not conducted there. New Zealand has a large coastal shelf and supports highly-developed fisheries, including set and driftnet fisheries.

Available fisheries information varies considerably throughout the South Pacific depending largely on the level of fisheries conducted. Passive net fisheries are primarily of three types: drift gillnets, deep and shallow set nets and reef-top and reef-passage set gillnets. Information is presented below for all areas for which it was available. Detailed descriptions of the fisheries were presented to the group by Cawthorn.

4.14.1 Set net fisheries in Fiji, Tonga, Samoa, Cooks and French Polynesia

Throughout these islands, set nets in lagoons and atop reefs are used in artisanal subsistence fisheries to collect migrating mullet and sedentary reef fishes for bait and

human consumption. The nets are generally of monofilament or multifilament nylon with a stretched-mesh measurement of from 5–12.5cm. Nets are slung in 25–50m lengths and set either at the surface, submerged in reef passages or staked on the reef tops. In some areas, such as Tonga and Fiji Islands, gillnets are set from the beaches inside lagoons and staked to form fish fences to catch mullet and other small school fish on the change of tide. No data are available on the quantities of mullet or reef fishes taken by these methods. We are not aware of cetacean mortalities in any local fisheries in these islands. For islands other than the Marquesas, where drive fisheries for small cetaceans have been conducted historically (for meat and for teeth for use as currency and adornment), there is no history of fisheries targeting small cetaceans. A long-lived fishery for humpback whales in Tonga ceased in 1978. The Fijian practice of trading in sperm whale teeth did not relate to a local fishery.

4.14.2 Gillnet fisheries in New Zealand

There are commercial set and drift gillnet fisheries (366 boats, 455 permit holders in the 1989–90 fishing year) and amateur gillnet fisheries operating in both North and South islands. Species taken include mullet, reef and coastal demersal, flatfish, sharks, elephant fish, groupers, semipelagic species, kingfish and ling. Nets are braided synthetic or monofilament with variable mesh sizes which are regulated to target species. Nets are set inside harbours, on mud flats and on the coastal shelf to waters 200m deep. Commercial landings totalled 39,894 tonnes in 1989. Amateur catch is unreported. Between 1984 and 1987, the set net catch declined by about 60%; this was a result of the introduction of the ITQ (Individual Transferable Quota) management system and the resultant exclusion of many part time fishermen. Currently, 56% of the set net fishers registered are in the north of North Island.

The combination of commercial and amateur inshore gillnet fishing has had a significant impact on the population(s) of Hector's dolphins in the Banks Peninsula region of the south island. Results of recent studies of population status and catch rates led to the establishment of a sanctuary in this area and to increased attention to this species throughout New Zealand. A deep set net fishery for grouper at Kaikoura takes a substantial number of dusky dolphins annually. Ten to 25 pinnipeds are killed annually in bait nets set around the South island. To date, no cetacean mortalities have been documented in this fishery. In apparently isolated incidents, a right whale stranded following entanglement in a rock lobster pot-buoy line and reports of minke and sperm whales entangled with netting and/or line have been received. Recently, a trawler, fishing for jack mackerel with mid-water trawl in the western approach to Cook Strait reported taking 35 common dolphins.

4.14.3 Recommendations

- (1) It is **recommended** that national and local island authorities be encouraged to monitor marine mammal fishery interactions systematically in all net fisheries.
- (2) Fishing fleets of the area require better documentation. It is **recommended** that an improved flow of information on marine mammal fishery interactions be achieved, possibly through the South Pacific Regional Environment Programme, which could co-ordinate such data collection.

- (3) It is **recommended** that the South Pacific Forum be encouraged to ensure that large scale driftnet fisheries do not operate in this area in view of the impact that such fisheries have had on local tuna stocks as well as their impact on cetaceans and other non-target species.

4.15 Micronesia and Central Pacific region

This region includes Guam, Federated States of Micronesia, Hawaiian Islands (US), Kiribati, Republic of the Marshall Islands, Nauru, Commonwealth of the Northern Mariana Islands (CNMI) and the Republic of Palau. Bottom-set gillnets are widely used in this area to catch a variety of lagoon, reef and nearshore fishes. Fishing operations are typically artisanal/subsistence or small-scale commercial. These fisheries are summarised below. Fisheries of the Hawaiian Islands are considered separately. Detailed information is given by Nitta (SC/O90/G33).

4.15.1 Artisanal and small-scale fisheries

Subsistence or small-scale commercial gillnet fisheries are found on Nauru, Kiribati, Guam, the Northern Mariana Islands, the Republic of Palau, the Federated States of Micronesia and the Republic of the Marshall Islands. Nets are typically bottom-set gillnets which are used to fish for reef fish, nearshore fish and lagoon fish. Common fish types include bigeye scad, mackerel, mullet, wrasses, goatfish and jacks. Nets are set by hand or from small skiffs, canoes or outboard-powered boats. Information on fishing effort is limited to Yap in CNMI where 3,483 gillnet trips were reported for 1987. The gillnet landings on Yap were 35 tonnes that year. The 1988 commercial (including but not exclusively gillnet-caught) landings of bigeye scad and reef fish on Guam were 61 tonnes (worth \$215,219) and on CNMI were 4.5 tonnes (worth \$19,364). The 1987 commercial landings of reef and lagoon fish for Tarawa (in Kiribati) was 3,628 tonnes (again including but not exclusively gillnet landings). No information was available at the meeting on landings or fishing effort in the other island nations. Some of the outer island villages and councils in the Federated States of Micronesia and the Republic of the Marshall Islands have banned the use of set gillnets in their jurisdictions. No incidents of incidental cetacean mortality in gillnets were reported at the meeting. It was noted, however, that small cetaceans had been taken in the past for subsistence purposes in Kiribati and the Marshall Islands.

4.15.2 Surround-net and gillnet fisheries in Hawaii

Inshore set gillnets are used to catch a variety of fish on reef flats, in bays and in nearshore areas around all of the main Hawaiian Islands. Species include bigeye and mackerel scad, squirrelfish, aholehole, goatfish, rudderfish, wrasse, parrotfish, surgeonfish and tangs. Surround nets are used to catch akule and opelu. Of 2,952 applications for commercial fishing licenses in Hawaii, 498 listed nets as their primary gear and 169 specified gillnets. The actual number of fishermen using gillnets is probably greater than 169. Vessels are typically 10–30ft (3–9m). Commercial landings in 1988 for reef fish, akule and opelu were 120 tonnes, 146 tonnes and 124 tonnes, respectively. Values of these landings were \$441,220, \$592,964 and \$438,845, respectively. Marine mammals reported taken in these fisheries include spinner dolphins and one monk seal. Humpback whales may also be entangled, but there are no confirmed reports of this.

4.15.3 Recommendations

- (1) It is **recommended** that fisheries data collection programmes be developed and implemented in those areas where they are currently lacking.
- (2) It is **recommended** that the appropriate US agency be urged to assist the Freely Associated States of the Federated States of Micronesia and the republic of the Marshall Islands in developing counterpart legislation similar to the US Marine Mammal Protection Act and Endangered Species Act. Similar assistance should be provided to Palau.

4.16 Japan coastal region

There are many trap net fisheries in Japanese coastal waters. These can be divided into large- and small-scale trap nets for miscellaneous coastal fishes throughout Japan and a large-scale trap net fishery for salmon in Hokkaido and northern Japan. Summaries of information on these fisheries are presented below. The Japanese large-scale driftnet fisheries originated in Japanese coastal waters, but Japan now prohibits the use of large driftnets within its 200 mile zone because of conflicts with other types of gear which were already used before the introduction of this technique (United Nations, 1990). Detailed information on trap net fisheries is given by Tobayama *et al.* (SC/O90/G36).

4.16.1 Japan coastal small-scale trap net fishery

Small-scale trap fisheries for a large variety of fish species are found along much of the Japanese coast. Typically the water depth at the pocket is less than 27m. There were 14,591 such fish traps in 1988 (this number has varied between 14,324 and 16,123 over the past 11 years). The total landings were 191,523 tonnes in 1988 and were worth \$424 million. Some of the 14 cetacean species listed in SC/O90/G36 could have been taken, but there are no statistics specifically for bycatch in this fishery.

4.16.2 Northern Japan coastal large-scale trap net fishery for salmon

Salmon are taken in large-scale trap fisheries in Hokkaido. In these traps, water depth at the pocket exceeds 27m. The number of nets has been stable, varying between 674 and 778 over the past 11 years. Most of the traps are 1–2km long and are fished from summer to autumn. The catch was 92,497 tonnes in 1988 and was worth \$481 million. Some of the 14 cetacean species listed in SC/O90/G36 could have been taken, but there are no statistics specifically for bycatch in this fishery.

4.16.3 Japan coastal large-scale trap net fishery

Large-scale trap fisheries for a variety of fish species exist along the Japanese coast. This fishery is limited to water depths at the pocket of greater than 27m (with some exceptions in Okinawa and the inland sea). The number of nets has been stable, with fluctuations between 791 and 909 over the past 11 years. Most traps are fished year-round. Total catches were 363,766 tonnes in 1988 and were worth \$500 million.

4.16.4 Recommendation

It is **recommended** that collection of statistics on the incidental capture of marine mammals in trap and gillnet fisheries in Japan be improved.

4.17 Korean coastal region

No information was made available to the meeting. A fishery yearbook for 1987 reported that 39,921 tonnes of fish were landed from 'large gillnets', 58,539 tonnes from 'small gillnets', 21,421 tonnes from 'large set nets' and 32,508 tonnes from 'small set nets' (Ministry of Agriculture, Forestry and Fisheries, 1988). There is no information available on incidental catches of cetaceans, but it must be assumed that some does occur and it is **recommended** that the national government begin efforts to collect such information.

4.18 China, Taiwan Insular region

Chen (1990) noted that bottlenose dolphins are taken in gillnets in China, Taiwan but did not specify if these are incidental or directed takes. In 1989, a variety of local (as opposed to far-seas) coastal and offshore fisheries using drift and set nets landed over 55,135 metric tonnes of fish and crustaceans caught in China, Taiwanese or adjacent waters, of nearly 100 species (Taiwan Fisheries Bureau, 1990). Information on bycatches is badly needed and it is **recommended** that the national government establish a programme to collect the information.

4.19 Mainland China region

There are a huge number of coastal and freshwater fisheries in Chinese waters that have the potential to impact cetacean populations. Until recently, and with the exception of the baiji, incidental captures of cetaceans have received little study. Since 1983, however, a total of 74 finless porpoise specimens have been recovered by researchers from passive fishing gear in Jiangsu province. [The highly endangered baiji continues to be threatened by incidental mortality in rolling hook longlines – a type of gear not discussed at this meeting]. The carcasses of other small cetaceans killed in coastal fisheries may be used locally for livestock feed. Chinese fisheries are reviewed by Zhou in SC/O90/G21.

4.19.1 Drift gillnets

These nets are widely used in Chinese coastal waters to take a great variety of target species. Mesh sizes vary from 4–16cm, depending on the target species. Unknown numbers of finless porpoises are taken by these nets in coastal waters and in the Yangtze River. Other species are probably also taken, although there are few records of entanglement. Rough estimates indicate that there may be as many as 10,000 drift gillnet vessels active in Chinese coastal waters.

4.19.2 Set gillnets

At least eighteen varieties of set gillnets are used in Chinese waters, with mesh sizes varying from 5.6–32cm. Although the nets are extensively used in shallow inshore waters, there are no data on cetacean entanglements. Approximately 7,000 set gillnet vessels operate along the Chinese coast.

4.19.3 Stow nets

These fixed traps are important components of the coastal fisheries of the East China Sea, Yellow Sea and Bohai Sea. Fish, shrimp and crabs are transported by nearshore currents into these nets. The nets are divided into six major categories, depending on their structural configuration.

Finless porpoises are known to be taken by Chinese stow nets. As many as 20,000 vessels are used in the Chinese stow net fishery.

4.19.4 Fish traps

Three major types of traps (other than stow nets) are used in both fresh and salt water to take a variety of species. Finless porpoises and false killer whales are taken alive by traps in coastal waters and occasionally transported to zoos and aquaria. Baiji are sometimes captured by stake net traps set in the lower Yangtze.

4.19.5 Recommendations

- (1) A general system to monitor the levels of marine mammal mortality in gillnet, stow net, trap and longline fisheries off the Chinese coast is urgently needed and it is **strongly recommended** that such a system be established as soon as possible.
- (2) The population status of the finless porpoise should be studied urgently. Although data are lacking for the Indo-Pacific hump-backed dolphin, it is believed that this coastal species may also be threatened by incidental catches in fishing gear. It is **recommended** that studies of the two species be initiated.
- (3) It is **recommended** that urgent measures be taken to strictly enforce the ban on longline snag fisheries ('rolling hooks') in the Yangtze.

4.20 Eastern North Pacific and Russian Far East region

This region includes the west coast of the USA and Canada and the east coast of the Russian Federation. Several of the more important gillnet and trap fisheries are summarised below. Not included in the summaries is the discontinued joint-venture driftnet fishery for flying squid in Canada. More detailed information is available in Barlow *et al.* (SC/O90/G29) and Burkanov (SC/O90/G10).

4.20.1 California drift gillnet fishery for swordfish and sharks

Nylon mono- and 3-filament nets are used to catch shark and swordfish in the offshore waters of California. Nets are 500–1,000 fathoms long (910–1,820m) and have a 18–24" (45–60cm) mesh. Vessels are approximately 30–75ft (9–23m) in length and carry a crew of 2–6 fishermen. There are 185 permits to participate in this fishery, but only 150 are active. The total effort consisted of approximately 8–10,000 net pulls per year, with a slight decrease in recent years. Nets are suspended 2–5m below the surface and are only allowed to soak at night. Assuming an average length of 750 fathoms (1,370m), total effort is about 10,000KND. Cetaceans taken have included gray, minke, Hubb's and Cuvier's beaked whales, common dolphins, northern right whale dolphins, short-finned pilot whales, Pacific white-sided dolphins, Risso's dolphins and killer whales. Annual mortality rates have been estimated only for California sea lions (150–5,100), harbour seals (0–150) and rorquals (73).

4.20.2 California set gillnet fishery for halibut and angel sharks

Bottom-set gillnets are used to catch halibut in central and southern California and angel sharks in southern California. Vessels range from 15–40ft (4.5–12m) in length and have crews of 1–3 fishermen. Currently there are 200 permits, but only 189 are actively fishing. Nets are made of nylon mono- or multi-filament with a mesh size of approximately 8" (20cm). Nets are 150–200 fathoms (275–365m) long. In 1986/87, about 30,000 sets were made for a

total fishing effort of 8–11,000KND. Effort is decreasing in central California and may be stable or decreasing in southern California, largely due to the impact of gillnet regulations. Annual marine mammal mortality has been estimated for harbour porpoises (50–300), gray whales (<10), California sea lions (2,000–4,000) and harbour seals (1,000–2,000).

4.20.3 Washington bottom-set gillnet fishery for salmon

A small fishery exists for chinook salmon in northern Washington State. This fishery is unique in that it uses bottom-set gillnets rather than the more typically floating gillnets for salmon. The fishery is run by native Americans. Vessels are typically small (16–24ft/5–7.5m). Mono- and multi-filament nylon nets are used, with mesh sizes of 7.75–8.5" (19.5–21.5cm). There are 6–10 vessels fishing a total of about 1,300–2,600 net-days each year. Total effort is thus about 240–480KND. Annual marine mammal catches include harbour porpoises (20–100) and minke whales (0–1).

4.20.4 Alaska and British Columbia driftnet fisheries for salmon

There are many separate areas where drift gillnets are allowed in Alaska and Canada. Although the fisheries may be regulated separately, the methods used are similar and all are combined for this summary. Nylon multifilament nets are used with lengths of 135–550m and mesh sizes of 4.5–8.5" (11.5–21.5cm). Vessels are typically 7–12m in length. The number of vessels is limited by the number of permits. Currently there are 3,230 license holders in Canada and 3,487 in the USA. Fishing effort is fairly stable, but catch varies with the strength of the salmon runs. Landings in 1988 were approximately 100,000 tonnes and were worth approximately \$647m. Marine mammal mortality in nets includes mostly harbour porpoises, Dall's porpoises, white whales and harbour seals. Mortality rates have not been estimated for most of this region.

4.20.5 Alaska set gillnet fisheries for salmon

Again, there are many separate areas where set gillnets are allowed for salmon fishing. All such areas are considered together in this review. Set gillnets are used to catch all five Pacific salmon species. Nets are 15–150 fathoms (27–275m) in length and are usually set to float at the surface, perpendicular to the shore. Nets are typically set with small (4–8m) vessels. There are 4,172 permit-holders allowed to fish with set gillnets in Alaska. The total value of landings was in excess of \$140m in 1988.

4.20.6 Salmon trap fisheries in the Kamchatka region

In eastern Russia, salmon are caught almost exclusively in trap nets. Gillnet fishing is not allowed, but is carried out illegally by vessels from several countries. Approximately 100 traps (100m x 800m dimension) are in the Kamchatka region. Each is operated by approximately 10–12 fishermen. The traps are typically operated 70–75 days each year. Fishing effort varies with the strength of the salmon run. About 40–60,000 tonnes of salmon are landed each year and total landings are worth 24–36 million rubles. The only historical records of cetacean mortality include one narwhal and one gray whale (which was released). Seals (*Phoca larga*) commonly are found inside and outside the trap and are frequently shot. One stranded North Pacific right whale was found entangled in net fragments.

4.20.7 Bottom long-line fisheries in Kamchatka and Okhotsk Sea

Longlines are used to catch cod in eastern Russia. Vessels are large (500 tonnes) and fish one 51km line per vessel. There are 10 vessels in the fleet, each of which fish 120 days per year. Fishing effort is currently up. There are no known records of marine mammal mortality in this fishery.

4.20.8 Crab trap fisheries in the Kamchatka region

Crab traps are fished by large (300–900 tonne) vessels in eastern Russia. There are 50–80 vessels, each with 18–30 fishermen. Each vessel fishes approximately 450 traps during a 120–180 day fishing season. The fishery is stable. Marine mammal mortality has involved gray whales (only one known case) and seals (*Phoca larga* and probably *Phoca hispida*).

4.20.9 Recommendations

- (1) It is **recommended** that baseline data be gathered on levels of marine mammal mortality for all fisheries in the region based on direct observations and other appropriate methodology. Fisheries which are found to have a significant level of marine mammal mortality should be continuously monitored.
- (2) The population size of those species most likely to be affected by fishing mortality should be estimated. For most species it is **recommended** that this include determining stock boundaries, abundance and seasonal distribution. When possible, trends in abundance should also be measured.

4.21 Southeastern Pacific region

The mortality of cetaceans is known to be high in some areas within this region, which includes Ecuador (including Galapagos Islands), Peru and Chile (including Easter Island). Information from Ecuador is scarce, but the coastal artisanal and industrial fisheries of Peru and Chile are thoroughly described by Reyes and Oporto (SC/O90/G11). In central Peru small cetaceans are used for human consumption; in Chile, the meat from dolphins and porpoises is often used for bait.

4.21.1 Swordfish driftnet fishery

This fishery operates in Chilean waters from 15 to 200 n.miles from shore. The target species is swordfish, captured in driftnets up to 2.2km in length and 29–45m deep. The mesh size employed in this fishery varies from 45–56cm. Approximately 800 vessels are active in this fishery, which is currently stable or increasing in size. Landings in 1989 reached 5,824 tonnes, with a value of between \$12 and \$25m. An unknown number of sperm whales, killer whales and southern right whale dolphins are taken in these driftnets. It is interesting to note the similarities between this fishery and the former Italian swordfish driftnet fishery in gear type, operation and the incidental catch of sperm whales.

4.21.2 Chilean bottom set net fishery

Ratfish and sciaenids are taken in demersal set gillnets in southern Chilean coastal waters. The nets are made of 15cm mesh and vary in length, depending on the location, from 200–800m and are from 4–6m deep. The nets are set in water depths of 15–80m and allowed to soak for 10–12 hours. In 1989, 57 Burmeister's porpoises and 51 Chilean dolphins were landed; catches of Peale's dolphins are also occasionally recorded. Approximately 90 small vessels are active in the fishery, but this number is expected to triple in the next few years.

4.21.3 Chilean salmon cage fishery

Peale's dolphins, together with sea lions and fur seals, are occasionally captured in anti-predator nets set around salmon aquaculture operations in Chilean waters. These anti-predator nets are made of 47cm mesh. The numbers of dolphins killed is unknown, but there are about 3,400 active salmon cages operating in this expanding industry.

4.21.4 Ecuadorian gillnet fisheries

This category encompasses a variety of disparate fisheries that operate in both coastal and offshore areas. Cotton and monofilament nets are used, with mesh sizes of 5–20cm and lengths of 70–200m, depending on the target species. The nets are set for a variety of fishes, from sharks and billfish to jacks and catfishes. Bottlenose and pantropical spotted dolphins are taken in these fisheries in relatively small numbers.

4.21.5 Peruvian gillnet fisheries

A diverse group of artisanal gillnet fisheries exists in Peruvian waters. These fisheries target a variety of species, ranging from bonito and blue sharks to demersal rays. The mesh size varies with target species from 3–44cm. The nets are constructed from multifilament and are from 70–270m in length and from 2–27m deep and may be operated as both bottom set and surface driftnets. Approximately 2,600 artisanal vessels are active in this growing fishery. The minimum count at one port in central Peru was 868 Burmeister's porpoises, 5,115 dusky dolphins, 476 common dolphins, 132 bottlenose dolphins and smaller numbers of 11 other odontocete species landed between 1985 and 1989. In addition, at least one humpback whale was entangled but released alive.

Gillnet fisheries in Peru blur the traditional distinction between directed and incidental take, because all small cetaceans are used for human consumption. Thus, captures of dolphins and porpoises are welcomed by fishermen as additional sources of income. In several cases, such as the offshore driftnet fishery, dusky dolphins and other odontocetes have themselves become the target species. It is likely that the utilisation of cetacean bycatches in this manner developed after the crash of the industrial anchoveta fishery in 1972.

4.21.6 Recommendations

- (1) It is **recommended** that national fisheries agencies in the region should collect and report fishery statistics separately for gillnets and for other types of gear.
- (2) It is **recommended** that information be obtained on cetacean entanglement in the swordfish and set net fisheries of Chile.
- (3) It is **recommended** that all three nations collect more comprehensive statistics on cetacean catches and in number rather than weight.
- (4) Alternative fishing methods should be sought to reduce marine mammal mortality without affecting fishery yields. It is **recommended** that technological programmes to this end be established.
- (5) The crab fishery in Chilean and Argentine waters needs further study and an alternative to wildlife meat as crab bait needs to be found; it is **recommended** that a regional effort to do this be initiated.
- (6) It is **recommended** that regional cooperative educational programmes be developed to highlight the problem of cetacean mortality in fishing operations.

- (7) It is **recommended** that the impacts of marine farming on cetacean populations in Chile receive urgent attention.

4.22 North Pacific Basin (large-scale pelagic driftnet fisheries)

Driftnet fisheries are conducted in the North Pacific basin by Japan, South Korea and China, Taiwan. Detailed information is given by Jones *et al.* (SC/O90/G43), Nagao (SC/O90/G55) Northridge (SC/O90/G35), Watanabe (SC/O90/G52) and Yatsu (SC/O90/G8),

4.22.1 Japanese salmon drift gillnet fishery

Surface driftnets are set for Pacific salmonids (pink, sockeye, chum, coho and chinook) by mothership and landbased fleets in the western North Pacific and the Bering Sea. Nets are nylon monofilament of 11–13cm stretched mesh. Regulations require vessels to set no more than 15km of net, which is usually deployed in three sections. Vessels in each fishery are mostly less than 30m in length. The mothership fleet included 43 catcherboats in 1989 and operated from June 1 to early July. Vessels averaged 30 fishing days. Effort was approximately 19,350KND. Landings totalled about 1,150 tonnes of salmon. The landbased fleet operates from late May through June and totalled 108 vessels in 1989. Vessels also average 30 fishing days. Effort was approximately 48,600KND. Total landings were about 2,040 tonnes. There is a definite downward trend in this fishery. The predominate cetacean bycatch is of Dall's porpoises. US observers were placed in the mothership fleet inside the US EEZ from 1981 to 1987. Annual point estimates of the take ranged from 741 to 4,187 Dall's porpoises, the latter number occurring in 1982. A few harbour porpoises were also taken. Northern fur seals are incidentally taken.

4.22.2 Drift squid gillnet fishery

Japan, the Republic of Korea (ROK) and China, Taiwan operate fleets in the North Pacific targeting on neon flying squid (*Ommastrephes bartrami*). In 1989, a joint Japan-Canada-USA programme placed observers on 32 vessels. This programme has been expanded to 74 vessels in 1990. Joint programmes were arranged between the USA and China, Taiwan and the USA and ROK in 1989 as well, placing observers at sea in 1990. Information on the Japanese fishery is more complete and will be discussed separately.

The Japanese squid driftnet fleet includes 457 vessels and approximately 8,000 fishermen in 1990. The area of operation is the North Central Pacific, from 20°N–46°N (mostly north of 38°) and 170°E–145°W. The season is June–December, peaking in July–August. Vessels are 25–60m in length. The gear is nylon monofilament surface gillnet, usually 11–12cm stretch mesh. Data collected in 1989 indicated that an average of approximately 50km/vessel/day was set. There were 33,646 days fished in 1989, with 1,719,311km of net fished. The value of the 157,773 tonnes of squid landed in 1988 was \$300m. The number of vessels in the fishery appears to be stable. Data from the 1989 pilot observer programme yielded the following catch-rates (per 50km of net): northern right-whale dolphin = 0.32; Pacific white-sided dolphin = 0.18; Dall's porpoise = 0.10; common dolphin = 0.01; others/unknown = 0.04. The catch rate for all cetaceans was 0.64 per 50km of net. Scientists from Canada, Japan and the USA will be

analysing the data to estimate the catch for the entire fishery in the near future. Statistically reliable catch rates will be obtained from the 1990 observer programme.

China, Taiwanese and ROK squid driftnet fleets operate in the North Pacific between early March and late December. Fishing peaks in July-August. The area of operation is similar to that of the Japanese fleet, although both nations fish west of 170° East. Vessels range in size from 29–70m. There are approximately 150 Korean and 27 China, Taiwanese vessels with about 3,500 to 4,600 crew total. Vessels deploy surface gillnets of 7.5–13cm stretch mesh. Nets are usually 10–11m deep and up to 60 km or more in length. They are set out in 3 to 6 discrete sections. There is a trend towards fewer vessels, although the amount of gear deployed per vessel has increased. Effort data will be available after observers return from sea. The cetacean bycatch is undocumented, although the species taken will likely be similar to those of the Japanese fleet. Cetacean incidental take rates may differ from those in the Japanese fleets because smaller mesh sizes are used and different areas are fished.

4.22.3 Japanese large mesh drift gillnet fishery

Japanese vessels targeting on albacore and skipjack tuna, swordfish and marlin use nylon multifilament 170–210mm stretch mesh. The area of operation is north of 10°N, south of the squid fishing area, from approximately 145°W to Japan. This includes both coastal and high seas vessels, totalling 459 in 1988 (there will be less than 200 vessels in the high seas in the 1990/91 season). Coastal vessels set approximately 12km of net and high seas vessels set approximately 20–50km. The fishery is valued at \$70m, with 25,000 to 40,000 tonnes landed including 7,000–15,000 tonnes of albacore. There appears to be a stable or downward trend in fishing effort. Cetacean catch rates on high seas vessels will be obtained during the 1990 joint observer programme. Reports from a research cruise indicate the species taken includes Northern right whale, common, Pacific white-sided, striped, bottlenose, Risso's and spotted dolphins, pygmy killer whales, pygmy sperm whales and ziphiids.

4.22.4 China, Taiwanese large mesh drift gillnet fishery

China, Taiwanese vessels of 29–70m length operate in the North Pacific targeting on albacore and skipjack tuna, swordfish and marlin. Little is known of these fleets, although USA and China, Taiwanese observers will monitor fishing activities on about 20 of 123 vessels in the 1990 season. Fishing is mostly between May and November, north of 20°N and south of the squid fishing area. There are probably 2,000–3,000 fishermen of several different nations, including China, Taiwan, the Philippines, Thailand and South Africa. Limited information indicates nets are nylon multifilament, 18–21cm stretch mesh and from 6.5 to 21m deep. Normal net depth is 10–11m. Cetacean bycatch is unknown but probably includes many of the same species seen in the squid driftnet fishery. Several warmer-water species may be taken as well.

4.22.5 Recommendations

- (1) Japan, Canada, Korea, the USA and China, Taiwan are to be commended for the establishment of an international programme to collect data on incidental catches in the North Pacific. It is **recommended** that, should these fisheries continue, the observer programme continue to collect statistically adequate data.

- (2) It is **recommended** that the data collected on mammals taken in the squid driftnet and large mesh driftnet fisheries be analysed as soon as possible.

4.23 South Pacific Basin (large-scale pelagic driftnet fisheries)

This area has experienced extensive driftnet activity in recent years. Vessels from Japan, ROK and China, Taiwan have been active, although recent conservation measures have greatly affected the composition of the fishery. Northridge (SC/O90/G35) provides a review of this fishing activity. Additional information is provided by Hagler (1990), Coffey and Grace (1990), Murray (1990), Watanabe (1990) and Sharples *et al.* (1989).

4.23.1 Large-mesh driftnet fishery

Albacore and other large pelagic species are captured in driftnets between 20 and 55 km long, 10–15m deep and with mesh sizes of 16–20cm. The fishery operates in the Tasman Sea and in the waters east of New Zealand. Large-mesh driftnetting in this area was started in 1983 by Japanese vessels. By the 1988–89 season the fishery included 64 Japanese vessels, between 60 and 130 China, Taiwanese vessels and a single Korean fishery survey vessel. In 1988, catches by the Japanese fleet alone had reached 4,801 tonnes. These driftnets are known to have taken a variety of cetaceans, including common, striped and Risso's dolphins, short-finned pilot whales and southern bottlenose whales. Estimates of entanglement rates for common dolphins have varied between 56 and 70 individuals per 1,000km.

Concern over conservation of both tuna and non-target species gave rise to the Tarawa Declaration, adopted by the South Pacific Forum in 1989. The Declaration resolved to prevent and discourage the practice of driftnetting in the region. The Japanese fleet has since withdrawn from the area and China, Taiwan has indicated that it will also cease driftnetting activity in the South Pacific. There are currently no Korean vessels active in the region.

4.24 Indian Ocean Basin (large-scale pelagic driftnet fisheries)

The only large scale driftnet fishery that exists in this region is the China, Taiwanese high seas large-mesh driftnet fishery. Information was provided by Northridge (SC/O90/G35) and Cockcroft (SC/O90/G20).

4.24.1 Large-mesh driftnet fishery

There is little published information on this China, Taiwanese fishery. Albacore is the primary target species, but a variety of large pelagic fish are also captured. The gear used is similar to that used in other high seas driftnet fisheries: mesh sizes of 20–22cm, total net lengths of 37–47km and net depth of 2–24m. There are no data on actual fishing effort, but most fishing activity is concentrated in either the Arabian Sea or southern Indian Ocean. The fishery was started in 1985 and by 1989 included 139 vessels, with evidence of continued expansion. Catch estimates for 1989 were 19,523 tonnes. No data on cetacean entanglements are available, although incidental catches are likely to be substantial. Additional information is given in Indian Ocean Fishery Commission (1990).

4.25 North Atlantic Basin (large-scale pelagic driftnet fisheries)

The only documented large-scale driftnet fishery in the North Atlantic is the new and rapidly growing French

albacore fishery (SC/O90/G35,G53). The fishery has also been entered recently by Ireland on an experimental basis. There is circumstantial evidence that a China, Taiwanese driftnet fleet may also be operating in the North Atlantic (SC/O90/G35).

4.25.1 French albacore driftnet fishery

This fishery began as an experimental fishery in 1986. The primary target species is albacore, but bluefin tuna and swordfish are also taken. The area fished includes the offshore Bay of Biscay and waters extending from near the Azores to south of Ireland. The net mesh size ranges from 8–12cm; individual net panels are 50m long and 20–36m deep, with a hanging ratio of 0.6. Total net length ranges from 2,500 to 7,000m and varies with vessel size; a 20km net was reported observed by Greenpeace. The 37 vessels in the fleet in 1989 were all less than 25m long. The fishery has grown rapidly since its inception and is still expanding. The fishing season is approximately 3.5 months long, yielding a rough estimate of several hundred thousand KND per year. The catch in 1988 was 750 tonnes. Cetaceans known to be taken incidentally include striped, common and bottlenose dolphins. Other species are probably also taken. The incidental catches have been estimated at 131 dolphins in 1989 and 420–460 in 1990, at a rate of 0.03 to 0.08 per km of net (Antoine, 1990). There is no information on the bycatches in an Irish experimental fishery in the same region.

4.25.2 China, Taiwanese tuna/squid driftnet fishery

China, Taiwanese driftnet vessels have been seen in Port of Spain Harbour, Trinidad with driftnets stacked on their rear decks. The China, Taiwanese Government has stated that the nets are for flying squid rather than for tuna. Possible areas of fishing include off the mouth of the Amazon, in the region of the Azores and off West Africa. Nothing is known of landings or incidental catches.

4.26 South Atlantic Basin (large-scale pelagic driftnet fisheries)

An unacknowledged China, Taiwanese driftnet fishery for tuna exists in the South Atlantic (SC/O90/G4, G20, G35).

4.26.1 China, Taiwanese albacore driftnet fishery

A fleet of perhaps several hundred China, Taiwanese driftnet vessels is known to fish in the vicinity of the South Atlantic islands of Tristan da Cunha and Gough and farther to the east. One vessel that went aground in South African waters carried 145km of driftnetting. There is no information available on landings. Increased discharges and transshipments of frozen tuna in Cape Town indicate that the fishery has been rapidly expanding. Based on reports for one month on the fishing grounds and a total of 500 vessel months, 7,500–10,000 dolphins and 1,000–1,500 small whales may be killed annually; the species make-up of this bycatch is unknown.

5. IMPACTS ON SPECIES AND POPULATIONS

DeMaster chaired the sub-group established to evaluate the impact of passive nets and trap fisheries on species and populations of cetaceans. Hohn and Heyning served as rapporteurs and compiled the initial versions of this section of the report, with the assistance of Brownell, Perrin and Forney.

The terms of reference given by the IWC Scientific Committee were to estimate the mortality of cetaceans in passive nets and trap fisheries and assess the impact of that mortality on cetacean populations. The agenda included examination of what might constitute sustainable kill levels; identifying fisheries with kills clearly not sustainable, possibly not sustainable and sustainable; summarising the age and sex composition of the kill, summarising information on population trends, providing preliminary estimates of net replacement rates for populations under sustainable exploitation, and discussing problems of stock identity and their implications. It was agreed to accomplish this by constructing a table that listed, by species and stock or geographic region: (1) the annual level of kill in passive nets and traps; (2) the approximate annual level of mortality from other sources, including directed fisheries, incidental mortality in non-passive gear and accidental mortality such as boat collisions; (3) population size; and (4) the impact of the kill in passive nets and traps. Other relevant information is given below as notes to the table.

The impact of mortality in passive nets and traps on populations was calculated from estimated kills and population size, where possible. In addition, the impact was categorised as to the severity of the mortality to the population. For those few populations for which the level of mortality, population size and replacement rates were known or could be reasonably estimated, this task was relatively easy. For most populations, however, this evaluation was made on the basis of very scanty information, reflecting knowledge of the fisheries and very rough estimates of possible or probable levels of mortality in passive fishing nets and traps.

5.1 Definitions

The various broad levels of impact used in the table are defined below.

- (1) *Not sustainable*. Kill and population data indicate that the mortality rate exceeds the expected replacement rate of the population.
- (2) *Possibly not sustainable*. Kill and population data indicate that the mortality rate is close to the expected replacement rate of the population, giving reason to believe that the population may decline.
- (3) *Potential*. Adequate data on kill, population size or both are lacking. The available data suggest that the kills may not be sustainable. More data need to be collected. For cases where adequate data were not available but information from similar situations/areas/species was available and indicated that the kill was not sustainable, it was considered likely that the population in question probably cannot sustain the kill.
- (4) *Minimal*. Data suggest some impact on the population although mortality rates do not exceed the level that should cause an immediate decline in the population.
- (5) *Not significant*. Mortality in passive gear is known to occur, but data suggest that the levels are low relative to population size.
- (6) *Unknown*. Used when sufficient data for even the crudest evaluation were unavailable.

The members of the sub-group were assigned species/regional reviews and asked to complete a form that was drafted to help members compile the information in a consistent manner. These data were tabulated and re-examined by the sub-group for consistency, as possible.

Table 1

A summary of information on the number of cetaceans killed annually by passive gear and impacts of these mortalities on the populations. Stocks are not listed if the workshop received no data or was not aware of any data confirming kills in such fisheries. Population estimates were obtained from the literature or from workshop participants. Species are presented by known stock or geographic regions where data were available. Stocks/areas with unsustainable catches are highlighted in bold text. *This Table must be used in conjunction with the extensive annotations given in the text of Section 5.*

Terms, abbreviations and symbols used in the table:

No. killed p.a. - refers to annual kills in passive gear and traps only; '>' or '<' beside the number indicates that the figure represents a minimum or maximum, respectively. A minimum estimate might be available because the sampling effort was low relative to likely fishing effort, e.g., only a small number of fishing ports were observed. A maximum may be given if the mean mortality is less than a whole number and the estimate is rounded up, generally done when fewer than one animal was recorded killed per year or if the number places a likely upper bound on the kill.

Additional killed p.a. - refers to annual kills caused by other forms of non-natural mortality, such as kills in non-passive gear, directed kills and accidental kills such as boat collisions. '>' or '<' has the same meaning as above.

Population size - abundance was unknown for most populations. For some populations/regions, an abundance estimate was not available but the population was suspected to be small ('small?'). When the population size given is thought to be a minimum or maximum, the estimate is preceded by '>' or '<', respectively.

Impact of passive kill - when data were available, the percentage of the population killed annually in passive nets and traps is given. In addition, five qualitative levels of impact are used: not sustainable; maybe not sustainable; potential; minimal; and not significant. A '*' beside the designation 'potential' indicates that although the population size is unknown, it is thought to be low relative to the magnitude of kill in passive gear.

5.2 Populations experiencing levels of mortality that are not sustainable

For seven of the 54 species/populations/regions for which abundance estimates and data on incidental mortality in passive gear were available, the level of mortality in passive gear and traps was determined to be not sustainable.

Two of these species, the baiji and the vaquita, have such low abundance that even relatively low levels of mortality in passive gear and nets are devastating. Two more populations, the Indo-Pacific hump-backed dolphin off the Natal Coast of South Africa and the bottlenose dolphin off the South Natal coast of South Africa have suffered relatively high levels of mortality in anti-shark nets.

The sixth 'population' currently suffering unsustainable levels of incidental mortality in passive gear is that of the harbour porpoise in the western North Atlantic. The population is relatively large, but the level of incidental mortality in gillnets has also been very high and has occurred for many years. The population has been affected in both summer and winter in different parts of its range by various fisheries.

The seventh population identified as experiencing levels of mortality in passive gear and traps that are not sustainable is the striped dolphin in the Mediterranean. The now-banned swordfish driftnet fishery¹ was primarily responsible for the highest levels of incidental mortality of striped dolphins. This fishery operated for only a few years, but the estimated levels of annual kill were extremely high, over 5,000 animals.

¹ Editor's note: The fishery has since been legally re-instituted.

5.3 Explanation of Table 1 summarising impacts on species and populations

The data used in Table 1 were compiled from published sources, documents available at the symposium and workshop, and unpublished information, such as recent survey results, provided by participants during the workshop. Table 1 comprises an overall survey of what is known and unknown about the impact of passive gear on populations of cetaceans. It must be stressed that the estimates of impact are not definitive; they are based for the most part on fragmentary information and are meant only to point out dangerous or potentially dangerous situations that may require urgent management action or investigation. They also, of course, highlight the fact that most impacts are 'unknown'. For roughly 60% of the known cases of interactions between marine mammals and fisheries, not even tentative conclusions could be drawn, because no data were available on population size or on the size of the incidental catch. Stocks/regions were not included in Table 1 if no known kill in passive nets or traps occurred or if the participants in the workshop were unaware of such a kill. Species or populations, e.g., the Indus susu, subjected to other forms of non-natural mortality than in passive gear or nets were not included, even if such effects were non-sustainable.

Because of the limitations of the table, the levels of mortality and impact on the populations may be underestimated. In situations in which the observed mortality represented only a small portion of the likely mortality, e.g., when only one or a few fish markets were observed, and a reliable estimate of effort was not available, the observed mortality was listed without an

attempt to extrapolate in the absence of accurate and precise data on effort or representativeness of a set of data for a region. In many of these cases, the numbers of animals killed is likely to be significantly higher than reported. This situation occurred, for example, for the northeast Indian Ocean and the Pacific coast of South America.

5.4 Annotations to Table 1

The first section of the annotations contains general notes that pertain to a region or fishery that may affect more than one species or stock. Those in the second are relevant to specific species/stocks in a geographic region and are listed in the same order as in Table 1.

5.4.1 Regional or fishery-specific general notes

MEDITERRANEAN

Notarbartolo di Sciara reported that data for estimates of incidental catch and population size for populations of cetaceans in the Mediterranean have not been systematically collected. Minimum estimates were derived from extensive contacts with the fishing communities and from 20 months of dedicated cruises in the past five years. Extrapolations to the entire Mediterranean were made on the basis of these results. He noted, however, that these estimates have not yet been published or peer-reviewed. A marked increase in incidental catch rates was observed throughout the past 20 years. The estimates given are for the past five years (1986–1990). No reliable information exists for earlier years.

WEST AFRICA

Only a small portion of the coast has been surveyed for incidental mortality of cetaceans in passive gear. The numbers of animals killed is likely to be significantly higher than reported. Mid-water trawls and tuna purse-seines catch common dolphins, bottlenose dolphins and oceanic dolphins of the genus *Stenella* in offshore waters. This catch is thought to be large.

SRI LANKA AND THE COASTAL NORTHEAST INDIAN OCEAN

Very large catches of cetaceans have been reported in the waters around Sri Lanka. Leatherwood supplied estimates of catches updated from Leatherwood and Reeves (1989); details of the revised methodology are given in Annex D. As noted in that Annex, it must be emphasised that all these estimates are biased downward to an unknown extent by cetaceans which are killed but not landed or landed but not tallied and most are further biased downward by the use of the number of registered vessels rather than the number of vessels actually fishing.

Because of the disparity in knowledge of levels of mortality between Sri Lanka and the other countries, for the table the data for Sri Lanka have been listed separately from those of the other countries along the coasts of the northern Indian Ocean.

CENTRAL NORTH PACIFIC HIGH SEAS DRIFTNET FISHERIES FOR SALMON AND SQUID AND LARGE-MESH DRIFTNET FISHERY

Estimates of annual mortality in the central North Pacific squid driftnet fishery were made on the basis of 1989 catch rates and 3×10^4 km of netting set (SC/O90/G35).

COASTAL PERU AND CHILE

Direct and incidental mortality of several species of dolphins and porpoises occurs in set nets. In addition, there is a direct catch by means of harpoons. The data on

levels of kill are available from only a few fishing ports. The kill levels reported in the table are from animals counted in the fish markets in those restricted ports. No attempt has been made to extrapolate over the entire coastline, as fishing effort and cetacean densities are unknown. However, cetaceans are known to be killed in these fisheries throughout the coastal waters. The actual numbers of animals killed are almost certainly significantly higher than those reported.

5.4.2 Species/population/region-specific notes

FAMILY BALAENIDAE

Eubalaena australis (southern right whale)

Levels of kill in passive gear for *South Africa* and *New Zealand* were reported by Cockcroft and Cawthorn, respectively. The population estimate is from IWC (1986).

Eubalaena glacialis (northern right whale)

In the *western North Atlantic*, five animals are known to have been killed in collisions with ships. Of 118 right whales photo-identified, 57% showed scars typical of entanglement (Kraus, 1990). The population estimate is from IWC (1986).

In the *North Pacific*, some gillnet mortality is known to occur (SC/O90/G31). The size of the population is not known precisely, but it is very small (IWC, 1986).

Caperea marginata (pygmy right whale)

Mortality in passive gear has been reported along the *coast of South Africa* by Ross *et al.* (1975).

FAMILY ESCHRICHTIIDAE

Eschrichtius robustus (gray whale)

For the *North Pacific (eastern stock)*, the majority of animals entangled off southern California are sexually immature, and 67% entangle on the northern migration (Heyning and Lewis, 1990). Of stranded animals examined along the west coast of North America, 8.7–25.8% died due to entanglement. In addition, collisions with ships kill an unknown number of animals annually (SC/O90/G2). The 1990 IWC catch limit is 179. The population estimate is from IWC (1993).

FAMILY BALAENOPTERIDAE

Balaenoptera sp. (unidentified balaenopterid)

Vidal reported a kill of a unidentified balaenopterid whale in the *Caribbean* off the coast of Venezuela.

B. acutorostrata (minke whale)

The incidence of kill in passive gear in the *Mediterranean* was reported in SC/O90/G31. Levels of kill and estimates of relative abundance were reported by Notarbartolo di Sciara.

In the *western North Atlantic* region, which includes coastal US and coastal Canadian waters, although the minke whales probably constitute a single stock, the actual stock structure is unknown. A minimum of 320 minke whales have been estimated to occur in US waters (Winn, 1982), although this estimate is thought to be very low. Few whales, probably less than 1 per year, are killed in coastal US waters (Kraus *et al.*, 1990; SC/O90/G6), while 10–20 are known killed in Canadian waters (SC/O90/G6).

For the *Southern Hemisphere*, Cockcroft reported the estimated level of kill in passive gear and traps off South Africa. Directed kills occurred in past years under IWC regulations. More recently, a small directed kill of about

300 animals occurred under scientific permits issued by Japan (e.g. IWC, 1990a). The current 'best' abundance estimate is about 760,000 (IWC, 1991b).

For the *western North Pacific*, mortality figures include animals from the West Pacific/Okhotsk Sea stock and East China Sea/Sea of Japan stock. Data for these two stocks have been combined due to lack of information on incidental takes (SC/O90/G36). The last commercial catch occurred in 1987.

For the *eastern North Pacific*, the limited observer data do not always identify baleen whales to species (Heyning and Lewis, 1990). Heyning reported that some animals are killed by collisions with ships.

B. edeni (Bryde's whale)

Information from *coastal Brazil* is reported in SC/O90/G26.

B. physalus (fin whale)

The incidence of mortality in the *Mediterranean* was reported in SC/O90/G34. Levels of kill in gillnets and estimate of relative abundance were reported by Notarbartolo di Sciara.

For *eastern Canada*, levels of mortality and population estimates are given by several authors (Mitchell, 1974; Winn, 1982; Mizroch *et al.*, 1984; Lien *et al.*, 1985; SC/O90/G6).

Information on the *northern Indian Ocean* is reported in Leatherwood and Reeves (1989).

Megaptera novaeangliae (humpback whale)

In the *western North Atlantic*, the animals found off coastal Canada, the USA and Greenland and that winter in the Caribbean constitute a single stock, which is reflected in the abundance estimate (Katona and Beard, 1990). Mortality in passive gear has occurred at a level of 5–17 per year during the past 12 years in Canadian waters (Lien *et al.*, 1985; 1988b; SC/O90/G6). Kraus *et al.* (1990) reported mortality of less than five per year in coastal US waters. Few are known killed in the Caribbean (SC/O90/G7). A catch limit of three humpbacks per year is currently in force for subsistence whalers of St Vincent & The Grenadines. In recent years, usually only 1–2 have been killed annually. During a 5-week period beginning in November 1987, 14 humpback whales died in Cape Cod Bay and Nantucket Sound after eating Atlantic mackerel containing a dinoflagellate neurotoxin (Geraci *et al.*, 1989). Other animals may have died and remained at sea.

Leatherwood and Reeves (1989) provide information for the *Indian Ocean*.

The *western North Pacific* 'population' is the smallest of the North Pacific groupings. To date, 164 individuals have been identified through photo-identification (Kaufman *et al.*, 1989; K. Mori, pers. comm. to T. Kasuya, 1990).

In the *eastern North Pacific* (Hawaii/Alaska and Mexico/California) all of the entanglements documented have occurred in southeast Alaska, British Columbia and California. Two animals were caught in the offshore driftnet fishery off Southern California (Heyning and Lewis, 1990). Additional information is provided by several authors (e.g. Baker and Herman, 1987; Baker *et al.*, 1990; Calambokidis *et al.*, 1990; Straley and Baker, 1990).

Majluf and Reyes (1989) provide information from *coastal Peru*.

FAMILY PLATANISTIDAE

Platanista gangetica (Ganges susu)

Both direct (harpoon) and incidental kills occur along the Brahmaputra River. Incidental catches occur during the dry season. Incidental mortality increased with the introduction of synthetic nets and the number of nets has been increasing (Mohan, 1989).

FAMILY INIIDAE

Lipotes vexillifer (baiji)

Most are entangled by bottom snaglines ('rolling-hook'). Some are caught in traps (Zhou, 1982; 1986; Lin *et al.*, 1985; Zhou and Li, 1989; SC/O90/G21).

Pontoporia blainvillei (franciscana)

In addition to the kill in passive gear, bottom trawls catch and kill *Pontoporia* at Samboraubon Bay, Argentina, although the catch is considered negligible. In Brazil and Argentina, most of the animals killed are juveniles (SC/O90/G3). Sex and age structure of the kill is available. Other information is given by several authors (e.g. Brownell, 1975; Kasuya and Brownell, 1979; Pinedo, 1982; Pérez Macri and Crespo, 1989; Praderi *et al.*, 1989; Corcuera *et al.*, 1994; SC/O90/G1).

Inia geoffrensis (boto)

Of a sample of 35 dolphins, approximately 70% died in lampara seine nets and 30% in gillnets. Two of the 35 were harpooned, possibly because of their interference with fishing operations (Best and da Silva, 1989; Perrin and Brownell, 1989).

FAMILY MONODONTIDAE

Delphinapterus leucas (white whale)

For *Bristol Bay*, the estimate of incidental catch is based on a small sample of years. There is an aboriginal harvest (Hazard, 1988). Hazard (1988) also provides data for *Cook Inlet*.

FAMILY PHOCOENIDAE

Australophocaena dioptrica (spectacled porpoise)

This species is the second most frequently killed cetacean in passive gear in Tierra del Fuego (Goodall *et al.*, 1990; 1994) although the number killed is unknown. A direct fishery exists for use as crab bait. Several others papers provide information (e.g. Goodall and Cameron, 1980; Goodall *et al.*, 1988a; Lichter and Goodall, 1988).

Neophocaena phocaenoides (finless porpoise)

Data for *Thailand/Pakistan/India* are reported in SC/O90/G12, G22 and G30.

Levels of mortality in passive gear in the *Yangtze River* and *Yellow Sea* were given in SC/O90/G21. Unpublished estimates of abundance were reported by Zhou.

For *coastal Japan*, the population estimate is the preliminary sighting estimate for the population in the Inland Sea only. Mortality in passive gear occurs in other areas around Japan as well. Finless porpoises migrate into the Inland Sea for calving in Spring. Their distribution suggests that Japanese trap net operations may have a significant effect on their survival (Kasuya and Kureha, 1979).

Phocoena phocoena (harbour porpoise)

The *Baltic* region includes information from Sweden's east coast, Finland, Russian Federation, Lithuania, Latvia, Estonia, Poland and Germany's Baltic coast (Kremer and Schulze, 1990; SC/O90/G25).

Several papers include information for the *Kattegat and Belt Seas* (e.g. Danielsen *et al.*, 1989; Lindstedt and Lindstedt, 1989; Lindstedt, 1990; SC/O90/G57).

For the *North Sea* area (including the Faroe Islands), estimates of levels of incidental mortality in passive gear from three separate papers are widely disparate, ranging from 100 animals per year (Bjørge and Øien, 1990) to 700 animals per year for the Skagerrak (Kinze, 1994). Clausen and Andersen (1988) reported that up to 3,000 animals are killed per year, but the numbers are unsubstantiated. The estimate of abundance from the North Sea area has a CV of 0.24 (Bjørge and Øien, 1990).

Levels of mortality for *Northern Norway/Barents Sea* were given in Bjørge and Øien (1990). The estimate of abundance from northern Norway has a CV of 0.44 (Danielsen *et al.*, 1989).

Duguy and Hussenot (1982) report mortality in nets along the coast of *France*.

In *Western Greenland* and the area from *Newfoundland to western Greenland*, both incidental and directed catches are large (Gaskin, 1984; Lien *et al.*, 1988b; Kinze, 1994). Insufficient data exist to allow determination of the impact of this long-term fishery on the population, but, given the high levels of mortality, there is reason to be concerned.

For the *Gulf of St. Lawrence and Nova Scotia* region, a sample of fishermen reported taking over 600 porpoises in 1988, but total mortality is unknown (Fontaine *et al.*, 1994). Most of this mortality occurred in groundfish gillnets and some of the carcasses are kept for human consumption. This fishery has existed for some time (Laurin, 1976).

The population grouping of the *northeast coast of the USA, the Bay of Fundy and southwestern Nova Scotia* may also include southwestern Nova Scotia. Estimates of fishery mortality range from 280 (Polacheck, 1989) to almost 1,000 (Kraus *et al.*, 1983; 1990). The estimates are not based on systematic sampling of the entire range of the groundfish gillnet fishery. Other takes are known to occur, but their magnitude is unknown. The estimate excludes an occasional and probably small kill in gillnet fisheries to the south of the Gulf of Maine. Best available estimates of abundance range between 8,000 and 15,300 (Kraus *et al.*, 1983), with the lower number thought to be biased downward (SC/O90/G44). An even lower estimate of 3,500 (Winn, 1982) may be unreliable. Current research is attempting to refine estimates of both abundance and mortality (Read and Gaskin, 1988), but there are already indications that the population is in decline (Read and Gaskin, 1990).

Information on *West Africa* is given in Gaskin (1984) and SC/O90/G5.

For *coastal Japan*, some data are given in SC/O90/G36. Kasuya reported that the impact of passive gear is potentially significant because of the large number of trap nets off Hokkaido (950 large-scale and 4,000 small-scale trap nets along less than 3,000km of coastline).

In the *central North Pacific/Bering Sea* area, the high seas driftnet fishery for salmon kills 0–2 harbour porpoises annually (SC/O90/G35).

Observations of fisheries in the *coastal waters of Alaska* suggest that the Prince William Sound/Copper River Delta area probably has the highest level of mortality of harbour porpoise in Alaskan waters (K. Wynne, pers. comm.; SC/O90/G28).

Along the *Pacific coast of the USA and Canada*, the stock structure of *Phocoena* is unknown. For the USA, limited evidence exists to support the hypothesis that separate

populations exist in Washington, Oregon and California (Calambokidis, 1986). Mortality estimates have been further stratified to reflect regions where known levels of mortality occur. The potentially large impacts given for northern Washington (Gearin *et al.*, 1994) and central California represent gillnet mortality in very specific areas (Brownell, 1964; Hanan *et al.*, 1987) and assume that the porpoises in those subareas comprise separate populations within the overall populations within the states. Because of the uncertain stock status of the subareas, the regional impacts have been designated as 'maybe not sustainable' rather than 'not sustainable'. The population in central California has been subjected to long-term losses due to interactions with fishing gear (Szczepaniak and Webber, 1985). It is currently estimated to be at 30–97% of original population size (Barlow and Hanan, 1994). Mortality in passive gear has declined during the last two years because of restrictions on the use of set gillnets. The take in gillnets has been biased towards juveniles (Hohn and Brownell, 1994). The number of harbour porpoises in British Columbia appears to be declining, possibly due to gillnet mortality (Cowan, 1988; Stacey *et al.*, 1994).

P. sinus (vaquita)

The incidental kill in passive gear is known to have been at least 32–33 per year in 1985 and 1990 based on direct counts (Turk Boyer and Silber, 1990). At least seven vaquitas have been caught in shrimp trawls since 1985. The population size is unknown but could be as low as several hundred (Vidal, 1994). The vaquita has the smallest geographic range of any marine cetacean.

P. spinipinnis (Burmeister's porpoise)

The *western South Atlantic* region includes Uruguay and Argentina. Burmeister's porpoises are killed in gillnets set for fish and sharks (Corcuera *et al.*, 1994). In the 1970s, at least some were taken in centolla (crab) tangle nets in Tierra del Fuego (Goodall and Cameron, 1980). The estimated kill for one port in Argentina, Necochea/Claromecó was 12 animals/year (SC/O90/G2). Along the rest of the coast, no estimates are available. In Uruguay, the estimated take is less than one year, although all organised shark fisheries along the Uruguayan coast are thought to kill this species (SC/O90/G1).

In the *eastern South Pacific*, this species is taken in a variety of coastal fisheries from northern Peru to southern Chile (SC/O90/G11; SC/O90/G54). Counts of animals killed have been reported for specimens landed at the fish markets at Pucusana, Peru, while additional animals are known to be killed in the sciaenid fishery in southern Chile. The total kill probably numbers in the low thousands (Brownell and Praderi, 1982; Read *et al.*, 1988) and is increasing in some areas (Van Waerebeek and Reyes, 1990a; b). More males than females are caught in the Peruvian fishery.

Phocoenoides dalli (Dall's porpoise)

Stocks in the *coastal and offshore Japan* region can be incidentally taken by Japanese large-mesh driftnets and Korean squid gillnets, but the details are unknown. In coastal waters they are killed in trap nets. In addition, there is a direct kill, totalling 30,000 animals in 1989, in the Sea of Japan and Okhotsk Sea (SC/O90/G36). The kill is of both the *dalli* and *truei* types, although the proportion of the kill of each type is unknown (SC/O90/G8).

In the *western and central North Pacific*, two putative stocks inhabit the range from 155°–172°E (IWC, 1990b).

Incidental kill is by the Japanese high seas salmon fisheries and Korean, Taiwanese and Japanese high seas driftnet fisheries for squid. The estimate of kill was made on the basis of observations on Japanese squid driftnet vessels and extrapolated to all nations fishing the region (SC/O90/G8). For the salmon fishery, the mean kill rate from 1981–87 in the US Fisheries Conservation Zone (FCZ) collected by US and Japanese scientific observers was used with the relevant fishing effort data for each fishery. Kill rates outside the US FCZ may be somewhat lower than the rate used. Although the number of observations from Japan is high, the observations do not cover the entire fishing season and may not be representative of the areal distribution of the fishing effort. In addition, Korean and Taiwanese vessels were not observed; they used different mesh sizes and operated in different areas and time periods. The kill estimate is therefore preliminary. Information is available on life history.

For the *Bering Sea*, population estimates are based on the US Platform of Opportunity Programme (NMFS, unpubl. data). Sightings data are collected during surveys by trained observers and analysed using line transect methodology. Jones reported that these estimates were used in US official determinations of status of the populations. Kill estimates are based on the mean kill rate over the period 1981–87. Data were collected by Japanese and US scientific observers on salmon catcherboats. Fishing effort and area are currently decreasing. Additional mortality may be incurred in the extensive trawl fisheries in the Bering Sea (SC/O90/G35). Data are available on life history.

In the *eastern North Pacific*, mortality occurs in the Alaska trawl fishery (SC/O90/G28) and in nets off the coast of British Columbia (Stacey *et al.*, 1994).

FAMILY DELPHINIDAE

Cephalorhynchus eutropia (Chilean dolphin)

This species is killed incidentally in passive gear in southern Chile. There is also incidental kill in purse-seines and a harpoon fishery where the animals are taken for crab bait (Goodall *et al.*, 1988b).

C. heavisidii (Heaviside's dolphin)

Mortality occurs in near-shore set nets and in trawls and purse-seines along the southern African coast. Some animals are also taken illegally with hand harpoons (Best, 1984).

C. hectori (Hector's dolphin)

Mortality figures are from 1984–88 from Pegasus Bay/Canterbury Bight only. Entanglement rates are probably highest in this area, but additional entanglements undoubtedly occur elsewhere (Dawson and Slooten, 1988; Slooten and Dawson, 1988). The Banks Peninsula Marine Mammal Sanctuary was established in 1989 to reduce incidental mortality of this species (Dawson, 1991).

C. commersonii (Commerson's dolphin)

Kill occurs in gillnets in southern Patagonia, on the northeast coast of Tierra del Fuego and in Chile (Goodall *et al.*, 1988a; Leatherwood *et al.*, 1988; Lichter and Goodall, 1988). Bottom and mid-water trawlers kill an additional unknown number in northern Patagonia. In Tierra del Fuego, this species is intentionally killed by harpoon and gunshot for use as crab bait. No systematic

monitoring of mortality or collection of carcasses has occurred but the number killed is thought to be high. Abundance has decreased to low levels in the Magellan Straits (Goodall *et al.*, 1988a; Lichter and Goodall, 1988).

Delphinus delphis (common dolphin)

In many ocean basins, there are two reported morphological forms of common dolphins, a long-beaked and a short-beaked form. In the eastern North Pacific the long-beaked form has been described as *D. bairdii* or *D. delphis bairdii*. Off South Africa it has been called *D. capensis* and in the northern Indian Ocean *D. tropicalis*. The short-beaked form has been referred to as *D. delphis*. It has not been fully resolved whether these two forms represent two species of common dolphins or two distinct ecological races². In either case they need to be managed as separate populations. Most reports only list the kill as common dolphins, making the impact of such kills impossible to ascertain, but potentially a problem.

The incidence of mortality for the *Mediterranean* was given in SC/O90/G34.

In the *eastern North Atlantic*, common dolphins are killed in French and Irish driftnet fisheries (Duguy and Hussenot, 1982; SC/O90/G35).

In the *western North Atlantic*, a recently expanded driftnet fishery for swordfish and tuna has developed along the continental shelf edge of the northeastern United States and is currently being monitored. During August–November 1989, 19 common dolphins were caught on 12 trips (SC/O90/G6). The number of common dolphins killed annually has been estimated on the basis of 5–10% of fishing trips observed. Common dolphins are also killed in the squid trawl fisheries in the shelf and shelf-edge region of the northeast US (Waring *et al.*, 1990). Abundance estimates from aerial surveys are given in Winn (1982).

Estimates for the *Brazil region* are given in SC/O90/G26.

In *coastal Argentina*, mortality in gillnets was estimated to be eight animals/fishing season for one port (Claromecó). Additional mortality occurs in bottom trawls and purse-seines. The annual level of mortality in purse-seines is estimated to be 50–100. This total also includes kills of dusky dolphins, likely the predominant species (Corcuera *et al.*, 1994; SC/O90/G2).

In *coastal West Africa*, numerous fisheries probably kill common dolphins in passive gear. Other kills occur in tuna purse-seines (SC/O90/G5).

In the *eastern South Atlantic Ocean* basin, kills occur in high seas driftnets and around islands (SC/O90/G20).

In the *southwestern Indian Ocean* basin, dolphins are taken in high seas driftnets and around islands (Cockcroft and Peddemors, 1990; SC/O90/G20).

For the *Indian Ocean coast of South Africa*, estimates are reported in Cockcroft (1990) and Cockcroft and Peddemors (1990).

In the *northern Indian Ocean*, mortality in passive gear has been reported from the Arabian Sea (Papastavrou, 1990), India (SC/O90/G12; SC/O90/G22), Sri Lanka (Alling, 1983; Leatherwood and Reeves, 1989) and Pakistan (SC/O90/G30).

Over a two-year period in the *Tasman Sea*, 4,600 dolphins, mostly *Delphinus delphis* were killed in driftnets (SC/O90/G35).

² Editor's note: The IWC Scientific Committee accepted the species *Delphinus capensis*, the long-beaked common dolphin, at its 1994 meeting (IWC, 1995, in press) based on Heyning and Perrin (1994).

In *coastal Japan*, this species has been taken by drive fisheries in the past. Currently data are being collected by means of an observer programme (SC/O90/G36).

In the *central North Pacific*, data are currently being collected in observer programmes in the high seas squid driftnet programme and large-mesh driftnet programme (SC/O90/G35, SC/O90/G52).

In *coastal California and Baja California* common dolphins are caught in set and drift gillnets along central and southern California (SC/O90/G24) and may be caught in high number in the Gulf of California (SC/O90/G7). The majority of common dolphins killed off California are of the long-beaked form (Evans, 1982; Perrin *et al.*, 1985).

For *coastal Peru*, Heyning, Reyes and Van Waerebeek reported that mortality is of the long-beaked form. The estimate of mortality is for the ports of Pucusana and Cerro Azul only (Read *et al.*, 1988; Van Waerebeek and Reyes, 1990a; SC/O90/G54). Van Waerebeek reported that the mortality off northern Peru is thought to be much higher.

Feresa attenuata (pygmy killer whale)

For *coastal Sri Lanka*, estimates are reported by Leatherwood and Reeves (1989).

In the *central North Pacific*, data on the mortality of this species in the large mesh driftnet fishery in the central North Pacific are being collected (SC/O90/G52).

For *coastal Peru*, one specimen is known to have been taken (Read *et al.*, 1988; Van Waerebeek and Reyes, 1990a).

Globicephala sp. (unidentified pilot whale)

In the *western North Atlantic*, pilot whales are killed incidentally in the drift gillnet fishery and distant-water fleet mackerel and squid trawl fisheries. The mortality has not been recorded by species; the fishery operates well beyond the known range of the short-finned pilot whale. Seven animals were observed killed on 12 trips in the swordfish driftnet fishery during 1989. It is estimated that 5–10% of the fishing trips were observed. From 1977–1990, a minimum of 409 specimens have been observed killed in the mackerel and squid fisheries, with an annual average of 46 observed killed from 1984–88. The estimate of population size (Winn, 1982) given in the table pertains to both species over the range of the survey and does not cover the known range of the short-finned pilot whale in the North Atlantic. When extrapolated over total fishing effort, the total mortality in the foreign squid and mackerel trawl fishing gear is 2.0–2.7% of the estimated population size (Waring *et al.*, 1990). This rate may not be sustainable. From 1948–1971, the Newfoundland drive fishery killed an average of 2,260 each year (Mercer, 1975).

Globicephala melas (long-finned pilot whale)

For the *Mediterranean*, Notarbartolo di Sciara reported that other sources of man-induced mortality include entanglement in longlines and direct kill by gunshot. This species is distributed mainly in the western basin.

In *France*, some kill occurs in gillnets (Duguy and Hussenot, 1982).

G. macrorhynchus (short-finned pilot whale)

Some kill occurs in the *Caribbean* in passive gear (SC/O90/G7). A directed fishery for pilot whales occurred in the waters around St. Vincent (Caldwell and Caldwell, 1975).

For the *northern Indian Ocean*, Leatherwood reported that incidental mortality probably occurs in the China, Taiwanese (abbreviated as 'Taiwanese' in the remainder of

this section) driftnet fishery. Pilot whales are killed in the coastal fisheries around Sri Lanka (Leatherwood and Reeves, 1989) and in the waters of Pakistan (SC/O90/G30).

Pilot whales of the *Japanese southern form* are killed in trap nets and in the drive fisheries and small-type whaling (SC/O90/G36; Kasuya and Miyashita, 1989; Miyashita, 1993). Data are being collected from whaling operations.

Some individuals of the *Japanese northern form* are killed in Japanese and Korean gillnets. The other fishery mortality is from small-type whaling (SC/O90/G36; Miyashita, 1993). Data are being collected from whaling operations.

In *coastal California*, prior to the early 1980s, a migratory group of pilot whales entered the Southern California Bight in winter to feed on spawning squid. The developing squid fishery resulted in the deaths of an unknown number of whales by entanglement in nets and by gunshot (Miller, 1983). Since 1983, a year with a major El Niño Southern Oscillation event concomitant with the years of highest incidental mortality, few pilot whales have been seen nearshore. Pilot whales are currently killed in drift gillnets (SC/O90/G28).

In *coastal Peru*, counts of pilot whales in the fish market at Pucusana gave one whale each in 1985 and 1986, years of relatively low observer coverage, three whales in 1987 with 298 days of coverage and five whale in each 1988 and 1989 with 492 days of monitoring. As only one fishing market was sampled, these estimates are undoubtedly low (Read *et al.*, 1988; Van Waerebeek and Reyes, 1990a; b; SC/O90/G54).

Grampus griseus (Risso's dolphin)

In the *Mediterranean*, Risso's dolphins are killed in several gillnet fisheries (SC/O90/G34). Notarbartolo di Sciara reported that, in addition to mortality in driftnets, kills include those resulting from harpoons, gunshot and entanglement in longlines. Risso's dolphins are distributed mainly in the western basin. For the *eastern North Atlantic*, some kills were reported by Duguy and Hussenot (1982).

Along the *western North Atlantic coast of the USA*, mortality has occurred in the swordfish driftnet fishery and the foreign trawl fisheries for mackerel and squid (Waring *et al.*, 1990; SC/O90/G6). During August–November 1989, three *Grampus* were caught in the driftnet fishery on 12 observed trips, representing an estimated coverage of 5–10%. The estimate of population size (Winn, 1982; Kenney, 1990) was based on a survey that may not have covered the entire range of Risso's dolphin in the western North Atlantic.

Caribbean data are provided in SC/O90/G7.

In *coastal Sri Lanka*, a harpoon fishery exists in addition to the incidental kills in coastal gillnets and in the Taiwanese driftnet fishery (Leatherwood and Reeves, 1989).

In *coastal Japan*, incidental mortality occurs in trap nets and possibly in the large-mesh driftnet fishery. Kasuya reported that the impact of kills in trap nets is thought to be not significant. Risso's dolphin was previously taken in the drive fishery at Iki Island (SC/O90/G36; Miyashita, 1993).

In the *central North Pacific*, mortality results from the high seas driftnet fishery and the large-mesh net fishery. Data are being collected by means of an observer programme (SC/O90/G52).

Along the *Pacific coast of the USA*, some animals are thought to be killed in gillnets. The squid purse-seine fishery is responsible for additional mortality (SC/O90/G24).

In *coastal Peru*, only one Risso's dolphin was observed in the fish market in Pucusana, Peru in 1987, when there were 298 days of monitoring (Van Waerebeek and Reyes, 1990b). Another specimen was landed in Pucusana in 1988–89 during 492 days of monitoring (SC/O90/G54).

Lagenodelphis hosei (Fraser's dolphin)

Mortality in *coastal Sri Lanka* has been reported by Leatherwood and Reeves (1989).

In the *Philippines*, mortality occurs in driftnets, as bycatch in purse-seines and by harpoon (SC/O90/G29).

In *coastal Japan*, the documented take is by Japanese trap nets. This stock may also be taken by large-mesh gillnets in higher numbers (SC/O90/G36). Data are being collected by means of an observer programme (SC/O90/G52). This species is also killed in drive fisheries.

Lagenorhynchus acutus (Atlantic white-sided dolphin)

Along the *western North Atlantic coast of the USA*, Gilbert and Wynne (1987) reported the incidental take of several of this species in the winter surface-gillnet fishery for mackerel in Cape Cod Bay. A small number of white-sided dolphins have been reported killed in the foreign trawl fisheries for mackerel (Waring *et al.*, 1990). The estimate of abundance was given by Kenney (1990).

L. albirostris (white-beaked dolphin)

For the *western North Atlantic*, reports of mortality in passive gear were given in Alling and Whitehead (1987).

L. australis (Peale's dolphin)

In *coastal South America*, incidental kill in passive gear occurs in gillnets in the south of Patagonia and in Tierra del Fuego. Two specimens were observed caught in bottom and mid-water trawls at Puerto Deseado (SC/O90/G2). A direct fishery kills some animals for use as crab bait. In 1978, 23 dolphins were known killed (Goodall and Cameron, 1980).

L. obliquidens (Pacific white-sided dolphin)

In *coastal Japan*, incidental mortality occurs in trap nets. Partial observations showed an average of 7.8 dolphins killed annually (SC/O90/G36). Population estimates are for the East China Sea – Sea of Japan (Miyashita, 1986).

In the *central North Pacific*, most of the kill in passive gear is in the high seas driftnet fishery (SC/O90/G8; SC/O90/G35; SC/O90/G42). The total mortality of this species in high seas squid driftnets has been extrapolated from the observed Japanese take rate. Japanese salmon driftnets have killed 0–2 animals annually from 1978–87 (SC/O90/G35). One animal was reported killed in a research operation using large-mesh gillnets.

In the *eastern North Pacific*, two stocks may occur, with the northern temperate and southern temperate forms meeting in the Southern California Bight (Leatherwood *et al.*, 1984; Walker *et al.*, 1986). Incidental mortality occurs in the California and British Columbia driftnet fisheries (Stacey *et al.*, 1994; SC/O90/G28). Some animals stranded along the California coast were thought to have been killed in gillnets (SC/O90/G24). Some mortality occurred during the experimental fishery for squid but that fishery did not develop. Additional sources of mortality are Alaskan trawls (SC/O90/G28).

L. obscurus (dusky dolphin)

For *coastal Argentina*, mortality in gillnets was estimated to be 1.4 animals/fishing season for one port (Necochea/Claromecó). The catches were considered sporadic.

Additional mortality occurs in bottom trawls in northern Patagonia and purse-seines in Necochea/Claromecó. In 8–10 months, eight dolphins were recovered from one bottom trawl vessel (Corcuera *et al.*, 1994; SC/O90/G2). The annual level of mortality in purse-seines is estimated to be 50–100, a total which also includes kills of common dolphins, although the majority of the kill is suspected to be of dusky dolphins (Corcuera *et al.*, 1994; SC/O90/G2).

In *coastal South Africa*, mortality in mullet and elephant fish gillnets occurs but at an unknown and probably minimal level. Additional mortality occurs in purse-seines and there is also some removal for transfer to oceanaria (SC/O90/G20; Best and Ross, 1977).

Cawthorn reported that in *New Zealand* mortality occurs in deep-set gillnets.

For *coastal Peru*, the reported kill of >1,800 includes landings at the port of Pucusana only. Mortality is incidental as well as directed using drift gillnets, with a few specimens taken by harpoon (Read *et al.*, 1988; Van Waerebeek and Reyes, 1990a; b). Some counts from other ports are available but the representativeness of the counts throughout a single year and across years and ports is unknown. All age classes are taken and the sex ratio is about 1:1.

Lissodelphis borealis (northern right whale dolphin)

In the *central North Pacific*, right whale dolphins are killed incidentally in the squid driftnet area (SC/O90/G8, G35, G52). In 1989, 455 were observed killed in Japanese squid gillnets. This number represented partial coverage only. When extrapolated over the Japanese, Taiwanese and Korean fleets, the total estimated kill is 19,000 (SC/O90/G35). Some (0–4 per year) also are killed in Japanese salmon driftnets (SC/O90/G35). In research cruises using large-mesh gillnets, 22 right whale dolphins were killed (SC/O90/G52).

Along the *Pacific coast of North America*, two mortalities are known to have occurred in drift gillnets in US waters, while in four years 13 were known to have been killed in Canadian waters (SC/O90/G28). A population size for *Lissodelphis* in the Northeast Pacific is available for limited regions along the coast of California through a series of aerial surveys (Leatherwood and Walker, 1979). However, stock structure and total distribution is unknown.

L. peronii (southern right whale dolphin)

Along the *Pacific coast of South America*, three were reported killed in gillnets in Peru from 1985–90. In Chile, several were found near fish terminals and landings sites after having been killed in swordfish driftnets. The number reported accelerated rapidly in 1989–90, which is cause for concern. A few are also harpooned by artisanal fishermen in Chile in the swordfish harpoon fishery (SC/O90/G11). Van Waerebeek reported that the animals landed in Peru have been adults.

Orcaella brevirostris (Irrawaddy dolphin)

In most areas where this species occurs, data on incidental kills are limited. Some kill is known from India and the northern Indian Ocean coast (SC/O90/G12; SC/O90/G22). In the Queensland, Australia area from 1967–1989, a total of 522 dolphins was killed in shark nets (Harwood *et al.*, 1984; Harwood and Hembree, 1987; Paterson, 1990). Four species of dolphins were involved: *Tursiops truncatus*, *Delphinus delphis*, *Orcaella brevirostris* and *Sousa chinensis*. The number of each species killed is not known.

because mortality counts were not stratified by species. The fishery subsequently moved into the waters of Papua New Guinea and Indonesia (Liu, 1989), probably eliminating that fishery as a source of additional mortality in coastal waters of Australia but inflicting mortality on animals in nearby waters that probably constitute the same population. In some areas, this species is killed for local consumption and some live capture occurs (Marsh *et al.*, 1989).

Orcinus orca (killer whale)

The incidence of mortality in the *Mediterranean* was given in SC/O90/G34. Notarbartolo di Sciara reported estimated mortality rates and relative abundance.

The abundance of killer whales in the entire *North Atlantic* is unknown. Killer whales are reported to become entangled occasionally in inshore herring nets off Norway (Lien *et al.*, 1988a). Changes in killer whale migrations, caused by changes in herring migration, may explain the increase in abundance of killer whales in Norwegian coastal and inshore waters since the early 1980s (Christensen, 1988) and subsequent entanglements. Directed fisheries for killer whales that take an average of less than 10 animals per year occur in Greenland (Heide-Jørgensen, 1988). Approximately 700 killer whales (average 58 per year) were killed in the North Atlantic by Norwegian vessels between 1970–1981 (Øien, 1988). From 1976–1988, 59 killer whales were caught off Iceland for public display (Sigurjónsson and Leatherwood, 1988).

Some kill has been reported in the Caribbean off Trinidad and Tobago (SC/O90/G7).

In *coastal Argentina*, one kill is known to have occurred in the Necochea gillnet fishery in October 1990 (Corcuera *et al.*, 1994).

In *Sri Lanka*, an average of <1 animal per year is killed (Leatherwood and Reeves, 1989; Leatherwood *et al.*, 1991).

Information for *Indonesia* is given in Hembree (1980).

In the *central North Pacific/Bering Sea* region, some kill has been reported in Japanese salmon gillnets (SC/O90/G35). Squid gillnets and large-mesh gillnets may also take this species. Some additional kill by US salmon boats in the Bering Sea has been documented (Dahlheim, 1988).

In the *eastern North Pacific*, a low level of kill has been reported from gillnets (SC/O90/G24). In the period 1986–88, two animals were known killed in the Alaska trawl fishery for pollock (SC/O90/G28).

Peponocephala electra (melon-headed whale)

For the *northern Indian Ocean* area, a small kill has been documented for Sri Lanka (Leatherwood *et al.*, 1991). In addition, there is a small live-capture removal of this species. Leatherwood reported that this species is likely taken in coastal and high seas gillnet operations throughout the temperate and tropical Indian Ocean.

Pseudorca crassidens (false killer whale)

In the *Brazil* region, some mortality in passive gear occurs (SC/O90/G26).

This species is killed in the coastal net fisheries of *Sri Lanka* (Leatherwood and Reeves, 1989; Leatherwood *et al.*, 1991).

In *Australasia*, this species is one of several killed in Taiwanese drift gillnets off the coast of northeast and northwest Australia (Harwood *et al.*, 1984; Harwood and

Hembree, 1987). From 1981–1985, an annual mortality of 11 animals was estimated on the basis of an observer programme. Significant declines in cetacean catch rate with both time and increasing cumulative effort occurred from 1981–83. Similar analyses for 1984–85 were not done because of changes in observer coverage, fishing methods and area of operation. The fishery subsequently moved into the waters of Papua New Guinea and Indonesia (Liu, 1989), probably eliminating the fishery as a source of additional mortality in coastal waters of Australia but inflicting mortality on animals in nearby waters that probably constitute the same population. One kill in longline gear offshore has been recorded. Two animals were removed by live capture in 1989. Some seasonal movement is known.

In *coastal China*, mortality in passive gear has been reported by several authors (Wang, 1979; Zhou *et al.*, 1982; Shi and Wang, 1983; SC/O90/G21).

In *coastal Japan*, incidental mortality occurs in Japanese trap nets (SC/O90/G36). Additional kills occur in the drive fishery and in culls (Tamura *et al.*, 1986). The population estimate is 2,700 in the East China Sea and 13,000 off the Pacific coast (Miyashita, 1993). Several stocks may be included. Biological information suggests a low reproductive rate.

Mortality has been reported for *coastal Peru* in SC/O90/G11.

Sotalia fluviatilis (tucuxi)

Two stocks are recognised, a marine and a freshwater form (Borobia and Sergeant, 1989). Both stocks are killed in passive fishing gear (SC/O90/G7; SC/O90/G26). Artisanal net fisheries in Brazil kill at least some of the marine form (Simões-Lopes and Ximenez, 1990).

Sousa chinensis (Indo-Pacific hump-backed dolphin)

Hump-backed dolphins are killed in anti-shark nets off Natal, South Africa. Available information suggests that the level of mortality may lead to the depletion of local groups (SC/O90/G20; Ross, 1984; Ross *et al.*, 1989).

Kills for *coastal Sri Lanka* were reported by Leatherwood and Reeves (1989).

In the *northern Indian Ocean*, incidental mortality is known to occur in Sri Lanka, India, Pakistan and Thailand (Bhatia *et al.*, 1989; SC/O90/G22, SC/O90/G30) and probably occurs in other countries as well.

In *Australasia*, this species is one of several killed in Taiwanese drift gillnets off the coast of northeast and northwest Australia (Harwood *et al.*, 1984; Harwood and Hembree, 1987). From 1981–1985, an annual mortality of 11 animals was estimated on the basis of an observer programme. Significant declines in cetacean catch rate with both time and increasing cumulative effort occurred from 1981–83. Similar analyses for 1984–85 were not done because of changes in observer coverage, fishing methods and area of operation. This fishery has since moved into waters of Papua New Guinea and Indonesia (Liu, 1989), probably eliminating the fishery as a source of additional mortality in coastal waters of Australia but inflicting mortality on animals in nearby waters that probably constitute the same population. Other incidental catches include observed catches of up to an average of 25 dolphins/year in shark nets (that estimate includes four species of dolphins) (Paterson, 1990). Anderson reported that inshore set nets kill about 80 per year, although this number is probably an underestimate, and that some may

be killed in the shark/tuna/mackerel driftnets in the Northwest Territory. Estimates of total incidental take are probably low.

S. teuszii (Atlantic hump-backed dolphin)

Mortality along the *West coast of Africa* was reported by Cadenat and Paraiso (1957).

Stenella attenuata (pantropical spotted dolphin)

For the *northern Indian Ocean*, incidental kill has been reported from coastal Sri Lanka and Pakistan (Leatherwood and Reeves, 1989; SC/O90/G30) and it probably occurs in other regions.

In *Australasia*, this species is one of several killed in Taiwanese drift gillnets off the coast of northeast and northwest Australia (Harwood *et al.*, 1984; Harwood and Hembree, 1987). In the period 1981–1985, an annual mortality of 126 animals was estimated on the basis of an observer programme. Significant declines in cetacean catch rate with both time and increasing cumulative effort occurred 1981–83. Similar analyses for 1984–85 were not done because of changes in observer coverage, fishing methods and area of operation. This fishery has since moved into waters of Papua New Guinea and Indonesia (Liu, 1989), probably eliminating the fishery as a source of additional mortality in coastal waters of Australia but inflicting mortality on animals in nearby waters that probably constitute the same population. Estimates of total incidental take are probably low.

In the *Philippines*, these dolphins are taken by purse-seines, harpoons and driftnets (SC/O90/G29).

In the *western North Pacific*, research operations with large-mesh gillnets incurred some incidental kill (SC/O90/G52). A drive fishery is still active but at lower levels than in the past. The estimate of population size may include more than one stock (Kasuya and Miyashita, 1989).

Some animals are known to be caught in gillnets off central *Peru* (Read *et al.*, 1988). This stock is of the coastal subspecies of the spotted dolphin that ranges from Mexico to Peru and is killed in the tuna purse-seine fishery in small numbers (Perrin *et al.*, 1985). The abundance was estimated as 36,000 in 1989 (Gerrodette and Wade, 1991).

S. clymene (clymene dolphin)

For the *Caribbean*, Vidal reported an animal killed off Venezuela.

S. coeruleoalba (striped dolphin)

Notarbartolo di Sciara reported that in the *Mediterranean*, large numbers were killed in the recently-banned driftnet fishery. Other sources of mortality include purse-seines, longlines, trawls, harpoons and gunshot (SC/O90/G34) and a recent mass die-off due to unknown causes.

For the *eastern North Atlantic*, mortality was reported by Duguy and Hussenot (1982) and in SC/O90/G35.

In the *western North Atlantic*, four striped dolphins were observed killed during 1989 in the swordfish driftnet fishery conducted in northeast US shelf-edge waters (SC/O90/G6). The annual kill has been estimated on the basis of 5–10% of trips observed. The estimate of abundance was reported in Kenney (1990).

In addition to the incidental kill in *coastal Sri Lanka*, there may be a small directed harpoon fishery (Leatherwood and Reeves, 1989). Leatherwood reported that there are probably additional takes in the large-mesh gillnet and Taiwanese driftnet fisheries in the Indian Ocean.

In *coastal Japan* and the *western North Pacific*, incidental mortality occurs in the gillnet fishery (SC/O90/G8) and possibly in the large-mesh gillnet fishery (SC/O90/G52). Until the 1960s, the drive fishery killed 15–30,000 each year. The level has gradually declined to 2–5,000 (Kasuya and Miyashita, 1989).

S. frontalis (Atlantic spotted dolphin)

In the *western North Atlantic*, this species is killed in the swordfish driftnet fishery in US shelf-edge waters (SC/O90/G6). The annual kill has been estimated on the basis of 5–10% of trips observed.

For the *Caribbean*, some mortality has been reported off Venezuela (SC/O90/G7).

Mortality in the *Brazil region* was reported in SC/O90/G26.

S. longirostris (spinner dolphin)

For the *Caribbean*, Vidal reported an animal killed in passive gear off Venezuela. A directed fishery occurred in the past (Caldwell and Caldwell, 1975) that may still be active.

This species is killed in large numbers in *Sri Lanka* (Leatherwood and Reeves, 1989). Observations of fisheries in Sri Lanka suggest that even larger numbers may be killed in gillnets when all regions of the northern Indian Ocean are considered. A small harpoon fishery also exists. Mortality in Taiwanese driftnets is likely. This dolphin may be the most common species in the northern Indian Ocean, but the cumulative impact of the various fisheries may be dangerously high.

A dwarf form of spinner dolphin is killed in waters of *Thailand* (Perrin *et al.*, 1989).

In *other northern Indian Ocean* areas, this species is killed in Bangladesh, India and Oman, but the levels of mortality are unknown (SC/O90/G12; SC/O90/G22; SC/O90/G30).

In *Australasia*, this species is one of several killed in Taiwanese drift gillnets off the coast of northeast and northwest Australia (Harwood *et al.*, 1984; Harwood and Hembree, 1987). From 1981–1985, an annual mortality of about 1,000 animals was estimated on the basis of an observer programme. Significant declines in cetacean catch rate with both time and increasing cumulative effort occurred from 1981–83. Similar analyses for 1984–85 were not done because of changes in observer coverage, fishing methods and area of operation. This fishery has since moved into waters of Papua New Guinea and Indonesia (Liu, 1989), probably eliminating the fishery as a source of additional mortality in coastal waters of Australia but inflicting mortality on animals in nearby waters that probably constitute the same population. Estimates of total incidental take are probably low.

Mortality in the *Philippines* is reported in SC/O90/G29.

Steno bredanensis (rough-toothed dolphin)

The occurrence of incidental mortality in the *Mediterranean* is reported in SC/O90/G34. Notarbartolo di Sciara reported that this species is an occasional visitor to the Mediterranean.

Incidental mortality for the *Brazil region* is reported in SC/O90/G26.

Low numbers are killed in gillnets in *coastal Sri Lanka* (Leatherwood and Reeves, 1989).

In *coastal Japan*, some dolphins are killed in Japanese trap nets (SC/O90/G36). They are occasionally killed in Japanese drive fisheries.

Tursiops truncatus (bottlenose dolphin)

For the *Mediterranean*, Notobartolo di Sciara reported that mortality occurs in drift gillnets, longlines and trawls and by harpoon and gunshot. The abundance estimate was based on a series of research cruises. See the explanation of the abundance estimate in annotation section I (above).

In the *offshore western North Atlantic*, mortality has occurred in the swordfish driftnet fishery operating at the shelf-edge of the northeast US (SC/O90/G6). During August–November 1989, 10 offshore bottlenose dolphins were observed killed. The estimated kill represents an adjusted number for a maximum of the 5–10% of the trips observed, as reported by Waring and Payne. Abundance estimates are reported in Kenney (1990).

In the *coastal areas of the western North Atlantic*, a die-off of bottlenose dolphins occurred along the US Atlantic coastline during 1987–88 (Scott *et al.*, 1988). From June 1987 through June 1988, over 700 dolphins stranded from New Jersey south to Florida. Scott *et al.* (1988) suggested that the coastal form was reduced by as much as 53% and, assuming a constant rate of mortality equal to pre-epidemic estimates, the average expected recovery time for this population while sustaining human-induced mortality is greater than 100 years.

Few direct reports are available for the incidental kill in the *Gulf of Mexico*. Interviews with fishermen and examination of stranded animals suggested that in some areas up to 1% of local populations may be taken each year (Reynolds, 1985; Burn and Scott, 1988). Bottlenose dolphins in this region are also removed by live capture. Burn and Scott (1988) summarised stranding data for the southeastern USA and found that human-related mortality may range as high as 7% of all observed mortality in the region.

Mortality in the *Caribbean* is reported in SC/O90/G7.

In *Uruguay*, bottlenose dolphins are killed incidentally in the catfish fishery but reportedly 'cooperate' with mullet fishermen (Simões-Lopes, 1991). Mortality in Uruguay is reported in SC/O90/G1.

Mortality for *coastal West Africa* is reported in SC/O90/G5.

The population along the south coast of Natal, South Africa, may be unable to sustain the level of incidental take in shark nets and may be declining. Most of the kill comprises lactating females and their calves (Cockcroft, 1990; Cockcroft and Ross, 1991). The population along the north coast of Natal may also be adversely affected by the level of shark-net catches, and (as for the south coast) most of the kill comprises lactating females and their calves (Cockcroft, 1990; Cockcroft and Ross, 1991). In addition, studies have shown that the population may be suffering further impact from the high levels of pollutants (Cockcroft *et al.*, 1990).

Mortality in *Sri Lanka* alone is estimated to be over 500 annually (Leatherwood and Reeves, 1989). Observations of fisheries in Sri Lanka suggest that large numbers of this species may be killed in gillnets when all regions of the northern Indian Ocean are considered.

In the *northern and western Indian Ocean*, incidental mortality of coastal forms also occurs in gill nets along the east coast of Africa (Mozambique, Madagascar) and the northern Indian Ocean (e.g. Thailand, Pakistan). Information is given in Leatherwood and Reeves (1989)

and SC/O90/G12, G20, G22, G26 and G30. Local populations may have become depleted in many of these areas.

In *Australasia*, this species is one of several killed in Taiwanese drift gillnets off the coast of northeast and northwest Australia (Harwood *et al.*, 1984; Harwood and Hembree, 1987). From 1981–1985, an annual mortality of about 1,700 animals was estimated on the basis of an observer programme. Significant declines in cetacean catch rate with both time and increasing cumulative effort occurred from 1981–83. Similar analyses for 1984–85 were not done because of changes in observer coverage, fishing methods and area of operation. This fishery has since moved into waters of Papua New Guinea and Indonesia (Liu, 1989), probably eliminating the fishery as a source of additional mortality in coastal waters of Australia but inflicting mortality on animals in nearby waters that probably constitute the same population. Estimates of total incidental take are probably low. Other incidental catches include observed annual catches of up to an average of 25 from shark nets around Australia (that estimate includes four species of dolphins – Paterson, 1990). Anderson reported that inshore set nets probably kill a few per year and that some (<10) may be killed in the shark/tuna/mackerel driftnet in the Northwest Territory. The inshore population is probably vulnerable in some areas.

In the *western North Pacific and coastal Japan*, incidental kill occurs in trap nets (SC/O90/G36) and in research operations using large-mesh gillnets (SC/O90/G52). A direct kill occurs by Japanese harpoon and drive fisheries (Kasuya and Miyashita, 1989). The estimate of population size is only for the East China Sea–Sea of Japan area (Miyashita, 1986).

In *coastal California and the Gulf of California*, two stocks are currently recognized (Walker, 1981). The stock structure of the incidental kill is unknown, however, making it difficult to assess the impact of local mortality. Abundance in California was estimated by Hansen (1990). Sources and levels of mortality are discussed in SC/O90/G7, G24 and G28.

Inshore and offshore stocks exist along the *Pacific coast of South America*. Incidental mortality occurs in the artisanal drift gillnet fishery which takes animals mainly from the offshore stock. The estimates of kill are based on observations made in the port of Pucusana only (Read *et al.*, 1988; SC/O90/G54).

FAMILY ZIPHIIDAE

Ziphiids (unidentified beaked whales)

The 19 nominal species in this family are often difficult to identify in the field, especially for untrained observers. This difficulty is compounded by the fact that, due to their size, entangled animals are usually cut adrift from nets rather than hauled aboard. This lack of species identification is a problem in determining the impact of fisheries.

Berardius arnuxii (Arnoux's beaked whale)

Information is given in SC/O90/G52.

B. bairdii (Baird's beaked whale)

This species is taken in a direct fishery off Japan. The number taken is controlled by a Japanese quota that has ranged from 40 to 57 animals annually. Ohsumi (1975)

documented the kill of Baird's beaked whale in Japanese high seas salmon drift gillnets. Miyashita (1990) estimated population size.

Hyperoodon ampullatus (northern bottlenose whale)

Although there are few documented cases of entangled bottlenose whales, this species was subjected to heavy exploitation in a direct fishery. The species was provisionally listed as a Protected Stock by the IWC in 1977.

H. planifrons (southern bottlenose whale)

Although no absolute abundance estimates are available, this species seems to be the most abundant beaked whale species in sub-Antarctic and Antarctic waters (Kasamatsu *et al.*, 1988).

Pygmy beaked whale (unidentified mesoplodont)

This group of 13 species is extremely difficult to identify in the field. In two regions, the western North Atlantic and coastal Sri Lanka, kills of pygmy beaked whale are potentially high. In addition, the Sri Lankan data probably underestimate the kill of all ziphiids as the catch must be brought ashore in small boats to be counted in the fish markets. Only calves or small juvenile animals are represented in the estimates. Without identification, the most conservative approach would be to assume that all the kills in each region are from only one species.

In the *western North Atlantic*, 12 mesoplodonts of unknown species were observed killed during 1989 in the swordfish drift gillnet fishery conducted in northeast US shelf-edge waters. The total kill presented in the Table has been estimated on the basis of 5–10% of fishing trips observed during 1989.

Information for *coastal Sri Lanka* is reported in Leatherwood and Reeves (1989).

M. carlhubbsi (Hubbs' beaked whale)

Information for the *eastern North Pacific* is reported in SC/O90/G24 and G28.

M. densirostris (Blainville's beaked whale)

Information for *coastal Sri Lanka* is reported in Leatherwood and Reeves (1989).

M. peruvianus (lesser beaked whale)

This new species of beaked whale was described from specimens killed in gillnets along the coast of Peru (Reyes *et al.*, 1991).

Ziphius cavirostris (Cuvier's beaked whale)

Notarbartolo di Sciara reported that this species is taken in gillnets in the *Mediterranean*.

Information for *coastal Sri Lanka* is reported in Leatherwood and Reeves (1989).

In the *western North Pacific*, Kasuya and Miyashita reported that carcasses of this species were sighted during the Japanese sighting cruises. Miyashita also confirmed a carcass entangled in a monofilament gillnet.

Information for the *eastern North Pacific* is reported in SC/O90/G24.

FAMILY PHYSETERIDAE

Physeter macrocephalus (sperm whale)

Notarbartolo di Sciara reported that the stock structure in the *Mediterranean* is unknown. If this population represents a separate stock from the North Atlantic, then

the kills of sperm whales may not be sustainable. However, it is likely that the small numbers of sperm whales in the Mediterranean represents part of some larger North Atlantic stock that migrates in and out of this sea. If the latter scenario is correct, then the kills in swordfish driftnets represent a smaller impact to this population of sperm whales.

Information for *coastal Sri Lanka* is reported in Leatherwood and Reeves (1989).

Information for the *eastern North Pacific* is reported in SC/O90/G11, Perrin (1990) and Darling (1988).

Kogia sp. (unidentified kogiid)

These two closely related species are difficult to identify in the field (Ross, 1984). Because of this, incidental kills are sometimes only identified to genus.

In the *central North Pacific*, an unidentified kogiid was reported killed in the Japanese driftnet fishery by Omura *et al.* (1984).

Kogia breviceps (pygmy sperm whale)

Information for the *Caribbean coast of Colombia* is reported in SC/O90/G7.

Information for *coastal Brazil* is reported in Caldwell and Caldwell (1989) and SC/O90/G26.

Information for *coastal Sri Lanka* is reported in Leatherwood and Reeves (1989).

Kasuya reported that this species has been taken in Japanese squid gillnets in the *North Pacific*.

Kogia simus (dwarf sperm whale)

Information for *coastal Brazil* is reported in Caldwell and Caldwell (1989) and SC/O90/G26.

Information for *coastal Sri Lanka* is reported in Leatherwood and Reeves (1989).

Information for *coastal Peru* is reported in Van Waerebeek and Reyes (1990a).

6. CAUSES AND SOLUTIONS

Lien chaired the sub-group reviewing causes of entanglement and possible solutions. Donovan acted as rapporteur with assistance from Lien. The sub-group agreed to review the following topics:

- (1) behaviour and sensory abilities;
 - (2) modifications to existing fishing gear; and
 - (3) alternative technology and management;
- making use of the meeting documents and information furnished directly by the participants and from the published literature.

6.1 Sensory abilities – thresholds and detection

The sub-group agreed that under this section of its report it would concentrate on the physiological thresholds and sensory capabilities of cetaceans. The relevance of this information to possible solutions to the fishing gear entanglement problem is discussed further under Item 6.6, although inevitably some aspects are discussed here also.

6.1.1 Acoustics

The acoustic capabilities of cetaceans have probably been better studied than other sensory capabilities they have (e.g. see review in Watkins and Wartzok, 1985). Details are not presented here. Several papers were available that provided information on the detection on nets by odontocetes using echolocations (SC/O90/G9, G15; Au,

1990; Au and Jones, 1991) and on echolocation in general (SC/O90/G13, G16, G17). Table 2 shows, for some species, the theoretical echolocation detection ranges for monofilament gillnet used in the North Pacific salmon mothership fishery and for polyester rope/metallic bead chain. Bubbles created by high sea states (see Item 4.2.6) will decrease these detection ranges. Table 2 and field observations (SC/O90/G9) indicate that dolphins are able to detect the monofilament section of gillnets at sufficient ranges to avoid entanglement. Gillnets modified by added gear such as rope and metallic bead chain should be detected at considerably greater distances than unmodified gillnet. However, experiments with such modification added to increase sonar detection have not been successful in reducing entanglements (e.g. SC/O90/G13, G15, see also Annex E). Possible reasons why dolphins are still being entangled in modified and unmodified nets despite their acoustic capabilities are summarised below. They are discussed in more detail under the indicated report items.

Table 2

Theoretical 90% probability of detection ranges as a function of biosonar source level, based on bottlenose dolphin biosonar performance data, for sea states 0-3 (Au, pers. comm.)

Peak-to-peak source level (dB re 1µPa)	Monofilament gillnet ¹	Polyrope ²	Metallic bead chain ³
150	2.2m	8.9m	7.3m
160	4.0m	15.9m	13.0m
170	7.1m	28.2m	23.0m
180	12.6m	50.1m	41.0m
190	22.4m	89.1m	72.9m
200	39.8m	158.5m	129.6m

¹ 0.49mm diameter nylon monofilament, 10cm mesh size; ² 0.635cm twisted polyester rope; ³ household light switch chain.

- (1) Dolphins may not echolocate all the time. Some species such as Hector’s dolphin often do not echolocate when navigating in a familiar environment (Dawson, 1988) and may echolocate only when foraging for food (SC/O90/G16). However, Norris reported that there is a school phenomenon with some pelagic dolphins whereby a number of individuals in a school are always echolocating.
- (2) Dolphins may detect a gillnet but may not perceive the net as a barrier. Barriers may be totally alien to pelagic dolphins accustomed to roaming freely in the ocean and they may not have evolved behaviour patterns to deal with them (see Item 6.2.2). The diffuse echoes from nets (SC/O90/G15) may resemble a penetrable volume such as the deep scattering layer or kelp and other seaweed.
- (3) Dolphins may be foraging for food in the vicinity of nets and be oblivious to nets and other obstacles while focusing their attention on prey (see Items 6.1.2 and 6.2.1). Attention to social activity such as play or competitive behaviour may also distract them (see Item 6.3).
- (4) There are indications that dolphins are attracted to nets either by the presence of entangled fish or the presence of prey congregated near the nets (see Item 6.2.1). Some dolphins may be caught through ‘carelessness’ or inattention when around nets (see Item 6.3.2). Dolphins, especially young and inexperienced ones, may be attracted to nets as novel objects to explore and play with.

- (5) Sleep, especially at night when most dolphin entanglement seems to occur, may be a factor in the non-detection of nets (see Item 6.2.2). However, as noted above in some schools of pelagic dolphins it seems that a number are always awake.

It should be also be noted that fishing gear emits noise that might be detected by cetaceans (see Item 6.5.2). The ‘self noise’ generated by water movement through a set net or by wave action pulling at surface float lines may be very loud, louder than the returning echoes produced from the dolphins, echolocating signals (Lien *et al.*, 1990). The acoustic energy is low frequency and large cetaceans with good low frequency hearing may be better able to take advantage of gear noise than small cetaceans that do not typically have good low frequency hearing. Detection and localisation of nets by passive hearing (i.e. when the animals are not echolocating) will be less precise than by echolocation.

The sub-group agreed to the following recommendations for future research:

- (1) determine the sonar detection capabilities of some of the smaller odontocetes such as Dall’s porpoise, harbour porpoise, Commerson’s dolphin and Hector’s dolphin;
- (2) perform research to understand the acoustic and behavioural dynamics involved with dolphin-gillnet interaction and with fish-gillnet interaction, to determine why and how dolphins get entangled and the proportion of a pod or school of dolphins that typically gets entangled;
- (3) determine the amount of self-noise in nets for different sea states for surface nets and current conditions for bottom set nets, and compare fish and dolphin entanglement with sea state conditions (see Item 6.2.6).

6.1.2 Prey size/ target strength

SC/O90/G16 examined the acoustic behaviour of a wild bottlenose dolphin during foraging. Slowest sonar click rates corresponded to maximum search range and may be related to the detection of preferred prey size and effort to capture. The dolphin was insensitive to secondary echoes from ranges beyond those defined by the click rate. Sonar click rate also varied inversely with the dolphin-prey closure range, becoming higher as the closure range decreased.

6.1.3 Vision

In addition to echolocation and hearing, vision is important to many cetaceans. Cetaceans have excellent underwater vision (e.g. Dawson, 1980; Watkins and Wartzok, 1985). It is important to understand the characteristics of cetacean eyes in order to assess the visual problems they may face in dealing with nets. One tends to think of dolphins as echolocating animals, forgetting that they may sometimes carry out much of their behaviour wholly without phonation, especially in times of danger. Baleen whales are not known to orient by echoes, although the possibility of such a capability should not be discounted (Lien, 1987). They can orient in very murky water and over considerable distances in conditions when vision would not seem to serve them well (Lien, 1980). Listening to the sounds produced by objects themselves may be the basis for detection (Lien *et al.*, 1990) but the possible use of vision cannot be eliminated.

Vision is important to cetacean orientation and it appears to mediate some aspects of the schooling of dolphins; manoeuvring may be related to pattern marks and their movement across the visual field of adjacent animals. Such patterns are best developed in clear water cetaceans and are reduced to whole-body flash signalling in murky water animals (Madsen and Herman, 1980; Norris and Dohl, 1980; Norris *et al.*, 1985). In the dark, bioluminescence is certain to be important, especially in the visualisation of moving nets. Cetacean eyes are especially adapted for low light levels (e.g. Herman *et al.*, 1975). They are amongst the few mammalian species in which the optic cup is fully tapetalised over its entire area (Dawson *et al.*, 1987a; 1987b). Their eyes are also able to deal with the extremely difficult visual environment of the surface sea, where the flicker effect may reverse intensities many times a minute, sometimes reaching peaks at several times the intensity of direct sunlight.

Most evidence suggests an almost or total lack of colour vision in cetaceans, although the highest sensitivity of the retina in coastal species is centred in the blue to yellow green, while that of open sea species emphasises the blue (Madsen and Herman, 1980).

For these reasons the visibility of nets may provide important orientation signals during both night and day and even in rather murky water. The question of diurnal variation is discussed under Item 6.2.2.

As in the case of acoustic perception of nets, there are many behavioural observations indicating that cetacean species *can* perceive nets using sight (e.g. bottlenose and hump-backed dolphins off Natal: Cockcroft, 1990; Dall's porpoises in the high sea: SC/O90/G9; humpback whales off Newfoundland: Lien, 1980). The potential reasons why entanglement still occurs are similar to those listed above in Item 6.1.1.

6.1.4 Other

The sub-group agreed that acoustics (hearing/echolocation) and vision were the most important sensory capabilities of cetaceans with respect to the entanglement problem. However, the other senses may also play some role and they are reviewed briefly below. It should be noted that little direct evidence of their role is available.

MECHANICAL

Mechanical senses include touch, pressure, position, acceleration and vibration sensing. The anatomy of many of these receptors is reviewed in SC/O90/G18. The author concludes that in general cetaceans appear well-equipped to sense the mechanical aspects of their surroundings and that this may include an ability to follow currents in the water. This is of some interest in the light of a review of environmental factors and entanglement of bottlenose and hump-backed dolphins off the Natal coast of South Africa by Cockcroft (1990). He found that current direction on the day of capture was often different from the normally prevailing direction. No correlation between entanglement and fullness of stomach was found, suggesting that it is not simply a function of dolphins following prey species that may be influenced by the currents.

Clearly, mechanical senses will detect the gear itself only when the animals come into contact with it, by which time entanglement may have already occurred. However, since nets may be set either with or across currents, analysis of entanglements with respect to orientation of the nets and current direction may be useful.

THERMAL

The anatomy and physiology of thermal control are reviewed in SC/O90/G18. The ranges and/or seasonal distribution of many cetacean species can be described with reference to surface isotherms or to the temperature characteristics of particular water masses. The range of temperatures at which most cold-blooded prey species can live tends to be narrow, in comparison with the ranges which cetacean species can tolerate. Water surface temperature and temperatures at specific depths are sometimes used to locate fishery target species (e.g. SC/O90/G14 – swordfish fishery; SC/O90/G8 – flying squid fishery).

All cetaceans have the means to sense environmental temperature and at least some fishing gear is set in relation to water temperature. If cetaceans follow temperature gradients as a travel cue or as a guide to prey, they could be brought into collision with nets set across the travel path. This possibility requires investigation.

CHEMORECEPTORS

The anatomy of chemoreceptors and the experimental investigation of chemoreception is reviewed in SC/O90/G18. Chemoreception may provide social information (e.g. reproductive state, alarm), directional information (e.g. following salinity gradients) or foraging information (e.g. detecting the excreta of prey). Evidence for this is at present anecdotal and further research is needed to establish the true role of chemoreception in the life of cetaceans.

Natural history literature often refers to the presence of blood in the water as an 'alarm' substance. Italian fishermen reportedly throw back carcasses of incidentally killed dolphins, believing that this will deter other animals. Lien (1980) reported that fresh humpback blood did not prevent another humpback whale getting caught in a set net off Newfoundland. Hawaiian fishermen were unsuccessful in discouraging bait stealing by dolphins (including bottlenose and rough-toothed dolphins and pygmy and false killer whales) by lacing the bait with quinine. However, bottlenose dolphins readily eat fish containing quinine in captivity so perhaps this is not surprising (Schallenger, 1979).

Myrick (1988) reported that spotted dolphins chased and set upon by purse-seiners are hypocalcaemic, a common stress reaction in other mammals. A further characteristic of stress in mammals is the presence of chemicals in the urine that may constitute an 'alarm' substance. Kleinenberg *et al.* (1964) report an incident of an unmolested group of white whales fleeing when they reached an area where an earlier group had fled due to the presence of hunters. This could be indicative of an alarm substance.

Fishing gear has its own chemical characteristics, as do target and non-target species caught in that gear. Lien reported that older Newfoundland fishermen relate that there were fewer collisions by animals with cotton and hemp nets that were dipped in oily tar; they believed that animals such as whales and seals could smell them. Chemoreception may play some role in entanglements either due to stimulants provided by gear, prey species or conspecifics, but considerable research is needed to determine this and investigate the possibility of developing effective chemical 'deterrents'.

MAGNETIC AND ELECTRICAL

SC/O90/G18 reviews magnetic and electrical detection by cetaceans. Behavioural evidence suggests that cetaceans may be able to sense the flux density of the earth's magnetic field as a travel guide, generally swimming parallel to the contours (i.e. in areas with low field gradient). Beaches where strandings and drive fisheries for long-finned pilot whales have taken place tend to have perpendicular magnetic contours. Travelling (but not feeding) fin whales have been shown to use magnetic contours as a travel guide, based on data from the UK, Ireland and USA east coast. There is also some evidence for a 'travel clock' re-set by geomagnetic information and used in monitoring position and progress (Kirschvink, 1990; Klinowska, 1990).

While it seems unlikely that gear itself would provide any magnetic information, it is not inconceivable that cetaceans following magnetic contours could be brought into collision with gear deployed across these contours. In such situations gear could be re-oriented to align with cetacean movement.

6.2 Environmental/ecological correlates

6.2.1 Food

Entanglements may occur where: the target species are prey or potential prey for cetaceans; the fish caught are not prey species but cetaceans are attracted to the nets because other potential prey are associated with the net; the target and incidental species are seeking similar prey; or the cetaceans and fisheries occur in the same vicinity for reasons related to physiography and biological productivity.

(1) SITUATIONS IN WHICH MARINE MAMMALS ATTEMPT TO REMOVE PREY FROM NETS

There is evidence from some fisheries that marine mammals attempt to remove prey from nets. This includes harbour porpoises in the North Atlantic (e.g. SC/O90/G46; SC/O90/G8; Read and Gaskin, 1988). Lien (1994) reported that in Newfoundland, long-finned pilot whales intentionally frequent traps to remove the target species of squid (*Illex illecebrosus*). There are no reports of such behaviour in baleen whales. Many pinniped species are known to actively and efficiently remove prey from nets and traps (e.g. see Beddington *et al.*, 1985).

(2) SITUATIONS IN WHICH MARINE MAMMALS ARE NEAR NETS, BUT DO NOT REMOVE PREY FROM THE NETS

Nets may serve as attractants which lure fish and other animals to the area of the net; nets are known to have a 'calling area'. The use of fish attracting devices (FADS) is a technique whereby objects are installed which serve as the focus for the establishment of a marine community. Prado reported that FADS are known to draw in fish from distances of 4–5 n.miles. Cetaceans may be attracted to nets in a similar manner, or may respond to prey species which react in this way.

Marine mammals may also be attracted to scavengers feeding on fish in the nets.

Another possibility is that target and non-target species have similar prey items or are linked in some way through the food web. This is probably common in many situations e.g. *Tursiops* in South African shark nets (Cockcroft, 1990; SC/O90/G20), Dall's porpoises in salmon driftnets reported by Jones), harbour porpoises in the halibut fishery and vaquitas in the totoaba fishery.

In some cases marine mammals, for example humpback whales in Newfoundland, use nets as a backdrop to corral fish (Lien, 1980). Minke whales may be attracted to nets by the scrapefish discarded by fishermen as they clean their gear (Lien, 1994).

In many cases nets are set in areas of high biological productivity and as a result both target species and mammals are present.

6.2.2 Physical conditions

DIURNAL CYCLES

Diurnal behaviour patterns may be considered with regard to the timing of net sets, the soak time and the behaviour of both target and non-target species.

Like most organisms, cetaceans have specific diurnal patterns and cycles (e.g. Klinowska, 1980). These cycles may contribute to the likelihood of entanglement. Some species may travel considerable distances on a daily basis. Diurnal travel patterns may increase the likelihood of encountering nets, and travel may be associated with food sources, migration or other factors such as tides and currents (Klinowska, 1980).

Many diurnal cycles are linked closely to prey behaviour. One of the most obvious is the daily vertical migration of the deep scattering layer (DSL). Linkage to the DSL is probably strong in most oceanic species, notably *Stenella longirostris* (Norris *et al.*, 1985).

Some cetaceans descend to rest, sleep or reduce their activity during parts of the day. This behaviour may increase the chances of entanglement due to decreased awareness of surroundings, but it also reduces travel and the probability of encountering a net. Some species have a general tendency toward increasing group size later in the day (Norris and Dohl, 1980; Scott *et al.*, 1990) and large groups may have a greater ability to detect threats such as nets. Some cetaceans are active at dawn and dusk, when low or changing light levels may decrease the likelihood of net detection, although as noted under Item 6.1.3, cetacean vision is good in low light.

The diurnal behaviour patterns of target and incidental species are probably closely linked. However, in fisheries where this is not the case it may be possible to reduce entanglement rates while concurrently maintaining catch levels by adjusting the timing of gear setting and soak durations.

TURBIDITY

This is potentially an important factor if vision is the major sense used by the cetacean to detect fishing gear. There is little direct information of the effect of turbidity on entanglement rates of cetaceans. The only attempt at a quantitative study is that described by Cockcroft and Ross (1991) for dolphins caught in shark nets off the Natal coast of South Africa. Nets are examined daily and so turbidity on the day of capture is known but turbidity at the precise time of capture is not.

Cockcroft found that animals were caught at all levels of turbidity, although at one location near a river mouth where the water visibility was <1m, hump-backed but not bottlenose dolphins were caught. This is thought to reflect the fact that bottlenose dolphins tend to avoid turbid water off that coast while hump-backed dolphins are often associated with riverine conditions (e.g. Ross, 1977; Norris *et al.*, 1985). Turbidity may also be a factor in the seasonal changes in distribution of bottlenose dolphins off the coast (Cockcroft, 1990).

Visual characteristics of fishing gear, including brightness, colour and size, were found to be less important than turbidity in determining distances at which gear could be visually detected (Lien, 1980).

AMBIENT NOISE

Ambient noise could be an important factor as it has the potential for making gear less acoustically detectable. Again, almost no quantitative information exists on entanglement rates at different levels of ambient noise. In the Cockcroft (1990) study off Natal, no direct measure of ambient noise was available. However, the author looked at swell height and depth of net as some indication of likely ambient noise and found no significant correlation with entanglement rate, although he noted the paucity of data. Lien *et al.* (1990) suggest that high risk areas for entrapments of humpback whales may be characterised by high levels of ambient noise.

Ambient noise may be a factor in entanglements for certain fisheries and species. However, this cannot be determined without carefully designed experiments. Until these are completed it will be impossible to consider ambient noise when trying to develop possible modifications to fishing practice or gear which may help to reduce entanglement problems.

TIDES AND CURRENTS

Tides and currents are known to affect the distribution of some cetacean species in certain areas (e.g. Würsig and Würsig, 1979), probably by influencing the distribution of prey species. Again there is almost no direct information on the influence of either tide or currents on entanglement rates of cetaceans. In the Cockcroft (1990) study off Natal, however, there was a significant correlation between current direction and entanglement rate, with most captures occurring when the current direction was northerly. The reason for this is unclear.

Tides and currents may be a factor in entanglements for certain fisheries and species. However, as for the other factors discussed, without carefully designed experiments it will be impossible to try to develop possible modifications to fishing practice or gear which may help to reduce entanglement problems. This is discussed further under Items 6.1.4 and 6.3.3.

DEPTH

This is clearly an important factor in some entanglement situations. Different cetacean species spend differing amounts of time at different depths depending on their feeding strategy and whether they are travelling, etc. The depths at which fishermen set their nets depends on the target species and the type of gear. The potential for deploying nets at depths less likely to cause potential contact with cetaceans is high for some fisheries. Experiments along those lines have already been carried out with some degree of success (SC/O90/G58; Harwood and Hembree, 1987). These are discussed further under Item 6.2.2.

SEA STATE AND BUBBLES

The surface sea is often turbulent and waves can drive plumes of bubbles into the water for several meters. Such bubble plumes will probably be largely opaque to echolocating cetaceans. The bubbles can be divided into three categories: (1) tiny bubbles that quickly dissolve; (2) mid-range bubbles that may develop films over their surfaces that can cause them to persist for long periods; and

(3) larger bubbles whose greater hydrostatic lift causes them to rise quickly to the surface.

The mid-sized bubbles can be very persistent, remaining in the upper sea water column for a matter of hours. They are also of a range of diameters that form excellent echolocation reflectors (*ca* 60 microns and above) and may appear as much as seven times their actual size to an echolocating animal. This means that the surface sea, especially during times of rough weather, can completely obscure the echolocation trains of dolphins. Translated to the driftnet problem this could mean that in the upper few meters of the sea, bubbles might completely blot out echo returns from nets in the area.

If cetaceans typically swim through such acoustically-opaque water, they could be especially vulnerable to entanglement. Since there are no true obstacles at sea except for occasional floating debris, dolphins may deliberately swim 'blind' through such water, making them especially prone to entanglement. Differential entanglement during various sea states should be examined as part of a preliminary assessment of this question (see Item 6.1.1).

6.3 Behaviour

While we understand some cetacean behaviour, there is much more to know. In particular the behaviour of cetaceans near nets is little studied and poorly understood; there is little systematic knowledge of many behavioural processes which may dispose them to entrapment risk near fishing gear.

6.3.1 Curiosity, exploration

There are few published accounts which describe exploration behaviour of cetaceans (SC/O90/G49) and it is not possible from these studies to infer how cetaceans might react when first encountering fishing gear or what changes these initial encounters may produce in subsequent activities near nets.

Entrapments frequently involve disproportionate numbers of young cetaceans, which may be due to the animals lack of experience with fishing gear. This lack of familiarity may encourage curiosity, exploration or play which could result in entrapment (Cockcroft, 1990; SC/O90/G51). Age-dependent mortality resulting from risky exploration and play activities has been observed in terrestrial animals. Studies of social and play activities have found that they commonly have high costs in terms of injury or predation in young animals (Fagen, 1981). The observed age or sex skew in frequency of entrapments of young cetaceans in some fisheries may be a result of age or sexual segregation in certain species and some increased probability that these groups encounter fishing gear (Cockcroft, 1990).

For small cetaceans in particular, many close encounters with nets result in mortality (Table 3, Item 6.4), with consequently no opportunity for an individual's initial curiosity about nets to change. Observational learning is well documented in odontocetes; entrapment events could result in changes in the behaviour of other animals in a group. Cetaceans may learn to associate nets with negative events. They may also habituate to the novelty of nets as they more frequently encounter them. While this may produce fewer approaches for exploration, close approaches because of lack of attention may occur.

In baleen whales, it is also younger animals that appear to be those most commonly caught in fishing gear. In Newfoundland, entrapments typically involve small

humpbacks (Lien, 1980; Lien, 1994). Humpback collisions with fishing gear appear to result from their failure to detect it; the higher probability of accidents by young animals would appear to reflect 'recklessness' or inexperience.

There is an urgent need for studies to examine the exploratory behaviour of young cetaceans and the role this behaviour may have in producing entrapments in fishing gear.

6.3.2 Attention and perception

Although in some populations the frequency of incidental entrapments by cetaceans is quite high, it is likely that the animals usually detect nets and avoid entrapment (Awbrey *et al.*, 1979; Cockcroft *et al.*, 1990; Hatakeyama, 1986). Generally, it has been assumed that detection of nets is accomplished by their acoustical properties (see Item 6.1.1).

While nets appear to be within dolphins' acoustical detection thresholds (SC/O90/G15; Au, 1990; Au and Jones, 1991), there may be reduced attention to acoustic cues or selective processing of information that is simultaneously being presented while feeding, travelling or resting. Animals may attend to particular stimuli over others both because the ability to process information is limited and through more 'voluntary' control over their attentional capacity (SC/O90/G48).

It is known that dolphins and porpoises may spend large amounts of time during which they produce no echolocation signals. Dawson (1990) found that Hector's dolphin did not echolocate regularly while navigating in a familiar environment. SC/O90/G16 reported that a wild bottlenose dolphin echolocated only when foraging for food. During periods while not echolocating, dolphins may be less capable of detecting nets.

Humpback whales have been observed feeding near fishing nets at night and to avoid becoming entrapped, without vocalising. (Lien, 1980). Collisions with fishing gear by this species in Newfoundland most frequently occur on the first day the gear is placed in the water; probability of a collision with a particular net decreases as soak time increases (Lien, 1988). It appears the animals are 'surprised' by the presence of new fishing gear but, following an encounter, learn its location. Similarly, accidents are most common on the first day whales move into an area where fishing gear has previously been installed; accidents decrease over time (Lien *et al.*, 1990).

Many observations indicate that dolphins are aware of the presence of nets as judged by their swimming behaviour around the gear (e.g. Silber *et al.*, 1994). In some cases the dolphin may perceive the net as a barrier. Tests of terrestrial species that have evolved in circumstances without barriers typically find that these animals have great difficulties learning to solve barrier problems (Maier and Maier, 1970). Fishermen setting on swordfish in the northwest Atlantic leave gaps between nets in a fleet to allow marine mammals to escape; Smolowitz reported that if there are no gaps fishermen feel that animals encountering the net are more likely to get caught.

6.3.3 Orientation

Orientation cues used by an animal can affect the likelihood of entrapment in fishing gear. If travelling, the navigational strategy used by an animal may modify the probability of encountering and detecting fishing gear (see Item 6.1).

According to Keeton (1974), animals generally have redundant navigation systems which are used in a hierarchical order. Little is known of cetacean navigation strategies; the satellite technology which may provide this information is still developing.

Proximate orientation by an animal while near nets may also be a factor in entrapments. If a dolphin echolocates on a fish target near nets, it may have difficulty detecting the net behind it (SC/O90/G17). Depth of field in the echolocation abilities of dolphins is poorly understood (Penner, 1988).

6.3.4 Escape patterns

There are few studies which provide information on escape efforts of small cetaceans when they collide with fishing gear or once they are entrapped in nets (SC/O90/G51; Hatakeyama *et al.*, 1988). The percentage of animals that encounter nets and successfully escape is not known; it is believed that this varies among species (Table 3, Item 6.4). Smaller cetaceans may not escape as often as the larger whales and the nature of the fishing gear and the depth of set may also be important factors.

Anecdotal accounts of observed escapes from fishing gear entrapments vary. Systematic disentanglement of dead animals from nets may provide information on their escape efforts (J. Coe, pers. comm.; Barham *et al.*, 1977). Lien reported that in Newfoundland, monitoring by side scanning sonar and underwater video cameras of fishing gear installed at locations where collisions are frequent may provide information on collisions and escape efforts of humpback whales.

6.3.5 Social patterns

There are important differences in social organisation among species of cetaceans; these differences may result in species being differently vulnerable to entrapment. They will also determine, in part, the effectiveness of efforts to minimise bycatch.

A body of theory (Norris and Dohl, 1980) proposes that schools, such as those of open-ocean dolphins, are sensory integration systems which mediate the behaviour of individual animals in the presence of danger in the three dimensional world of the open sea. Understanding how such cetacean schools communicate and process information may facilitate analysis of behaviour observed during encounters with nets. Norris reported that open ocean dolphins seem to have much difficulty if required to swim in smaller groups, or to pass through escape gates or spaces between nets smaller than will allow the school to pass. In dealing with these species, schools rather than individuals may be the appropriate unit for analysis with respect to the entanglement question. Cetaceans living in more restricted, nearshore habitats tend to travel in smaller groups.

In some cetaceans, the tendency for reciprocal or kin altruism acts (Caldwell and Caldwell, 1966; Conner and Norris, 1982) may contribute to entrapments. Many have reported mothers and young which are captured together in nets (Cockcroft, 1990); in some cases entrapped young have tooth marks on the body which appear to be the result of adult attempts to remove them from the net (Dawson, 1990).

6.3.6 Feeding behaviour

As noted under Item 6.2.1, feeding behaviour by cetaceans may be a significant contributing factor in many entanglements. Animals may be chasing prey species that

are either the target species of the fishery, or others that occur in the same area as the target fishery. In some cases, animals may actually be taking prey species from the net (SC/O90/G2), or they may simply be attracted by entangled fish. Harbour porpoises in the Bay of Fundy feed on hagfish (*Myxine glutinosa*) that are feeding on fish captured in the nets (SC/O90/G6).

There is evidence that the smaller odontocetes are capable of acoustically and visually locating nets and observational data suggesting that free-ranging animals avoid capture in nets (Dawson, 1990; Hatakeyama, 1986; SC/O90/G9, G13, G15 and G20). This information implies that the entanglement problem may be less one of detection capabilities than one of alertness and attention (see Item 5.2). Observations of feeding porpoise and dolphins indicates that high speed chases culminating in prey capture is common in several species. If prey fish attempt to escape by swimming into or through a nearby net, a dolphin predator maybe so focused upon the target of the pursuit that the less salient visual and acoustic signals of a net fail to alert the animal (SC/O90/G17; SC/O90/G48).

For the more gregarious species, an additional confounding feature of feeding behaviour may be the feeding 'frenzy' that occurs in several species of small cetaceans when a school of fish is encountered. Highly active behaviour of a large group of feeding dolphins may reduce visibility or mask cues that would normally alert animals to the presence of nets and may distract normally wary animals in the excitement. Further, large schools of prey species may obscure visual or acoustic cues that would alert cetaceans to the presence of nets.

In the mysticetes, the levels of entanglement involving humpback and right whales in the North Atlantic, gray whales along the Pacific coast of North America and minke whales in the several areas of the Northern Hemisphere suggest that the animals have difficulty detecting the presence of gear, at least under certain conditions, or that they fail to attend properly to the gear while they are feeding or engaged in other activities. Mysticetes are not known to echolocate but from environmental constraints it seems likely that they detect the presence of gear using acoustical cues. Humpbacks in Newfoundland feed on capelin (*Mallosus villosus*) at night in turbid water next to cod traps in complete silence but their behaviour indicates that they can locate fishing gear and avoid it (SC/O90/G51; Lien, 1994).

The feeding lunges of humpback and minke whales and the bubble clouds used by humpbacks in feeding activities may make these animals susceptible to entanglement. In Newfoundland, capelin collect and school densely next to the leaders of cod traps; most collisions by humpbacks are observed to occur with leaders during these times (Lien *et al.*, 1988b). Entrapment of humpback whales is frequently by a net and rope bridle through the mouth, indicating it has been feeding when the collision occurred (Lien, 1980). Right whales may be vulnerable to entanglement while feeding because they engage in long skimming transits with their mouths open; in the northwest Atlantic about 50% exhibit scars in the corners of their mouths which are believed to be the result of fishing gear (Kraus *et al.*, 1984; Kraus, 1990).

6.4 Morphology: anatomy of entrapment

Cetacean entanglement in fishing gear probably occurs in a variety of ways, but there are almost no quantitative data on this. Where detailed reports exist, it appears that the

head, mouth, flippers, dorsal fins and flukes are involved (SC/O90/G1, G2, G8, G25 and G26; Heyning and Lewis, 1990; Lien *et al.*, 1990). In a four year study of 10,259 Dall's porpoise entanglements in the North Pacific salmon driftnet fishery, Snow (1987) found that 27% were caught by the flukes, 10% by the pectoral flippers, 9.5% by the mouth and 24% in a 'complex' fashion. In anecdotal reports, the evidence indicates that the animals strike the net with their rostrum first, then roll themselves up into the net, presumably in the panic following the initial strike. There is one record of a Dall's porpoise breaking and swimming through a drift gillnet in the North Pacific (SC/O90/G9). In the case of many of the larger whales, particularly the mysticetes, lines or nets are caught in the mouth and may end up being carried around for several years (e.g. Kraus, 1990). Animals trailing such gear appear to be at a higher risk for subsequent entanglements (Lien, 1980) and may have a lower survivorship. The barnacles and callosities of humpback, gray and right whales may render these species more susceptible to entanglement (Lien, 1994).

The level of mortality associated with observed entanglements appears to be related to the size of the animal, although other factors such as gear type, mesh size and proximity to the surface, may also affect mortality rates. Small cetaceans suffer extremely high mortality from gillnets, but lesser mortality from encounters with weirs or seines (unless, as in the eastern tropical Pacific, deliberately captured in the purse seines). Larger animals tend to escape from most gillnets, probably because the gear is not strong enough to contain them, but in fisheries with heavier gear (e.g. cod traps or weirs), larger whales usually require assistance to escape.

Information on entanglement/mortality rates has two significant gaps: (1) animals may be entangled but escape carrying gear and/or injuries, thus lowering their probability of survival and (2) animals may strike the fishing gear and 'bounce' off without becoming entangled. Both possibilities will lead to undercounting cetacean/fishing gear encounters. Scarring indicating prior entanglement events and animals carrying gear have been reported in right whales (Kraus, 1990) and humpbacks (Lien, pers. comm.). About 4 to 5 times as many holes (presumably made by whales) as whales have been reported in nets by fishermen in Newfoundland and California (Lien, 1980, reported by Lagrange).

If animals escape entanglements but are carrying gear that subsequently affects survival, then the lethal effects of entanglements will be underestimated. Alternatively, if animals are bouncing off gear without any adverse effects, then the degree of mortality from net encounters will be overestimated. Given these caveats, data on survivorship from observed entanglements are presented in Table 3.

6.5 Types of gillnet and marine mammal bycatch risk

It is important that in the description of gillnet fisheries (as for any other) and in reports on research and experiments, the specifications of the gillnet or other gear used are complete and unambiguous. The lack of such information will preclude understanding of the true situation and comparison among experiments. Annex F presents guidelines for the correct description of gillnets.

Different types of gillnet are involved with entanglement of different cetacean species under different conditions. Entanglement problems should be considered case by case,

Table 3

Mortality in observed entanglements of cetaceans. These data do not include records of animals that struck gear but did not become entangled or those that became entangled and then escaped.

Species	Location	Year	Type of gear used	n	Mortality	Source
Harbour porpoise	Gulf of Maine	1975-89	Gillnet, bottom or midwater	71	99%	SC/O90/G6
Harbour porpoise	Baltic Sea	1988-89	Gillnet, bottom or midwater	70	100%	SC/O90/G25

considering the characteristics of the particular fishery, as well as the characteristics and behaviour of the susceptible cetacean species.

6.5.1 Bottom gillnets

Gillnets set on the bottom in coastal waters from nearshore areas to depths of around 200m are commonly used to catch demersal fish. Although they have been shown to entangle several cetacean species, the most critical problem area currently appears to involve coastal bottom-feeding small cetacean species such as the harbour porpoise. These species may be more susceptible to mortality in gillnets than larger cetaceans because they are less able to escape by breaking the gear. Other factors which may be involved in coastal bottom gillnet entanglements include:

- (i) turbid water;
- (ii) shared prey species (herring, mackerel, etc.);
- (iii) depth of net relative to depth of water (in very shallow places);
- (iv) long net soak time, in some cases;
- (v) proximity to shore;
- (vi) acoustically complex environment;
- (vii) strong construction.

Relevant characteristics of the small cetacean species involved include their general tendency to stay in relatively small groups and use echolocation more than the open ocean species.

6.5.2 Bottom driftnets

The use of coastal bottom driftnets, particularly for shrimp, has increased tremendously during the past ten years. This technology sometimes gives artisanal fishermen access to a valuable resource. Although a small scale fishing method, the aggregate quantity of gear in the water in a given area may be substantial. Reliable information from such fisheries is not available but cetacean mortality may not occur at a high rate, possibly due to the following factors:

- (i) the relatively short soak times (commonly 15–120 minutes);
- (ii) continuous monitoring of the condition of the gear;

- (iii) the acoustically ‘noisy’ character of nets drifting on the bottom;
- (iv) the relatively small mesh size of shrimp driftnets (65–80mm stretched);
- (v) the depth of the net relative to depth of water in shallow places.

6.5.3 Coastal drifting midwater or surface gillnets

Coastal drifting midwater or surface gillnets are used to catch salmon, mackerel, sardine, herring, etc. They are also known to take cetaceans, and relevant factors may include:

- (i) the depth of net relative to the depth of water (in very shallow places);
- (ii) the target fish species also being the cetaceans’ prey species;
- (iii) the nets often being aimed at dense schools of fish, rather than dispersed populations – a foraging strategy known for many cetacean species.

6.5.4 Large-mesh pelagic driftnets

Large-mesh pelagic (also often used within 200 n.miles) driftnets of the type used for swordfish, sharks and other large pelagic fish are known to entangle cetaceans.

Swordfish and shark driftnets are often made of relatively strong multifilament twine with diameter over 2mm, which is more visible than the monofilament often used on smaller mesh nets. Stretched mesh size often exceeds 200mm and often ranges up to 560mm. These nets are either surface or midwater set. Smaller cetaceans appear to be more susceptible to mortality. Relatively large mesh driftnets (>100mm mesh size) are also used to catch several species of tuna.

6.5.5 High seas monofilament driftnets

High seas monofilament driftnets are set at or near the surface stretch up to 60km or more in length and are known to entangle several species of open-ocean cetaceans (SC/O90/G4, G8, G9, G43). Some species of small cetacean such as Dall’s porpoise appear to be particularly vulnerable. The low visibility of monofilament and the flexibility associated with its drifting condition may be factors which increase its tendency to take mammals.

6.5.6 Traps and weirs

Fish traps and weirs comprise another type of passive fishing gear which takes cetaceans. This type is not intended to entangle fish, but rather to guide fish into some type of 'pen' from which escape is difficult. Both large and small cetaceans are caught in these traps. It appears that mortality for small cetaceans in this gear is relatively low, and in some areas both large and small cetaceans are routinely released alive. Several studies have documented tendencies for cetacean entanglement in such gear and recorded relevant information regarding deterrence, learning and particularly high entrapment rates at specific sites (Lien *et al.*, 1988b; 1990).

6.6 Technical aspects of modifying gillnets

Cetacean entanglement has been documented from many different types of gillnets. Attempts to alleviate this problem have sometimes involved modifications of the fishing gear and methods, and this continues to be a very important area of study and development.

A gillnet is a combination of several components. The characteristics of each component should be considered, as well as the ways the components are assembled. A great many technical options are available. Different types of modifications are likely to be appropriate for different types of fisheries, different environments and different cetacean species. Research and development should be planned accordingly.

There are a number of problems with designing and evaluating experiments on gear modification. These include:

- (a) the fact that experiments must be carried out on a sufficient scale and over a long period of time for statistically significant results to be obtained;
- (b) the lack of baseline data;
- (c) the fact that results from one area under one set of conditions may not be valid for another area.

Annex E lists papers describing gear modification experiments.

6.6.1 Types of modifications

MODIFICATIONS TO INCREASE THE TARGET STRENGTH OF GILLNETS

Japanese researchers have experimented with two types of passive modifications to gillnets (SC/O90/G9, G13) to reduce entanglement of Dall's porpoise in the North Pacific driftnet fishery for salmon. In the first, three hollow air-tube threads were intertwined into the central band of an otherwise standard gillnet. The air-tube threads had a target strength only marginally higher (3–4dB) than standard monofilament. Mean catches of cetaceans in these modified nets were about 21% lower than those for standard nets, although the reduction was not statistically significant in two of the six seasons tested. Practical difficulties were encountered in handling the modified nets.

The second modification consisted of intertwining three multifilament threads into the central band of an otherwise standard gillnet. These threads had a target strength about 10dB higher than standard monofilament. Overall, these nets had marginally lower catch rates than the air-tube nets (above), but the reduction was not significant in either season tested (1986, 1987). Data comparing only adjacent sets showed a significant difference in June 1987, but not July. Paradoxically, the distribution of entanglements within the nets showed that significantly more porpoises

were caught in the central (modified) band of multifilament nets than in the corresponding band of the air-tube nets.

The strongest test yet of the effect of passive acoustic modifications to gillnets was conducted by Harwood and Hembree (1987). The target strength of the nets was raised by over 20dB by weaving 4mm bead chain into the driftnets used for sharks in northern Australian waters (SC/O90/G15). No significant difference in the catch rate of cetaceans (predominantly bottlenose and spinner dolphins) was found. Hembree and Harwood (1987) also tested 8mm air-filled plastic tubing, but found it operationally unusable (for practical constraints see SC/O90/G13).

There are designs for acoustic reflectors that would have much higher target strengths than any of the materials tested so far (SC/O90/G17) and these warrant further research. Such reflectors may have the additional advantage of allowing fishermen to find lost gear. However, it should be noted that while such designs are much more promising for acoustical reasons, the effectiveness of all types of acoustic reflectors is subject to the constraints outlined in section 6.1.1 above and in several papers (SC/O90/G13, G15, G16 and G17).

ACTIVE SOUND EMITTERS

The benefit of adding sound emitters to gillnets to reduce entanglement of small cetaceans appears equivocal. When sound emitters were added to Japanese air-tube nets, there was no significant decrease in catch rates in any of the years tested (data from Ogiwara, 1986; Hatakeyama, 1988; Snow *et al.*, 1988). Neither did the addition of sound emitters significantly effect the horizontal distribution of entanglements (SC/O90/G13).

Even if sound emitters reduced catches of dolphins and porpoises it is extremely unlikely that it would be practical in the foreseeable future to place them in all gillnets. Current devices are large, heavy (Hatakeyama, 1986), reasonably expensive (Ogiwara, 1986) and need to be regularly recharged (Hatakeyama, 1988). It is possible that many small sound emitters that are designed to have short ranges would be more effective at alerting cetaceans to the presence of nets than are the current large, long-range emitters.

There are also a number of problems which may occur in efforts to reduce entanglement of cetaceans by adding sound emitters to nets (SC/O90/G13):

- (a) any sound sufficiently aversive to scare cetaceans away may also decrease fish catches;
- (b) sounds might attract the attention of nearby cetaceans and encourage them to investigate the source of the danger;
- (c) cetaceans must associate the sound with the danger of entanglement, which, in the absence of sophisticated communication between individuals, will only be learned by animals that experience both the danger and the warning sound and survive to associate the two – the proportion of small cetaceans that experience entanglement and survive is unknown but presumably small (see Item 6.3 above);
- (d) habituation to the sounds is a general problem – randomising the sounds used (e.g. Hatakeyama, 1986) might prevent habituation, but it would also prevent association of any particular sound with the danger of gillnets;
- (e) there are cases in which marine mammals appear to feed directly on fish caught in gillnets, or on fish

associated with nets (SC/O90/G6) – attaching sound emitters to nets could have the effect of ‘ringing the dinner bell’.

These problems apply chiefly to small cetaceans. Large cetaceans, because they have higher survival rates in interactions with gear, have a far greater potential to be conditioned to avoid fishing gear (or at least fish traps, SC/O90/G51). Early tests (Lien *et al.*, 1994) show some promise.

SUB-SURFACE GILLNETTING

Hembree and Harwood (1987) examined the effect of setting driftnets lower in the water column. They compared nets set 4.5m below the surface with nets set at the surface. The sub-surface nets had significantly lower (50%) catches of cetaceans, but also significantly lower (25%) catches of target fish. SC/O90/G58 presents preliminary results of Japanese research examining the effect of sub-surface setting in both the North and South Pacific. Encouragingly, the sub-surface nets took very few cetaceans, while catch rates of target species were about the same, but the small sample sizes make statistical comparison with nets set at the surface difficult. The economic viability of sub-surface driftnetting in these fisheries is not yet clear, as the nets are more expensive and have longer handling times than normal driftnets set at the surface. SC/O90/G45 reported on the commercial use of subsurface nets in the California swordfish gillnet fishery.

6.6.2 Summary and conclusions

Reductions so far achieved in entanglement rates of small cetaceans via modifications to gillnets have been equivocal and of a marginal nature. However, there are many aspects of the acoustical interaction between cetaceans and gillnets that warrant further study. Current knowledge suggests that it is unlikely that acoustic modifications will provide a total solution in the foreseeable future. Acoustic modification may be useful in reducing entanglement in species where impacts on populations are not immediately threatening. In addition, acoustic modifications could be used in concert with other management actions (e.g. gear or area restrictions) to achieve necessary reductions in catch. For seriously reduced (or rare) species or populations of cetaceans it will be necessary to implement other means of reducing entanglement rates.

In view of the promising results obtained from the subsurface gillnet experiments, it is recommended that further experiments be carried out to address the following:

- (1) the statistical validity of the results;
- (2) seasonal or geographical effects;
- (3) applicability of the technique to other gillnet fisheries.

6.7 Alternative technologies

When a new technology becomes available there is a group of fishermen, sometimes referred to as early innovators and who are usually local industry leaders, who utilise it in solving problems they have before them. There is a second group of people within the industry who will then apply the technology when it has proved its value. A third group often exists that will oppose the technology (‘the Luddite Tendency’).

Properly defining a problem is half its solution. What is necessary in the case of cetacean capture in fixed gear is to help the fishermen understand that this is a problem that they have to face and that will affect their livelihood

(possibly by draconian regulatory methods if a solution is not found) and encourage them to solve it. Incidental catch of cetaceans in fishing gear is, first of all, a fisherman’s problem. The Workshop believes that the approach most likely to succeed is to identify and talk to these early innovators in the relevant fisheries, help them to define the problem and give them the equipment and assistance (in expertise and personnel, particularly with respect to cetaceans) they need to find a solution.

A less desirable way to let fishermen know they have a problem is to place a financial disincentive on the taking of cetaceans (SC/O90/G40). This has the advantage of not defining the solution. It presumes the problem is ‘the taking of cetaceans’.

If governments define solutions *vis a vis* regulations (e.g. banning gillnets, modifying gear characteristics, fishing methods and strategy etc.) it risks perverting innovation and causing inefficiencies in the fishery and may result in unforeseen and undesirable consequences (e.g. increasing takes of other non-target species).

It must also be recognised that the problems and their severity vary from species to species and area to area. In certain cases immediate action may be required to save a cetacean species from local extinction (see also Item 11).

6.7.1 Industry involvement

Experience has shown that fishermen must be involved from the earliest opportunity in solving fisheries’ problems. For many years, various organisations in diverse situations have worked to improve fishing technology and introduce new methods. Both the improvement of existing fishing technology and the introduction of new technology have the best chance of success if the fishermen themselves are directly involved in the process. Many fishermen have a great deal of knowledge and expertise with local technology, species, fishing conditions and ecology. They are also familiar with the economic and social conditions in their fishery. Their involvement throughout the project enhances the potential of obtaining the best solution and the fastest application.

In some areas, fishermen have demonstrated concern for mammal entanglement problems and have expressed an interest in collaborating with scientists and authorities to help solve the problems.

6.7.2 Understanding why a fishery uses gillnets

When alternative fishing technologies are considered, many characteristics of the envisioned alternatives should be compared with the characteristics of gillnets. Effects on resources, technical feasibility, economic feasibility and social acceptability should be considered. The first step would be to examine alternative gears in use in the specific fishery in question or used in similar fisheries in other areas for the same target species.

An essential pre-requisite to assisting fishermen changing from gillnets is to understand why particular fishermen are using them. Gillnetting often:

- (i) has been traditionally used;
- (ii) matches the vessels and technology locally available;
- (iii) involves lower operational costs;
- (iv) results in greater profits;
- (v) is used for species that do not take bait or hooks;
- (vi) is used where the bottom is too rough for trawling;
- (vii) results in a lower fish bycatch problem (size and species);

(viii) is used where there are neither the means nor incentive to develop alternatives

In considering alternative gear and methods, a large number of factors should be considered, including the following:

- (i) effectiveness for taking the target species and likely catch levels;
- (ii) effects on target and incidentally caught resources;
- (iii) fish market considerations and opportunities;
- (iv) capital costs of fishing and economic feasibility under local conditions;
- (v) foreign exchange inputs required;
- (vi) energy costs of fishing;
- (vii) appropriateness for economic and educational levels of fishermen;
- (viii) safety factors for fishermen.

Several possible scenarios emerge if one considers proposals to ban gillnetting in an area.

- (1) The fishermen may stop fishing entirely and find alternative employment and/or suffer economically.
- (2) Larger gillnet boats may be able to convert to trawling. However, most coastal gillnet vessels lack the size and power to trawl effectively. Trawling in general is more capital intensive, consumes more fuel and often involves more serious problems with fish bycatch, as illustrated by a comparison of shrimp trawl fisheries and shrimp gillnet fisheries.
- (3) A few vessels may be able to convert to purse-seining, which is practised on both large and small scale in different areas. Effects on resources, as well as technical and economic feasibility, would have to be evaluated.
- (4) Some coastal gillnetters may convert to longlining, which can be done effectively in many areas from relatively small boats, without great capital investment and with relatively low fuel consumption. There are many different types of longlining, coastal and open ocean, and each must be evaluated individually. In many conditions, economic longlining takes up more bottom area than gillnetting, possibly leading to increased conflicts with other gear types. Longlining in many areas can be less selective for fish species and size and more dangerous for fishermen.
- (5) Some gillnetters, particularly those in areas with significant pelagic resources, may convert to trolling. Although this method is used effectively in some areas, its disadvantages must be considered. It is effective for a limited number of species, many of which are highly seasonal. Fuel consumption and time required for finding fish may be high. Productivity per line is often low and it is generally only commercially feasible only for relatively high-priced species. It is practised primarily by small-to-medium sized vessels and may be an auxiliary method practised in combination with others.
- (6) Fishing with vertical lines and hooks may be considered as an alternative in some areas. Handlines, automated reels and jigging machines are all in use in different areas. The productivity of handlines may be relatively low and the technology for automated systems may be appropriate only in certain fisheries at this time.

Many other fishing methods are practised commercially in different areas and their potential for a given area should be considered. It should be noted that many organisations have devoted substantial resources to the development and

introduction of improved fishing methods. The problems encountered are often substantial and in many cases the success rate has not been very encouraging.

6.8 Disentanglement technology and resources

It is frequently possible to disentangle large whales from fishing gear if appropriate methods are used (Lien, 1988). Large whale entanglements can be classified into those where animals are anchored or fixed in place (such as an entanglement in a codtrap) and those where animals are free-swimming (such as an animal with gillnetting through the mouth or around the tail which has broken away from the anchors). All disentanglement procedures with cetaceans entail an element of risk to the rescuers and should be undertaken with caution. However, these efforts are important, particularly for endangered species.

For entangled cetaceans that are well anchored, current procedures use vessels of various sizes and lift the animals tail to the surface where it is accessible from the vessel. Cutting of the gear away from the whale is done from the vessel until the animal is free. Cooperation with the fishermen, who have a good working knowledge of where different lines are attached and/or anchored, is important to minimise both the time the disentanglement takes and the damage to the gear (Lien, 1988; Lien *et al.*, 1990). Divers are never placed in the water, because of the risk involved with large amounts of fishing gear.

For free-swimming animals, two approaches have been employed. Both require catching and clipping ropes onto the fishing gear trailing from the swimming animal. Lien (pers. comm.) favours anchoring the whale immediately at this point and working the animal as described above. Mayo (pers. comm.) has used inflatables to attach (with carabineers) buoys and sea-anchors to slow the whale down. When the whale becomes tired, Mayo uses the inflatable as the working platform to slide up to the tail area along the entangled gear and cuts away the gear as it is accessible. Di Natale (pers. comm.) has attached a large vessel to free-swimming entangled sperm whales, then used divers to cut away netting from the tethered animal. However, several large diameter ropes have been broken during some of these disentanglement operations by the thrashing of the animal.

Generally, larger vessel disentanglement efforts pose the least risk to researchers and fishermen; any operation which places divers in the water is the most dangerous. A list of some institutions which have disentangled whales regularly and may serve as information and/or rescue centres is given below.

Memorial University of Newfoundland, 230 Mt Slio Road, St. John's, Newfoundland, Canada, A1B 3X9.

Center for Coastal Studies, PO Box 1036, Provincetown, MA 02657, USA.

New England Aquarium, Central Wharf, Boston, MA 02110, USA.

Natural History Museum of Los Angeles County, 900 Exposition Blvd, Los Angeles, CA 90007, USA.

Tethys, Istituto per lo studio e la tutela dell'Ambiente Marino, piazza Duca D'Aosta 4, 20124 Milano, Italy.

6.9 Management

The Workshop had been asked to address the management options for controlling, reducing or eliminating the cetacean bycatch. It recognised the importance of determining management objectives and methods implementation as primary elements in the alleviation of marine mammal bycatch in specific fisheries. However, it

also recognised that, in addition to its areas of interest, fruitful discussion of functional management would range across subjects outside its expertise, including legal authority, jurisdictions, economics, social and cultural considerations and enforcement resources and technology. Throughout the report the group's recommendations and priorities are made or set in full recognition that non-scientific constraints on the management process may affect their utility.

Notwithstanding the above, the group noted the following general points with respect to management and the incidental take of cetaceans.

- (1) Bycatch is the collection of non-target species caught but not retained in any fishery. Bycatch may be unharmed, injured or dead when discarded. It includes both commercial and non-commercial fish and shellfish, marine mammals, birds, turtles and invertebrates. Bycatch is a fact of life for most fisheries. It typically becomes a management issue when a second or third party attaches some value to the discarded animals. The higher the value, the more likely some authority will be created or invoked to justify management actions to control, reallocate or eliminate the bycatch.
- (2) Marine mammals usually have almost no commercial value to passive gear fishermen. As bycatch they are cumbersome, aggravating and occasionally dangerous. However, many people attach considerable value to marine mammals and wish to protect them from harm in fisheries through statute and regulation. By establishing an economic consequence to the taking of marine mammals in the act of fishing, some control may be exercised over that taking. This type of 'artificial' valuation of marine mammals may be necessary if their bycatch in passive fishing gears is to be reduced or eliminated. It implies the creation of authority permitting governmental agencies to apply appropriate measures. This type of authority varies widely around the world, as does the value people and cultures attribute to marine mammals.

Recognising these limitations on management capabilities, some examples of management methods that may be employed to help control the bycatch of marine mammals and other species are discussed below. Almost all will reduce the economic productivity of the target fisheries and it might be expected that fishermen will try to avoid being included e.g. by changing country of registration or vessel class.

6.9.1 Time and area restrictions

Recent developments in satellite transmitter technology have made it possible to track and record the movements of vessels far from shore, thereby making the application of time and area restrictions feasible in medium to large scale fisheries. The success of such restrictions in reducing bycatches depends on the degree to which the target and non-target species separate. This information is lacking for most passive fisheries.

6.9.2 Bycatch quotas

This method limits the number/weight of the bycatch of one or more species. Its implementation presumes some means to track the take of controlled species in a near-real time frame. Obvious problems with this approach lie in deciding which species or species group will be limited and how the limitation (closure, relocation, gear change, etc.) may affect other bycatch species.

6.9.3 Effort and access limitations

This could achieve a broad target limitation on combined bycatches. For example, if bycatch levels are known for certain fishing zones and acceptable aggregate targets or limits for the bycatch exist, a simple limitation on effort by zone could achieve the desired result. It is a less stringent hybrid of the time/area and bycatch quota methods.

6.9.4 Bans on practices and technologies

This approach has always been a tool for the management of living resources in specific situations. Examples include bans on the use of explosives for fishing, on sundown sets by US tuna seiners and on import of fisheries products not taken in conformity with domestic regulation. It is under consideration as a solution to the high seas driftnet bycatch problem.

6.9.5 Individual or fleet performance criteria

With enough information concerning the bycatch performance of a specific fishing technology, it is possible to establish performance targets that allow fishermen some influence over their regulation. Setting a take-per-unit-effort limit per vessel or fleet that is monitored and reported on a regular schedule may engage the ingenuity of individual fishermen to find ways to keep the rate below the limit, thus extending their access to the fishery. Typically, this approach is used in conjunction with direct or implied quotas and effort limitations. For example, when the current take rate exceeds the specified limit it triggers closure or relocation of the fishery or mandates the use of alternate technology (e.g. from gillnets to longlines).

6.9.6 Retention of all catch – the 'no bycatch' option

This is not being used as a management method at this time but its impact on fishery profitability could motivate current high bycatch fishery participants to seriously explore bycatch reducing measures or alternate gears. This is an artificial manipulation of the economics of the fishery that is difficult to enforce and has unknown practical and market consequences.

6.9.7 Limitations on non-marine mammal bycatch levels

In cases where authority exists to limit takes of species other than marine mammals, this authority might be exercised to control marine mammal bycatch indirectly. For example, both halibut and harbour porpoises are taken as bycatch in certain coastal gillnet fisheries. Controlling the fishery to limit the bycatch of halibut and protect another commercial fishery might also reduce the take of harbour porpoises. This approach can take advantage of existing fishery management laws and implied property rights of conflicting fisheries to reduce bycatch of many other species.

6.9.8 Stipulations on gear and procedures

Gear and procedures that are effective and economical are likely to be implemented with little difficulty since less bycatch means more efficient fishing operations. Gear and procedures which are expensive or reduce vessel efficiency will meet significant resistance, requiring solid justification and potent authority. This is the approach whereby techno-behavioural solutions can be implemented.

6.9.9 Economic assistance and subsidies

If the above methods do not work or cannot be implemented, then it is conceivable that the implied property rights of fishermen can be purchased. By

measuring what tangible losses must be inflicted to achieve a bycatch goal, society/government/managers, etc. may make a first approximation of its cost. Governments have devised myriad ways to transfer value to industry ranging from direct payments, to subsidies for construction, insurance and price support, to protection from both foreign and domestic competition. Under this heading it should be recognised that market manipulation can be used both to support and coerce industry.

6.9.10 Conclusions

Each management situation will be in some ways unique. As an initial step in evaluating management latitude and options for controlling marine mammal bycatch, the Workshop **recommends** that the following questions be addressed:

- (1) What is/are the specific management objective(s), including full definitions of the terms used?
- (2) Who is being managed?
- (3) Under what authority(s) is this objective legitimate?
- (4) Under what/whose jurisdiction(s) does the problem reside?
- (5) What other management objectives interact with this, and how?
- (6) What entity(s) is responsible for attaining the objective(s)?
- (7) What resources are available for management and enforcement?
- (8) What management methods are applicable?
- (9) What alternatives are available to those being managed?

In answering these questions, the ease or difficulty of achieving a specific objective will become obvious. Also, a number of further, more detailed questions will arise, giving insight into needed work plans and strategies to build the information (including technical and scientific) and authority foundation for meeting the objective. In cases where authority and jurisdiction are limited or absent, this process may be lengthy and political.

7. CONCLUSIONS AND RECOMMENDATIONS

In a plenary session on the last day of the Workshop, the group reviewed and adopted the conclusions and recommendations put forward by the three sub-groups.

7.1 Global review of fisheries

7.1.1 General

(1) Throughout all regions there is a general lack of adequate statistics on gillnet and trap usage and on marine mammal entrapment.

It is **strongly recommended** that:

- (a) fishery agencies and regional bodies (including those of the FAO) ensure that statistically valid data on gillnet and trap effort and cetacean catches are collected and promptly analysed and reported;
 - (b) adequate statistics on marine mammal entanglement be obtained through independent observer programmes, following scientifically established designs.
- (2) Fleets from China, Taiwan and some other distant-water driftnet fleets continue to operate without documentation in the Atlantic and with inadequate data for operations in the Indian and Pacific Oceans.

This is a matter of grave concern, not only for nations adjacent to the fishing areas but also with respect to the status of marine mammals taken in these fisheries.

It is **recommended** that, while such activities continue, data on all distant-water fleets must be collected by the flag nations and nations servicing these fleets and independent observers placed on board vessels. The bycatches must be reported and evaluated and appropriate management actions taken before further fishing is authorised.

- (3) The Workshop **recommends** that the development of any new fisheries, or expansion of existing fisheries, should only be countenanced after a rigorous multidisciplinary environmental impact assessment that includes the potential effects on target and non-target species, including cetaceans. To this end, aid and development agencies, including UN, national and non-governmental organisations, should be advised of the potentially detrimental effects of these fisheries.
 - (4) It is **recommended** that national and international organisations address the education of fishermen, officials and scientists as well as the general public concerning the problem of cetacean interactions with gillnet and traps. Specific recommendations for the nations most critically involved are listed in the regional reviews.
 - (5) Japan and the USA are conducting research to assess the possible impact of lost and discarded fishing gear ('ghost nets'). The Workshop **recommends** that similar research programmes be initiated elsewhere. Specific goals of such programmes should be to reduce the number of nets and pieces of net webbing lost and discarded and to alter net manufacture and design to minimise danger from them.
 - (6) As has happened in Peru and Sri Lanka, a dolphin bycatch can become a directed fishery under certain economic conditions, leading to heavy exploitation of cetacean stocks of unknown size and status. This could happen in regions such as India and the Philippines where the bycatches are already fully utilised. This is a particular danger to cetacean conservation.
- It is **recommended** that national and international fishery and environmental agencies monitor such situations closely. Such directed fisheries should not be allowed to develop until the status of affected stocks has been evaluated.
- (7) Many developing countries are unable to fund the stock assessment and fishery monitoring programmes that must be carried out to ensure that incidental catches of cetaceans in particular fisheries are sustainable. It is **recommended** that:
 - (a) such nations consider the incorporation of such costs in license fees for fishing in their exclusive economic zones (EEZs);
 - (b) intergovernmental and private international funding organisations and agencies give high priority to financing such activities.
 - (8) Given the broad scope of the fishery/cetacean (and other bycatch species) interactions, regional cooperation in examining and addressing the various issues is extremely important. The Workshop **recommends** that such cooperation should be encouraged among, for example, the Baltic and northeastern European states through the agencies of the European Community and International Council for the Exploration of the Sea (ICES), among Caribbean states, between Argentina and Chile

(because of the crab-bait situation – see regional account for Southeastern Pacific), among West African states, among Indian Ocean states, among the North Pacific Rim nations and among the Pacific island nations.

7.1.2 High priority recommendations for specific regions

A series of recommendations for regional action are given above in the report of the sub-group on the global review of fisheries. Some of these recommendations are considered to be of especial urgency and are repeated here for emphasis.

- (1) It is **recommended** that solving problems associated with the incidental capture of the vaquita in totoaba gillnets in Mexico and the baiji on longline hooks in China is accorded the highest priority. In the case of the totoaba the fishery is illegal, except for some fishing under experimental permits. The fishery affecting the baiji is totally illegal. However, both fisheries continue to operate at high levels because of inadequate enforcement and continue to threaten the species with extinction.
- (2) The Workshop commends Italy for its decision to ban swordfish and albacore driftnets in Italian waters and their use by Italian vessels in other parts of the Mediterranean. It is **recommended** that similar actions be taken elsewhere in the Mediterranean. International cooperation and action by the General Council for Mediterranean Fisheries (CGPM) is required to ensure that large-scale driftnet fisheries do not restart from other nations and that reflagging of vessels for the purpose of continuing the fishery does not occur.
- (3) Gillnet fisheries continue to expand rapidly in Pakistan, India, Sri Lanka and Bangladesh. As noted in General Recommendation 4 above, it is **recommended** that new fisheries should not be initiated in this region or existing fisheries expanded until after evaluation of their effects on non-target species.
- (4) Throughout the Indo-Pacific region, and particularly in Southeast Asia, drift and set gillnets are widely used, but there is extremely limited information on incidental catches in such gear in these fisheries. It is **recommended** that this area be given high priority for future research into the impacts of gillnets and other fishing gear on marine mammals.
- (5) Large numbers of coastal trap and gillnet fisheries exist in Chinese coastal waters; one estimate is that 3,500,000 gillnets are in use. It is **recommended** that incidental mortality of cetaceans in these fisheries be addressed as a matter of urgency.

7.2 Impacts on species and populations

7.2.1 Conclusions

- (1) Cetacean populations in general seem unable to sustain rates of kill of more than a small percentage of the population per year. Even kill rates as low as 2% per year may not be sustainable, depending on the life history of the species and the age and sex composition of the kill.
- (2) Agencies that are responsible for the management of marine resources should manage from a conservative point of view, i.e. fisheries should not be allowed to operate at a particular level until there is evidence that the kill of cetaceans associated with that level of fishing effort is sustainable.

- (3) Information on kill rates and total fishing effort in passive net and trap fisheries and on the size of cetacean populations can be difficult to accumulate. Kill rates and fishing effort can be expected to vary among years, areas and seasons. Estimates of population size will necessarily be imprecise, especially where data on stock structure are lacking. Despite problems with the collection and analysis of data on kill rates, total fishing effort and population size, it is important that the agency responsible for managing a particular fishery collect these data on a systematic basis. In the absence of such information, the environmental impact of most gillnet and trap fisheries cannot be assessed.
- (4) The impacts of coastal gillnet and trap fisheries on strictly coastal species are especially noted. Such fisheries and cetacean populations are in urgent need of assessment and in many cases the levels of fishery mortality need to be reduced or eliminated.
- (5) The best available information at this time indicates that several stocks of cetaceans are unable to sustain current levels of removal caused by passive net and trap fisheries. These include:
 - (a) vaquita in the Gulf of California;
 - (b) baiji in the Yangtze River;
 - (c) Indo-Pacific hump-backed dolphins on the Natal coast of South Africa;
 - (d) striped dolphins in the Mediterranean Sea;
 - (e) harbour porpoises in the western North Atlantic;
 - (f) bottlenose dolphins on the Natal south coast, South Africa.

Furthermore, there are additional stocks where all of the information needed to evaluate the impact of passive net and trap fisheries is not available, but where the potential for current levels of removals not being sustainable is likely. This is particularly true where rates of kill are known to be large. Of particular concern are the following stocks:

- (a) dusky dolphins in the eastern South Pacific,
- (b) northern right whale dolphins in the central North Pacific;
- (c) sperm whales in the Mediterranean Sea.

7.2.2 Recommendations

Arising from the discussions in the working group on the impact of fisheries on species and populations of cetaceans, the Workshop agreed to the following recommendations.

- (1) It is **recommended** that the killing of:
 - (a) the vaquita in the Gulf of California;
 - (b) the baiji in the Yangtze River;
 - (c) Indo-Pacific hump-backed dolphins on the Natal coast of South Africa;
 - (d) striped dolphins in the Mediterranean Sea;
 - (e) harbour porpoises in the western North Atlantic;
 - (f) bottlenose dolphins on the Natal south coast, South Africa;

in passive and trap fisheries be reduced immediately.

Mechanisms for reducing the take of these species will have to be developed by the agencies with management authority.

- (2) Where the directed or incidental kill of any cetacean stock is thought to exceed a small percentage of the population or where a particular stock is declining and known to be taken in passive net and trap fisheries, it is

recommended that the fishery bycatch should be limited while the following information is collected:

- (a) *Kill rates*. These can be collected either by placing observers on fishing vessels, placing observers on research vessels that can observe fishing vessels or making experimental sets of gear similar to that used in the fishery. Estimates of kill rates from mail surveys to fishermen or dockside interviews alone are not adequate. For directed fisheries, kill rates can be estimated by monitoring the number of cetaceans landed.
- (b) *Age and sex composition of the kill*. This will require biological specimens to be collected by trained technicians.
- (c) *Stock identification*. Specimen material must be collected.
- (d) *Total fishing effort for all passive net and trap fisheries*. These data should be collected and analysed prior to the start of the next fishing season.
- (e) *Population size*. Initially, estimates of minimum population size on a stock-by-stock basis are adequate for management purposes. However, these estimates should be replaced by estimates of absolute abundance with their associated levels of precision. Estimates of population trends alone are not adequate.

7.3 Causes and solutions

7.3.1 Conclusions

- (1) The incidental capture of cetaceans appears to be almost universal in drift and set gillnets and a common occurrence in some trap fisheries. Wherever cetaceans and gillnets are found in the same area, at least some cetaceans are caught.
- (2) However, there is no universal cause or solution to the incidental capture of cetaceans in fishing gear. The precise nature of the interaction varies from area to area, fishing gear type to fishing gear type, species to species, culture to culture, and any combination of these.
- (3) Small cetaceans have sensory abilities which can detect the webbing and rigging of gillnets and other passive fishing gear. Encounters with nets may occur as they forage or engage in other activities which increase the chances that they will fail to detect nets. Less is known of the sensory abilities of large cetaceans. There are a variety of environmental, social and sensory conditions which may interfere with detection of nets. Additional study on the role such factors play in entrapment of cetaceans is necessary.
- (4) Even if the cetaceans detect nets, a variety of behavioural factors contribute to the entrapment or entanglement. These include curiosity, exploration and perception, escape reactions and social organisation.
- (5) There is almost no behavioural information on how and when entanglement of cetaceans occurs. There is little quantitative information on how many animals in the vicinity of a net become entangled, or on how many entangled animals escape. There are few quantitative data on many of the factors which cause entanglement or which might provide solutions. Basic information on entanglement must be collected as a matter of urgency. More rigorous scientific procedures must be followed

in experiments so that causes and solutions can be properly evaluated.

- (6) As noted in (2) above, at this time there is no practical, universal modification of fishing gear which can be suggested to solve all problems of incidental entrapment of cetaceans. In urgent cases, such as that of the vaquita, there may be no alternative but to ban the fishery.
- (7) Some fishing gear modification and management regimes do provide potential solutions and can be suggested for specific fisheries where entanglements of cetaceans occur. In all cases careful assessment and monitoring of the effectiveness and impact of modifications introduced to lower incidental catches of cetaceans must be made.
- (8) There are a number of promising research areas which may lead to reduction of incidental catches of cetaceans and which should be further explored; these include time/area restrictions on fisheries, adjustment of gear strategies and selectivity of gear, and the enhanced detection of gear. Management techniques for dealing with the incidental take of cetaceans which are most promising at this time are time/area restrictions and area closures.
- (9) In most areas fishermen are unaware of the extent and impact of cetacean entanglement. Fishing communities should be made aware of this and become involved in the process of finding solutions. Methods to accomplish this should be carefully researched and evaluated.

7.3.2 Recommendations

In addition to the specific research recommendations included in the body of the report, the Workshop agreed to the following more general recommendations.

- (1) It is **recommended** that research on causes and solutions of entanglements focus on those fisheries where urgent action is required. This should be achieved by organising local workshops including scientists, engineers, fishermen, managers and others.
- (2) It is **recommended** that particular priority in research be given to:
 - (a) behavioural factors which predispose cetaceans to entanglement including those immediately prior to and during entanglement;
 - (b) monitoring time and area closures;
 - (c) gear strength and strategy adjustments and alternative gears;
 - (d) environmental and ecological factors influencing these behaviour patterns.
- (3) It is **recommended** that studies on solutions to cetacean bycatch be conducted in such a manner that bycatch of other species is also considered.
- (4) It is **recommended** that significant technological changes within fisheries be preceded by an assessment of their likely impacts.

8. EDITING AND PUBLICATION OF REPORT

Although the major conclusions and recommendations of the sub-groups were adopted in full in plenary session, it was not possible to review fully and finalise the complete sub-group reports during the workshop. It was agreed that the participants would forward comments on the draft reports to the sub-group chairmen for consideration and that the chairmen would finalise the reports, with the help of the rapporteurs and forward them to the workshop

chairman for inclusion in the workshop report. The workshop report will be published in a special issue of *Reports of the International Whaling Commission*, which will include selected working papers from the workshop and submitted papers from the symposium that preceded the workshop and will be edited by Perrin, Donovan and Barlow. It was noted that authors wishing to submit working papers or symposium papers for publication in the special issue should revise them in light of comments received at the meeting and have them reviewed by at least two colleagues before sending them to the Scientific Editor. The submitted papers will then be subject to anonymous peer review.

9. OTHER BUSINESS

The Workshop thanked the Director of the Southwest Fisheries Science Center for hosting the Workshop and the Center staff for their very efficient and cheerful services during the meeting. The Chairman expressed his appreciation to the sub-group chairmen and the rapporteurs for their hard work and dedication to the success of the Workshop.

Annex A

List of Participants

G=Global Review Sub-Group (Item 4); I=Impact Sub-Group (Item 5);
C=Causes and Solutions Sub-Group (Item 6).

Gordon Anderson (G)
Marine Conservation Unit
Australian Nature Conservation Agency
PO Box 636
Canberra
ACT 2601
Australia

Whitlow Au (C)
Naval Ocean Systems Center
P.O. Box 997
Kailua, Hawaii 96734
USA

Jay Barlow (G)
Fisheries/Marine Mammal Interactions Division
Southwest Fisheries Center
U.S. National Marine Fisheries Service
P.O. Box 271
La Jolla, CA 92038
USA

Arne Bjørge (G)
Norwegian Institute for Nature Research
University of Oslo
PO Box 1037
Blindern
0315 Oslo
Norway

Robert L. Brownell, Jr. (I)
Southwest Fisheries Science Center
PO Box 271
La Jolla
CA 92038
USA

V. N. Burkanov (G)
Kamchatka Department of the Environment
Pacific Institute of Geography
Academy of Sciences
Prospect Ribakov 19/a
Petropavlovsk-Kamchatsk.
683024
Russian Federation

Martin W. Cawthorn (G)
53 Motuhara Road
Plimmerton
Wellington
New Zealand

Bjarne Clausen (G)
DMU
Box 358
Fredriksbergvej 399,
D-4000 Roskilde
Denmark

Victor Cockcroft (G)
Port Elizabeth Museum
P.O. Box 13147
6013 Humewood
South Africa

James M. Coe (C)
NMFS Marine Entanglement Research
Alaska Fisheries Science Center
7600 Sand Point Way NE
BIN C15700
Seattle, Washington 98115-0070
USA

Enrique A. Crespo (G)
Centro Nacional Patagónico
28 de Julio 28
9120 Puerto Madryn
Chubut
Argentina

Stephen M. Dawson (C)
Zoology Department
Otago University
P.O. Box 56
Dunedin
New Zealand

Douglas P. DeMaster (I)
National Marine Mammal Laboratory
7600 Sand Point Way NE
Seattle
WA 98115
USA

Antonio Di Natale (G)
Aquastudio
Via Trapani isol. 466 n. 6
98121 Messina
Italy

M. Louella Dolar (G)
Marine Laboratory
Silliman University
Dumaguete 6200
Phillipines

G. P. Donovan (C)
Scientific Editor
International Whaling Commission
The Red House
135 Station Road, Histon
Cambridge CB4 4NP
United Kingdom

Steven Drew (I)(C)
Manomet Bird Observatory
Manomet, MA 02345
USA

Michael Earle (G)
Greenpeace International
Rue Cochetay, 54
B-4140 Gomze-Andoumont
Belgium

Shannon Fitzgerald (G)
Resource Ecology and Fishery Management
U.S. National Marine Fisheries Service
7600 Sand Point Way NE
Seattle, WA 98115
USA

Karin Forney (I)
Southwest Fisheries Science Center
P.O. Box 271
La Jolla, CA 92038
USA

Ray Gambell (I)
International Whaling Commission
The Red House
135 Station Road, Histon
Cambridge CB4 4NP
United Kingdom

A. D. Goodson (C)
Sonar and Signal Processing Group
Electronic and Electrical Engineering Department
Loughborough University of Technology
Loughborough, Leicestershire LE11 3TU
United Kingdom

Doyle A. Hanan (C)
California Department of Fish and Game
Southwest Fisheries Science Center
P.O. Box 271
La Jolla, CA 92038
USA

Y. Hatakeyama (C)
National Research Institute on Fishery Engineering
5-5-1, Kachidoki, Chuo-ku
Tokyo
Japan

John E. Heyning (I)
Natural History Museum of Los Angeles County
900 Exposition Boulevard
Los Angeles, CA 90007
USA

Aleta Hohn (I)
National Marine Fisheries Service
Office of Protected Resources, F/PR1
1335 East-West Highway
Silver Spring, MD 20910
USA

P.U. Jepsen (C)
Wildlife Research Station,
Aalholtvej 1
Okstol. DK 6840
Denmark

Linda Jones (C)
Northwest Fisheries Science Center
2725 Montlake Blvd E
Seattle
WA 98112
USA

Toshio Kasuya (I)
Section of Cetacean Research
National Institute of Research on Far Seas Fisheries
5-7-1 Orido, Shimizu-shi
Shizuoka-ken 424
Japan

Michael Kingsley (I)
Maurice Lamontagne Institute
Fisheries and Oceans
P.O. Box 1000
Mont-Joli (Quebec)
Canada

Carl Kinze (G)
Zoological Museum of Copenhagen
Universitetsparken 15
DK-2100 Copenhagen
Denmark

Margaret Klinowska (C)
University of Cambridge
Animal Welfare and Human-Animal
Interactions Group
Dept. of Clinical Veterinary Medicine
Maddingley Road
Cambridge
CB3 0ES
United Kingdom

Scott D. Kraus (C)
New England Aquarium
Central Wharf
Boston, MA 02110
USA

Roger Krohn (G)
Benguela Ecology Programme
University of Cape Town
Cape Town
South Africa

John LaGrange (C)
Captain, "Cloud Nine"
533 North Rios Ave.
Solana Beach
CA 92075
USA

David M. Lavigne (C)
Department of Zoology
University of Guelph
Guelph, Ontario N1G 2W1
Canada

J. Stephen Leatherwood (G)
 Ocean Park Conservation Foundation
 Ocean Park
 Aberdeen
 Hong Kong

Jon Lien (C)
 Whale Research Group
 Memorial University of Newfoundland
 St. Johns, Newfoundland
 Canada A1C 5S7

Ingalill Lindstedt (G)
 Institute of Marine Research
 P.O. Box 4
 S-453 00 Lysekil

Annex D

Re-estimation of Incidental Cetacean Catches in Sri Lanka

S. Leatherwood

Very large catches of cetaceans have been reported in the waters around Sri Lanka. That country’s National Aquatic Resources Agency (NARA) estimated that approximately 12,950 individuals are incidentally caught in gillnets, and others (no estimate) are harpooned for use as food and bait in longline fishing (Dayaratne and de Silva, 1990). Methods used to estimate mortality were not presented in sufficient detail to support critical evaluation. Methods of estimating the total catch in Sri Lankan fisheries are reported here as an update from Leatherwood and Reeves (1989).

1. SPECIES COMPOSITION OF THE CATCH

The most complete data on composition of the cetacean bycatch in Sri Lanka are from the fish landing site at Trincomalee, on the northeastern coast, where landings were monitored by the same worker (W. P. Prematunga) for major portions of 1984–86 (Leatherwood and Reeves, 1989: table 12). The species composition of the observed landings at Trincomalee during those years is given in Table 1.

Table 1

<i>Stenella longirostris</i>	45.3%	<i>Pseudorca crassidens</i>	1.4%
<i>Stenella attenuata</i>	16.8%	<i>Globicephala macrorhynchus</i>	1.1%
<i>Grampus griseus</i>	14.7%	<i>Kogia breviceps</i>	0.9%
<i>Stenella coeruleoalba</i>	8.0%	<i>Mesoplodon</i> spp.	0.9%
<i>Tursiops truncatus</i>	5.4%	<i>Steno bredanensis</i>	0.6%
<i>Kogia simus</i>	2.6%	Unidentified dolphin	0.4%
<i>Feresa attenuata</i>	1.9%	<i>Lagenodelphis hosei</i>	0.1%

To obtain some estimate of takes of each species in all of Sri Lanka, the total estimated kill (see below) can be apportioned among species based on the composition of the observed landed catch at Trincomalee. This approach assumes that the species composition throughout the country is the same as that observed in Trincomalee. This assumption is violated to some extent, for example by the presence of other species (e.g. *Ziphius cavirostris*, *Orcinus orca*, *Peponocephala electra*, *Megaptera novaeangliae*, *Physeter macrocephalus* and *Balaenoptera physalus*) in small numbers in landed catches in western and southwestern Sri Lanka as well as at Trincomalee during recent seasons since monitoring ceased (e.g. *Delphinus delphis*, 1987) and by the fact that some species (e.g., *Lagenodelphis hosei*, *Kogia breviceps* and *Feresa attenuata*) are found more frequently in the fish landing sites in the west and southwest than they are in Trincomalee. However, in the absence of more detailed data for the country as a whole, estimates based on landed catches observed at Trincomalee are probably the best that can be made at present.

2. EFFORT PER BOAT/FISHING VILLAGE

Prematunga attempted to examine every cetacean landed at the Trincomalee fish landing site for three years, 1984–6, although his work was compromised to an unknown extent in 1986 by the civil strife in the region, resulting in lower counts of cetaceans than in previous years. Therefore, the total observed kills for 1984 and 1985 (310 and 323, respectively) were used to estimate average minimum landings per year at this site (316.5). There were 103 inboard boats registered at Trincomalee during that period, but Prematunga was not able to note how many of these boats were fishing and, therefore, contributing to the cetacean kill, at any given time (Leatherwood and Reeves, 1989, p.47)

3. NUMBER OF INBOARD FISHING BOATS IN SRI LANKA AND NUMBER OF FISHING DAYS PER YEAR (TOTAL EFFORT)

According to government statistics, there were an average of 2,943.8 inboard fishing boats registered in Sri Lanka 1984–1986 (Leatherwood and Reeves, 1989: table 3). However, not all registered boats are thought to be fishing all or even part of the year; so workers have used the figures 2,284 (Josephs and Siddeek, 1985) to 2,568 (Leatherwood and Reeves, 1989: table 7) in characterisations of fishing effort. In the absence of better statistics, the more conservative of these two figures is used for the present calculations. A total of 1,385 of the boats are believed to fish in the Mannar District to Kulmanai District (west and southwest region); 899 in the Batticaloa District to the Jaffna District (east and northeast region) (Joseph and Siddeek, 1985; Leatherwood and Reeves, 1989: table 7). In previous calculations by Sri Lankan government scientists, it has been assumed that inboard vessels in the country fish at least 75% of the time (274 days/year) (Joseph and Siddeek, 1985).

4. CATCH RATES

The catch rate for the east and northeast coast can be estimated only with the data from Trincomalee. The resultant catch rate will be biased downward to an unknown extent because of overestimates in the number of vessels actually fishing at any time and the fact that some animals were discarded at sea and some of the animals landed were very probably not accounted for in Prematunga’s tallies. When the average minimum annual catch observed landed at Trincomalee in 1984 and 1985 (316.5) is divided by the maximum number of inboard boats registered in Trincomalee in that period (103), and the resultant minimum annual catch rate (3.07 cetaceans/boat/year) is

then multiplied by the minimum number of inboard boats thought to be operating in the east and northeast region (899), one obtains a minimum estimate of 2,763 cetaceans landed per year in the region. This is lower than the range reported by Leatherwood and Reeves (1989: table 7). However, their calculations of minimum mortalities for this area as presented in that table contain an error (the catch rate is off by one decimal point). When the erroneous catch rates are replaced with the catch rate for Trincomalee recalculated for this report (0.0084), the resultant estimates of minimum annual mortality in the east and northeast region ranged from 2,297 – 3,729.

For the west and southwest region, Mannar District to Kulmanai District, the best catch rates available are those from observers stationed in four villages for 21–98 days each. These observers noted minimum landings of cetaceans (466) (Other duties prevented complete tallies.) and total numbers of inboard boats actually fishing during periods of observation (mean for the four combined = 134.3) (calculated from Leatherwood and Reeves, 1989: table 5). These estimates of fishing effort are more likely to be accurate than those calculated, as in Trincomalee, based on the total number of boats registered. The general utility of these estimates is further enhanced by the fact that the observers worked in four fish landing sites rather than one, suggesting that their figures are more likely to be representative of the entire region than figures from a single landing site would be. When catch rates for the west and south coasts are recalculated using this minimum estimated catch rate (0.0163 cetaceans/vessel/day) and multiplied by the minimum number of fishing boats thought to be in the area (1,385) and the number of fishing days (274), following Josephs and Siddeek (1985), one obtains a minimum estimate of 6,182 cetaceans killed in the

west and southwest region each year. When the same conservative catch rate is used to recalculate the estimates in Leatherwood and Reeves (1989: table 7), the range of estimates corrects to 5,745–8,092.

The minimum annual landed kill for all of Sri Lanka, derived by combining the above two regional estimates, is 8,951 using the very conservative approach outlined above and 8,042–11,821 using the conservative approach taken by Leatherwood and Reeves (1989) in revising their table 7. The numerical catch estimates in Table 1 of the Workshop report are derived from the minimum estimate of 8,951 and the species composition of observed landings at Trincomalee.

It must be emphasised that all these estimates are biased downward to an unknown extent by cetaceans which are killed but not landed or landed but not tallied, and most are further biased downward by the use of the number of registered vessels rather than number of vessels actually fishing. As stated by Leatherwood and Reeves (1989:47)

“All attempts to estimate mortality of cetaceans in Sri Lankan fisheries from the data available are compromised in significant ways... The best (one) could do was to calculate a series of estimates using conservative assumptions and present the basis and details for those estimates in sufficient detail that they can be recalculated as more information becomes available.”

Annex E
Guidelines for the Correct Description of a Gillnet
(either driftnet or bottom set)

- (1) Target species:

(2) Country or region:

(3) Mesh size: preferably to be given as stretched length, if not (e.g. bar length), specify precisely

(4) Twine webbing material: e.g. PA for nylon, PE for polyethylene, PP for polypropylene, PES for polyester. For other material, indicate the full trade name

(5) Twine construction: multifilament, monofilament or multimonomofilament

(6) Twine size:

— for multifilament, indicate either number of denier, Rtex, or yard/lbs, m/kg. For any other measurement indicate its equivalence with one of the above or give the diameter

— for monofilament, indicate the diameter

— for multimonomofilament, indicate the number of monofilaments and the diameter of one of these

(7) Height of the net: number of meshes or stretched height of the netwebbing, specify

(8) Length of the net: total strengthened length of the net webbing or number of meshes in the horizontal direction

(9) Hanging ratio (E): if possible

(10) Framelines (upper=floatline, lower=leadline, side=sidelines): indicate their material (see 4), diameter, length
- (11) Floatation: needed measure is floatation per meter, so indicate: float material + main dimensions of the float + number of floats either per metre of the floatline or per given length of gillnet

(12) Weight on the leadline: indicate either: weight of a unit of lead + number of units either per metre of leadline or on the whole net or if the lower frameline is made of a lead core rope, indicate the weight of this rope per metre

(13) Make a drawing or sketch of the net in the fishing position: show the position of the gillnet versus the surface or the bottom, the anchor if any, buoy(s) and buoyline(s), secondary floatlines or leadlines if any (in this case give an indication of the floatation and the ballast)

(15) Total length of the string (or fleet) of net:

(16) Time of fishing:

(17) Duration of soak:

(18) Areas:

(19) Depth range:

(20) Approximate price:

(21) Vessel length:

(22) Vessel horsepower:

(23) Source of information and date:

Annex F

A Review of Modifications to the Webbing and Setting Strategies of Passive Fishing Gear to Reduce Incidental Bycatch of Cetaceans

Sean Todd and Dawn Nelson

Biopsychology Programme, Department of Psychology, Memorial University of Newfoundland, St. John's, Newfoundland, Canada, A1B 3X9

INTRODUCTION

This Annex reviews all known studies to date in which gear was modified to reduce cetacean bycatch. Certain fields have been deliberately excluded; for example, the methods used in pinniped-fishery interactions have been omitted, as well as studies in which modifications were not actually attached to nets. As a result, this review focuses specifically on in situ research. For a detailed review of the practicalities of gear modification, see Dawson (1991).

Modifications to passive fishing gear

Modifications can be divided into three broad categories; active sound generators, passive reflectors and changes in setting strategy. Active sound generators and passive reflectors are used on the assumption that they increase the acoustic and/or the visual detectability of fishing gear, whereas changes in setting strategy attempt to reduce the initial interaction between the bycatch species and the gear. Each type of modification is dealt with in turn.

ACKNOWLEDGEMENTS

The authors would like to thank Dr. Jon Lien, Julie Huntington and Frank Chopin for their constructive criticisms in writing this paper and the members of the Causes and Solutions Sub-Committee at the IWC Workshop on the Mortality of Cetaceans in Passive Fishing Gear and Traps, especially Linda Jones, for their help in supplying source material.

Modification type	Results/Comments	Source ¹
Active Sound Generators		
SG-1 9kHz pulse generator	No significant reduction in bycatch, awkward operation.	Hatakeyama, 1986a Hatakeyama <i>et al.</i> , 1991a,b Kumagai <i>et al.</i> , 1983 Ogiwara, 1986 Ogiwara <i>et al.</i> , 1985
SG-2 145kHz, simple form	Avg. <10% reduction in bycatch In 1984, a 5% decrease in directed catch was reported (no significance given).	Hatakeyama, 1986a Hatakeyama <i>et al.</i> , 1990a,b Kumagai <i>et al.</i> , 1983 Ogiwara, 1986 Ogiwara <i>et al.</i> , 1985 Ogiwara <i>et al.</i> , 1986
SG-3 145kHz, 'porpoise-like'	Avg. <10% reduction in bycatch, significant in 1983, 1984, but not 1985.	Hatakeyama, 1986a Hatakeyama <i>et al.</i> , 1990a,b Kumagai <i>et al.</i> , 1983 Ogiwara, 1986 Ogiwara <i>et al.</i> , 1985 Ogiwara <i>et al.</i> , 1986 Hatakeyama, Ishii and Taketomi, 1985
SG-4 20-50kHz, random pulse	Avg. <30% non-significant reduction in bycatch. Generally, entrapment occurred in areas of net where alarms were not positioned. Some problems with alarm entanglement.	Hatakeyama, 1986a,b, 1987 Hatakeyama <i>et al.</i> , 1990a,b Ogiwara, 1986 Ogiwara <i>et al.</i> , 1986 Takagi, 1987
0.5-1kHz 'clanger'	No significant reduction in bycatch, awkward operation.	Lien <i>et al.</i> , 1990
27-50kHz 'pinger'	No significant reduction in bycatch, but a significant decrease in damage cost.	Lien <i>et al.</i> , 1990
3.5kHz 'beeper'	Significant reduction in bycatch and damage cost.	Lien <i>et al.</i> , 1990
Low frequency 'clanger'	No change in dolphin movements near nets. Increase in directed catch. Corrosion problems.	Peddemors <i>et al.</i> , 1991 Peddemors and Cockcroft, 1990
Low frequency 'rattle'	No change in dolphin movements near nets. Reliant on sea state. Awkward operation.	Peddemors <i>et al.</i> , 1991 Peddemors and Cockcroft, 1990
Low frequency bell buoy	No change in dolphin movements near nets. Reliant on sea state. Awkward operation.	Peddemors <i>et al.</i> , 1991 Peddemors and Cockcroft, 1990
Passive Devices		
1m ABS air-filled piping	No significant reduction in bycatch.	Lien, 1980
1m ABS water-filled piping	No significant reduction in bycatch.	Lien, 1980
White plastic disc	No significant reduction in bycatch.	Lien, 1980
Plasticised aluminium foil squares	Tests inconclusive, problems with corrosion.	Peddemors <i>et al.</i> , 1991 Peddemors and Cockcroft, 1990
Aluminium discs	Tests inconclusive, problems with corrosion, awkward operation.	Peddemors <i>et al.</i> , 1991 Peddemors and Cockcroft, 1990
Stainless steel twine	Tests inconclusive, unmanageable.	Peddemors <i>et al.</i> , 1991 Peddemors and Cockcroft, 1990
AT-1 3 air-filled tubes in central portion of net	Avg. <30% reduction in bycatch, significant for years 1981 and 1982, but not for 1983. Data for 1984, 1985 and 1986 show an ambiguous significant decrease in bycatch (depending on type of statistical test).	Hatakeyama <i>et al.</i> , 1990a,b Hatakeyama, 1987 Jones, Bouchet and Turnock, 1987 Kumagai <i>et al.</i> , 1983 Ogiwara, 1986 Ogiwara <i>et al.</i> , 1985 Ogiwara <i>et al.</i> , 1986 Ogiwara <i>et al.</i> , 1987 Snow <i>et al.</i> , 1988 Takagi, 1987

Modification type	Results/Comments	Source
AT-2 5 air-filled tubes in central portion of net	<10% non-significant reduction in bycatch.	Kumagai <i>et al.</i> , 1983 Ogiwara, 1986 Takagi, 1987
AT-3 3 air-filled tubes in top 1/3 of net	<25% non-significant reduction in bycatch.	Hatakeyama <i>et al.</i> , 1990b Ogiwara, 1986 Ogiwara <i>et al.</i> , 1986 Takagi, 1987
MT-1 multi-filament thread	<30% reduction in bycatch, but of ambiguous significance. In 1987, there was a significant reduction in bycatch relative to AT-1 (solo) tests, with a slight non-significant) reduction in directed catch.	Hatakeyama <i>et al.</i> , 1990b Ogiwara, 1986 Ogiwara <i>et al.</i> , 1987 Snow <i>et al.</i> , 1988
Air filled tubes	No significant reduction in bycatch, problems with maintenance.	Hembree and Harwood, 1987
Bead chain	No significant reduction in bycatch, but decrease in directed catch.	Hembree and Harwood, 1987
Vinyl string (horizontal)	Tests inconclusive, some losses of strings from net.	Hasegawa <i>et al.</i> , 1987 Hatakeyama <i>et al.</i> , 1990a
1 rope (vertical)	Tests inconclusive.	Hasegawa <i>et al.</i> , 1987 Hatakeyama <i>et al.</i> , 1990a
3 ropes (vertical)	Tests inconclusive.	Hasegawa <i>et al.</i> , 1987 Hatakeyama <i>et al.</i> , 1990a
Blister sheet	Tests inconclusive, some losses of blister sheets from net.	Hasegawa <i>et al.</i> , 1987 Hatakeyama <i>et al.</i> , 1990a
Setting Strategies		
Lowering net by 2m	No bycatch in modified net, but some experimental design problems. Also a significant decrease in directed catch.	Hayase <i>et al.</i> , 1990
Lowering net by 4.5m	Significant decrease in bycatch by 50% (approx.). Also a decrease in directed catch, significant for one species only.	Hembree and Harwood, 1987
Lowering net by 2m	Tests inconclusive, but some decreases in bycatch.	Hayase <i>et al.</i> , 1990
Lowering trap leader by 5m	Modified traps resulted in no entrapments.	Kingsley, 1982
Combinations		
AT-1 with SG-1	<40% reduction in bycatch, no significance reported.	Ogiwara, 1986 Takagi, 1987
AT-1 with SG-2	<20% non-significant decrease in bycatch.	Hatakeyama <i>et al.</i> 1990b Ogiwara, 1986 Ogiwara <i>et al.</i> , 1987 Takagi, 1987
AT-1 with SG-3	<30% non-significant decrease in bycatch.	Hatakeyama <i>et al.</i> , 1990b Ogiwara, 1986 Ogiwara <i>et al.</i> , 1987 Takagi, 1987
AT-1 with SG-4	<40% non-significant decrease in bycatch. In 1987, inconclusive tests showed a reduction in bycatch relative to AT-1 (solo) tests.	Hatakeyama, 1988 Hatakeyama <i>et al.</i> , 1990b Ogiwara, 1986 Ogiwara <i>et al.</i> , 1987 Snow <i>et al.</i> , 1988 Takagi, 1987

Annex G
List of Cetacean Species

There follows a list, in taxonomic order, of the living cetacean species recognised by the IWC Scientific Committee (scientific names and English common names).

Order Cetacea (whales and porpoises)	
Suborder Mysticeti (baleen whales or mysticetes)	
Family Balaenidae	
<i>Eubalaena australis</i>	southern right whale
<i>Eubalaena glacialis</i>	northern right whale
Family Neobalaenidae	
<i>Caperea marginata</i>	pygmy right whale
Family Eschrichtiidae	
<i>Eschrichtius robustus</i>	gray whale
Family Balaenopteridae	
Subfamily Balaenopterinae	
<i>Balaenoptera acutorostrata</i>	minke whale
<i>Balaenoptera borealis</i>	sei whale
<i>Balaenoptera edeni</i>	Bryde's whale
<i>Balaenoptera musculus</i>	blue whale
<i>Balaenoptera physalus</i>	fin whale
Subfamily Megapterinae	
<i>Megaptera novaeangliae</i>	humpback whale
Superfamily Physeteroidea	
Family Physeteridae	
<i>Physeter macrocephalus</i>	sperm whale
Family Kogiidae	
<i>Kogia breviceps</i>	pygmy sperm whale
<i>Kogia simus</i>	dwarf sperm whale
Suborder Odontoceti (toothed whales including porpoises)	
Superfamily Platanistoidea	
Family Platanistidae	
<i>Platanista gangetica</i>	Ganges river dolphin
<i>Platanista minor</i>	Indus river dolphin
Family Pontoporiidae	
Subfamily Lipotinae	
<i>Lipotes vexillifer</i>	baiji
Subfamily Pontoporiinae	
<i>Pontoporia blainvillei</i>	franciscana
Family Iniidae	
<i>Inia geoffrensis</i>	boto
Superfamily Delphinoidea	
Family Monodontidae	
Subfamily Delphinapterinae	

<i>Delphinapterus leucas</i>	white whale
Subfamily Monodontinae	
<i>Monodon monoceros</i>	narwhal
Family Phocoenidae	
Subfamily Phocoeninae	
<i>Phocoena phocoena</i>	harbour porpoise
<i>Phocoena spinipinnis</i>	Burmeister's porpoise
<i>Phocoena sinus</i>	vaquita
<i>Neophocaena phocaenoides</i>	finless porpoise
Subfamily Phocoenidinae	
<i>Australophocaena dioptrica</i>	spectacled porpoise
<i>Phocoenoides dalli</i>	dall's porpoise
Family Delphinidae	
Subfamily Stenoninae	
<i>Steno bredanensis</i>	rough-toothed dolphin
<i>Sousa chinensis</i>	Indo-Pacific hump-backed dolphin
<i>Sousa teuszii</i>	Atlantic hump-backed dolphin
<i>Sotalia fluviatilis</i>	tucuxi
Subfamily Delphininae	
<i>Lagenorhynchus albirostris</i>	white-beaked dolphin
<i>Lagenorhynchus acutus</i>	Atlantic white-sided dolphin
<i>Lagenorhynchus obscurus</i>	dusky dolphin
<i>Lagenorhynchus obliquidens</i>	Pacific white-sided dolphin
<i>Lagenorhynchus cruciger</i>	hourglass dolphin
<i>Lagenorhynchus australis</i>	Peale's dolphin
<i>Grampus griseus</i>	Risso's dolphin
<i>Tursiops truncatus</i>	bottlenose dolphin
<i>Stenella frontalis</i>	Atlantic spotted dolphin
<i>Stenella attenuata</i>	panropical spotted dolphin
<i>Stenella longirostris</i>	spinner dolphin
<i>Stenella clymene</i>	clymene dolphin
<i>Stenella coeruleoalba</i>	striped dolphin
<i>Delphinus delphis</i>	short-beaked common dolphin
<i>Delphinus capensis</i>	long-beaked common dolphin
<i>Lagenodelphis hosei</i>	Fraser's dolphin
Subfamily Lissodelphinae	
<i>Lissodelphis borealis</i>	northern right whale dolphin
<i>Lissodelphis peronii</i>	southern right whale dolphin

Subfamily Cephalorhynchinae		Family Ziphiidae	
<i>Cephalorhynchus commersonii</i>	Commerson's dolphin	<i>Tasmacetus shepherdi</i>	Shepherd's beaked whale
<i>Cephalorhynchus eutropia</i>	black dolphin	<i>Berardius bairdii</i>	Baird's beaked whale
<i>Cephalorhynchus heavisidii</i>	Heaviside's dolphin	<i>Berardius arnuxii</i>	Arnoux's beaked whale
<i>Cephalorhynchus hectori</i>	Hector's dolphin	<i>Mesoplodon pacificus</i>	Longman's beaked whale
Subfamily Globicephalinae		<i>Mesoplodon bidens</i>	Sowerby's beaked whale
<i>Peponocephala electra</i>	melon-headed whale	<i>Mesoplodon densirostris</i>	Blainville's beaked whale
<i>Feresa attenuata</i>	pygmy killer whale	<i>Mesoplodon europaeus</i>	Gervais' beaked whale
<i>Pseudorca crassidens</i>	false killer whale	<i>Mesoplodon layardii</i>	strap-toothed whale
<i>Orcinus orca</i>	killer whale	<i>Mesoplodon hectori</i>	Hector's beaked whale
<i>Globicephala melas</i>	long-finned pilot whale	<i>Mesoplodon grayi</i>	Gray's beaked whale
<i>Globicephala macrorhynchus</i>	short-finned pilot whale	<i>Mesoplodon stejnegeri</i>	Stejneger's beaked whale
Subfamily Orcaellinae		<i>Mesoplodon bowdoini</i>	Andrews' beaked whale
<i>Orcaella brevirostris</i>	Irrawaddy dolphin	<i>Mesoplodon mirus</i>	True's beaked whale
Superfamily Ziphiioidea		<i>Mesoplodon ginkgodens</i>	ginkgo-toothed beaked whale
		<i>Mesoplodon carlhubbsi</i>	Hubbs' beaked whale
		<i>Mesoplodon peruvianus</i>	pygmy beaked whale
		<i>Ziphius cavirostris</i>	Cuvier's beaked whale
		<i>Hyperoodon ampullatus</i>	northern bottlenose whale
		<i>Hyperoodon planifrons</i>	southern bottlenose whale

Significant Direct and Incidental Catches of Small Cetaceans

A REPORT BY THE SCIENTIFIC COMMITTEE
OF THE INTERNATIONAL WHALING COMMISSION
TO THE
UNITED NATIONS CONFERENCE ON ENVIRONMENT AND DEVELOPMENT
(UNCED)

Significant Direct and Incidental Catches of Small Cetaceans

Edited by A. Bjørge, R.L. Brownell Jr, G.P. Donovan and W.F. Perrin

INTRODUCTION

Background to the Review

The Commission's Resolution

In the Resolution on Small Cetaceans (IWC, 1991a) adopted by the IWC last year, the Commission requested the Scientific Committee to commence a process of drawing together all available relevant information on the present status of those stocks of small cetaceans which are subjected to significant directed and incidental takes and on the impact of those takes on the stocks, and to provide such scientific advice as may be warranted.

The report to UNCED

The Commission also decided to present a report on the work carried out under the terms of the Resolution on Small Cetaceans to the United Nations Conference on Environment and Development (UNCED) in June 1992.

Editors' notes on the 1994 version

The present report comprises the relevant section (section 5) of the review of small cetacean stocks subjected to significant directed and incidental takes carried out by the sub-committee on small cetaceans and agreed by the full Scientific Committee and sent to the UNCED meeting. For convenience, the report follows the numbering system of the report of the sub-committee on small cetaceans published in *Rep. int. Whal. Commn* 42: 178–234. Similarly the use of the word 'sub-committee' has been retained. The only changes that have been made to that report is the updating of 'In press' or 'unpublished' references where these have subsequently been published; Appendices 1 and 4 of the sub-committee report are not included as they are not relevant to the review.

Species names

The report uses English common names recognised by the IWC for small cetacean species as of October 1994. A full list of species in taxonomic order is given in Appendix 2. It should be noted that at the time of the report, only one species of common dolphin, *Delphinus delphis* was recognised. Since then two species, the short-beaked common dolphin (*D. delphis*), and the long-beaked common dolphin (*D. capensis*) have been recognised. Appendix 2 has been modified to this effect, but in most cases it is impossible to retrospectively reallocate animals assigned originally to 'common dolphin' to the two species.

5. REVIEW OF SIGNIFICANT DIRECTED AND INCIDENTAL CATCHES OF SMALL CETACEANS

Four categories of catches were identified and discussed; directed fisheries, incidental catches, deliberate incidental catches and live-capture fisheries. Information published in *Rep. int. Whal. Commn* or elsewhere, information presented to the IWC Workshop on Incidental Mortality in Passive Fishing Nets and Traps (IWC, 1994) and new information submitted to the sub-committee were reviewed. Priorities were given to those fisheries in each category where significant impacts on stocks are likely to occur. For these fisheries, previous recommendations made by the Scientific Committee, and any management response upon such recommendations were evaluated. New recommendations were made where appropriate.

The sub-committee, however, reviewed only those fisheries and stocks of small-cetaceans for which detailed information was available for consideration. It was emphasised, therefore, that while the review addresses many of the stocks which are significantly impacted by directed or incidental catches, it cannot be considered to be comprehensive, either with regard to species or to geographic regions covered. The sub-committee emphasised this problem that apply to all four categories of catches, and **recommends** that areas should be identified where there are urgent needs for basic information on status of small cetacean stocks and on impacts of any takes of those stocks. The sub-committee further **recommends** that areas should be specified where international cooperation is required (or beneficial) for developing further competence in research and management.

Problems related to pollution and habitat degradation were not addressed in the IWC Resolution on Small Cetaceans. These factors may have significant impacts on small cetaceans, in particular for those species occurring in coastal, inshore and riverine habitats. The sub-committee **underlines**, therefore, that these factors should be emphasised in a comprehensive assessment of threats to small cetaceans.

5.1 Directed fisheries¹

5.1.1 Directed fisheries on small cetaceans in Japan

Over 20 species of small cetaceans are found in the nearshore waters around Japan. Various local fisheries for some of these species have a long history. This section

¹ Initial draft by Kasuya and Brownell.

reviews the history of exploitation for the four main small cetaceans (Dall's porpoise, striped dolphin, short-finned pilot whale, and Baird's beaked whale) hunted in Japanese waters and presents a brief review of the situation with other small cetaceans caught in direct Japanese fisheries.

5.1.1.1 *Phocoenoides dalli*

COMMON NAMES

Dall's and True's porpoise, *ishi iruka* and *rikuzen iruka* (Japanese names for *dalli* and *truei* forms, respectively), *belokrylaya morskaya svin'ya* (Russian).

DISTRIBUTION

This genus is endemic to the North Pacific basin. Its southern limits during winter are around the Boso Peninsula, near Tokyo (about 35°N) in the western Pacific and off northern Baja California, Mexico (approximately 28°N) in the eastern Pacific. The southern boundary in the central Pacific is about 39°N during summer (Jones *et al.*, 1987). In northern waters, sightings are infrequent above 62°N in the Bering Sea (Nishiwaki, 1967). In the western Pacific, these porpoises are also widely distributed in the Sea of Japan and the Okhotsk Sea (Kasuya, 1982; IWC, 1991c).

Based on the distribution of cow-calf pairs in August-September, colour pattern, body size, and geographical variation in parasite loads, the Scientific Committee proposed seven stocks of Dall's porpoises (IWC, 1991c). These are: (1) the central Bering Sea (*dalli*-type), (2) south of the Kamchatka Peninsula (*dalli*-type), (3) south of the Aleutian Islands (*dalli*-type), (4) central Gulf of Alaska (*dalli*-type), (5) northern Okhotsk Sea (*dalli*-type), (6) central Okhotsk Sea (*truei*-type) and (7) eastern North Pacific (*dalli*-type).

Understanding of the Okhotsk Sea stocks has since been refined (Miyashita, In press-b). During recent surveys the density of the *dalli*-type was low in the central Okhotsk Sea where the density of the *truei*-type (including cow-calf pairs) was high. Cow-calf pairs of *dalli*-type were concentrated to the north and south of this area of concentration of the *truei*-type in the central Okhotsk Sea (Miyashita, In press-b). The breeding ground (for the *truei*-type) south of the Kamchatka Peninsula (east of the Kuril Islands) was discontinuous with those in the Okhotsk Sea. Thus, Miyashita (In press-b) proposed three Dall's porpoise breeding stocks for the Okhotsk Sea (i.e. northern Okhotsk Sea – *dalli*-type; central Okhotsk Sea – *truei*-type; and southern Okhotsk Sea – *dalli*-type). This brought to eight the number of stocks known or postulated in the North Pacific.

PROBLEMS AND CATCH STATISTICS

This species has been hunted in Japanese waters since at least the early 1940s (Hirashima and Ohno, 1944). Porpoises are caught from two stocks (i.e. the *dalli*-type, southern Okhotsk Sea stock, and the *truei*-type, central Okhotsk Sea stock). During the 1960s and 1970s, the hand harpoon fishery in northern Japanese waters landed between 5,000 and 10,000 porpoises annually. In its early years, the hand harpoon fishery operated during winter off the Iwate coast (northern Honshu), but as the fishery started to expand, the season lengthened and the fishing ground moved into waters around Hokkaido. By 1988 the reported catch had increased to over 40,000 individuals. The Government of Japan established regulations for the hand harpoon fishery in early 1989, which resulted in a reduction of the annual catch to a total of 29,048 for that

year. The estimated removals by the direct fishery from both stocks between 1986 and 1989 totalled 111,530 porpoises (IWC, 1991c). The large increases in take of this species since 1986 have been used to compensate for the shortage of whale meat due to the IWC moratorium on whaling. The increase has also been intended to compensate for the decrease in catches of striped dolphins in recent years. During the 1970s, Dall's porpoises were consumed largely in the Shizuoka area, but they are now shipped to Taiji as well. In addition to these high numbers caught and landed, other Dall's porpoises are struck and lost and therefore, probably die in this fishery. Struck and loss ratios in this fishery have been found to be highly variable by vessel, crew and area (Fujise, 1991).

The reported catches since 1963 are given Table 1. Recent catch statistics are reported as meat weight or whole animals, and the factor used to convert values for meat landed to whole animals taken is not consistent. Therefore, the Scientific Committee has expressed concern about the accuracy of the reported catches. It was also noted that meat products cannot accurately be attributed to stocks if the hunting operations are conducted in areas where both stocks occur.

Table 1

Reported landed catches of Dall's porpoises from the hand harpoon fishery in Japanese coastal waters (IWC, 1991c). Both *dalli* and *truei* types are included.

Year	Catch	Year	Catch	Year	Catch
1963	9,040	1972	5,190	1981	9,767
1964	9,440	1973	7,230	1982	12,833
1965	9,180	1974	6,470	1983	12,776
1966	7,980	1975	7,350	1984	9,764
1967	5,150	1976	9,899	1985	10,378
1968	6,020	1977	9,358	1986	16,515
1969	7,020	1978	8,426	1987	25,600
1970	8,060	1979	6,843	1988	40,367
1971	5,210	1980	6,920	1989	29,048
				1990	21,802

POPULATION ESTIMATED

Bouchet (1981) estimated that 920,000 Dall's porpoises occur in the North Pacific and Bering Sea portions of their range, excluding the Sea of Japan and Okhotsk Sea. This estimate was revised upwards to 953,000 (Turnock, 1987). The latter estimate included 212,000 porpoises in the Bering Sea stock and 741,000 porpoises in the western and central North Pacific between 150°E and 172°W. A large but unknown population(s) occurs in the eastern North Pacific.

Miyashita and Kasuya (1988) reported minimum estimates for the *dalli*-type stock in the southern Okhotsk Sea of 47,000 (plus an unknown number of animals in adjacent Soviet waters) and for the *truei*-type stock in Japanese and USSR waters of 58,000. Using porpoise sightings from 1990 surveys, Miyashita (Miyashita, In press-b) estimated the three stocks off Japan to be: 111,000 (CV=0.29), *dalli*-type, northern Okhotsk Sea stock; 226,000 (CV=0.15), *dalli*-type, southern Okhotsk stock; and 217,000 (CV=0.23), *truei*-type, central Okhotsk Sea stock.

These estimates are substantially different from the previous estimates for part of the area; so, with help from a review by Buckland the sub-committee examined the new results in some detail. The design was found to be acceptable. Although bad weather did prevent surveys from achieving uniform coverage, it did not significantly affect results. Buckland suggested that a more appropriate method of calculating variance would yield a higher variance. If the porpoises are attracted to vessels, as are Dall's porpoises in other areas, results will be biased upward; if they avoid vessels the results will be biased downward. This was not possible to assess with the data available.

ASSESSMENT AND STATUS

From data then available (catches through 1987, population estimates from Miyashita and Kasuya (1988)) the Scientific Committee concluded in 1989 that the take of Dall's porpoises in the Japanese hand harpoon fishery was clearly not sustainable (IWC, 1991b; c). In 1988 and 1989, respectively, totals of 40,367 and 29,048 porpoises were taken in this fishery. These represented 38% and 28%, respectively, of the minimum population estimates then available. Takes during the 1990 season were estimated to consist of 9,360 of the *dalli*-type and 12,442 of the *truei*-type (uncorrected for animals struck but lost). The Japanese statistics report the catch by colour type based on the area of operation for catches landed as meat (i.e. 100% *dalli*-type off Hokkaido and 90–95% *truei*-type off Sanriku). In 1990, then, the reported takes of Dall's porpoises in the Japanese harpoon fishery comprised 4.1% of the revised estimated population of *dalli*-type from the southern Okhotsk Sea stock and 5.7% of the estimated population of the *truei*-type from the central Sea of Okhotsk stock. These percentages must be increased by some amount to account for porpoises struck but lost. Estimates of the average struck-and-lost ratio ranged from 3.3% to 9.8% of those struck, depending on region (Fujise, 1991). Although some of these struck and lost animals may survive, applying the above range of struck and lost ratios suggests that 1990 takes accounted for 4.2–4.6% of the southern Okhotsk Sea stock and 5.9–6.3% of the central Okhotsk Sea stock. While these levels are very much lower than the catch rates reported for 1988 and 1989, it cannot necessarily be assumed that they are sustainable. The sub-committee in 1990 (IWC, 1991c) stated that it believed 'that allowable harvest and incidental take rates should be lower than half of the estimated value for r_{\max} ' and noted that 'all estimates of r_{\max} presented in the submitted papers in 1990 are less than 0.10'. This implies that annual takes should be less than 5% of the estimated population size; how much less is still open to question. In addition, demographic implications of the sharp differences in age and sex structures of catches in different regions (Fujise *et al.*, 1991) must be taken into account in assessing impact.

RECOMMENDATIONS

In 1990 the highest priority recommendations of the Scientific Committee related to small cetaceans were that the planned Japanese sightings surveys be carried out and that new population estimates be developed for the stocks taken in the hand harpoon fishery (see new results in Miyashita, In press-b). It was also recommended that a plan for monitoring trends in the populations be developed. The sub-committee was pleased to receive the new estimates and **recommends** that surveys be continued

as a basis for monitoring trends in population sizes for hunted stocks.

Additional recommendations in 1990 were that analyses of parasite loads in the eastern North Pacific and other areas be compared to those already studied (Walker, 1990) to help identify other possible stocks. Along these lines, it was also recommended that studies be continued or undertaken to differentiate stocks using a combination of techniques, such as differences in life-history parameters (e.g., asymptotic length), parasite and contaminant loads, reproductive seasonality, DNA and isozymes.

In 1989, the Scientific Committee recommended that catch statistics for this fishery be collected and reported on a stock-by-stock basis. Considering the possible take from the stocks off Japan, it was also recommended that the Republic of Korea be requested to report to the IWC by-catches of Dall's porpoises (and other cetaceans) in its squid driftnet fishery (IWC, 1990b).

In 1990, the Scientific Committee recommended that information on struck-and-lost rates be collected and analysed for each gear type in the Japanese harpoon fishery, to allow more accurate estimation of total mortality. It also recommended a clarification of the basis for revision of the 1986 and 1987 catch statistics (IWC, 1991c). The sub-committee was pleased to acknowledge the Japanese Government's quick response to these requests. Given that continuing problems have been identified, however, the sub-committee **advises** that there be increased effort in improving catch statistics for this fishery, and that this includes steps to distinguish the two colour types in landings of meat only. Noting the high variability in estimates currently available for struck-but-lost rates, the sub-committee **advises** that additional information be collected on these rates by area, season, vessel and other significant variables. Further, it **encourages** the continuation of steps taken to improve precision in estimates of take (Kasuya, 1991).

The sub-committee is pleased that catches have been reduced, perhaps to levels very near sustainable rates. However, given the uncertainty about the age and sex structure of catches, and pending a detailed age-structure assessment, it is again **reiterates** that catches in this fishery be further reduced.

5.1.1.2 *Globicephala macrorhynchus*

COMMON NAMES

Short-finned pilot whale, *tappa-naga* for the northern stock and *ma-gondo* for the southern stock (Japanese).

DISTRIBUTION

This species is found in tropical and warm temperate waters world wide. Short-finned pilot whales from at least two different stocks are hunted in Japanese waters (Kasuya *et al.*, 1988). The northern stock is found along the Pacific coast of northern Japan between 35°N and 43°N (IWC, 1987). Most sightings of whales in this stock during recent surveys were concentrated between 40°N and 43°N and west of 143°E (Kasuya *et al.*, 1986). Whales belonging to the southern stock were found during summer survey cruises in 1984 and 1985 in Japanese waters south of 37°N from the coast east to 125°E. No whales were seen south of 25°N or east of 152°E. This suggests that whales of the southern stock are restricted to this area off the Pacific coast of Japan. Wada (1988) reported, based on electrophoretic data, that the two stocks were genetically isolated.

PROBLEMS AND CATCH STATISTICS

Northern stock

The northern stock of pilot whales was exploited by Japanese small-type whaling vessels before World War II, but no statistics are available. During the late 1940s and early 1950s, the annual catches declined rapidly from 400 to less than 50 animals. In addition, the proportion of males in the catch declined. After a pause of about 25 years, small-type whaling on this stock resumed in 1982. Two to seven vessels have operated and landed their catch at three land stations in Ayukawa. The gunners select large whales. The total reported catch for eight seasons (1982–1990) was 700 whales (see Table 2).

Table 2

Catch statistics for northern stock of short-finned pilot whales taken by Japanese small-type whaling vessels, based on gunner's reports.

Year	No. of whales	No. of vessels	Operational-vessel days
1982	172	5	119
1983	125	7	100
1984	160	6	94
1985	62	7	77
1986	28	3	14
1987	0	0	0
1988	98	4	90
1989	50	2	78
1990	10	2	58

Since 1982, the regulations by the central government have changed several times: (1) no catch limit was set during the October–November 1982 season; (2) a quota of 175 was set for the 1983 and 1984 seasons; (3) a fixed fishing season of 255 vessel days was established for seven small-type whaling vessels during the 1985 season; (4) the government and industry decreased the fishing effort for the 1986 season to 40% of the previous season and set a quota of 50 whales from 5 October to 18 November for three vessels; (5) no whaling occurred during the 1987 season and the quota of 50 whales was carried over to the 1988 season; (6) four vessels were allowed to operate from 5 September to 30 November in 1988 with a two year quota of 100 whales; and (7) an annual quota of 50 whales was set for the 1989 and 1990 seasons and only two of the four vessels previously involved were allowed to operate from 1 September to 18 November each year.

Southern stock

In Japanese waters the southern stock has been exploited since before World War II by local fishermen in three isolated areas. Fishermen from various villages have operated a drive fishery for pilot whales along the Izu Peninsula since the early 1900s. Statistics are available since 1950. Annual catches ranged between 31 and 650 from 1950 to 1956. Statistics are incomplete between 1957 and 1971. From 1972 to the present, the annual catches have ranged from 0 to 80 whales. Today, only the fishermen from Futo (Izu Peninsula) still hunt pilot whales, but the last catch was 20 whales in 1981. Available catch records are summarised in Table 3. No catch limits are set for this fishery by the Shizuoka Prefectural government, but the Fisheries Agency requested a limit of 657 individuals of all dolphin species for the 1991 season.

Table 3

Drive fishery statistics for southern stock of short-finned pilot whales landed at Izu Peninsula, Japan.

1957	---	1965	33	1973	0	1981	20

Off Nago, Okinawa, the fishermen have hunted pilot whales in a drive fishery for a long time, but catch statistics are only available for years since 1960. Annual catches have varied from 0 to 500 animals per season (not calendar year). In 1975, the fishermen started to harpoon pilot whales from 5–7 fishing vessels. This method has replaced the traditional drive fishery in the area. The reported catches since 1960 are given in Table 4. This crossbow fishery came under regulation in 1989. A quota of 100 individuals (all species) was established for the Nago fishery with four vessels licensed for the 1991 season by the local governor.

The major pilot whale fishery is the one at Taiji (Kii Peninsula) that started in the 17th century (Kasuya and Marsh, 1984). Statistics are fragmentary for years before World War II. After the war, both small-type whaling and a drive fishery operated in the waters off Taiji. A total of 200–300 whales was taken annually between 1949 and 1951 by small-type whaling vessels. After 1951, lower catches were made and only a single small-type whaling vessel operated to meet local demand for pilot whale meat. The drive fishery started in 1969 and, since 1980, has been the only pilot whale fishery operating off Taiji. Annual catches ranged between 90 and 605 whales between 1975 and 1985. In 1982, the Japanese government placed all drive fishermen under the control of the relevant Prefectural governments (IWC, 1987). The Wakayama Prefecture (Taiji) has set an annual catch limit of 500 pilot whales since that time. Recent catch statistics are summarised in Table 5. Small-type whaling from Taiji started again on the southern stock of short-finned pilot whales in 1988 when 20 whales were caught (Kishiro and Kasuya, 1993); 3 vessels operated that year. An annual quota of 50 whales was set

1969	75	77			

for 1989 and 1990 but only 5 and 8 whales were taken, respectively. This quota was set by the Japanese Fisheries Agency.

ASSESSMENT AND STATUS

Northern stock

The provisional total estimated population size of the northern stock, based on summer surveys during 1984 and 1985, was 5,344. In 1986, the Scientific Committee expressed considerable concern that the available data suggested a decline in the northern stock (IWC, 1986b). Using data collected in September and October of 1982 through 1988, Miyashita (1993) re-estimated the population size of the northern stock to be 4,239 (CV=0.61). The annual catch of about 87 whales since 1982 represents more than 2% of the estimated present population size, but the current quota of 50 is about 1% of the estimate.

Southern stock

The estimated size of the southern population based on five cruises conducted during the summers of 1984 and 1985 was 53,000 (IWC, 1987). Based on new sighting data collected in 1986 through 1988, Miyashita (1993) revised the estimate for the southern stock of pilot whales down to 24,474 (CV=0.61). Recent total annual catches (uncorrected for any struck/lost whales) represent 1 to 2% of the estimated present population size of this stock.

RECOMMENDATIONS

In 1986, the Scientific Committee recommended that the biological monitoring programme be expanded on the northern stock and that additional vessel surveys be conducted to improve the population estimate and to collect data on the proportion of adult males present (IWC, 1986b). Additional sighting surveys were conducted by the Japanese and the results presented in Miyashita (1993). The sub-committee understands that biological materials have been collected routinely from whales

landed in this fishery. It is requested that these materials be studied and reported on.

In 1986, the Committee also requested that fishing effort, sighting and catch data continue to be collected for the drive fishery along with the collection of biological materials from the catch. The Committee noted that no biological materials had been collected from the drive fishery since 1981. The Committee also suggested that investigations be initiated on stock identity of the whales taken in the three different southern fishing areas.

In 1986, the Scientific Committee felt it appropriate, from a biological point of view, that no animals be taken from the northern stock until a clearer understanding of the status of this population became available (IWC, 1986b). It recommended that if a pause in whaling was not possible, the catch should be reduced by significantly curtailing the total effort in the fishery. Japan reduced the annual catch limit from 175 whales in 1984 to 50 in 1987 and the number of vessels licenced to hunt pilot whales from the northern stock were reduced; from 6 vessels in 1984 to 2 vessels in 1989.

In 1986, the Committee also considered that the exploitation of the southern stock should not be intensified because of the recent catch levels and the fact that gross productivity of this species is low. However, effort on this stock has increased since small-type whaling on the southern stock started again in 1988. The sub-committee again **recommends** that catches from the southern stock not exceed levels prior to those in 1986.

5.1.1.3 *Berardius bairdii*

COMMON NAMES

Baird's beaked whale, *tsuchi kujira* (Japanese), *severnyi plavun* (Russian).

DISTRIBUTION

These whales are found only in the North Pacific Ocean and adjacent seas. Based on migration patterns, at least three stocks exist in the western Pacific around Japan: a western Pacific stock; a Sea of Japan stock; and an Okhotsk Sea stock (Kasuya and Miyashita, 1988).

PROBLEMS AND CATCH STATISTICS

Japanese fishermen have hunted Baird's beaked whales since at least the 17th century. Fishermen using hand harpoons from small boats operated out of Katsuyama in Chiba Prefecture (near Tokyo) until the start of the Meiji era (1867). The annual catch was only four or five whales. In 1908 *tsuchi-kujira* whaling resumed again off Chiba Prefecture from a small wooden boat with a Norwegian-type harpoon gun. After the end of World War II, coastal whaling increased, and by 1952 the Fisheries Agency of Japan had licensed 76 small-type whaling vessels. The largest catch was in 1952 when 322 Baird's beaked whales were landed (Omura *et al.*, 1955). Since 1952 the catches have declined. The Government of Japan established a national quota of 40 whales in 1983 (IWC, 1984b). The small-type whaling association divided this quota into 35 for the western Pacific and 5 for the Okhotsk Sea. In 1988 the national quota was increased 50% (from 40 to 60) as a one-year emergency increase for the small-type whaling vessels to partially replace the former catch of minke whales (IWC, 1980c). However, this higher quota was maintained in 1989 and 54 whales were landed. In 1989 one vessel with a quota of six whales did not operate in the fishery. During 1990 the quota was 54 whales and all were

taken. Table 6 lists the catch of Baird's beaked whales between 1961 and 1990.

Soviet whaling operations were reported to have taken 143 whales between 1934 and 1964 off Kamchatka and the Kuril Islands. Small numbers were also taken in the eastern North Pacific and landed at various shore stations in the USA (14 whales) and Canada (135 whales) between 1934 and 1966.

A few Baird's beaked whales are known to have been caught incidentally in the Japanese salmon driftnet fishery (from both research and commercial vessels) (Ohsumi, 1975). None has been identified as incidentally taken in any of the high seas pelagic driftnet fisheries in the North Pacific (L. Jones, pers. comm.). A few have been taken in gillnets off California (California Department of Fish and Game records).

Table 6

Statistics for Baird's beaked whales taken in Japanese coastal waters.

Year	Catch	Year	Catch	Year	Catch
1961	133	1971	118	1981	39
1962	145	1972	86	1982	60

1964	189	1974	32	1984	38
1965	172	1975	46	1985	40
1966	171	1976	13	1986	40
1967	107	1977	44	1987	40
1968	117	1978	36	1988	57
1969	138	1979	28	1989	54
1970	113	1980	31	1990	54

ASSESSMENT AND STATUS

Based on sightings data, Miyashita (1986) estimated that 4,220 Baird's beaked whales occurred in the western North Pacific. The most recent estimate of abundance for this species – 5,870 whales in the western North Pacific and adjacent seas (Miyashita, 1990), based on 11 surveys conducted between 1983 and 1989 (IWC, 1991c) was presented to the Committee in 1990. This new estimate included 3,950 (CV=0.28) for the Pacific coast, 1,260 (CV=0.45) for the Sea of Japan and 660 (CV=0.27) for the Okhotsk Sea. The Committee noted that the estimates of 3,950 and 4,220 whales were not statistically different from each other but that they did differ from the estimate of 2,500 from 1989 that was based on data from all months rather than just the survey data for the season of greatest abundance in coastal waters (August).

The CPUE data did not show a clear annual trend from 1947 to 1983 (Kasuya, 1984). It is not known if the population is declining or stable (IWC, 1989).

At the 1985 Scientific Committee meeting, it was noted that the national quota of 40 whales was approximately 1% of the population estimate of 4,220 (Miyashita, 1986). It is 2.4% of the 1989 estimate (2, 500). It was also noted that historically, approximately 70% of the annual catch has been males (Ohsumi, 1983). In the absence of an estimate of gross reproductive rate, the Committee did not know whether or not the population could sustain the present level of catch. During the past five years the average catch in the western Pacific by Japan has averaged about 41 whales. This is around 1% of the population size depending on the estimate used. The corresponding figures for the Okhotsk Sea stock are 8 whales and about 1.2%.

RECOMMENDATIONS

In 1990, the Committee recommended that monitoring of trends in these populations in Japanese waters continue, taking special notice about the complications to stock assessments introduced by migration of animals (IWC, 1991c).

In 1990, the Committee again noted that there was insufficient data to judge whether annual catches of approximately 60 whales are sustainable and recommended 'as in the past (IWC, 1989) that research to develop an understanding of the life history, behaviour and social system that will allow estimation of growth rate potential be continued.' It was also noted that 'this should include continued collection and analysis of data and samples from the catch'. The sub-committee noted that Japan had increased its biological sampling to 100% of the catches; the sub-committee encourages continuation of that level of sampling and prompt evaluation and publication of results.

5.1.1.4 *Stenella coeruleoalba*

COMMON NAMES

Striped dolphin, *suji-iruka* or *suzi-iruka* (Japanese).

DISTRIBUTION

This species is found in tropical and warm-temperate waters around the world. In Japanese waters it is associated with the advancing northern front of the warm Kuroshio Current (Miyazaki *et al.*, 1974). During the winter, the northern boundary is around 33°N; during the summer it extends to 46°N. Ohsumi (1972) and Miyazaki *et al.* (1974) suggested that all striped dolphins caught in Pacific Japanese waters belong to one stock. Recently, Kasuya and Miyashita (1989) suggested there were coastal and offshore stocks of striped dolphins off the Pacific coast of Japan.

PROBLEMS AND CATCH STATISTICS

Drive fisheries for small cetaceans have a long history in Japanese waters. The first known drive fishery operated during the Genroku Age (1688–1703), but the types of dolphins caught were not recorded. The first recorded drive fishery for striped dolphins was started by the Kawana fishermen on the Izu Peninsula on 17 December 1888 (Miyazaki, 1983). Ten villages are known to have operated the fishery in the early 1900s (Kasuya, 1985). The number has declined, and since 1984 only Futo has continued to operate. Catch statistics for the Izu area are found in Table 7.

Striped dolphins were also caught in the harpoon fishery off Taiji until 1972. Starting in 1973 a local group of fishermen formed a new drive fishery for these dolphins. Catches by this drive fishery at Taiji between 1963 and 1990 are given in Table 8. The highest catch was 11,017 in 1980. Beginning in 1982 a voluntary catch limit of 5,000 dolphins was set by the fishermen in Taiji based on advice provided by the prefectural government. In 1989 the 5,000 limit became a condition of the license. In addition, the Fisheries Agency of Japan has requested a voluntary limit of 3,100 for 1991. Striped dolphins have made up 15% – 67% of the catch at Taiji between 1982 and 1990. No catch limit has been set for the Izu Peninsula area, but the Fisheries Agency requested a limit of 657 for all species of dolphins for 1991.

Matsuoka stated that these catch limits can be achieved by adjusting the catch by releasing a certain proportion of schools driven into a bay. For example, in early 1991, when

Table 7

Catch statistics for striped dolphins landed along the Izu Peninsula. Statistics are incomplete before 1961. Data for 1942-81 from Miyazaki (1983) and 1982-1990 from Japanese Progress Reports to the IWC.

1956	8,507	1973	6,799	1990	0
1957	2,751	1974	11,715		
1958	3,681	1975	5,996		

approximately 2,000 striped dolphins out of 7,000–12,000 sighted were driven into the bay of Taiji, only 600 of them were killed; the rest were released.

Striped dolphins have also been reported taken in gillnets and set nets in Japanese waters (Miyazaki, 1983). Between 1976 and 1981, a total of 772 striped dolphins was taken in fishing gear. Recent reports of incidental catches in various types of gear in Japanese waters are also available (Anonymous, 1990d). Watanabe (1994) has also reported catches in large-mesh drift nets during research cruises in the central North Pacific. Estimates of total catches of striped dolphins in this fishery are not yet available.

ASSESSMENT AND STATUS

The largest directed fishery (both drive and hand-harpoon) for small cetaceans in Japanese waters was that conducted on the striped dolphin, until the Dall’s porpoise fishery expanded in the mid 1970s. Kasuya and Miyazaki (1982) estimated that the initial population of striped dolphins off Japan had been 320,000–340,000, but by the late 1970s it was down to between 130,000 and 180,000. At the 1982 Scientific Committee meeting, Kasuya reported that recent life-history and populations studies led him to believe that

Table 8

Catch statistics for striped dolphins landed at Taiji, Japan between 1963 and 1990. Data for 1963-1978 from Miyzaki (1980), 1979-1981 from Miyazaki (1983) and 1982-1990 from Japanese Progress Reports to the IWC.

1969	499	1978	1,644	1987	358
1970	997	1979	2,397	1988	1,767
1971	1,717	1980	11,017	1989	1,000
				1990	682

these estimates were unreliable, for the reasons noted below.

The full statistics for the earlier years (before 1961) of the fishery on striped dolphins are not available, but in some years the catches exceeded 20,000 animals. Catch statistics from 1961 onward indicate a statistically significant downward trend in the total catches on the Izu Peninsula between 1961 and 1981, with a high of 11,715 landed in 1974 (Miyazaki, 1983). Catches of around 10,000 in the early 1960s declined to about 1,000 or less after 1980 using the same equipment (four vessels) and driving teams (Kawana and Futo). This decline occurred while the demand for dolphin meat remained high in the area. Kasuya and Miyashita (1989) reported that after the catch of striped dolphins decreased, the people in the Shizuoka area increased their use of Dall’s porpoises. Kasuya (1976), Kasuya and Miyazaki (1982) and Kasuya (1985) noted that the striped dolphin population in Japanese waters has declined in abundance due to over-exploitation. Kasuya and Miyashita (1989) reported a hiatus in the density of sightings of this species at about 30°N during the summer, and suggested the possibility that there was another stock to the south of 30°N. They also identified a large number of striped dolphin sightings in the offshore water (145–160°E) between 33° and 40°N. During the same surveys, sightings of striped dolphin were scarce in the Japanese coastal waters. These data suggest that the stock of coastal striped dolphins is depleted and that the striped dolphins found offshore belong to another stock or stocks.

RECOMMENDATIONS

At the 1982 meeting, the Committee noted that the catches of these dolphins had declined over a long time period on the Izu Peninsula, that reproductive parameters had possibly changed in response to this heavy exploitation and that available analyses of CPUE were not adequate to determine the status of the stock (IWC, 1982b). Therefore, it recommended that Japan be urged to collect and analyse more detailed effort data and other relevant information on this species including:

- (a) effort data in hours and days, by vessel, area, season and year;
- (b) detailed oceanographic data;
- (c) data on other major fisheries in the area, especially for squid, and;
- (d) information on yearly changes in seasonal abundance, effort and catch.

Noting that catch limits are now voluntary, the sub-committee **advises** the establishment of mandatory catch limits on a species and stock basis, according to the status of the population.

Noting that the fisheries department has not sampled the catch of striped dolphins in ten years, the sub-committee **recommends** that Japan be encouraged to undertake a study of the age and sex composition of the catch and of reproductive parameters of the affected population.

Given reports that there have been changes in drive procedures, and total effort, the sub-committee **requests** an updated description of the drive fishery’s current methods and procedure.

5.1.1.5 Other species

Several additional species are taken in Japanese direct fisheries (see past Japanese progress reports to the Committee, e.g. Anonymous, 1985a; 1986; 1987b; 1990d).

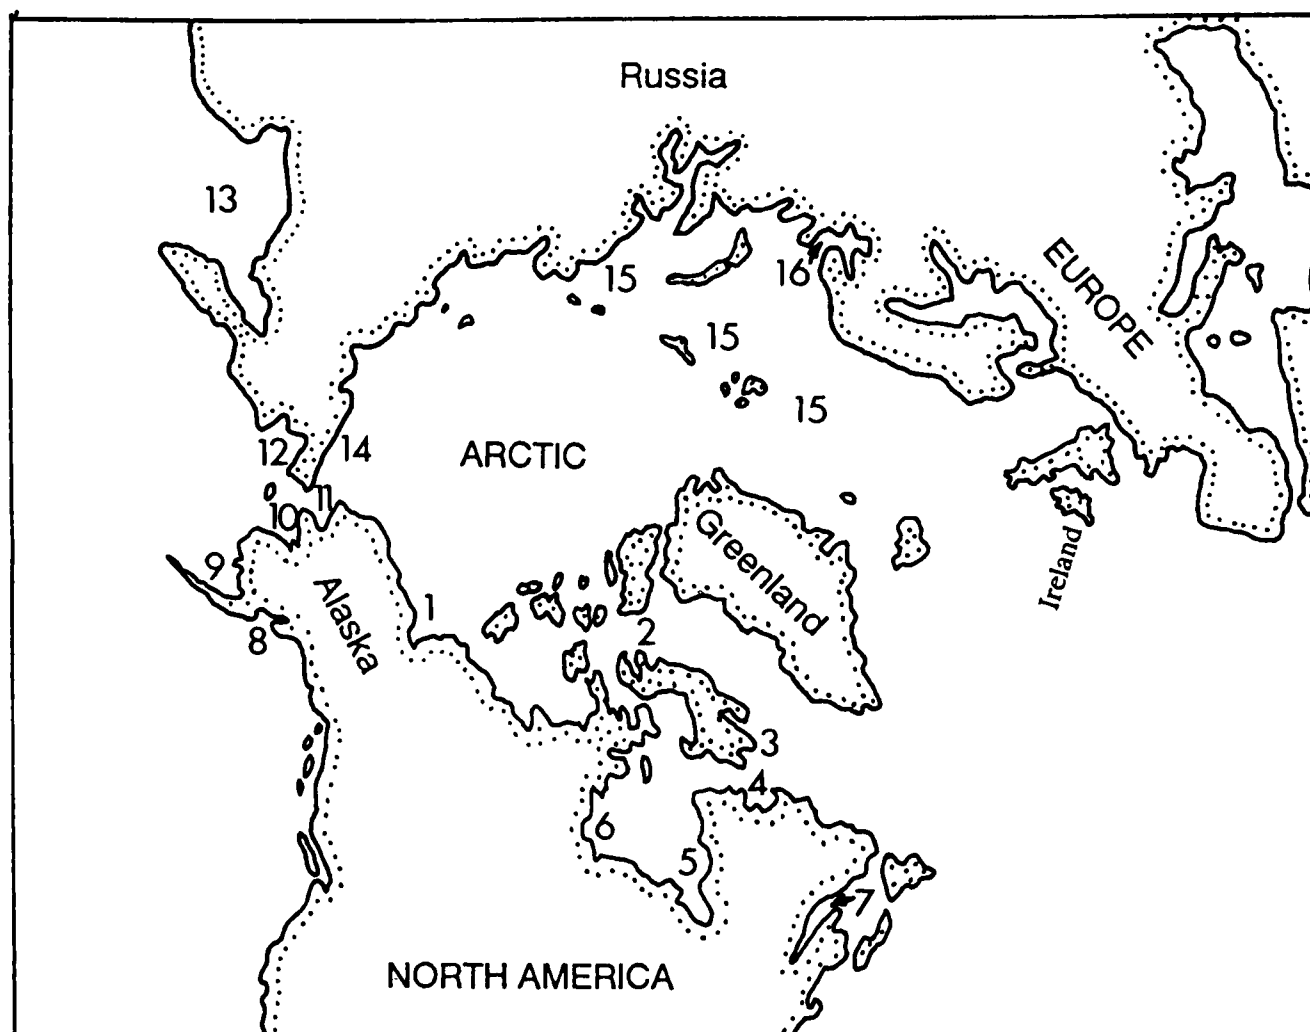

Fig. 1. White whales. Numbers refer to those in Table 9.

For example, 1,274 bottlenose dolphins were taken in drive fisheries in 1990 (SC/43/ProgRep Japan). The impacts of these takes on the populations are unknown.

5.1.2 Direct fisheries for small cetaceans in the Arctic²

Two species of small cetacean – the white whale and the narwhal – have distributions centred in the Arctic, and both have been exploited for centuries. In the past, commercial operations took thousands of white whales and hundreds of narwhals in some years. In recent years, most of the hunting for both species has been done by aboriginal peoples for domestic subsistence use and for the sale of muktuk and ivory. This section reviews recent developments in the exploitation of white whales and narwhals throughout their ranges, with emphasis on those areas where an immediate conservation problem is recognised or suspected.

5.1.2.1 *Delphinapterus leucas*

COMMON NAMES

White whale, beluga, belukha (Alaska and USSR), *qilaluaq* or *qaqortoq* (Greenlandic), *qilalugaq* (Inuktitut), *hvidhval* or *hvidfisk* (Denmark), *situaq* (Bering Strait Inupiat), *sisuaq* (Northern Alaskan Inupiat), *cetuaq* (Alaska mainland Yupik).

DISTRIBUTION

The white whale has a circumpolar distribution in the Arctic and subarctic, mainly north of 55°N. The world population is subdivided into at least 16 stocks that are isolated from one another to varying degrees (see Fig. 1 and Table 9). White whales tend to congregate in estuaries in summer, and the resulting aggregations have provided the basis for defining some of the stocks. Most populations are migratory, and their distribution is partly shaped by

seasonal changes in ice conditions. Several stocks may mix during winter when they are excluded from the summering areas by ice (IWC, 1980c). For analytical convenience, distribution and other topics are discussed below by country. It is important to bear in mind that some of the stocks occur within the coastal jurisdictions of more than one country.

Greenland

White whales occur infrequently in East Greenland coastal waters, and those that do occur there are considered wanderers from the Svalbard area (i.e., the Barents Sea) (Dietz *et al.*, 1985).

The white whales off the west coast of Greenland belong to a stock probably shared with Canada. They ranged historically all along the coast to at least as far south as Qaqortoq (Julianehaab, ca 61°N), where they were hunted in winter (Winge, 1902; Degerboel and Nielsen, 1930). They now occur as far south as Nuuk (Godthaab, ca 64°N) only infrequently but are still abundant in outer Disko Bay and in the open pack ice along the Greenland coast south to approximately Sisimiut (Holsteinsborg, ca 67°N) in winter (McLaren and Davis, 1981; 1982). Surveys in 1990 and 1991 confirmed that this is the core area for white whales in winter; most animals were observed within 50km of the coast (M.P. Heide-Jørgensen, pers. comm. to Reeves, 30 April 1991).

Canada

Seven white whale stocks are provisionally recognised in Canada, based on varying degrees of difference in body sizes, catch histories and hiatuses in distribution. These are Beaufort Sea-Mackenzie Delta, High Arctic (Lancaster Sound region), Southeast Baffin (Cumberland Sound, Frobisher Bay and Lake Harbour area in Hudson Strait – see Richard and Orr, 1986), Ungava Bay, East Hudson Bay-James Bay, West-South-North Hudson Bay (=West

² Initial draft by R.R. Reeves.

Table 9

Status of world white whale stocks (modified from Braham, 1984). Fig. 1 shows the stock areas. Status: (A) large (3000+) and lightly or sustainably exploited; (B) large and exploited at rates that give cause for concern; (C) medium (500-3,000) and lightly or sustainably exploited; (D) medium and exploited at rates that give cause for concern; (E) small (500 or less) and vulnerable to hunting or habitat deterioration.

Centre of Summer distribution	Est. abundance		Est. ann. removal rate		Refs	Status
	Init. ¹	Current	Kill	(% stock size)		
Canada						
1. Beaufort Sea/Mackenzie Delta	--	11,500	232 ²	2.0	1,2	A

16. White Sea	--	500-1,000	?	?	17	?

¹Based on cumulative catches, to be regarded as minimum estimates of pre-exploitation population size.
²Assumes an average catch of 123 per year in Mackenzie Delta, 1985-89, corrected on the basis of 1 killed and lost for 4 landed (ref. 21), giving an estimated total kill (ETK) of 151. Assumes an average catch of 43 (40-46) in Alaskan waters, 1987-90 (Table 4), corrected on the same basis as in Ref. 2:table 5, giving an ETK of 81.
³Assumes an average catch of 813 per year in West Greenland (Table 2, 1975-85); corrected on the basis of a 25% loss rate (1 killed and lost for 3 landed) (ref. 5), giving an ETK of 1084. Assumes an average catch of 87 per year in Canada, 1974-87 (Table 3); corrected on the basis of a 25% loss rate, giving an ETK of 116.
⁴Assumes that 40% of the catch in Hudson Strait and 100% of the catch on the east side of Hudson Bay is from this stock (Table 3). A loss rate of 30% of the total kill is applied arbitrarily.
⁵Combines estimates for west, south and north Hudson Bay (ref. 11).
⁶Assumes that 60% of the catch in Hudson Strait and 100% of the catch in western and northern Hudson Bay is from this stock (Table 3; and see text). A loss rate of 30% of the total kill is applied arbitrarily.
⁷Based on total kill estimate of 10 (ref. 14) and secured catch estimate 10-12 (ref. 15).
⁸Catches from Table 4, corrected for hunting loss by ETL:ETK ratio of Ref. 2:Table 5. Norton Sound loss rate may have declined in recent years with the use of aeroplanes to locate animals that sink during the hunt (ref. 21).
⁹Considered to include Kuskokwim Delta. Population estimate is not based on survey data; a single sighting of more than 2000 white whales was made near the mouth of the Yukon River in 1956 (ref. 21)
¹⁰Based on a guesstimate for the total annual kill at or near Sireniki in the mid-1980s (ref. 20).

Hudson Bay in previous IWC reports) and St. Lawrence River. There is considerable uncertainty about the relations among the groups of whales in Hudson Bay and adjacent waters (Richard *et al.*, 1990). The delineation of stocks based on body size differences (Sergeant and Brodie, 1969) has been found by Doidge (1990) to be less useful for some stocks than was thought previously. However, white whales in Hudson Bay are consistently smaller than those in other areas studied. Preliminary attempts to use mitochondrial DNA markers to distinguish white whale stocks suggested that white whales in eastern Hudson Bay are distinct from those in the Mackenzie Delta, western Hudson Bay, Cumberland Sound and Jones Sound (Helbig *et al.*, 1989). The Beaufort Sea-Mackenzie Delta stock is shared with Alaska (USA) and possibly the USSR; the High Arctic stock probably with Greenland.

The winter and spring distribution of the Hudson Bay, Ungava Bay and SE Baffin populations is centred in Hudson Strait, the Labrador Sea and Davis Strait (Boles, 1980; Finley *et al.*, 1982; Richard and Orr, 1986), although

some white whales overwinter in Hudson and James bays (Reeves and Mitchell, 1989a). Whales from several stocks may have a common wintering area. Those that summer in the Canadian High Arctic and off northwest Greenland probably winter primarily along the east side of Baffin Bay and Davis Strait in open water or unconsolidated pack ice. Some winter in the Baffin Bay North Water (Vibe, 1950; Freeman, 1968; Finley and Renaud, 1980).

Alaska (USA)

Four provisional management stocks are recognised in Alaskan waters, in addition to the Beaufort Sea-Mackenzie Delta stock shared with Canada. These are the Cook Inlet, Bristol Bay, Norton Sound-Yukon Delta and eastern Chukchi Sea stocks (Hazard, 1988; Lowry *et al.*, 1989). All the populations except the one in Cook Inlet are believed to winter mainly in the Bering Sea. The evidence for stock differences is mainly the discontinuity of summer distributions (Lowry *et al.*, 1989; Frost and Lowry, 1990). Burns and Seaman (1985) have argued that all the 'stocks'

that winter in the Bering Sea comprise a single genetic population, although no direct genetic evidence is available to evaluate this argument.

USSR

White whales are widely distributed along the Soviet Arctic coast, and they have been exploited intensively in many areas (Ivashin and Mineev, 1981; Ognetov and Potelov, 1984). The estuaries of all the major rivers along the coast of Siberia are said to be visited by white whales in summer. Yablokov (1979) proposed eight stocks in Soviet waters, as follows: White Sea (2), West Siberian (Barents-Kara-Laptev seas) (2, possibly 3), East Siberian (Chukchi-East Siberian seas), Anadyr Bay (Bering Sea) and Sea of Okhotsk (2). Berzin *et al.* (1986) showed major concentrations in three areas of the Okhotsk Sea: Sakhalin-Amur, Shantar and the northern bays (Gizhiginskaya and Penzhinskaya). Five stocks are provisionally listed in Table 9, pending a more detailed justification for subdividing them.

The East Siberian and Anadyr Bay stocks probably winter mainly in the Bering Sea, where they could mix with whales belonging to the Alaskan stocks (Burns, 1984; Burns and Seaman, 1985; Hazard, 1988). Some white whales overwinter in offshore areas of the Barents, Chukchi and probably Kara seas (Belikov *et al.*, 1990).

PROBLEMS AND CATCH STATISTICS

Greenland

Preliminary summaries of white whale catch statistics for Greenland have been published by Kapel (1977; also see Kapel in Reeves and Mitchell, 1987b). Reported secured catches for 1975-87 are summarised in Table 10. These are consistent with the estimate of recent annual catches of 500-1,000 by Heide-Jørgensen (1990). The completeness and reliability of the Greenland catch statistics has declined in recent years as fewer hunters have participated in the reporting scheme (E.W. Born, *in litt.* to Reeves, 3 October 1985; Heide-Jørgensen, MP, 1990). The reporting system is no longer functioning reliably. High catches have been made in some years at *savssats* (ice entrapments) in Disko Bay (e.g. about 500 in February 1990 - M.P. Heide-

Jørgensen, pers. comm. to Reeves, 30 April 1991). Most of the Greenlandic catch of white whales (except for *savssats*) is made in the drive fishery in Upernavik district (Heide-Jørgensen, 1990).

The demand for white whale muktuk and meat in Greenland is strong and likely to grow along with the human population. Although much of it is consumed in the villages after being shared according to local customs, some is also sold for resale in urban centres (Dahl, 1989). There are no catch limits. Local regulations and customary rules govern some aspects of the hunting (Dahl, 1990; Qujaakitsoq, 1990), but these may not be adequate in the light of changing hunt technology and consumption patterns (Dahl, 1990; Heide-Jørgensen, 1990).

Canada

White whales are protected from commercial hunting under the Beluga Protection Regulations (Fisheries Act) introduced initially in 1949 and amended many times since (Reeves and Mitchell, 1989b; Department of Fisheries and Oceans, 1990a). The St. Lawrence stock was given full protection from exploitation in 1979 and a quota of 40 whales per year (secured catch; no allowance for hunting loss) was set for Pangnirtung in Cumberland Sound in 1980. The reported catch since 1980 at Pangnirtung has exceeded the quota in some years (Richard and Orr, 1986; Cosens *et al.*, 1990). White whale products cannot be exported from the Northwest Territories (NWT) but are traded or sold within the NWT. Some is shipped to urban centres where it is sold (Reeves, unpubl. data).

Prior to 1975, there was no monitoring or reporting of catches in northern Quebec (primarily East Hudson Bay - James Bay, West-North and South Hudson Bay and Ungava Bay stocks in Tables 9 and 11). Estimates of secured catches in 13 northern Quebec communities were derived from 'harvester recall' surveys and a self-monitoring programme begun in 1975 (Boulva, 1981; Usher and Wenzel, 1987). The introduction of regular reporting from northern Quebec in the mid-1970s may give the impression of a dramatic increase in the total Canadian white whale catch, but there is no reason to believe that

Table 10

Reported white whale catches in Greenland, 1975-87, from IWC Denmark progress reports. For previous years, see Kapel (1977). Note that figures listed for 1983-85 are estimates which include an allowance for unreported catches (but not for hunting loss). The figures for 1986 and 1987 are incomplete and preliminary.

¹For communities assigned to each area, see Kapel (1977). ²Annual estimate - Kapel (1983).

Note: The relatively large catches assigned to Ammassalik in 1986-87 are in error. (M.P. Heide-Jørgensen, pers. comm. to Reeves, 30 April 1991). West Greenland catches for 1988-90, as estimated by the Greenland Fisheries Research Institute, are: West Greenland - 275 in 1988, 457 in 1989 and 1,000 in 1990.

catches in northern Quebec were much different immediately before 1973–74 than since then.

A confounding aspect of the catch statistics for settlements along the coasts of northern Hudson Bay and Hudson Strait is that more than one management stock uses these areas (Finley *et al.*, 1982; Anonymous, 1987a; Richard *et al.*, 1990). Attempts to prorate catches and assign them to the different stocks are made difficult by the lack of an easily applied genetic, morphometric, behavioural or other marker.

Statistics on catches of white whales in Canada before 1972 are imprecise and incomplete. In 1972 the federal Department of Fisheries and Oceans assumed responsibility for compiling information on white whale catches (Kemper, 1980; Usher and Wenzel, 1987). Before then, the compilation of such data was idiosyncratic or unreliable. The pre-1972 data (e.g. as reported in *International Whaling Statistics* – see Reeves and Mitchell, 1987b; Strong, 1989) should be discounted or interpreted cautiously, particularly in evaluating year-to-year variability or trends through time. Although a more systematic effort has been made since 1972 to document the white whale harvest (Table 11; Strong, 1989), the problem of incomplete reporting of landed catches remains in some areas (Usher and Wenzel, 1987).

Before Canada’s withdrawal from the IWC, catches of white whales and other whales were reported and published annually in the Canadian progress reports. Although a progress report has continued to be compiled and submitted annually to the IWC (Department of Fisheries and Oceans, 1990b) the most recent published report was in 1984 (Goodman, 1984). Catches are included in the Tables of reported catches worldwide published each year as part of the report of the sub-committee on small cetaceans (e.g. IWC, 1989).

Alaska (USA)

The quality and regularity of Alaskan catch statistics have improved over the past 15 years (see Seaman and Burns, 1981; Feldman, 1986; Hazard, 1988; Lowry *et al.*, 1989). K.J. Frost (*in litt.* to Reeves, 1 April 1991) reports good cooperation with hunters in obtaining accurate catch

statistics for recent years (Table 12). Because of the improved reporting, comparisons of catch levels through time should be made with caution.

USSR

Catch figures provided by the USSR are difficult to interpret because little information is available concerning the hunting methods, effort, product utilisation etc. The official catch totals (e.g., Ivashin and Mineev, 1981; IWC progress reports e.g. Ivashin, 1986) presumably reflect mostly or entirely commercial catches. The totals given by Ivashin and Mineev (1981) are separated into a vessel catch in the western areas and a shore-based catch in all areas. Catches by aborigines and others for subsistence, if they occur (cf. Ivashin and Shevlyagin, 1987), may be under-reported or unreported. Burns and Seaman (1985) referred to a report received in 1985 that 25–30 white whales were taken annually at Sireniki, on the southeast coast of Chukotka. The same source confirmed that although white whales are occasionally hunted at other localities in the Bering and Chukchi seas, the average number taken is very low. The opportunistic hunt at a *savssat* in the Bering Strait region in winter 1984–85 resulted in a catch of 506 whales and an estimated 500 more dead due to ‘hunger, lack of air and injuries’ (Ivashin and Shevlyagin, 1987). After reviewing available information, Burns and Seaman (1985) concluded that the Soviet harvest in the Bering and Chukchi seas was on the order of 60 white whales per year in the mid-1980s. They considered it likely that 60% of the whales killed were lost (see below), indicating a total kill of about 150 per year.

Berzin (1981) implied that commercial hunting for white whales ended in the Soviet Bering and Okhotsk seas in 1963. However, the table of catches published by Ivashin and Mineev (1981) shows no catch for the Bering Sea from 1960 to 1972, then a total catch of 160 between 1973 and 1980. For the Okhotsk Sea, it shows no catch from 1960 to 1963, then a total catch of 293 between 1964 and 1969 and no catch from 1970 to 1980. Commercial catching apparently continued in the White and Kara seas through the mid 1980s (Table 13). Yablokov’s (1979) summary of annual catches in Soviet waters, apparently referring to the

Table 11
Reported catches of white whales in Canada, 1974-87. See note for communities included within each statistical area.

1970s, indicated: 100–300 along Kanin Peninsula in trap nets; 10–15 in Onega Bay and other parts of the White and Barents seas by rifle; 200–400 in trap and gillnets and 20–50 by rifle in the Kara and Barents Seas (Yenisey and Pyasina bays); 100 or less in the Laptev, East Siberian and Chukchi seas by rifle; 20–50 in the Bering Sea by rifle; and 100 or less in the Sea of Okhotsk in seines. The total annual catch in

all areas of the USSR, according to Yablokov (1979), was 550–1,015.
According to Ivashin and Mineev (1981), the commercial exploitation of white whales is regulated by catch limits, although for unstated reasons the quotas have almost always been higher than the actual catches.

Table 12

Recent landed catches of white whales in Alaska (AIBWC via K.J. Frost, in litt. to Reeves, 1 April 1991). For data from earlier years, see Seaman and Burns (1981) and Lowry *et al.* (1989). Frost (in litt. to Reeves, 1 April 1991) considers the data for 1987–90 the most complete ever available for Alaska.

Year	Beaufort ¹	E Chukchi	Norton Sd/ Yukon Del.	Kusko-kwim Del. ²	Bristol Bay	Cook Inlet
1987	31-52	78	60-68	3-5	6	8-10

Hunting loss in all areas

Estimated loss rates for white whale hunting in Greenland ranged from 14 – 19% in West Greenland south of Thule and were less than 10% for the Thule district (IWC, 1980c:appendix 4). Set nets used in Upernavik for catching white whales (Kapel, 1985) presumably cause few losses. Communal hunts using boats to drive whales or trap them in shallow water before killing them with rifles (as described by Oldendow [1935] and Dahl [1990] for the Disko Bay area and by Heide-Jørgensen [1990] for Upernavik district) also may result in relatively small losses. On the other hand, the winter and spring hunting over deep water (at *savssats* or along an ice edge) results in substantial hunting loss (Kapel, 1977). ‘As a preliminary figure an overall loss rate of 25% seems reasonable for white whales’ (Heide-Jørgensen, 1990).

Seaman and Burns (1981; also see IWC, 1980c, Appendix 5) reported much higher losses for white whales killed in deep water, such as when they are hunted by seal or bowhead hunters during spring, than for those killed in shallow coastal water during open-water hunts. They estimated loss rates of 60% for deep-water hunting and 20% for shallow water hunting. Their estimated total kills were based on the assumption that for all parts of Alaska, one-fourth to one-third of the white whales are taken in deep water and two-thirds to three-fourths in shallow water. Lowry *et al.* (1989) provided estimates of loss rates on a finer scale than that of Seaman and Burns (1981). They considered losses in nets (some set deliberately to catch white whales, others intended mainly to catch fish, with white whales being caught incidentally) to be negligible. Also, they estimated the loss rate for open-water hunting from boats in areas with deep, muddy water (e.g., the Yukon-Kuskokwim Delta and Bristol Bay) to be 40%. In estimating catches throughout Alaska, Lowry *et al.* (1989) applied appropriate loss rates to each harvesting situation. However, it should be noted that the loss rates applied by Burns and Seaman (1981) and Lowry *et al.* (1989) were somewhat subjective.

According to K.J. Frost (*in litt.* to Reeves, 1 May 1991) the loss rate of 20% for shallow-water hunting in parts of the eastern Chukchi Sea and Northern Sound is probably too high, particularly since small aeroplanes have been used in recent years to search these areas after the hunt to find any animals that were killed but not secured. She suggests 10% as a more appropriate estimate.

For the Mackenzie Delta, Fraker (1980) reported estimates by hunters of loss rates (percentage of killed whales that were not secured) of 32% (1973) and 27% (1977). Fraker suggested that Hunt’s (1979) estimate of a 40% loss rate in the Mackenzie Delta hunt included an allowance for injured animals that escaped but eventually died from their wounds (c.f. Brodie, 1981). Fraker considered a loss rate of 33% appropriate for correcting catch statistics for this area. More recent monitoring of the Mackenzie Delta hunt has resulted in loss rate estimates of 20 to 38% of the landed catch (Strong, 1990; Weaver, 1991). Weaver (1991) attempted to account for orphaned calves by noting the number of lactating females taken, then counting their calves part of hunting mortality. The

Fisheries Joint Management Committee has funded systematic collection of data on harvest and loss in recent years. For 1985–89 the average catch was 123 (116–133) and the average number struck and lost was 28 (17–38); this would suggest 1 whale lost for every 4 landed (Alaska and Inuvialuit Beluga Whale Committee, via K.J. Frost, *in litt.* to Reeves, 1 May 1991).

For the SE Baffin region, during hunts monitored both in and outside Clearwater Fiord, the main hunting area, in 1982–84, only one instance was reported of a white whale being killed but lost (by sinking) (Orr and Richard, 1985). Most killed whales floated and thus were relatively easy to secure (c.f. Brodie, 1981). Burns and Seaman (1985) queried Orr and Richard's conclusion, noting

'In our experience, whales that sink before being harpooned or speared, would not be seen unless they were subsequently grappled, or floated to the surface, usually a day or more after death.'

Richard and Orr (1986) noted that losses were higher in hunts conducted in and near Cumberland Sound outside Clearwater Fiord. The overall loss rate for this stock may be in the order of 10–30% of the total kill (Richard, 1991a).

No data are available for the USSR. In areas where trap and gillnets have been used to capture white whales (e.g., White, Barents, and Kara seas – Yablokov, 1974; 1979; Mitchell, 1975a), the loss rate presumably has been low. However, in those areas where the whales are hunted with rifles, hunting loss must be significant (cf. Burns and Seaman, 1985; see above).

POPULATION ESTIMATES

Greenland

No independent estimate of population size for white whales in Greenlandic waters is available. Heide-Jørgensen (1990) considered the estimate by Smith *et al.* (1985) for the Canadian High Arctic stock as applicable to West and North Greenland, on the still unproven assumption that the whales found as far west as Peel Sound and Barrow Strait in summer migrate east and south in the fall to winter off West Greenland. McLaren and Davis (1981; 1982) surveyed a large area of northern Davis Strait and southern Baffin Bay in March 1981. They estimated that about 2,400 white whales were present in waters south of 70°N, north of 66°N and east of 55°30'W; their estimate made no allowance for animals that were submerged or under the ice. Surveys in 1990 and 1991 of the same area using similar methods revealed an approximately 40% decline in the number of white whales present (M.P. Heide-Jørgensen, pers. comm. to Reeves, 30 April 1991).

Canada

The stock summering in the Mackenzie Delta and eastern Beaufort Sea has been estimated recently at 11,500 (Davis and Evans, 1982).

A detailed reconstruction of the catch history in western Hudson Bay and Foxe Basin revealed no pattern of intensive exploitation and depletion that could be used for a cumulative catch estimate (Reeves and Mitchell, 1989a). The highest documented kill for any decade before 1949, when the commercial white whale processing plant at Churchill began operations, was somewhat less than 1,600 whales taken at York and Churchill, combined, in the 1880s. Richard *et al.* (1990) estimated the white whale population in western Hudson Bay as more than 23,000 in 1987. They also estimated summering populations in northern Hudson Bay of more than 700 and southern

Hudson Bay of more than 1,300. These three areas have been treated as a single stock area in Table 9.

Cumulative catches indicate a minimum population in southeastern Hudson Bay (mainly summering in the Great Whale and Little Whale river estuaries) of 6,600 in the 1850s (Reeves and Mitchell, 1987c). Aerial surveys in summer 1985 produced current estimates of 1,123 (95% confidence limits 740–1,970) in James Bay and 1,124–1,904 (offshore estimate plus estuarine count) in eastern Hudson Bay south of 59°N (Smith and Hammill, 1986). The totals for southeastern Hudson Bay and James Bay are combined for an estimate of the East Hudson Bay – James Bay stock (Table 9).

At least 800–1,000 white whales summered in southern Ungava Bay during the 1870s (Reeves and Mitchell, 1987a). Systematic and coastal reconnaissance aerial surveys of Ungava Bay in the late 1970s and early 1980s suggested a remnant population of less than 50 (Finley *et al.*, 1982; Smith and Hammill, 1986).

At least 5,000 white whales summered in Cumberland Sound (SE Baffin stock) in the early 20th century, judging by the catches made in this area (Reeves and Mitchell, 1981). The most recent estimate of population size, based on aerial photographic surveys in 1985–86, is less than 500 (Richard *et al.*, 1990).

Alaska (USA)

Population estimates for all Alaskan coastal stocks were provided by Hazard (1988) and Lowry *et al.* (1989) (see Table 9). Additional surveys summarised by Frost and Lowry (1990) and Frost *et al.* (1991) gave no reason to change the earlier estimates. Surveys planned for 1991 should provide additional data for Cook Inlet and the eastern Chukchi Sea. It should be noted that there is no recent basis for the Norton Sound/Yukon Delta stock estimate; this area has never been properly surveyed for white whales (K.J. Frost, *in litt.* to Reeves, 1 May 1991).

USSR

Yablokov (1979) stated that there were no good census data from Soviet Arctic waters. He guessed that some 1,000–2,000 white whales summered in the East Siberian and western Chukchi Seas and some 2,000–3,000 in the Soviet Bering Sea. Burns (1984) assumed that at least 3,000–4,000 white whales were present in summer in offshore waters of the western Beaufort, northern Chukchi and East Siberian seas and that another 6,000–8,000 were present in coastal waters along the Asian sides of the Chukchi Sea, Bering Strait and Bering Sea, including Wrangel Island (Burns and Seaman, 1985). Gaev *et al.* (1987), as summarised by Ivashin (1990) claimed that white whales were rare in coastal waters around Wrangel Island, although Berzin (1981) cited reports of migrating herds of up to 500 white whales seen southeast of Wrangel Island in October 1960. An estimated 2,500–3,000 white whales became trapped in ice in Senjavin Strait along the eastern coast of Chukotka in December 1984 (Ivashin and Shevlyagin, 1987).

Results of aerial surveys in 1987 suggested a Sakhalin-Amur population of not more than 7,000–10,000 white whales (Popov, 1990). In addition, it was estimated that there were 3,000–5,000 white whales in the Shantar Islands area in 1987 and roughly 15,000 in the northern Sea of Okhotsk. Thus, the total estimated current population in the Okhotsk Sea is 25,000–30,000. However, the reliability of this estimate is uncertain.

Ognetov and Potelov (1984) referred to observations of a few hundred to several thousand white whales in different areas of the Kara Sea at different times, but they gave no recent population estimate for the Kara Sea stock. Judging by the large commercial catches summarised by Kleinenberg *et al.* (1968) for the Kara Sea in the 1930s (1,922 in Yenisei and Pyasina bays from 1930 to 1936; 2,092 in the Gulf of Ob from 1931 to 1935) and 1950s (743 near Dickson Island from 1953 to 1958), the Kara and Barents seas combined in the 1950s (3,664 from 1953 to 1959 by vessels of the Arkhangel'sk and Tyumen Sovnarkhozes) and near Svalbard by Norwegian vessels after World War II (3,407 from 1945 to 1960 [Lønø and Øynes, 1961]), the West Siberian stock must have been very large historically. Yablokov (1979) estimated current stock sizes of 500–1,000 for the White Sea and 7,000–10,000 for the Barents-Kara-Laptev Seas.

ASSESSMENT AND STATUS

In general, white whale stocks can be assigned to five categories: (A) large (3,000+) and lightly or sustainably exploited; (B) large and exploited at rates that give cause for concern; (C) medium (500–3,000) and lightly or sustainably exploited; (D) medium and exploited at rates that give cause for concern; (E) small (500 or less) and vulnerable to hunting or habitat deterioration. Of the 16 stocks tentatively identified (Table 9), at least 3 are in category A, 1 in B, 2 in C, 2 in D and 4 in E.

Greenland

Using annual estimates of 875–1,500 whales killed from a population of 6,300–18,600 whales (Smith *et al.*, 1985), and citing estimates of permissible exploitation rates of 2% for white whales (IWC, 1984b) and 3–4% for narwhals (Kingsley, 1989), Heide-Jørgensen (1990) concluded that the Canadian High Arctic-West Greenland white whale population is being exploited at a level above sustainable yield. White whales have virtually disappeared from the southern districts of West Greenland where large catches were made in the 19th and early 20th centuries (Kapel *in* Reeves and Mitchell, 1987b). Catches listed for South and Southwest Greenland in recent years (Table 10) indicate mainly catches made by hunters who travelled to the more northern districts for hunting (M.P. Heide-Jørgensen, pers. comm. to Reeves, 30 April 1991).

Three factors that may cause white whale catches in Greenland to increase are: the high and increasing price of muktuk, the improved technology for hunting white whales and transporting muktuk, and the expansion of freezer facilities allowing preservation of muktuk in most settlements (M.P. Heide-Jørgensen, pers. comm. to Reeves, 30 April 1991).

Alaska

Major reviews of the status of white whales in Alaskan waters have been published recently (Seaman and Burns, 1981; Hazard, 1988; Lowry *et al.*, 1989; Frost and Lowry, 1990). The Beaufort Sea/Mackenzie Delta stock shared with Canada is not considered to be in jeopardy at present (see below). Of the other four provisional stocks in Alaska, the Norton Sound-Yukon Delta stock is of greatest concern because there is no reliable stock estimate and there are substantial removals. For the other three, the stock estimates are far more current and reliable and harvest levels have been relatively stable in recent years (Lowry *et al.*, 1989; Frost and Lowry, 1990).

Aerial survey results, hunter information and reduced catch levels have been interpreted to indicate a decline in the use of southeastern Kotzebue Sound by white whales (eastern Chukchi Sea stock) (Lowry *et al.*, 1989; Frost and Lowry, 1990). Local informants have suggested that boat traffic, noise and other disturbances (Burns and Seaman, 1985; Frost and Lowry, 1990) have contributed to this decline in local availability of white whales. When this migratory stock has been surveyed farther north off Point Lay, there has been no indication of a substantial change in numbers between 1979 and 1990 (Frost and Lowry, 1990; Frost *et al.*, 1991).

Frost and Lowry (1990) concluded that the Bristol Bay stock is stable at or near its historical size. The Cook Inlet stock has been small (a few hundred) for a considerable time (at least 25 years) (Hazard, 1988).

The Alaska and Inuvialuit Beluga Whale Committee (AIBWC) was established in 1988 with the objectives of conserving white whales and their habitat and preserving traditional white whale hunting in Alaska and the western Canadian Arctic. A draft management plan has been published (Anonymous, 1990b). This plan includes provisions for ensuring full reporting of catches (including struck but lost whales), reduction of hunting loss and monitoring of populations. Harvest levels are to be based on 'the number of animals in the populations and cultural and nutritional needs.'

Canada

Exploitation of the Beaufort Sea stock within Canadian waters is managed under the Inuvialuit Final Agreement of 1984, which entrenches the preferential rights of the Inuvialuit to harvest white whales and to sell or barter the products of the harvest to other beneficiaries of the claim, and commits the Canadian federal government to a process of joint management with the Inuvialuit (Anonymous, 1984). The Inuvialuit are also represented in the AIBWC (see above). Recent reviews have concluded that this stock is large and healthy and that its rate of exploitation is within sustainable limits (Fraker, 1980; Finley *et al.*, 1987; Lowry *et al.*, 1989).

The relatively large Canadian High Arctic population is thought to be shared with Greenland (see Greenland section above). It is expected that problems associated with the management of this stock's exploitation will be a principal concern of the Greenland-Canada Joint Commission on Conservation and Management of Narwhal and Beluga (Lemche, 1991).

A scientific advisory committee within the Canadian Department of Fisheries and Oceans (DFO) stated in its prognosis for the SE Baffin stock:

'Pre-exploited' stock size is irrelevant to the current management decisions because unknown ecosystem changes may have altered carrying capacity, and 'historical' levels may no longer be attainable (Cosens *et al.*, 1990).

Rather than using a target level related explicitly to the minimum estimated pre-exploitation population size of 5,000, the committee recommended a target level of 'a few thousand (e.g. 3,000), to provide an adequate buffer from ... natural hazards.' To achieve the objective of allowing this limited recovery, the committee recommended complete closure of the white whale hunt in Pangnirtung and Iqaluit and a closed season from June to October in Lake Harbour. In addition, it recommended that the stock not be allowed to fall below its current level of 400–500 in the late 1980s. Richard (1991a) has predicted that continued hunting could extirpate the stock in less than a

decade. However, the expected decline in the population due to hunting removals of around 100 per year during the 1980s apparently did not occur. Results of aerial photographic surveys in August 1990 were similar to those of surveys conducted in 1979–82 (Richard and Orr, 1986; P. Richard, pers. comm., 22 April 1991). In 1990, following a decision of the Nunavut Wildlife Management Board, DFO introduced annual quotas of 5 white whales each for Iqaluit and Lake Harbour and reduced the quota for Pangnirtung from 40 to 5 whales (Department of Fisheries and Oceans, 1990a; Richard, 1991a). This change provoked much controversy (e.g., Amagoalik, 1990; Anonymous, 1990b; Tinling, 1990), and the hunters in Iqaluit claimed to have taken about 60 and those in Pangnirtung more than 40 white whales in the 1990 season (Smellie, 1990a; b). The matter of SE Baffin white whale stock assessment has been referred within Canada to an independent committee for re-evaluation.

The Ungava Bay stock is severely depleted, and its conservation and recovery are a high priority (Anonymous, 1987a; Reeves and Mitchell, 1989b). Exploitation has continued in recent years (Table 11; Department of Fisheries and Oceans, 1990b), regulated at least to some degree by an informal cooperative agreement between the responsible federal agency and local or regional Inuit groups (Osherenko, 1988). It is unclear whether the community quotas and hunting ban for the Mucalic River (S. Ungava Bay) agreed in 1987 have been effective in reducing the hunting pressure on this stock.

The Eastern Hudson Bay stock is listed as 'threatened' by the Committee on the Status of Endangered Wildlife in Canada (Campbell, 1989; Reeves and Mitchell, 1989b). It continues to be hunted at levels that may exceed replacement yield (Anonymous, 1987a). An important further concern is that major hydroelectric damming and diversion projects are planned for several of the rivers used by white whales in summer (e.g. Great Whale and Nastapoka), and other large-scale industrial developments, including the impoundment of James Bay to supply fresh water to southern states and provinces, is being considered.

With respect to the Western, Northern and Southern Hudson Bay 'stocks'; the question of whether more than one stock should be recognised for the western half of Hudson Bay remains open (Richard *et al.*, 1990). If the whales summering from the Southampton Island area in the north to James Bay in the south are treated as a single population, they comprise a stock of more than 25,000. Approximately 185 white whales were taken per year by hunters in western and northern Hudson Bay (average for 1974–87 – Table 3). Whales from these areas are also hunted in Hudson Strait during autumn, winter and spring (possibly also in Foxe Basin). Arbitrarily attributing 60% of the reported or estimated catch in Hudson Strait to this stock increases the yearly average (1974–86 – Table 11) to 302–07. Applying a loss rate of 30% of the total kill, annual hunting removals in the order of 431 from this 'stock' are suggested. These calculations are necessarily very crude, but it seems safe to conclude that this stock (or these stocks) are in relatively good shape.

USSR

Without better information on population sizes and recent removals, it is impossible to make useful assessments of stocks in the Eurasian Arctic. However, despite considerable variation in the population estimates for the Sea of Okhotsk, the stock or stocks there apparently

remain large (certainly in thousands or low tens of thousands). If commercial exploitation has stopped and the subsistence catch is low as implied by available information, there should be no acute conservation problem for white whales in the USSR.

RECOMMENDATIONS

The Scientific Committee (IWC, 1980a) reviewed the status of white whale stocks in 1979 and made the following recommendations as a result.

- (1) That the Cumberland Sound (=SE Baffin) stock be given complete protection, that it be censused regularly to estimate population size and gross recruitment, that its relations with 'stocks' in Hudson Strait be examined and that any whales taken (should there be a hunt) be examined and sampled. As demonstrated by the work cited above, considerable effort has been devoted to stock assessment since 1979, and the catch limit has been reduced.
- (2) That Canada initiate research on the stock identity and size of white whale populations hunted along the Quebec coasts of Hudson Strait and northeast Hudson Bay. Finley *et al.* (1982), Smith and Hammill (1986), Helbig *et al.* (1989) and Doidge (1990) have reported some of the relevant work conducted since 1979.
- (3) That the Canadian High Arctic (summer) and West Greenland (winter) populations of white whales be provisionally managed as one stock and that Canada and Denmark (Greenland) initiate a joint research programme on this stock. Particularly, the Committee called for censuses of white whales summering in Melville Bay-Thule district and Canadian and Greenland waters of Smith Sound and Kane Basin and for analysis of the stock affinities of these whales. The Greenland-Canada Joint Commission on Conservation and Management of Narwhal and Beluga has initiated a research programme on this stock. However, no census of the specified areas has been made.
- (4) That more accurate estimates be made of struck-but-lost rates in the white whale hunts of Greenland and Canada. No new data on loss rates in Greenland are available. For Canada, considerable effort has been directed at estimating loss rates in the Mackenzie Delta (Strong, 1990; Weaver, 1991; K. Frost, *in litt.* to Reeves, 1 May 1991).
- (5) That the USSR provide all available data on the white whales in the Barents, White, Kara and Laptev Seas and include 'a study of the components of the Barents Sea wintering group and an assessment of the stock or stocks involved.' Some information has become available since 1979 (e.g. Berzin, 1981; Ivashin and Mineev, 1981; Ognetov and Potelov, 1982; 1984; Berzin and Vladimirov, 1986).
- (6) That national research programmes on the white whales thought to winter in the Bering Sea be expanded and that a cooperative research programme be instituted by the USA, USSR and Canada. It was expected that such programmes would include documentation of catch statistics, loss rates and characteristics of the hunt and collection of biological samples for determination of vital parameters. Also, 'the temporal and spatial components of the populations should be determined, the populations censused and the inter-relationships among them identified.' No cooperative programme has been

established with the USSR to date. Several cooperative efforts between Canada and Alaska have been initiated and include sharing of harvest information, collection of samples for stock identification and vital parameters and planning further census efforts. Surveys will be conducted of the Cook Inlet and eastern Chukchi Sea stocks in 1991.

- (7) That the white whale be defined as a 'whale' and listed in the IWC schedule 'so that appropriate management procedures may be discussed and implemented in the future.' No action has been taken with respect to the later part of this recommendation.
- (8) That Canada provide complete catch statistics for Manitoba, Ontario and Quebec. Reporting for Quebec (mainly East Hudson Bay – James Bay, West-South-North Hudson Bay and Ungava Bay stocks) and Manitoba (West-South-North Hudson Bay stock(s)) has improved substantially over the past decade (e.g., Boulva, 1981; Gamble, 1987a; b; Reeves and Mitchell, 1989b; Strong, 1990). The white whale harvest in Ontario (southern Hudson Bay and James Bay) is negligible.

The substance of these same recommendations was reiterated in 1980 (IWC, 1981). It was noted with reference to No. 1 that a catch limit of 40 had been introduced for the Cumberland Sound stock. However, the Committee recommended that this be reduced to zero. It was noted with reference to No. 3 that the current rate of removals from the Canadian High Arctic-West Greenland stock could be 'too high for the overall population,' and this demonstrated the need for better data on population size, stock relations and removals. With reference to No. 5, it was noted that either the reported catch levels for white whales in the Barents, White, Kara and Laptev Seas (c.f. Ivashin and Mineev, 1981) were substantially above annual gross production or the current population estimates were too low. This problem highlighted the need for abundance estimates for this area.

The Scientific Committee carried out another review of white whale stocks in 1981 (IWC, 1982a, pp. 60, 121–2). The 'responsive and considerable expansion' of studies in Greenland and Canada was noted, and both governments were encouraged to continue this work, giving particular attention to stock identity, migration, abundance, calf production, collection of complete and accurate catch statistics and full collection of age and reproductive samples from the catch. Noting the 'seriously depleted status' of the Cumberland Sound, Ungava Bay and eastern Hudson Bay stocks (Finley *et al.*, 1982) and the importance to the species of 'estuarine calf-rearing grounds', the Committee recommended that all three stocks and their critical habitat be fully protected. The USA and USSR were again urged to initiate field studies to evaluate the stock structure, abundance and status of white whales summering in their waters. With respect to No. 7, the question of adding the white whale to the IWC Schedule, the Committee report noted that most members supported the earlier recommendation.

In 1982, the Scientific Committee noted that the research recommendations made in previous years had been acted upon by the USSR and Canada and that the results of research on population size, productivity and exploitation in the USSR and population size, discreteness, exploitation history and loss rates in Quebec, Hudson Strait, northeast Hudson Bay, the Canadian High Arctic and West Greenland had been reported in progress reports

and the SM series (IWC, 1983a, p.161). The Committee reiterated its recommendation that the summer populations in Cumberland Sound, eastern Hudson Bay and Ungava Bay be completely protected. It also called for catch statistics and population assessment from the USA and more nearly complete catch statistics from Canada.

The Scientific Committee made three recommendations in 1982 (IWC, 1983a, p.61):

- (1) that white whale catches in Alaska be 'minimised' until the uncertainty about stock identity, stock size, net recruitment and removal rates was removed;
- (2) that the three depleted stocks in eastern Canada be given complete protection;
- (3) that the USSR make available catch information for its white whale fishery.

In 1984, it was recommended again that the USA collect and report data on catches and loss rates (IWC, 1985, p.136). The AIBWC has been doing this since 1988 and the data are improving each year (K.J. Frost, *in litt.* to Reeves, 2 May 1991). The Alaska Department of Fish and Game reported catch figures for 1980–86 (Lowry *et al.*, 1989).

The sub-committee makes the following new recommendations:

- (1) that the USA obtain more accurate estimates of stock size for white whales in Alaska, particularly the Norton Sound/Yukon Delta stock for which there is no reliable estimate;
- (2) that more accurate and complete information be obtained on struck-and-lost rates for all areas where white whales are hunted and that methods for reducing the number of whales that are struck-but-lost be developed and implemented;
- (3) that the USA, USSR, Canada and Greenland conduct genetic studies to determine the stock identity of white whales;
- (4) that Greenland conduct an assessment of white whale stocks to serve as a basis for management, and that Greenland report data on white whale catches and loss rates.

The sub-committee welcomed the formation of the Canada-Greenland Joint Commission on Conservation and Management of Narwhal and Beluga and of the Alaska and Inuvialuit Beluga Whale Committee as bilateral initiatives that promise to provide intensified and coordinated research and management of shared stocks.

The sub-committee noted its continuing concern about white whale stocks in Canada that are harvested at rates above their estimated sustainable yield levels.

5.1.2.2 *Monodon monoceros*³

COMMON NAMES

Narwhal, *narhval* (Denmark), *killalugaq* (Inuktitut, Baffin Island), *tugalik* (Inuktitut, West Greenland), *qilaluaq qernertaq* (Greenlandic).

DISTRIBUTION

The narwhal's distribution is circumpolar north of about 65°N, but it occurs in much higher densities in Arctic waters adjoining the North Atlantic basin than in those adjoining the North Pacific. Three high-density summering areas have been identified in the eastern Canadian Arctic and off northwest Greenland: Repulse Bay and Frozen Strait, the Lancaster Sound region, and Inglefield Bay (Born, 1986; Strong, 1988). Small groups of narwhals

³ Initial draft from R. Reeves dissertation in preparation.

summer in many other areas, including Jones Sound, Smith Sound, Melville Bay, western Baffin Bay and Davis Strait, and northern Foxe Basin. Narwhals winter mainly in the open and close pack ice of Baffin Bay and Davis Strait as far south as *ca* 64°N and in the Labrador Sea and Hudson Strait (Kapel, 1977; McLaren and Davis, 1981; 1982; Mitchell and Reeves, 1981; Turl, 1987; Richard, 1991). They rarely occur in the main body of Hudson Bay south of Southampton Island. There are few definite records from eastern Hudson Bay, but narwhals are killed occasionally on the west side of the bay as far south as Whale Cove (*ca* 62°N).

Narwhals occur in many fiords along the east coast of Greenland north from Ammassalik (Dietz *et al.*, 1985). Two offshore areas have been identified in the Greenland Sea where 19th-century whalers consistently observed narwhals, on some occasions in large numbers. These areas are centred west of Spitsbergen at 78–81°N, 05°W–10°E, and off the Greenland coast between latitudes 72–76°N (Dietz *et al.*, 1985). A possible third concentration area was identified off the northeast coast of Greenland at 79–81°N. There is no direct evidence that the narwhals in the Greenland Sea belong to a separate stock from those in Davis Strait, Baffin Bay and Smith Sound.

PROBLEMS AND CATCH STATISTICS

Greenland Sea

The narwhals in the Greenland, Barents and Kara Seas, and in the Arctic basin north of these, were exploited to some degree by European commercial whalers during the bowhead whaling era and by the Inuit of east Greenland. However, this exploitation is believed to have been light in terms of the numbers of animals killed relative to the population size.

Tomilin (1957) estimated the annual catch in Scoresby Sound as 20. Incomplete statistics for east Greenland from 1954–75 indicate annual catches ranging from 2 to 65, with a mean of about 21 (Kapel, 1977). The total reported catch in Ammassalik district during the 1970s was 141 (Dietz *et al.*, 1985). Reported catches increased during the 1980s, averaging 87 per year for Scoresbysund and Ammassalik districts, combined, from 1980 to 1987 (Table 14).

West and North Greenland

Catch statistics are provided through the Greenland Hunters' Lists of Game (Kapel, 1977; 1978; Born and Olesen, 1986; Table 14). Participation in the reporting

scheme has declined during recent decades, and this has meant that a higher proportion of the reported catch is estimated rather than being an actual count (E.W. Born, *in litt.* to Reeves, 3 October 1985; Heide-Jørgensen, MP, 1990). An important shortcoming of the statistics has been the lack of reporting for Thule district (North Greenland) and in recent years the entire system of reporting catch statistics for small cetaceans in Greenland has deteriorated. Thule provided reliable estimates of the narwhal catch for only three years in the early 1960s (M.P. Heide-Jørgensen, pers. comm. to Reeves, 30 April 1991). Heide-Jørgensen (1990) estimated the recent annual catch for all of West Greenland, including Thule district, as 200–600. The Greenland Fisheries Research Institute estimated the total catch for West Greenland as 600 in 1989 and 1,200 in 1990.

Canada

Narwhal catches in Canada are underreported for a number of reasons (Finley *et al.*, 1980; Finley and Miller, 1982; IWC, 1982a; Gamble, 1987a). The tag system used to implement the national quota is most effective for monitoring the number of large, unbroken tusks that are sold. It is considerably less effective for ensuring that kills of untusked whales (females, calves and juveniles) and whales with short or significantly damaged tusks are reported. Reported catches during the 1970s and 1980s show no clear trend of increase or decrease (Table 15). The total reported catch in all years has been below the total national quota of 525 (Strong, 1989). The catch in Arctic Bay (as observed by and reported to fisheries field personnel) is strongly biased toward males (Roberge and Dunn, 1990). This bias appears to be less consistent and strong at Pond Inlet (Weaver and Walker, 1988). Discussion of the trade in tusks and other products is given in Appendix 3.

Loss rates

Acknowledging that there are no data for estimating the loss rate directly in Greenland south of Thule district, Born and Olesen (1986) assumed that it was *ca* 20%, similar to the open-water loss rate in Canada. [Born and Olesen cited as their source for the 20% figure an unpublished report by Strong *et al.* (1985) which was published in abbreviated form as Strong (1988).] Most of the hunting south of Thule is done in open water, by shooting first and then

Table 14

Narwhal catches reported in IWC Denmark progress reports. For previous years, see Kapel (1977). Note that figures listed for 1983–85 are estimates which include an allowance for unreported catches (but not for hunting loss).

harpooning. Losses are low in Thule district, where most of the hunting is done from kayaks in open water, using a harpoon first and then killing with a rifle shot. Approximately 1 whale is lost for 20 landed in the summer hunt in Thule district (IWC, 1980b). Loss rates for hunting at *savssats* are much higher, on the order of 1 whale lost for every 2 landed (IWC, 1980b). Winter-spring hunting in Greenland generally is assumed to involve the loss of approximately 1 whale for every 4 landed (IWC, 1980b).

Nets are set for narwhals in Thule district beginning on 1 September each year. This net fishery apparently began about nine years ago after hunters noted that narwhals frequently entangled in seal nets (M.-P. Heide-Jørgensen, pers. comm. to Reeves, August 1990). The number of narwhals that are netted is unknown, except that it is small, probably less than 20 per year; the loss rate from netting is probably close to nil.

Direct observations of narwhal hunting in Canada have revealed significant hunting loss (Land, 1977; Finley *et al.*, 1980; Finley and Miller, 1982; Weaver and Walker, 1988; Roberge and Dunn, 1990). Cosens *et al.* (1990) cited a range in estimated loss rates (percentage lost of total killed) of 42–56%; thus, the estimated total of removals by hunting would be 1.72–2.27 times the landed catch. The range of 42–56% apparently is based mainly or entirely on data from Pond Inlet, which may not be representative for all catch areas. For example, at Arctic Bay, the estimated loss rates for five years with data (1983, 1986–89) ranged from 20% to 34% (Weaver and Walker, 1988). The secured catch at Arctic Bay is often as high as or higher than that at Pond Inlet (Strong, 1989). In the absence of data on loss rates from other settlements that hunt narwhals, it is impossible to decide which of the two ranges of estimates is more representative. In general, losses are highest during the ice-edge and ice-crack phases of the hunt and lowest during the open-water phase.

MANAGEMENT

In Greenland, the hunting of narwhals is regulated mainly by local legislation (Born, 1986; Qujaakitsoq, 1990).

In Canada, narwhal hunting is regulated under the Narwhal Protection Regulations (Fisheries Act) introduced in 1971 (Strong, 1988). In addition to specifying that females with calves not be hunted, waste be minimised and only high-power ammunition be used, these regulations include a national quota, allocated by community primarily on the basis of historic catch levels. The total quota is 525.

The Canada-Greenland Joint Commission on Conservation and Management of Narwhal and Beluga met for the first time in January 1991 (Lemche, 1991). This commission was established under the terms of a Memorandum of Understanding between the responsible Canadian and Greenlandic government agencies. No decisions on management were made at this session. A Scientific Working Group was charged with reviewing information on potentially shared stocks and providing advice on research and management needs. It was specified in the report that the scientific advisory group should consider knowledge from hunters in the development of its advice to the Joint Commission.

POPULATION SIZE

Greenland Sea

The only estimate is for a small part of the summer range. Larsen (1930) estimated that there were at least 176 narwhals in Scoresby Sound in September 1983, based on an aerial line-transect survey. No correction was made for animals below the surface.

Inglefield Bay

In mid-August 1984, Born (1986) counted 4,043 narwhals passing a clifftop observation site at the head of Inglefield Bay. This provides a minimum estimate for the number of narwhals summering off northwest Greenland. Additional animals apparently summer in Melville Bay (Meldgaard and Kapel, 1981) and in Smith Sound and other areas north of Inglefield Bay (Vibe, 1950).

Baffin Bay and Davis Strait

McLaren and Davis (1981; 1982) estimated that a minimum of 5,000 narwhals were present in the pack ice of northern Davis Strait and southern Baffin Bay in March 1981. This was considered an underestimate because many animals were thought to be submerged or under the ice and missed by the surveys. These wintering narwhals are considered part of the Inglefield Bay and/or the Canadian High Arctic stocks (see below).

Canadian High Arctic Stock

Smith *et al.* (1985) estimated that 13,200–18,000 narwhals summered in Lancaster Sound and adjoining waterways in 1981. This estimate was based on the results of a stratified strip-transect survey of Lancaster Sound, Barrow Strait and Prince Regent Inlet in August, and it included estimates of 2,000 and 2,117 to account for whales in two

unsurveyed areas (Peel Sound and Admiralty Inlet, respectively; the former based on Smith *et al.*'s own observation of 2,022 in July 1980, the latter on Fallis *et al.* [1983]). No allowance was made for whales summering in the Pond Inlet-Eclipse Sound-Navy Board Inlet complex or along the east coast of Baffin Island. Smith *et al.* (1985) considered the estimate by Davis *et al.* (1978) of 20,000 to 30,000 narwhals in the Lancaster Sound region in 1976 to be an overestimate caused by 'the inappropriate combination of shorebased counts (Greendale and Brousseau-Greendale, 1976) with their aerial surveys.' Aerial photographic surveys of Eclipse Sound, Admiralty Inlet, Prince Regent Inlet and Peel Sound in August 1984 resulted in an estimate of 17,900 narwhals, uncorrected to account for submerged animals or for those in unsurveyed areas (Strong, 1988). Confidence limits for this estimate are 13,100–21,400 (Cosens *et al.*, 1990). It should be noted that Born (1986) and Born and Olesen (1986), citing an earlier unpublished report by Strong *et al.*, referred to an estimate of 23,700 (95% CI 18,100–29,500) for the Canadian High Arctic stock. Combining his own count with the estimate from Strong *et al.*, Born (1986) suggested a combined Canada–Greenland High Arctic population size of at least 28,000, with confidence limits of about 22,000 to 33,500. According to J.T. Strong (pers. comm. to Reeves, 15 April 1991), the high estimate of 23,700 for the Canadian sector was released prematurely and should be ignored. A reanalysis of the 1984 aerial photographic survey data is planned (J.T. Strong, pers. comm. to Reeves, 15 April 1991).

Northern Hudson Bay Stock

Systematic photographic surveys centred in Repulse Bay and Frozen Strait in July 1982, 1983 and 1984 provided estimates ranging between 1,038 and 1,517 narwhals, with varying degrees of precision (Richard, 1991). Richard (1991) suggested that the narwhals in this area be managed as an isolated stock of about 1,300 animals.

ASSESSMENT AND STATUS

Table 16 summarises the current status of the world's narwhal stocks.

Barents and Kara Seas

The comments by Tomilin (1957) about narwhal abundance in the areas around Franz Josef Land and Novaya Zemlya are problematical. His account suggests a significant decrease in abundance post-1930, but no basis for this impression is offered nor is any possible reason given for such a decrease. Yablokov and Bel'kovich (1974) claimed that chronicles and the discovery of bones on beaches 'testify to the former greater distribution of narwhal in the seas of the European North (White and Kara seas).' However, they did not elaborate. The statement that the narwhal 'is thought to have disappeared from the northeastern part of its range (Novaya Zemlya and Franz Josef Land), presumably because of hunting' (Anonymous, 1978) apparently is based on the reports cited above. Yablokov (1979) indicated that observations of narwhals in Soviet waters were 'rare' but speculated that there could be several thousand animals in two populations in the Soviet High Arctic. Apart from occasional kills by commercial whalers hunting bowheads in the Barents Sea during the 19th century and kills by aborigines along the Yamal Peninsula during at least the 17th century (MacRitchie, 1909), no regular hunt for narwhals in the Eurasian Arctic is documented. Their offshore, high-

Table 16
Status of world narwhal stocks (modified from Braham, 1984).

Centre of summer distribution	Est. abundance	Est. annual kill	Removal rate (% stock size)	Refs
Barents & Kara Seas (Arctic Basin)	no estimate	none known	-	-
Greenland Sea	no estimate ¹	89 ²	unknown	-
Canadian High Arctic (Lancaster Sound region)	17,900 ³	397-568 ⁴	2.2-3.2	1,2
NW Greenland (Inglefield Bay)	4,043+ ⁵	616 ⁶	15 ⁷	-
N Hudson Bay	1,300	29-41 ⁸	2.2-3.2	3

¹Larsen (1985) gave conservative estimate of 176 in Scoresby Sound, September 1983.

²Based on average reported catch 1978-87 (Table 1), corrected assuming 1 whale killed and lost for 4 secured (see text).

³The data from the 1984 survey are being reanalysed.

⁴Secured catch 290/yr (average 1976-87; Cosens *et al.*, 1990), corrected using loss rates from pooled Pond Inlet data 1982-3 (Weaver and Walker, 1988), 49%, and from pooled Arctic Bay data 1983, 1986-89 (Roberge and Dunn, 1990), 27%, as a range.

⁵Number counted in one day from a shore observation site in Inglefield Bay (Born, 1986).

⁶Based on average reported catch 1978-87 (Table 1), corrected assuming 1 whale killed and lost for 4 secured (see text).

⁷Probably an overestimate since the population estimate is an underestimate of the stock(s) hunted.

⁸Based on average reported catch 1978-87 (Table 1), corrected using the same procedures as described in footnote 3 for Canadian High Arctic stock. Note that the catches included are those from Hudson Bay and Hudson Strait only; Foxe Basin catches are assumed to be from the High Arctic stock.

References: (1) Strong, 1988; (2) Cosens *et al.*, 1990; (3) Richard, 1991.

latitude distribution in this sector may explain, at least partially, the absence of a more detailed record. The continuing presence of small numbers of narwhals in the Barents and Kara seas (as well as in the western part of the East Siberian Sea) was noted by Belikov *et al.* (1990).

Greenland Sea

The basis for the statement that this stock was historically much larger and more widely distributed than currently (Anonymous, 1990c, p.136) is uncertain. Too little information is available about the past or present population size for narwhals in this region. Substantial recent catches, particularly in Ammassalik district (Table 14), demonstrate the need for better information on the stock(s) off east Greenland.

Canadian High Arctic

Although Cosens *et al.* (1990) indicated in their Introduction that there was no evidence of Canadian narwhal stocks being harvested at levels that could not be sustained, they concluded in their assessment of the High Arctic stock that harvests have exceeded the estimated net recruitment rate of 2–3% and that if the stock size is 17,900 as estimated, the population must be declining. Strong (1988), using similar estimates of population size and calf production, but a lower estimate of the annual kill rate, concluded that the stock was stable and that the current level of harvest could be sustained. Better information is needed about stock relations and removal rates.

Cosens *et al.* (1990) apparently did not include the two Foxe Basin communities' harvests (Igloodik and Hall Beach) in their assessment of removals from the High Arctic stock. Neither Smith *et al.* (1985) nor Richard (1991) covered Foxe Basin in their population assessment surveys. The stock affinities of narwhals hunted in northern Foxe Basin are unknown, but there is circumstantial evidence from local people suggesting that they come from the High Arctic, passing through Gulf of Boothia and Fury and Hecla Strait in late summer (P. Richard, pers. comm. to Reeves, 1 May 1991).

West and North Greenland

Annual catches of about 450 (the 1975–87 average from Table 14) would represent more than 10% of an estimated minimum stock size of 4043. However, both the catch level (incomplete reporting, no allowance for hunting loss) and the population size (based on a one-day count at a fixed location in Inglefield Bay – Born, 1986) are likely underestimates. Without improved census data and better information on stock relations of narwhals hunted in the Canadian Arctic and West Greenland, it is impossible to make a useful assessment. However, the available data are sufficient to warrant concern about the status of the stock.

Northern Hudson Bay

The combined quotas for communities in northern Hudson Bay (summering area) and Hudson Strait (wintering area) is 70, or 5.4% of the estimated stock size. Reported landed catches in most communities have been below the quota in most years (Strong, 1989), but since reporting is incomplete (Gamble, 1987a) and the quotas make no allowance for struck whales that are not secured, there is reason for concern about the impact of hunting on this stock.

RECOMMENDATIONS

The IWC Scientific Committee has made few recommendations concerning narwhals, apart from calling for their inclusion in the IWC Schedule (IWC, 1980b, p.124). In 1981, Canada and Denmark were encouraged to continue and expand research on stock identity, migration, abundance and calf production; to collect complete and accurate catch statistics; and to sample catches fully for studies of age estimation and reproduction (IWC, 1982a, p.121). Some effort toward achieving these objectives has been made by Denmark and Greenland (e.g. Born, 1986). In Canada, comprehensive research programmes have been implemented to address many of these concerns (e.g. Smith *et al.*, 1985; Gamble, 1987a; Strong, 1988; Weaver and Walker, 1988; Kingsley, 1989; Roberge and Dunn, 1990; Richard, 1991).

The sub-committee remains concerned about catch levels and loss rates in the Canadian and Greenlandic fisheries. It **recommends** particularly that more effort be made to assess stock size and removal rates for the narwhal population in the High Arctic, Baffin Bay and Davis Strait. In this regard, the sub-committee welcomes the formation of the Greenland-Canada Joint Commission on Conservation and Management of Narwhal and white whale, which is expected to implement a joint programme of research and management. The sub-committee notes with concern that the system for reporting catch statistics in Greenland has deteriorated, and recommends that such record keeping and reporting be made a high priority. In

view of the substantial catches in some years in east Greenland, the sub-committee also recommends that some attention be given to stock assessment in the Greenland Sea.

(Low, 1906; Bruemmer, 1966; Hansen, 1970; Hay and Sergeant, 1976; Riewe, 1977; Treude, 1977; Durham, 1978; Kapel, 1983; Anonymous, 1985b; Ivashin, 1988; Sergeant and Hoek, 1988)

5.1.3 Direct fisheries for *Globicephala melas*, in the North Atlantic⁴

COMMON NAMES

Long finned pilot whale. Faroe Islands: *grindahvalur*; *nydingur* (large pilot whale); *leiftur* (newborn). Iceland: *marsvín*. Greenland: *nisarnaq*. Newfoundland: pilot whale; blackfish; pothead; roundhead. Norway: *grindehval*. Shetland Isles: pilot whale; blackfish; caa'ing whale. Britain: long-finned pilot whale. Sweden: *grindval*. Finland: *pallopää*; *grindvalas*. Denmark: *grindehval*. Holland and Belgium: *griend*. Germany: *grindwal*. France: *globicéphale noir*; *dauphin pilote*. Spain: *calderòn*; *caldeirò* (Galician); *cap d'olla* (Catalan). Portugal: *boca de panela*. Italy: *globicefalo*. Greece: *mavrodelphini*.

DISTRIBUTION

In the North Atlantic, the long-finned pilot whale lives in cold temperate and subarctic waters. Its general distribution is from Northwest Africa, including the Mediterranean, to the Norwegian-Barents Sea in the east and from Bermuda and Cape Hatteras at the coast of North Carolina to central parts of Greenland in the west. The North Atlantic Sightings Surveys (NASS) in 1987 and 1989 have improved our knowledge of the abundance inside the northeast Atlantic distribution area. Concentrations of pilot whales were observed especially from 2–40°W and 45–65°N, (Lens *et al.*, 1989; Bloch *et al.*, 1989; Buckland *et al.*, 1993). There is some overlap in distribution of the northerly range of the short-finned pilot whale, *Globicephala macrorhynchus*, and southerly limit of the long-finned pilot whale.

Although the pilot whale occurs north to the Barents Sea (Mitchell, 1975b), the only record from the Norwegian coast from NASS surveys was a single observation off southwestern Norway (Øritsland *et al.*, 1989; Bloch *et al.*, 1989), although they occasionally beach on the Norwegian coast (Griffiths and Øen, 1990). Elsewhere the pilot whale is commonly distributed in the western basin of the Mediterranean (Gannier and Gannier, 1990), in the Gibraltar Strait (Hashmi, 1990) and off Spain (Lens *et al.*, 1989).

Pilot whales appear to move into coastal areas following their squid prey in the summer and are more concentrated offshore in deep waters in winter (Evans, 1987). Brown's (1961) summary of observations made from ocean weather ships, merchant vessels and other ships, provides information on the oceanic range of this species as far south as 45°N in the central area of the North Atlantic, suggesting occurrence throughout the year in oceanic waters between 45°N and 50°N and probably in all longitudes from the Bay of Biscay to Newfoundland. Observations during the NASS studies tend to confirm this, indicating a greater abundance of whales, including pilot whales, in the central parts of the North Atlantic.

⁴ Initial draft by D. Bloch and C. Lockyer

PROBLEMS AND CATCH STATISTICS

There is not enough information to separate North Atlantic pilot whales into discrete stocks. Previously, pilot whales were taken in the old Norse areas, including Norway, Iceland, Shetland, Orkney and Hebrides (Williamson, 1970; Joensen, 1976). Until 1972, the pilot whale was still taken in Newfoundland and until 1973 in Norway. Today, the pilot whale is only taken in the Faroe Islands and Greenland.

Between 1975 and 1987, a total catch of 487 pilot whales has been taken by small type whalers off Greenland (Table 17). The largest catch was 136 in 1977.

In the Faroe Islands, the fishery (*grind*) is opportunistic. Whales are observed either from land or from boat, and are driven on shore and killed, with entire schools taken usually. Between 1986 and 1988, 47 sightings of pods occurred (one third from land), followed by landings of 43 pods. The distance from the school to the shore ranged between 0.1 to 3.3 n.miles (Bloch *et al.*, 1990a). Traditional Faroese fishing boats are used (specialised boats or whalers have never been used). The whales are driven into suitable bays. Since November 1989, the Faroe Islands Government has restricted the use to 21 bays only.

The whales are hunted communally for food and are utilised non-commercially – the catch is shared free among the local inhabitants. Complex laws and regulations exist for the control of the catch and its utilisation. The first regulations, covering the total course of events from the initial sighting of a pod until the animals have been flensed and the beach cleaned, appeared in 1832. These have been updated several times, but the original regulations still form the backbone of today’s laws (Bjørk, 1956–63).

Pilot whales have been harvested in the Faroe Islands since the Norse settlement in the 9th Century (Thorsteinsson, 1986). Hunting statistics exist back to 1584, and unbroken records exist from 1709 to the present (Joensen and Zachariassen, 1982; Bloch *et al.*, 1990b). During the period 1709–1990, 1,646 pods (235,630 whales) were harvested. The statistics show a peak periodical occurrence of whales every 110–120 years (Joensen, 1962; Joensen and Zachariassen, 1982).

In the period 1709–1990, a range of 0–4,360 whales (0–23 pods) per year were harvested, averaging 990 (6.9 pods). The maximum harvest occurred in 1941 (23 pods and 4,325 whales). In three years, 1844, 1939 and 1941, the harvest exceeded 3,000 whales; in 25 years, more than 2,000 whales were landed, while in over 95 years (a third of the time period), the annual catch exceeded 1,000 whales.

By contrast, the period 1750–1795 showed poor harvests with a total of only 13 pods comprising 2,459 whales, averaging 55 whales per year. During the years around 1900, there were occasional years with no pods landed (1890–1, 1901, 1924 and 1927). Although pods were seen during those years, attempts to beach them met with no success. In all, there were 44 years when no pods were taken (Bloch *et al.*, 1990b).

The fishery has never been managed by quota limitation. However, since 1982, a district or a whaling bay can be closed by an executive order issued by the Faroe Islands

Government whenever the area in question is considered to already have an adequate supply of meat. Between 1986–1988, restrictions occurred in 4 (1986), 5 (1987) and 3 (1988) districts out of 9, and lasted for 0.5–3.5 months. So long as the pilot whale meat and blubber is used non-commercially, and only by Faroese people for local consumption, there will be an upper limit on the catch, regulated by demand.

In recent years, the Faroese Government has made limitations of the use of the gaff and spear in the fishery, in response to international concerns.

The complete pilot whale catch information is held at the Faroese Museum of Natural History in Tórshavn. There are other species taken by drive fisheries in the Faroes, including *Lagenorhynchus acutus* in some years. Catch statistics for some species are available for the past five years.

POPULATION ESTIMATE

The NASS-87 (June-August) survey of the Faroese-Icelandic area covered an area bounded by Spitzbergen and the Barents Sea in the north, the Spanish coast in the south, West Greenland in the west and the Norwegian coast in the east (Sigurjónsson *et al.*, 1989). A total of 109 sightings of approximately 4,413 animals were made onboard the four survey vessels. The sightings were concentrated southwest and west of the Faroe Islands, off the southeast coast of Iceland and in deep waters southwest and west of Iceland in the Denmark Strait; although some sightings were made west of the British Isles and Ireland, and along the East Greenland coast.

The resultant population estimates were 72,000 (CV 0.4) for the area covered by the Faroese vessel; partial population estimates for closing and passing mode are 18,950 (CV 0.5) and 12,945 (CV 0.25) whales respectively, for the areas covered by the Icelandic vessels. This gives a total ‘best’ estimate of close to 100,000 animals; it does not include a correction for submerged animals and assumes that all schools close to the trackline were sighted (Bloch *et al.*, 1989). When reviewing these estimates, the sub-committee discussed several factors that could bias the estimates, and noted that due to these factors, there was a greater uncertainty in the estimate than indicated by the calculated CVs (IWC, 1990b).

The area between 50–65°N and 06–45°W was covered by Iceland and the Faroe Islands during the NASS-89 survey, and a similar number of sightings of pilot whales was recorded but the data are still not fully analysed. There are no updated estimates from the other areas in the North Atlantic. However, there is an estimate of about 60,000 whales as the initial population in Newfoundland waters (Mercer, 1975), and about 13,000 whales from an aerial line-transect of a portion of the Newfoundland-Labrador area (Hay, 1982).

ASSESSMENT AND STATUS

There is no detectable evidence that the stock size of pilot whales appearing in the Faroese area has been affected by the drive fishery. The observed periodicity in the

occurrence of whales in the Faroese area (Fig. 2) is significantly correlated with the occurrence of the squid prey, *Todarodes sagittatus*, the presence of which is also correlated with the periodicity in the sea surface temperature (Hoydal, 1986). Any connection between the pilot whales occurring around Newfoundland in summertime and the all year round occurrence in the Faroes (Sergeant, 1986) is still not proven.

RECOMMENDATIONS

In 1985, the Scientific Committee recommended the funding of a proposal to examine the ecology of Faroese pilot whales (IWC, 1986a, p.52). Although IWC funding was not forthcoming, between July 1986 and July 1988, a comprehensive examination was undertaken of the ecology and status of the pilot whale in the Faroe Islands, under the auspices of the IWC and the United Nations Environment Programme (UNEP). The content of these examinations is outlined by Desportes (1990), and most of the results are published in Donovan *et al.* (1993).

In 1987 (IWC, 1988, p.51), the Scientific Committee noted that material being collected from the Faroese pilot whale fishery was particularly valuable for investigating the factors which determined the concentrations of organochlorine pollutants in whale tissue. These compounds are known to affect reproduction in other marine mammals. It therefore recommended that this opportunity should be brought to the attention of laboratories capable of performing standardised analyses for organochlorines and particularly for individual PCB congeners. Studies on these matters were instigated and the results are published in Donovan *et al.* (1993).

In 1989 (IWC, 1990a), the Scientific Committee made several recommendations. Concerns about past fisheries and by-catches were expressed, and in view of the fact that in the western North Atlantic the by-catch of pilot whales by foreign flag mackerel vessels in the US EEZ jumped sharply in 1988 to 140 and may have been larger in earlier years when the then larger mackerel fishery was

unmonitored, it was recommended that the historical data for this fishery be examined to estimate earlier removals of pilot whales.

The existence of a past Icelandic drive fishery was confirmed (Anonymous, 1990c) and the Committee recommended that the historical data for that fishery and for strandings be obtained and reported.

Information on these matters was published in Donovan *et al.* (1993).

Several recommendations specific to the Faroese drive fishery were also made. At that time, no new information was available on population dynamics, but it was recommended that attention be given to research on this topic using the Faroese frequency-at-age data. Extensive demographic information which has been, and will be, generated by the Faroese research programme could form the basis for a valuable mathematical model of the population dynamics of pilot whales, and possibly other odontocetes. The Committee therefore recommended that such an integrated model should be developed.

The Committee recommended that stock identity be addressed by genetic comparisons being carried out between pilot whales from the Faroes and from other regions in the North Atlantic using both analyses of isoenzyme allelic frequencies and appropriate analyses of DNA. Results of such studies were presented in Donovan *et al.* (1993).

Because of the importance of information about migration to questions of stock identity and status and because the pilot whale is a species particularly suitable for radio-telemetry studies, the Committee recommended that the proposed project using satellite-linked transmitters at the Faroes to study movements, described at an earlier meeting two years previously be undertaken. This particular project, while attempted, has not met with success. No further attempts have been made or are planned.

In teeth and hard tissues, depositional anomalies may be related to stress or other external factors and it was recommended that incidence of marker lines and other anomalies in teeth of pilot whales be examined in more

detail to determine possible links with oceanographic conditions, food availability and life history events. Research on this matter is continuing.

5.1.4 The Black Sea dolphin and porpoise fishery⁵

Three species of small cetacean were killed by fishermen from the four countries surrounding the Black Sea between 1870 and 1983. The common dolphin (*Delphinus delphis*) was historically the species caught in the largest numbers by the USSR, and although the limited catch statistics have generally been reported for all three species combined, it appears that the harbour porpoise (*Phocoena phocoena*) became the numerically dominant species in the catch from 1964 to the time the fishery ended in 1966 (except Turkey). The bottlenose dolphin (*Tursiops truncatus*) was of intermediate importance in the harvest. The Turkish catch reportedly consisted of 80% *Phocoena*, 15–16% *Delphinus* and 2–3% *Tursiops* in the early 1980s (Klinowska, 1991). No information is available on the composition of the earlier Turkish catches or on the Bulgarian and Romanian catches for any period. The abundance of all three species was greatly reduced by the fisheries (Zemsky and Yablokov, 1974; Smith, 1982).

DISTRIBUTION

The three species involved in the Black Sea fisheries are distributed widely, in disjunct populations, in temperate regions of the Northern Hemisphere (*Phocoena*) or the world (*Delphinus* and *Tursiops*). They are found throughout the Black Sea, reportedly moving seasonally to follow concentrations of various small pelagic fishes. For example, in the autumn they follow such prey fishes northward along the eastern Black Sea. The cetaceans formerly entered the Azov Sea, in the northeast corner of the Black Sea, along with the prey species. However, they no longer occur in that shallow sea, reportedly because it has become heavily polluted. The common dolphin historically occurred primarily in the central Black Sea, harbour porpoises and bottlenose dolphins primarily in the more coastal regions. However, sightings data suggest that there were shifts in ranges of the species in later years as the numbers of common dolphins declined. The animals in the Black Sea could move into the Mediterranean Sea, and bottlenose dolphins have been reported moving through the Bosphorous Straits. The extent of such movement is unknown, however. Tomilin (1957) presented evidence that all three cetacean species in the Black Sea differ morphologically from those elsewhere. Harbour porpoises do not occur in the eastern Mediterranean Sea at present, so those in the Black Sea are definitely an isolated stock. There is no information on the existence of separate breeding stocks within the Black Sea for any of the species. The genetics of the Black Sea dolphins and porpoise have not been studied. However, DNA-sequence comparisons with samples from other regions are presently being carried out for the common dolphin and the harbour porpoise (W. Perrin, pers. comm.).

PROBLEMS AND CATCH STATISTICS

Although the three species were harvested for many years at high levels, catch statistics are sketchy, being reported only irregularly and in total weight of the catch for all three species combined, as summarised up to 1974 by Smith (1982). The USSR catches apparently reached their

maximum of 135,000 to 140,000 animals in 1938, after which they declined. The average reported catches before World War II were roughly double those for later years, despite increasing fishing effort including the use of spotting aeroplanes. During the entire fishery, catches were made by both netting (mainly USSR) and shooting (mainly Turkey), with unknown loss rates in the latter. Smith reported that during a June 1981 joint USSR-US dolphin sighting survey, there was a decreasing rate of encounter of floating harbour porpoise carcasses with increasing distance from the Turkish coast (IWC, 1983b), suggesting the continuation of a harvest by shooting in the early 1980s and an apparently high struck-and-lost rate. The decline in catches of all three species to a few thousand per year by 1964–66 prompted first seasonal restriction, then a total moratorium in the USSR, Bulgaria and Romania from 1966. Little information has been reported for years since 1974 although it is known that the harvest continued in Turkey until it was banned in 1983.

Çelikkale *et al.* (1989) and Çelikkale (1990) described recent developments in the fishery, noting especially concern within Turkey that the dolphins and porpoises posed a serious threat to the continued success of local net fisheries for the European anchovy.

Recently, illegal takes of at least two of the three species have been reported in Turkey. The causes are not known but are variously described in newspaper accounts in March and April 1991 as incidental entanglement in net fisheries, directed take to reduce competition for the European anchovy, directed take to reduce the damage to fishing nets, utilisation of an incidental catch, and directed takes for commercial marketing of fertiliser, animal feed, and oil, perhaps for cosmetics. Catches are reportedly being made in 'turbot nets', and carcasses seen on the docks are being processed by boiling in vats. There have been no official estimates of the magnitude of this recent harvest, and no confirmation of their purpose; given the lack of systematic reporting in the years before the harvesting became illegal and the illegal nature of present harvests, accurate statistical reporting should not be expected.

POPULATION ESTIMATES

Following the 1966 moratorium on industrial Black Sea dolphin/porpoise hunting in the USSR, Bulgaria and Romania, a series of aerial sighting surveys was begun by the USSR, continuing at least through the early 1980s. The methods and some of the resulting data are described in Zemsky and Yablokov (1974), and analyses of the annual variability of estimates based on these data through 1973 are presented in Smith (1982). The abundance of all three species together was estimated to be 1.5 to 2.0 million animals in the 1930s, but only 250,000 over the period 1967 to 1974. There was no apparent trend in abundance in the latter period, but variability in the estimates between years was far greater than anything reasonably compatible with the biology of the species. The largest estimates in the later period were for the common dolphin (average roughly 150,000), while the smallest estimates were for harbour porpoise (average roughly 22,000), with bottlenose dolphins intermediate (averaging roughly 85,000). These estimates are based on expanding the numbers of animals sighted assuming an effective track width of three km in which 50% of the animals present were seen. The survey tracks covered most of the Black Sea, although certain areas were missed, including that within 12 miles of the Turkish coast.

⁵ Initial draft by T.D. Smith.

New surveys were conducted by Turkey in April and July of 1987 using standard line transect methods aboard four ships (Çelikkale *et al.*, 1989), and estimates for the three species combined of more than 450,000 animals obtained. The surveys were conducted seaward to 60 km, over roughly 1/6th the total area of the Black Sea, primarily along the southern coastlines. The estimates are based on assuming an effective track width of 5 km (2.5 km on each side of the vessel) and that the animals are distributed over the unsurveyed areas of the Black Sea at the same density as observed in the surveyed areas. Buckland *et al.* (1992) reviewed the statistical basis of these estimates, however, and suggested that they may be seriously biased by the use of the 'maximum effective sighting distance' as the 'effective search width', by size-biased sampling because the school sizes varied between several tens and several thousands of animals, and by extrapolating to unsurveyed areas. For example, they suggest that an estimate of just the surveyed area would be on the order of 76,000 animals, and that 'the true abundance might be substantially below the estimate of 454,440 animals, and may be well below half that estimate'. New estimates of 96,000 \pm 30,000, 10,000 \pm 3,000 and 7,000 \pm 3,000 for common dolphins, harbour porpoise and bottlenose dolphin, respectively, were reported in SC/43/Prog Rep USSR, but these estimates were not reviewed by the sub-committee.

ASSESSMENT AND STATUS

The populations of the three species in the Black Sea had clearly been greatly reduced by the time the fisheries closed between 1966 and 1983. While all three species continue to exist in the Black Sea, the degree of their recovery from previous depletion is not known with any precision. Based on the generally low rates of increase of cetacean populations, however, it is unlikely that they have increased to any substantial fraction of their pre-exploitation abundance in the few years that they have been protected. Further, given the reported declines in the fishery for at least one of their prey items, the recovery of the cetaceans may have been inhibited by reduced food resources. The reported Turkish takes, therefore, are of great concern, whatever their purpose.

RECOMMENDATIONS

The Scientific Committee made five recommendations concerning Black Sea dolphins in 1982 (IWC, 1983a, p.60):

- (1) that better information on catch levels and species composition be made available;
- (2) that the data from aerial surveys by the USSR be made available for analysis and evaluation;
- (3) that a Turkish scientist familiar with the fishery be invited to participate in the next meeting;
- (4) that the history of the anchovy fisheries in the Black Sea be reviewed; and
- (5) that Turkey and FAO be approached concerning the sampling of the Turkish fishery to obtain biological data of various sorts.

The Scientific Committee reviewed the above recommendations in 1983 (IWC, 1984a, pp.58-9) and noted that a general FAO fishery mission to Turkey had obtained some new data on the harvest of small cetaceans. However, the requested USSR sightings data had not been obtained, nor was the invitation for a Turkish scientist to attend the Scientific Committee meeting accepted. In view of the ban on the hunting of dolphins and porpoises

announced by the Turkish Government, effective mid-April 1983, the recommended sampling programme was no longer required. The Scientific Committee re-stated recommendations 2, 3 and 4.

No new data were available in 1984, and the Scientific Committee requested information from IUCN and UNEP and again expressed the desire to have a Turkish scientist attend the Scientific Committee meeting (IWC, 1985, p.53).

The paper on the anchovy fishery provided to the 1990 Scientific Committee meeting (Çelikkale, 1990) was welcomed as a partial response to recommendation 4, as was the participation of Çelikkale.

The Committee in 1990 recommended (1) that the current abundance estimates not be used as a basis for management and that they be reviewed independently; (2) that further population surveys be carried out, preferably involving at least the four nations bordering the Black Sea, and (3) that, because of the perception by fishermen in Turkey of competition by dolphins for fish, studies of feeding ecology of the small cetaceans be carried out.

The sub-committee makes two further recommendations below.

- (1) An evaluation of alternate possible causes for the declines in the anchovy fishery in Turkey should be made, including fishery resource surveys to monitor abundance and collection of specific catch and fishing effort statistics. The seasonal distribution of the anchovy population and the small cetaceans should be more fully described. Because the fish populations migrate throughout the Black Sea, similar information should be obtained in all countries surrounding the Black Sea, including information on possible incidental take or directed take of cetaceans.
- (2) The actual reasons for the reported takes of dolphins and porpoises in Turkey should be determined, and accurate statistics should be collected. Steps should be taken to ensure that these takes are reduced given the poor present understanding of the status of these populations. If the takes are motivated by perceived threats to the anchovy fishery, these threats should be further evaluated. If the takes are motivated by the commercial value of the products, these markets should be documented, and the existence of alternate sources of raw materials investigated. If the takes are incidental to commercial fishing operations, the causes of the entanglements should be determined, and steps taken to reduce the incidental take through education and possible changes to gear and fishing practices. Bulgaria, Romania and the USSR should also be encouraged to provide similar information.

5.1.5 The Peruvian small cetacean fishery⁶

Several species of small cetacean are taken by a variety of artisanal fisheries in Peruvian coastal waters and used for human consumption (Read *et al.*, 1988; Van Waerebeek and Reyes, 1990a). In Peru, the distinction between directed and incidental catches is blurred because small cetaceans possess commercial value, so all catches of dolphins and porpoises have been retained. Three species are commonly taken by these fisheries: dusky dolphin (*Lagenorhynchus obscurus*), Burmeister's porpoise (*Phocoena spinipinnis*), and common dolphin (*Delphinus delphis*).

⁶ Initial draft by A. Read.

DISTRIBUTION

The dusky dolphin occurs in cold-temperate waters along both coasts of South America and in presumably separate populations off southern Africa and New Zealand. On the Pacific coast of south America, it is distributed in coastal waters from Huacho, Peru (11°S) to southern Chile (Gaskin *et al.*, 1987). Burmeister's porpoises also occur in the cool waters of the coastal upwelling zone in Peru, extending from Paita (5°S) to the Beagle Channel in Chile and in the coastal waters of the Atlantic into southern Brazil (IWC, 1991c). Their entire range appears to be limited to coastal waters of South America. Common dolphins are widely distributed in pelagic and coastal waters throughout the world oceans, extending south in the Pacific to at least 40°S (Aguayo, 1975). Nothing is known about seasonal movements or stock structure of these three species in Peruvian waters.

PROBLEMS AND CATCH STATISTICS

Two sets of catch statistics describe the numbers of dolphins and porpoises captured in Peruvian waters. Official government statistics, compiled by the Ministerio de Pesqueria (MIPE), report the weight of all small cetaceans landed annually in Peruvian ports from 1966 to the present. Reported landings were at fairly low levels until the early 1970s, when catches rose dramatically (Read *et al.*, 1988). Recent annual landings have decreased from a peak of 1,408 tonnes in 1979 to 426 tonnes in 1989 (Van Waerebeek and Reyes, 1990b). Unfortunately these data are not collected on a species-by-species basis, so it is difficult to estimate the total number of individuals taken.

Estimates have also been made of the actual number of small cetaceans landed at several ports in central Peru since 1985 (Read *et al.*, 1988; Van Waerebeek and Reyes, 1990a; b). In the small port of Pucusana (12°S), the estimated total kill of small cetaceans has increased from 175 in 1985 to 2,320 in 1989 (Van Waerebeek and Reyes, 1990b). The majority of this catch is comprised of dusky dolphins, captured intentionally in a drift net fishery during the winter months (Read *et al.*, 1988). Comparison of these estimates with the published statistics show that the MIPE data are accurate for Pucusana, where small cetacean carcasses are weighed, but highly inaccurate for other ports where weights are estimated by port officials (Van Waerebeek and Reyes, 1990b).

Read *et al.* (1988) estimated the total number of dolphins and porpoises captured in Peruvian waters by combining official MIPE statistics on landed weights with data on species composition and mean weight of each species collected at Pucusana. These authors reported an approximate catch of 10,000 dolphins and porpoises during 1985, although they cautioned that this estimate depended on the accuracy of MIPE records and the extrapolation of species composition from central Peru to the remainder of the coastline.

A particularly troubling aspect of the situation in Peru is the recent development of the directed fishery for small cetaceans. Early reports of utilisation of small cetaceans in Peru (Mitchell, 1975a) indicated that the capture of these animals occurred incidentally to other fishing operations. In recent years, the majority of landed dolphins and porpoises have been deliberately captured, mostly in the directed net fishery for dusky dolphins (Read *et al.*, 1988), although a large catch of common dolphins was taken by harpoon in 1987 (Van Waerebeek and Reyes, 1990b). It has been suggested that this direct exploitation was initiated in the early 1970s following the collapse of the

industrial anchoveta fishery in 1972 (Read *et al.*, 1988). The commercial value of incidentally captured dolphins and porpoises presumably stimulated deliberate catches of these animals, particularly after the demise of the lucrative anchoveta fishery.

POPULATION ESTIMATES

There are no population estimates for any species of small cetacean in Peruvian waters.

ASSESSMENT AND STATUS

It is not possible to assess the status of small cetaceans in Peru, because estimates of total kill and abundance are lacking. The catch of dusky dolphins is known to be large, however, numbering in the thousands, and is thus cause for concern. In 1990, the IWC Workshop on Mortality of Cetaceans in Passive Fishing Nets and Traps expressed concern for this population of dusky dolphins (IWC, 1994). Notwithstanding the increase in catches at Pucusana, Van Waerebeek and Reyes (1990b) noted a negative trend in MIPE national landing statistics between 1979 and 1990, and suggested that this reduction in catches might indicate an unsustainable exploitation of declining populations. The Peruvian government reportedly closed the directed fishery for small cetaceans in November 1990, but the Scientific Committee had no detailed information about this closure and its effects.

RECOMMENDATIONS

Research is required to provide reliable estimates of total fishing mortality for each species in Peruvian waters. The sub-committee **recommends** that this be achieved by modifying existing MIPE data collection procedures to record the number of individuals of each species landed rather than total weight. Estimates of abundance of affected species and elucidation of stock structure are also urgently required to assess the impact of directed and incidental takes on affected populations, and the sub-committee **recommends** such studies to be undertaken.

The IWC Workshop (IWC, 1994) recommended that the Government of Peru collect and report catches of cetaceans at all ports, by species and number as well as weight. It also recommended that alternative fishing methods be sought to reduce marine mammal mortality without affecting fishery yields and that technological programmes to this end be established. If the incidental and directed kills continue, it is vital that an effort be made to assess the dolphin population(s), to at least obtain a minimum estimate of abundance.

5.1.6 The Sri Lankan small cetacean fishery⁷

Large catches of small cetaceans have been reported around Sri Lanka. Although some dolphins may have been harpooned by Sri Lankan fishermen at least as long ago as the late nineteenth century (Leatherwood and Reeves, 1989), the current situation appears to have developed along with the rapid expansion of use of synthetic gillnets, which were introduced in the 1950s and are now the fishing method of choice in most fishing areas of the country. Initially, incidentally gillnetted cetaceans may have been discarded by most fishermen, or retained for personal use by only a few. However, as uses were identified and markets established for flesh of small cetaceans, those animals incidentally caught began to be retained and practices were gradually expanded to include deliberate

⁷ Initial draft by R. Reeves.

taking (Leatherwood and Reeves, 1989). These developments may well have been fuelled by rapidly increasing human populations and declining availability of some other traditionally sought marine resources (Amarisiri and Joseph, 1985; Joseph, 1985). At present, dolphins are taken mostly in gillnets and by hand harpoons and are used for human consumption and as bait in longline fisheries. The taking of dolphins in Sri Lanka is now widespread and apparently growing (Leatherwood and Reeves, 1989).

SPECIES INVOLVED

The following species of small cetaceans, in approximately descending order of importance (i.e. numbers landed), have been identified in Sri Lanka since 1982: *Stenella longirostris*, *Grampus griseus*, *S. attenuata*, *S. coeruleoalba*, *Tursiops truncatus*, *Kogia simus*, *Feresa attenuata*, *Pseudorca crassidens*, *Globicephala macrorhynchus*, *Peponocephala electra*, *Lagenodelphis hosei*, *K. breviceps*, *Steno bredanensis*, *Orcinus orca*, *Mesoplodon sp.*, *Delphinus delphis* and *Ziphius cavirostris* (Leatherwood and Reeves, 1989). Catches also include a few large cetaceans (*Physeter catodon*, *Balaenoptera physalus* and *Megaptera novaeangliae*) and dugongs (*Dugong dugon*) (Leatherwood and Reeves, 1989). Most of the species involved in the Sri Lankan fisheries have pantropical or cosmopolitan distributions.

ESTIMATED CATCHES

The Sri Lankan National Aquatic Resources Agency (NARA) recently estimated that approximately 12,950 small cetaceans are caught in gillnets and others (no estimate) are harpooned annually in Sri Lanka (Dayaratne and de Silva, 1990). Methods used to estimate mortality were not presented in sufficient detail to warrant critical evaluation. Leatherwood (1994) reexamined data on fishing effort and dolphin catches in Sri Lanka from 1984–1986 originally presented in Leatherwood and Reeves (1989), and estimated that at least 8,042–11,821 small cetaceans were taken annually, depending on the assumptions used; he regarded even the highest of these figures as a substantial underestimate. In fact, data do show clearly that takes of small cetaceans are very large in Sri Lanka but are inadequate to permit calculation of reliable estimates with appropriate measures of confidence. With the kind and quality of data currently available

‘All attempts to estimate mortality of cetaceans in Sri Lankan fisheries ... are compromised in significant ways ... The best (one) could do was to calculate a series of estimates using conservative assumptions and present the basis and details for those estimates in sufficient detail that they can be recalculated as more information becomes available’ (Leatherwood and Reeves, 1989,p.47).

POPULATION STATUS

Although small-scale aerial and vessel surveys have helped describe distribution, relative abundance and behaviour of cetaceans in some areas of Sri Lanka (e.g. Alling, 1986; Leatherwood and Reeves, 1989), there is virtually no information available on stock identity, size or status for any species. Even if there were, data on fishing effort and catches of small cetaceans are inadequate to reliably define any trends in catches of small cetaceans. Therefore, it is not possible to assess effects of removals on the populations involved.

RECOMMENDATIONS

A well-established system for collecting statistics on fish catches exists in Sri Lanka. Observers in fish-landing sites record fishing effort and catches daily or weekly; these data are regularly compiled for each of the 14 fish-landing districts and reported to a national data centre. Catches of cetaceans are not routinely included in catch reports; they are available for only a few sites regularly visited by officials. By training local fisheries officers in identification of cetaceans and making reporting of cetacean catches a routine part of their duties, Sri Lankan authorities could use the existing fisheries reporting system to assess magnitude of catches. Biological studies of caught specimens, as have been initiated by NARA, combined with extensive surveys of the fishing grounds and adjacent EEZ, are then needed to assess effects of catches on affected populations.

It is already illegal to take cetaceans in Sri Lanka (Leatherwood and Reeves, 1989). However, pressures from increasing human populations and economic problems in the country are defining government policies favouring expansion of resource harvesting. As favoured status, and thus full protection, for cetaceans is unlikely, a conservative management programme is needed. To succeed, this programme must educate fishermen and field workers about differences between reproductive potentials of fishes and marine mammals, and thus consequences of overfishing the latter, and provide for careful monitoring and regulation of takes.

The IWC Workshop (IWC, 1994), in addition to a variety of recommendations applicable to Sri Lanka as one of many nations with large cetacean by-catches, recommended that new fisheries not be initiated and that existing fisheries not be expanded until after evaluation of their effects on non-target species.

5.1.7 *Platanista minor*⁸

COMMON NAMES

Indus susu, Indus river dolphin, *bhulan* (Pakistan)

DISTRIBUTION

This dolphin formerly inhabited the Indus River system, from upstream as far as Attock to downstream below Hyderabad. The historic distribution included the major tributaries of the main channel: Ravi, Sutlej, Chenab and Jhelum (Reeves, 1991). The present distribution is much less extensive (Fig. 3). A few dolphins may survive upstream of Chashma Barrage and below Sukkur Barrage, but most of the population is downstream of Chashma Barrage and upstream of Sukkur Barrage. They are now absent from the tributaries above Panjnad Barrage (Khan and Niazi, 1989).

Upstream movement through barrages is very unlikely to occur, and downstream movement, while possible, is probably only sporadic (Reeves *et al.*, 1991). The extant population is divided into five isolated subpopulations (Khan and Niazi, 1989).

PROBLEMS AND CATCH STATISTICS

No official statistics of any kind appear ever to have been kept on dolphin catches in the Indus system. Information about takes is limited to what can be learned from the literature on scientific collections and live captures, totalling at least 6 and 11, respectively, since 1968 (Herald *et al.*, 1969; Pilleri, 1970a; b; 1972; Pilleri *et al.*, 1976).

⁸ Initial draft by R.R. Reeves and R.L. Brownell, Jr.

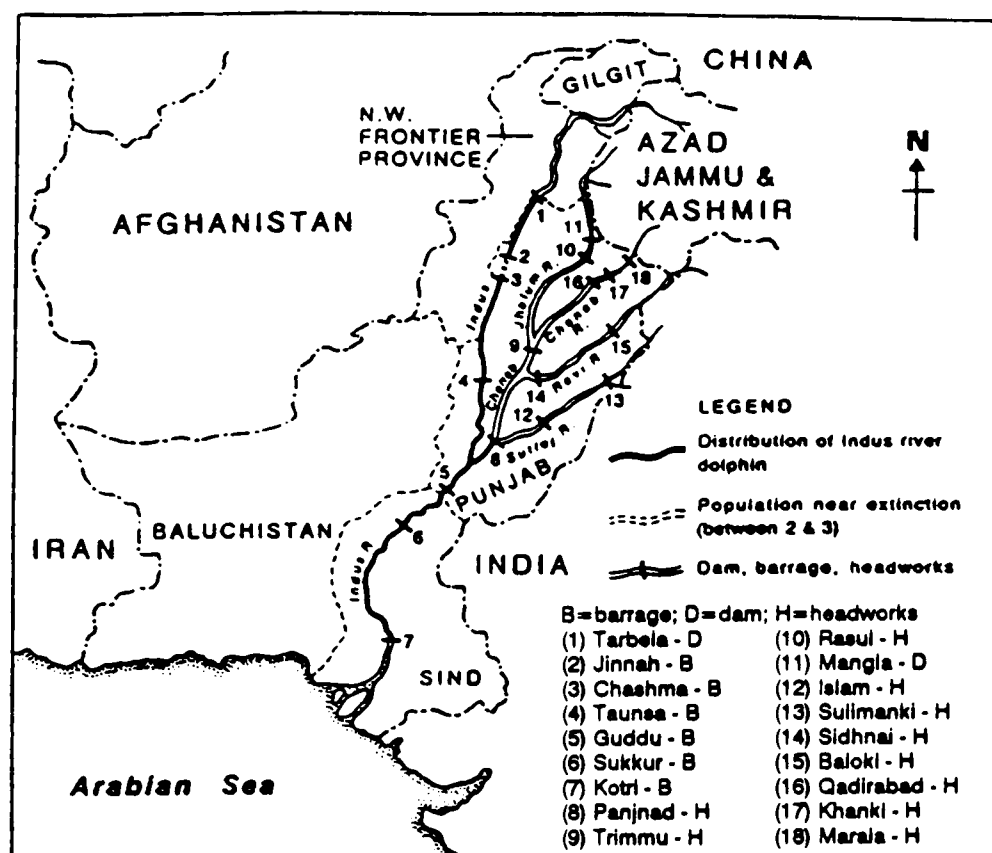

Fig. 3. Distribution of the Indus river dolphin.

Although the river dolphin has been legally protected in Sind province since 1972, the Punjab province since 1974 and the Northwest Frontier province since 1975 (Atkins, 1989), there have been reports of continued killing (Pilleri and Zbinden, 1974; Pilleri and Bhatti, 1978; Reeves, 1991). There is no reported regular incidental mortality in fishing gear or from boat collisions. However, fishing with gillnets, throw nets and various other gears takes place, and some motor traffic occurs, throughout much of the area inhabited by the dolphins.

The most serious conservation problem for this species is the loss of suitable habitat, including the partitioning of the metapopulation by barrages. All the barrages are being considered for retrofitting to produce hydroelectric power. The pressure is strong in Pakistan for intensified agricultural and industrial development, and the demand for water will certainly continue to grow.

POPULATION ESTIMATE

Counts of dolphins in the Sind Dolphin Reserve between Sukkur and Guddu barrages, carried out by the Sind Wild Life Management Board since the late 1970s, suggest a stable or increasing subpopulation there (Khan and Niazi, 1989). The most recent counts suggest a population size on the order of 400–450 dolphins. Because the details of survey methodology are unavailable, however, it is difficult to judge the validity of this estimate.

In the Punjab, counts by the Punjab Wildlife Research Centre between 1987 and 1990 indicate a subpopulation of about 100–110 in waters below Taunsa and Panjnad barrages and above Guddu Barrage (Chaudhry and Chaudhry, 1988; Chaudhry and Khalid, 1989; A.A. Chaudhry and U. Khalid, pers. comm. to Reeves, May 1990). The subpopulations in the Punjab and Northwest Frontier province upstream of Chashma Barrage and in Sind downstream of Sukkur Barrage range from a few to 10–20 individuals (Khan and Niazi, 1989; Chaudhry and Khalid, In press). Although the counts for the Punjab reported by Chaudhry and colleagues are substantially higher than those reported by Khan and Niazi (1989), there is no reason to suppose that the population has increased.

Khan and Niazi's counts were made in discrete portions of the area (see Niazi and Azam, 1988), whereas Chaudhry *et al.* attempted 100% coverage.

ASSESSMENT AND STATUS

The Indus River dolphin is critically endangered because of its restricted distribution and low population size. The subpopulation between Sukkur and Guddu barrages receives some protection, and its distribution and population size are monitored regularly by the Sind wildlife authorities. The same is true of the subpopulation between Taunsa, Panjnad and Guddu barrages, although since this area lacks explicit status as a dolphin reserve, policing efforts may be less effective. Even if protection from direct exploitation were complete, which it probably is not (Reeves, 1991), the deterioration of habitat is likely to continue.

RECOMMENDATIONS

International support is urgently needed for developing a programme of field research that addresses immediate management problems. Research should include (1) continued regular monitoring of population size and distribution, (2) noninvasive efforts to identify and track the movements and activities of individual dolphins, (3) estimating calf production and calf mortality, (4) identifying limiting habitat parameters, (5) precisely mapping and monitoring existing utilised and vacant habitat along the full length of the river, (6) determining and quantifying the cause(s) of mortality generally, determining whether the subpopulations are increasing or decreasing and projecting future trends in the subpopulations. Potential reserve areas need to be surveyed and appropriate reports and recommendations prepared. The advisability and feasibility of creating ways to allow mixing of the artificial subpopulations should be studied, perhaps as a component of the hydroelectric development work being supported with foreign capital (Reeves *et al.*, 1991).

Enforcement and strengthening of existing protective laws and creation of additional reserves should be high priorities. International support may be needed to ensure

adequate staffing, training and equipping of wardens. Further withdrawals of water from the main river channels for irrigation, power plant cooling or any other domestic or industrial use should be minimised. The Government of Pakistan and the international aid agencies involved in supporting development projects in the Indus basin should be made aware of the river dolphin's precarious status, required to assess the likely impact of the projects on dolphins and dolphin habitat, and encouraged to make every effort to reduce or eliminate any deleterious effects.

5.2 Incidental catches

5.2.1 *Phocoena sinus*⁹

COMMON NAMES

Vaquita, Gulf of California harbour porpoise

DISTRIBUTION

This porpoise is endemic to the warm-temperate waters of the upper Gulf of California. It has the smallest geographic range of any marine cetacean. A few sightings from farther south in the Gulf have not been confirmed. (Silber, 1990; Vidal, In press).

PROBLEMS AND CATCH STATISTICS

The vaquita has been incidentally caught in the gillnet fishery for totoaba (the large sciaenid fish *Totoaba macdonaldi*) since the mid-1920s (Vidal, In press). The fishery peaked in the 1940s and declined as the totoaba was depleted. The totoaba became fully protected in 1975, but the fishery has continued at lower levels, both as a legal experimental fishery and illegally. In addition, the vaquita is taken incidentally in gillnets in a growing shark fishery and a fishery for sierra (*Scomberomorus* sp.) and in shrimp trawls. The historical levels of incidental catches are impossible to reconstruct because of lack of information on fishing effort and vaquita catch rates. Records are available for 85 vaquitas taken incidentally since 1985 (Vidal, In press). This undoubtedly represents a very small proportion of the total mortality from fishing operations. The available information suggests that 30–40 vaquitas are killed each year (IWC, 1991c). Most recently, 13 vaquitas have been caught in the totoaba fishery during February and March this year (O. Vidal, pers. comm., 1991; not included in Vidal, In press).

POPULATION ESTIMATE

The size and status of the vaquita population are unknown. Extensive surveys by Silber (1990) and co-workers 1986–89 resulted in sightings of only 110 individuals in all surveys combined. Considering the scarcity of sightings relative to survey effort, the few individuals per sighting, and the very limited geographic range of the species, there can be no doubt that the population is very small, perhaps in the low hundreds (IWC, 1991c).

ASSESSMENT AND STATUS

The vaquita is the most endangered marine cetacean. The relatively high incidental catches and the difficulties and costs of enforcing long-term conservation measures quickly lead to the conclusion that the vaquita is in immediate danger of extinction (IWC, 1991c).

RECOMMENDATIONS

Because of the precarious status of the single population of this species, the Scientific Committee in 1990 (IWC, 1991b) recommended that further action be taken to stop the

major cause of entanglement by fully enforcing the closure of the totoaba fishery and reconsidering the issuance of future permits for experimental totoaba fishing, that immediate action be taken to stop the illegal shipment of totoaba (also and endangered species) across the US border, and that a management plan for the long-term protection of this species and its habitat be developed and implemented. The plan should include: (1) an evaluation of other fisheries that take or may take vaquitas; (2) investigation and implementation of alternative methods of fishing or other economically viable activities to prevent further incidental mortality; (3) education of the local fishermen and general public to increase awareness of the vaquita's dangerous situation; (4) monitoring of the status of the population of vaquitas; and (5) studies of the population biology of the species.

5.2.2 *Lipotes vexillifer*¹⁰

COMMON NAMES

Baiji, Chinese river dolphin

DISTRIBUTION

The species is presently restricted to the lower and middle Yangtze River, from the mouth to Yichang below the Three Gorges, where it occurs in small scattered groups over a distance of more than 1,000 km (Ridgway, 1966). It formerly occurred in other rivers and in the lakes feeding into the Yangtze.

PROBLEMS AND CATCH STATISTICS

The decline of the baiji is due to several causes: (1) habitat degradation (through depletion of fish stocks, development for water conservation and irrigation, and riverbank development, including explosion during construction), (2) increased river traffic resulting in deaths due to collisions with vessels, and (3) harmful fishing practices (Peixun and Yuanyu, 1989). The harmful fishing practices include the use of illegal bottom snaglines ('rolling hooks') and electrofishing. In 1984, in the section of the river from Honghu to Wuhu, 7 baiji were killed in explosions, 10 in illegal fisheries and one in electrofishing. Incidental kill data are not available for the entire length of the range of the species or for more recent years.

POPULATION ESTIMATE

The total number of baiji is estimated at 300 (Peixun and Yuanyu, 1989). This estimate is based on surveys conducted in 1985 and 1986. The density of dolphins per km of river searched ranged from 0.09 to 0.39. Further population surveys are planned.

ASSESSMENT AND STATUS

There is no estimate of original population size, but the range has contracted in historical times. The decline is thought to have been particularly steep during the last 35 years, as the Yangtze Valley has become industrialised and the river itself more heavily used (Perrin and Brownell, 1989).

RECOMMENDATIONS

The Workshop on Biology and Conservation of the Platanistoid Dolphins at Wuhan, People's Republic of China, in 1986 made a series of recommendations concerning conservation and management (Perrin and Brownell, 1989).

⁹ Initial draft by W.F. Perrin.

¹⁰ Initial draft by W.F. Perrin.

- (1) Further efforts should be made to eliminate or reduce the use of the 'rolling hook' fishing gear in the regions of high dolphin density.
- (2) Procedures should be developed to ensure that dolphins are absent or removed from the area before explosives are used in river-bank construction.
- (3) All the proposed and additional natural reserve areas should be established along the river, with commitment of sufficient resources for effective enforcement of protective regulations.
- (4) The two proposed semi-natural reserves at Shishou and Tongling should be constructed and the health of the captured dolphins placed in them monitored closely. Hydrologic surveys of the probable effects of high-dam construction on both sites should be carried out. Before dolphins are placed in the reserves, thorough studies of levels of contaminants in the water, bottom sediments and food fish should be completed. Seasonal change in the quantity and nutritive quality of the food fish should also be analysed. Finless porpoise should not be placed in the reserves; they may compete with the baiji for food in the situation of decreased species diversity of food fishes.

Since the workshop, several of these recommendations have been acted on. A patrol vessel has been put in service to enforce the ban on the use of 'rolling hooks'. An additional natural reserve has been established, and construction of the semi-natural reserve at Tangling has nearly been completed. An environmental study of the site of the proposed semi-natural reserve at Shishou has been carried out.

In addition the sub-committee **recommends** that monitoring of the population status should be continued.

5.2.3 *Tursiops truncatus* on the Natal South Coast of South Africa

COMMON NAMES

Bottlenose dolphin, *stumpneusdolfyn* (Afrikaans)

DISTRIBUTION

The bottlenose dolphin is found in tropical and temperate coastal waters around the world and in offshore waters in some regions (e. g. the eastern tropical Pacific: Scott and Chivers, 1990). In South African waters, the South Natal Coast population is apparently resident in a range approximately 30–40 km long (Ross *et al.*, 1989). Roughly 80–90% of dolphins seen in aerial surveys were within one km of the shore.

PROBLEMS AND CATCH STATISTICS

Approximately 20 dolphins die annually in anti-shark gillnets (Cockcroft, 1990; IWC, 1994). Most of the kill is made up of lactating females and their calves.

POPULATION ESTIMATE

Ross *et al.* (1989) estimated the population at 219–249, although some assumptions and factors in the assessment probably cause this to be an underestimate. They suggested a need for offshore aerial surveys, more detailed data on home range and daily movement patterns to assist in assessing the reliability of the aerial survey estimates, a means for estimating percentage of schools missed on the trackline, and mark-resighting studies of individual schools. Some of these problems were addressed in a series of surveys flown along the north coast of Natal in 1989

(Cockcroft *et al.*, 1991), from which it was estimated that the probability of seeing a dolphin group was 0.31 (approximate confidence limits 0.15, 0.46).

ASSESSMENT AND STATUS

The population may have been under pressure from the shark nets since 1952 (Ross *et al.*, 1989). The original size of the population is unknown. Although population size has been estimated as 219–249, the results of Cockcroft *et al.* (1991) suggest that this might be a substantial underestimate. Even so, the annual take of about 20 may be more than can be sustained, and it is likely that the population is declining (IWC, 1994).

RECOMMENDATIONS

Research needed to improve the population estimate is described above. The IWC Workshop (IWC, 1994) recommended that the killing of bottlenose dolphins in Natal waters be reduced immediately and that an immediate reassessment of deployment of the anti-shark nets be carried out. Information is also needed on relationships among contiguous stocks or herds of bottlenose dolphins.

5.2.4 *Stenella coeruleoalba* in the Mediterranean Sea¹¹

COMMON NAMES

Striped dolphin (English), *delfin listado* (Spanish), *dauphin bleu et blanc* (French).

DISTRIBUTION

The striped dolphin is found in tropical and temperate waters worldwide. It is one of the most abundant cetacean species in Mediterranean waters. Its distribution extends over both the eastern and the western basins, although it appears to reach higher densities in the latter. It prefers deep waters and is usually found beyond at least 5–10 miles of the coast with the highest densities being probably reached in open waters.

PROBLEMS AND CATCH STATISTICS

Because of their pelagic habits, striped dolphins do not usually interact with coastal and artisanal fisheries. The major problems appear to be pollution, incidental catches in offshore drift nets.

(i) Pollution

This is probably the most acute long term problem for the population. Western Mediterranean striped dolphins are amongst those mammals in which the highest concentrations of organochlorine pollutants have ever been detected. The blubber of specimens stranded on the Mediterranean coast of France showed concentrations averaging 267 ppm for PCBs and 344 ppm for DDTs (Alzieu and Duguy, 1979) and free-ranging striped dolphins off Spain carried levels averaging 326 ppm of PCBs and 165 ppm of DDTs (Aguilar and Perrin, 1988). Concentrations of heavy metals, especially mercury, are also known to be extremely high (Viale, 1978; 1981; Sanpera *et al.*, unpub. data). Although no studies to establish the impact of these pollutant levels on the population have been carried out, it is well documented that some pollutants, especially organochlorines, depress reproductive rates, produce alterations in skeletal development, and depress the immune system of mammals (Luster and Faith, 1979; Nicholson and Moore, 1979).

¹¹ Initial draft by A. Aguilar.

In 1990 an epizootic process broke out in the western Mediterranean and produced thousands of deaths of striped dolphins. The ultimate cause was found to be a morbillivirus infection, although levels of PCBs in diseased dolphins were found to be higher than in the healthy population, suggesting that individuals carrying high pollution loads were more susceptible to the disease. Also, abnormal weather conditions that decreased water productivity in the region (and subsequent lack of food for the dolphins) may have also played a role by weakening the dolphins and facilitating the infection and spreading of the disease (Aguilar and Raga, 1990).

(ii) Catches

The striped dolphin is seldom caught in coastal gillnets, bottom trawlers or long-line fishing (Duguy *et al.*, 1983). However, the recent development of pelagic gillnet fisheries in Italian, Spanish and African Mediterranean waters produced considerable by-catches of this species in the late 1980s (Magnaghi and Podesta, 1987; di Natale, 1990; di Natale and di Sciara, 1990). Large-scale drift nets were temporarily banned in 1990 in Italy and strictly regulated in Spain in 1991. However, some limited drift net operations by foreign flag vessels in the southern Mediterranean still remain totally unregulated. The Government of Italy is reportedly considering whether the temporary ban instituted last year will be continued. Very recent, and as yet unconfirmed, information indicates that Italian vessels may be permitted to restart driftnetting in 1991 [*The ban was lifted – Ed*]. Reliable quantification of past and current incidental kills of striped dolphins in the Mediterranean is not available. Illegal directed kills of striped dolphins also occur in France, Italy, southern Spain and northern Morocco at least (Duguy *et al.*, 1983; Aguilar, unpub. data; di Natale, 1990).

POPULATION ESTIMATE

The Mediterranean population of striped dolphins appears to be independent of that inhabiting North Atlantic waters, although some limited mixing through the Gibraltar Straits probably exists (Aguilar and Perrin, 1988). No reliable population estimate for the Mediterranean population of striped dolphins is available. In the western basin it has been suggested that the species may have expanded in the last decades to occupy the ecological niche of the common dolphin, a species in clear recession (due to unknown causes), at least in the northern fringe of the western Mediterranean (Viale, 1985).

ASSESSMENT AND STATUS

Because of lack of reliable information of population abundance, population trends and biological parameters, the status of the species in the Mediterranean can not be assessed. However, the pressure of human activities, especially through pollution, incidental catches and decrease of prey abundance is undoubtedly adversely affecting the population.

RECOMMENDATIONS

IWC (1994) recommended that actions similar to the ban instituted by Italy should be encouraged elsewhere in the Mediterranean, and that international co-operation and action by the General Fisheries Council for the Mediterranean (GFCM) are required to ensure that large scale driftnet fisheries do not restart from other nations, or

that reflagging for the purpose of continuing the fishery does not occur. A second recommendation was that wherever possible the consequences of banning drift nets for the fishermen involved should be studied, the economic impacts on the fishing community appraised and the subsequent development of alternative fishing methods monitored.

The sub-committee **recommends** that research efforts should be devoted to:

- (i) monitoring pollutant levels, especially organochlorines and heavy metals, and assessing their effect on population parameters such as reproductive rates, body and skeletal growth, and immunological strength;
- (ii) monitoring incidental and direct catches and identifying the fishing gear and areas in which the highest mortality occur;
- (iii) determining population size, structure and stock identity, and estimating local abundance, especially in the regions affected by the 1990 epizootic;
- (iv) monitoring fishing and anomalous natural mortality through examination of stranded animals. This will also permit continued monitoring of the health status of the population through necropsy.

The sub-committee also **recommends** that management measures should be adopted to ensure the enforcement of existing laws to restrict harmful fishing operations, and the reduction of pollutant shedding into Mediterranean waters.

5.2.5 *Phocoena phocoena* in the western North Atlantic¹²

COMMON NAMES

Harbour porpoise, common porpoise, *marsouin commun*, *pourcil*, (French); puffin' pig.

DISTRIBUTION

Distributed primarily in temperate and subarctic waters of the Northern Hemisphere, in the western North Atlantic, the distributional limits of this species are Upernavik (72°N) and northern Florida (28°N) (Gaskin, 1984; Polacheck *et al.*, In press). The vast majority of sightings have been made over the continental shelf, although harbour porpoises are occasionally found in deep waters further offshore (Stenson and Reddin, 1990). Gaskin (1984) suggested the existence of four stocks in the western North Atlantic based on indirect evidence from patterns of distribution and seasonal movements. From north to south, these proposed stocks are: (1) western Greenland, (2) eastern Newfoundland and Labrador, (3) Gulf of St. Lawrence, and (4) Bay of Fundy, Gulf of Maine and southwestern Scotian Shelf. Porpoises in all four stocks exhibit seasonal migrations and are common in inshore waters only during the summer months (Gaskin, 1984).

PROBLEMS AND CATCH STATISTICS

Harbour porpoises have been subjected to both directed hunting and incidental catches in commercial fisheries throughout their range. Aboriginal hunters in western Greenland took between 400 and 900 porpoises per year between 1900–50 and between 600 and 1,200 from 1950–87 except for the period 1968–71 when the catch was between

¹² Initial draft by A. Read.

1,300 and 1,500 (Kapel, 1977 and Danish Progress Reports to the IWC). It should be noted, however, that the reliability of the Greenlandic hunting statistics has been deteriorating during recent years. Harbour porpoises were also hunted in the Gulf of St. Lawrence (Laurin, 1976) and Bay of Fundy (Leighton, 1937; Prescott and Fiorelli, 1980) until recently (Gaskin, 1984). There are no reliable records of direct exploitation of this species in the waters of Newfoundland and Labrador.

Large numbers of harbour porpoises have been killed in salmon gillnets off the western coast of Greenland for several decades (Lear and Christensen, 1975). Foreign vessels were estimated to have taken approximately 1,500 porpoises in 1972 (Lear and Christensen, 1975) and the catch of the domestic fleet may have been almost as large (Kapel, 1977). No recent data exist on the numbers of porpoises killed in this fishery, although foreign vessels have been excluded since 1976 (Kapel, 1977). There is, however, reason to believe that the number of porpoises killed in this fishery has decreased since 1975 as the salmon quota has gone down from 2,000 tonnes in 1972 to around 800 tonnes in the most recent years (Lear and Christensen, 1975; Larsen, pers. comm.).

In Newfoundland and Labrador, harbour porpoises are killed in salmon gillnets, cod traps and groundfish gillnets. In 1980, 100 fishermen in Newfoundland reported taking 243 harbour porpoises in gillnets (Lien *et al.*, 1987). It is not possible to extrapolate a total catch from these data, because sampling was not proportional to fishing effort and no estimates of total effort are available. Nevertheless, the total annual incidental catch of harbour porpoises in this region probably numbers in the low thousands (Lien *et al.*, 1987).

Fontaine *et al.* (1992) sent questionnaires to 968 coastal fishermen in the Gulf of St. Lawrence and asked them how many porpoises they encountered in their nets during 1988. One-third of the fishermen responded, reporting that they caught 623 porpoises, mostly in groundfish gillnets. It is not known whether or not the respondents were representative of the entire fishing community, but it is clear that the incidental catch of harbour porpoises in the Gulf of St. Lawrence is substantial.

Harbour porpoises are also captured by bottom tending gillnets and herring weirs in the Bay of Fundy and Gulf of Maine (Smith *et al.*, 1983; Read and Gaskin, 1988). The largest incidental catches in this area are recorded by the groundfish gillnet fisheries. Reported kills by fishermen from the western Bay of Fundy and data on observed kill rates in the Gulf of Maine, combined with information on gillnet effort, suggest that the incidental catches are substantial, and it has been suggested that recent takes are on the order of 300 to 800 animals per year (IWC, In press). However it is not currently possible to extrapolate observed kill rates for the Gulf of Maine to obtain an accurate estimate of total takes for this area because of the non-representative sample of vessels from which kill rate data were obtained and problems with spatial/temporal resolution in the gill net effort data (Smith *et al.*, 1990). In addition, no information is available on possible kills in the eastern Bay of Fundy and the western Scotian Shelf. There are a few confirmed reports of incidental catches from fixed gear in waters south of Cape Cod during winter months (Polacheck *et al.*, In press). Current efforts by the US National Marine Fisheries Services (NMFS) are directed at improving estimates of incidental catches by placing observers aboard gillnet vessels in the Gulf of Maine (Payne *et al.*, In press).

POPULATION ESTIMATES

No reliable population estimates are available for harbour porpoise stocks in Greenland, Newfoundland and Labrador, or the Gulf of St. Lawrence. Aerial surveys in the Gulf of Maine resulted in a minimum abundance estimate of $3,541 \pm 1,486$ (Winn, 1982). Kraus *et al.* (1983b) performed a shipboard survey of the inshore waters of the Gulf of Maine and estimated harbour porpoise abundance at $7,956 \pm 1,327$. The results of an experiment on census techniques indicated that aerial and shipboard surveys both under-estimate actual harbour porpoise density because only a small proportion of individuals are at the surface when the survey vessel passes (Kraus *et al.*, 1983a). Application of *ad hoc* correction factors derived from this experiment suggests that actual abundance was at least 15,000 when these surveys were performed. It was noted that these surveys may have missed a substantial proportion of the range of the population in this area, so that this may still be a considerable underestimate of the true population size (IWC, 1991c). A comprehensive census of harbour porpoises in the Bay of Fundy and Gulf of Maine is planned by NMFS during the summer of 1991.

ASSESSMENT AND STATUS

A lack of accurate data on the magnitude of directed and incidental mortality prevents definitive assessments of the status of harbour porpoises in Greenland, Newfoundland and Labrador, and the Gulf of St. Lawrence. Preliminary evidence, however, suggests that incidental catches are large in these areas and are thus cause for concern. Two recent reviews (IWC, 1991c; 1994) have concluded that the incidental catch of harbour porpoises in the Bay of Fundy and Gulf of Maine is unlikely to be sustainable. These reviews both recommended that steps be taken immediately to reduce the incidental mortality of harbour porpoises in this region. At the present time, harbour porpoises are listed as 'threatened' in eastern Canada by the Committee on the Status of Endangered Wildlife in Canada (Gaskin, 1989). A status review of this species in the United States is currently being performed by NMFS.

RECOMMENDATIONS

In 1990, the Scientific Committee (IWC, 1991c) recommended that research be undertaken to (1) improve understanding of harbour porpoise stock identity, (2) estimate abundance for all stocks, and (3) refine estimates of the magnitude of directed catches and incidental mortality for all stocks. Also to, (4) conduct a joint US-Canada comprehensive sighting survey in the Bay of Fundy, Gulf of Maine and adjacent waters. Each of these research initiatives will require a substantial investment of time and resources. In addition, research should address degradation of the coastal habitat of this species and the effects of contaminants on the condition of particular stocks. Research is underway for these recommendations in the Bay of Fundy and Gulf of Maine. Further, more general, recommendations on harbour porpoise research were made by the Scientific Committee in 1990. These are summarised in Item 5.2.7 below.

The large kills of harbour porpoises in commercial fisheries, combined with substantial uncertainty regarding many aspects of the biology of this species, led the Scientific Committee to recommend that levels of incidental mortality be reduced throughout the range of the species.

5.2.6 *Phocoena phocoena* in the eastern North Atlantic¹³

COMMON NAMES

Harbour porpoise (English), *bruinvis* (Dutch), *Schweinswal* (German), *marsvin* (Danish), *tumlare* (Swedish), *nise* (Norwegian and Faroese), *muc mhara* (Irish), *Marsouin* (French), *Marsopa* (Spanish).

DISTRIBUTION

Although recent surveys show an offshore, oceanic occurrence of the harbour porpoise, this species is primarily distributed in coastal waters of the temperate and subarctic zone throughout the Northern Hemisphere, with a population occurring as far south as Senegal in the East Atlantic (IWC, 1991c). The extensive shallow waters of the North Sea are probably the most important habitat for harbour porpoises in the Northeast Atlantic.

PROBLEMS AND CATCH STATISTICS

The sub-committee on small cetaceans expressed concern for the status of the stock when it reviewed available information in 1990, and listed incidental catches, depletion of prey populations, pollution and human disturbances as possible threats to porpoise populations in these areas (IWC, 1991c).

Most countries in the region have legislation protecting the harbour porpoise. The only reported directed catches of harbour porpoises are small takes in the Faroe Islands, and these takes are likely to have a negligible effect on the stock. Habitat degradation and incidental catches in fishing gear have been proposed as more significant threats to harbour porpoises in this region.

The seasonal migration of porpoises through the Danish Belt Seas into the Baltic is well known (Möhl-Hansen, 1954). This migration through shallow and narrow waters gave rise to the long history of the Danish harvest of porpoises. This historical hunt is described by Kinze (in prep), who mentions six major catching sites. The most important site was the northern Little Belt, which was operative in the period from 1357 to 1892 and in the years 1916–19 and 1941–44. The overall annual take for this site may have been about 1,000 animals, with a minimum total take of 47,432 animals from 1827 to 1892. According to Kinze, this hunt continued for about five centuries. However, in the 1880s the annual catches increased and may have initiated the decline of the 'Baltic population' of porpoises. The relative importance of these takes compared with other negative influences on the Baltic population is unknown.

Clausen and Andersen (1988) collected 149 porpoises mainly from coastal gillnet fisheries in Danish waters during 1980 and 1981. They also noted the existence of further catches in wreck nets worked further offshore in the southern North Sea. They proposed a total catch of several thousand by Danish vessels in the North Sea. Kinze (1990a) reported the capture of 152 porpoises in Danish fisheries, mainly in the Skagerrak, between 1986 and 1989. One vessel, from a fleet of 15 similar vessels at Hantsholm, was monitored individually in 1988 and 1989. An annual catch rate of 30 porpoises was recorded, which lead Kinze to speculate that this fleet may take around 450 per year. Further catches are reported in gillnets in Danish waters.

Further incidental takes in the order of tens to a few hundreds are reported from most other countries in the region (e.g. Northridge, 1988; Kremer and Schulze, 1990; Northridge and Lankester, 1990; Benke *et al.*, 1991).

About 100 porpoises were recorded incidentally caught in a six-week period in 1988 by a drift net fishery for salmon in Norwegian coastal waters. The use of salmon drift nets was prohibited in Norway after the 1988 fishing season. Other Norwegian gillnet fisheries are known to catch porpoises, but less so than the former drift net fishery for salmon (Bjørge and Øien, 1990). Since the summer of 1988, a systematic scheme for collecting incidentally caught porpoises in Sweden has resulted in the collection of 178 individuals to December 1990, most of which came from gillnets in the Kattegat and Skagerrak (Lindstedt, 1990).

POPULATION ESTIMATES

The only estimates of population size based on survey results, are those of Bjørge and Øien (1990), who reported an estimated abundance of harbour porpoises in the Lofoten-Barents Sea area of 10,994 (CV 0.2381), and in the northern North Sea of 82,619 (CV 0.2165). There is little information on population trends in this area. In the Baltic Sea it is clear that harbour porpoise abundance has declined during this century (Andersen, 1982; Skora *et al.*, 1988; Määtänen, 1990). In the North Sea the situation is far from clear. The relatively large number of porpoises found in the central and northwestern North Sea gives no reason to neglect the possibility of a depletion of porpoise populations in neighbouring areas. Evans (1990) has reported declines in porpoise abundance in three separate areas in the Shetland Islands on the basis of boat surveys carried out locally in the early and late 1980s. Such results are difficult to interpret when so little is known of population distribution.

The stock identity of porpoises in the eastern North Atlantic is not well understood. A non-metric analysis of a large series of harbour porpoise skulls suggested the existence of several population units in this region (Kinze, 1990b), and a study based on isoenzyme electrophoresis indicated distinct Dutch and North Sea populations (Andersen, 1990).

ASSESSMENT AND STATUS

Although no single fishery is known to have a dramatically high incidental catch of porpoises (except for the possible large take in some Danish fisheries reported by Clausen and Andersen (1988)), the species is taken incidentally throughout the region, and there is a fear that the overall incidental catches could be above the sustainable level for the total population in the area. Although no reliable information is available at present on the population structure in the North and Baltic Seas, indications of distinct sub-populations exist. Taking into account the uneven distribution of fisheries, the impact of bycatches on any distinct sub-population may be more significant than overall takes on the total population in the northeast Atlantic region.

RECOMMENDATIONS

At its 1990 meeting, the Scientific Committee recommended, as a high priority, that incidental kills of harbour porpoises in gillnets should be reduced throughout their range (IWC, 1991c). Possible ways to reduce incidental kills include gear modifications, gear conversions, area or season closures and other restrictions in the fisheries.

The importance of determining harbour porpoise stock identities was also highlighted by the Scientific Committee in 1990 and it recommended that studies on stock identity should be undertaken through an integrated approach that

¹³ Initial draft by A. Bjørge.

includes a combination of pollutant levels, calving areas, non-metric variation, DNA allozymes and other types of research that may contribute to stock discrimination.

The Committee also recommended:

- (1) that the methodology for these different approaches be standardised so that results are comparable;
- (2) that where distribution extends beyond the boundaries of a single country, available samples and data should be pooled from as many potential sub-populations as possible, across national boundaries, and be analysed together;
- (3) that for the northeastern Atlantic the information on potential stocks, distribution, and other relevant data be synthesised in an attempt to produce a clearer picture of the stock identities in that region;
- (4) that abundance be estimated for populations where no such estimates exist, and especially for those for which there is or may be a large incidental kill;
- (5) that such studies consider the possibility that apparent declines in abundance may result from geographic shifts in distribution. Trends in abundance should be monitored on the basis of systematic surveys;
- (6) that dedicated sightings surveys should be conducted in the North and Baltic Seas;
- (7) that attention should be given to estimating $g(0)$ for harbour porpoise surveys;
- (8) that behavioural studies of free ranging harbour porpoises should be made to gain knowledge of habitat requirements in order to provide a framework for establishing management plans for the species and its habitat;
- (9) that tissues of stranded and incidentally killed harbour porpoises should be collected and analysed in order to monitor their contaminant levels;
- (10) that monitoring of pollutants be integrated with research on reproductive biology and other population parameters to increase the understanding of the possible effects of contaminant loads on the condition of the populations (this was considered especially important in the northeast Atlantic region);
- (11) that a high priority be given to monitoring, as well as reducing, levels of incidental mortality in all fisheries;
- (12) that when questionnaire and interview methodology is used to investigate or monitor incidental catches,

studies of reliability and scaling of reported take estimates should also be included.

An additional recommendation is that all countries of the northeast Atlantic region should implement a recording scheme for incidental captures of harbour porpoises in their waters.

5.2.7 High Seas driftnet fisheries

5.2.7.1 North Pacific

Driftnet fisheries in the North Pacific Ocean include the following: (1) Japanese salmon drift gillnet fishery, (2) Japanese, Taiwanese and Korean drift squid gillnet fishery and (3) Japanese and Taiwanese large mesh drift gillnet fishery for tunas and billfishes. The major small cetaceans taken in these fisheries are the northern right whale dolphin, *Lissodelphis borealis*, Pacific white-sided dolphin, *Lagenorhynchus obliquidens* and Dall's porpoise *Phocoenoides dalli*. Other small cetaceans that are known or likely to be taken included common dolphin, *Delphinus delphis*, striped dolphin, *Stenella coeruleoalba*, bottlenose dolphin, *Tursiops truncatus*, Risso's dolphin, *Grampus griseus*, spotted dolphin, *Stenella attenuata*, pygmy killer whale, *Feresa attenuata*, pygmy sperm whale, *Kogia* spp. and ziphiids. The three major species are reviewed in turn below.

*Lissodelphis borealis*¹⁴

COMMON NAMES

Northern right whale dolphin; *semi-iruka* (Japanese); *severnnyi kitovidnyi del'fin* (Russian).

DISTRIBUTION

The northern right whale dolphin is a cold-temperate water species endemic to the North Pacific Ocean. In the eastern North Pacific, it has been sighted from about 32° to 58°N (Fig. 4; Leatherwood and Walker, 1979; Kajimura and Loughlin, 1988). In the western North Pacific, the southern limit is as far south as 35°N from September to June (Kasuya, 1971) and about 40°N in the remainder of the year (Fig. 4); the northern limit is the southern Kurile Islands (Sleptsov, 1952; Klumov, 1959). The southern boundary in the central North Pacific is about 35°N (Fig. 4). Their temperature range is about 8° to 24°C, although the majority of the sightings have been in temperatures of 11° to 17°C (Fig. 4; Dohl *et al.*, 1983). Based on sightings

¹⁴ Initial draft by L.L. Jones and E. Miller.

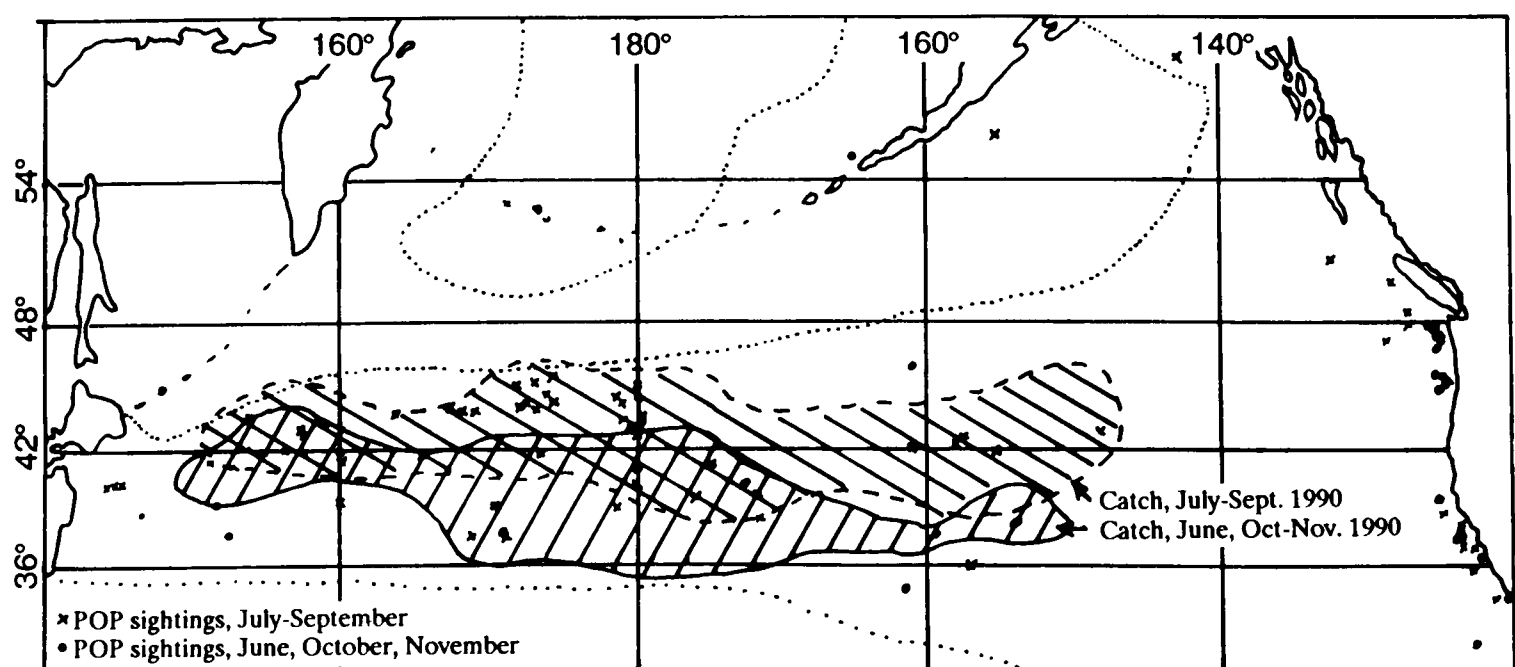

Fig. 4. Sightings of *Lissodelphis borealis* (1958-89) and high seas driftnet catch areas in 1990.

and bycatch data, off the Pacific coast of Japan and in the central North Pacific, seasonal movements appear to be related to the seasonal movements of the waters of the North Pacific Transition Zone.

Although this species occurs predominately in offshore waters, it does occur seasonally over the continental shelf in winter and spring off California (Leatherwood and Walker, 1979). Off Oregon and Washington it is also sighted more frequently nearer to shore in the colder water months (November to June; Fig. 4).

No colour morphs have been reported, although colour variants have (Nishiwaki, 1972; Leatherwood and Walker, 1979). Nishiwaki (1972) proposed two subspecies based on differences in colour pattern and dental formulae. However, Leatherwood and Walker (1979) examined these characteristics from animals from the eastern North Pacific and concluded there was not sufficient evidence for two subspecies.

PROBLEMS AND CATCH STATISTICS

Large numbers of northern right whale dolphins are currently taken incidentally in several high seas driftnet fisheries. Seven driftnet fisheries operate in the high seas in the North Pacific: Japanese squid, salmon mothership (now called the non-traditional landbased), salmon (traditional) landbased, and large-mesh for tuna and billfishes; Korean squid; and Taiwanese squid and large-mesh for tuna and billfishes. The northern right whale dolphin is probably taken in all except the salmon fisheries.

The largest known incidental take of northern right whale dolphins is in the Japanese high seas squid driftnet fishery which began in 1978. This fishery expanded rapidly, to a peak of 534 boats in 1981. In 1990, there were 457 vessels in the Japanese fleet which conducted 23,588 driftnet operations, deploying about 1,200,000 km of net (data from the Fisheries Agency of Japan).

Using a simple ratio estimator with the observed catch rate from June to September 1989, and reported fishing effort for the entire fishing season (33,646 operations, June-December 1989), nearly 11,000 northern right whale dolphins are estimated to have been incidentally taken by the Japanese high seas squid fishery in 1989. This estimate is based on a pilot observer programme in which 1,402 out of 33,646 driftnet operations (about 4%) were observed. The majority of the dolphins caught were dead but some (2%) were released alive. The survival rate of dolphins released is unknown.

In 1990, the scientific observer programmes were expanded in all the high seas driftnet fisheries in the North Pacific to increase observer coverage substantially and to cover all fishing seasons and grounds. These data are currently being analysed to provide more accurate estimates of the annual incidental take in these fisheries over the fishing areas and seasons. Summaries of the catch data from these fisheries will be available in June 1991.

Catch rates of northern right whale dolphins in other high seas driftnet fisheries may be lower than that of the Japanese squid fishery. Although the general fishing methods are similar, the driftnet fisheries use different mesh sizes, different amounts of net, and fish in different areas at different times of the year (Jones *et al.*, 1990). For example, the fishing grounds occupied by Korean squid driftnet vessels overlap with those occupied by Japanese squid driftnet vessels less than one-third of the season, mainly in June. The remainder of the season the Korean vessels fish further west than do Japanese vessels. Taiwanese vessels also tend to operate further west than

the Japanese squid vessels. Therefore, applying take rates from one fishery to another may result in inaccurate estimates of the total incidental take for a species.

Two previous calculations for incidental take of northern right whale dolphins in high seas driftnet fisheries have been reported. Northridge (In press) provided a crude estimate of some 19,000 northern right whale dolphins taken in the three squid fisheries in 1989. This estimate was based on the gross catch rate observed in the Japanese squid driftnet fishery (Gjernes *et al.*, 1990) and an assumed total fishing effort of 3,000,000 km of netting set. This latter figure was based on the reported numbers of vessels operating in 1988 in each of the three fleets, with some allowance for differences in the average amounts of netting deployed by vessels from each of the three fleets. The actual fishing effort may have been lower than this in 1989, as the number of vessels and catch by the Republic of Korea which were recently reported by the Korean Government were lower than assumed by Northridge.

Beamish *et al.* (1989) stated that 50,718 northern right whale dolphins were caught each year in high seas squid driftnet fisheries. Their calculation was based on a total of 63 retrieval observations collected in 1986 and 1988, and the reported Japanese squid fishing effort in 1987. They also assumed the same kill rate for all fisheries and estimated the fishing effort for the Korean and Taiwanese fisheries as a proration of the Japanese fishing effort, based on the number of vessels in each fishery.

These two estimates of total kills demonstrate the problems inherent in extrapolating estimates of kill rates to entire fleets when adequate data on all parts of the fleet are not available.

In addition to these catches in driftnet fisheries, the northern right whale dolphin has been hunted in Japan historically (Gilmore, 1951; Wilke *et al.*, 1953; Mitchell, 1975a). Ohsumi (1972) reported that harpoon fishermen took northern right whale dolphins when billfish and tuna catch was low. From 1976 to 1982, a total of 252 northern right whale dolphins were reported caught by the harpoon fishery for Dall's porpoise (*Phocoenoides dalli*) off Sanriku in northern Honshu (Miyazaki, 1983). This species currently is also incidentally taken by Japanese coastal driftnets. The reported catch in 1988 was 268 (Anonymous, 1990d). Small numbers are also taken in gillnet fisheries in California (IWC, 1994).

POPULATIONS AND ESTIMATES

The northern right whale dolphin is reported to be an abundant species in temperate waters. Nishiwaki (1972) provided an unrealistic low abundance estimate of 10,000 northern right whale dolphins in the North Pacific Ocean. Subsequently, Leatherwood and Walker (1979) estimated the population in the Southern California Bight in winter, when density is known to be highest, to be about 17,800 (no variance given). Japan has conducted sightings surveys in offshore areas, including the area of the driftnet fishery. Results from these surveys will be presented in the near future. US sightings data are also currently being analysed to provide abundance estimates for the offshore area of the North Pacific.

ASSESSMENT AND STATUS

The number of stocks which the fisheries affect is not known, but probably includes more than one stock. Lacking population estimates and information on stocks, and with only a preliminary estimate of incidental take in one fishery, status of the northern right whale dolphin is

unknown. However, large incidental catches for more than ten years raise concern for possible impacts by these fisheries, and the Scientific Committee (IWC, 1994) considered that the large catches of northern right whale dolphins were potentially not sustainable.

ADDITIONAL INFORMATION NEEDS

Incidental take in the high seas driftnet fisheries will continue to be monitored under international agreements at levels that will provide reliable estimates of incidental take in 1991 and early 1992. Biological samples are being collected to determine age structure, reproductive parameters, food habits and stocks. Sighting data are being collected on commercial and research vessels to provide estimates of abundance. However, the survey effort will be low over much of the species range. The USA and Japan will both conduct sighting surveys in July and August 1991 to obtain estimates of abundance on the fishing grounds during the peak of the fishing season, and to relate cetacean distribution to Japanese fishing effort data and oceanographic features.

*Lagenorhynchus obliquidens*¹⁵

COMMON NAMES

Pacific white-sided dolphin, *kama iruka* (Japanese)

DISTRIBUTION

This species is found only in the North Pacific Ocean. In the western North Pacific it is found as far south as Taiwan, in the eastern North Pacific to southern Baja California, Mexico, and across the temperate waters of the North Pacific (Leatherwood *et al.*, 1984; Miyashita, 1989). Two stocks may occur within the coastal waters of both the western and eastern Pacific (Walker *et al.*, 1986; Miyazaki and Shikano, 1989).

PROBLEMS AND CATCH STATISTICS

Pacific white-sided dolphins are the second most frequently caught small cetacean in the high seas Japanese squid driftnet fishery in the central North Pacific. Northridge (In press) has provided a rough estimate of the number killed in 1989 at around 11,000 (see method used and caveat under *Lissodelphis borealis* section above). Additional Pacific white-sided dolphins may also be killed in the Japanese and Taiwanese large-mesh high seas driftnet fisheries that target tunas and billfishes (Watanabe, 1994). These dolphins are also known to be caught incidentally in the Japanese fisheries.

Small numbers of Pacific white-sided dolphins are killed each year in Japanese waters for human consumption. Larger numbers of these dolphins were taken in cull programmes during the 1970s and 1980s. Additionally, small numbers of Pacific white-sided dolphins are incidentally killed in various coastal fisheries on both sides of the North Pacific (e.g. Anonymous, 1987b; Barlow *et al.*, 1992).

POPULATION ESTIMATES

The total size of the populations throughout the range of this species is unknown.

ASSESSMENT AND STATUS

The number of stocks affected by high seas driftnet fisheries is unknown but probably more than one stock is taken. The Scientific Committee (IWC, 1994) considered that the large kills of Pacific white-sided dolphins were

potentially not sustainable. Large incidental catches have occurred for more than ten years (since the start of the high seas squid driftnet fishery) and the total population size is unknown. Therefore, concern is noted over the status of the stocks taken in high-seas driftnet fisheries.

Dall's porpoise, *Phocoenoides dalli* (True, 1885)¹⁶

COMMON NAMES

Dall's porpoise, *ishi iruka* (Japanese).

DISTRIBUTION

The distribution of this species is described above in Item 5.1.1. The main stock of concern is that south of the Aleutian Islands.

PROBLEMS AND CATCH STATISTICS

This species has been taken in all four of the major driftnet fisheries of the North Pacific. In the past, incidental kills of 10,000 to 20,000 Dall's porpoises per year were considered possible in the Japanese high seas salmon driftnet mothership fishery (Mizue and Yoshida, 1965) which started in 1952. This fishery operated within the US 200 mile limit between 1978 and 1988. Eleven motherships and 368 catchers operated in this fishery during the 1960s, compared to only 4 motherships and 172 catchers in 1978. The estimated annual incidental catch of Dall's porpoises in the fishery between 1981 and 1987 within the US EEZ ranged from a low of 741 in 1987 to a high of 4,187 in 1982 (IWC, 1991c). In the western North Pacific, these porpoises are also taken in the Japanese land-based salmon gillnet fishery. Between 1981 and 1986 the estimated annual catch averaged 1,645 (Ito, 1986).

Incidental catches of Dall's porpoise have also been reported in the driftnet fishery for squid, operated by Japanese, Taiwanese and Korean vessels. An extensive observer scheme in the Japanese fishery in 1989 revealed catches of around 1.98 Dall's porpoises per 1,000km of netting set. Northridge (in press) suggested a possible total of around 3,000,000 km of netting set in these fisheries, which might suggest a total catch of about 6,000 animals. Jones and Miller (*Lissodelphis* section above) thought that total effort was less than this, and that this estimate might be therefore high because of variation in take rates between fisheries. Catch rates vary from year to year and fleet to fleet, so any estimate of total catch is necessarily very crude at this stage.

POPULATION ESTIMATE

There is no population estimate for the Dall's porpoise stock south of the Aleutian Islands, but (Turnock, 1987) gave an estimate of 741,000 porpoises for the western and central North Pacific region (see 5.1.1.).

ASSESSMENT AND STATUS

The pelagic squid drift net fishery may have taken around 6,000 porpoises in 1989 from a wide area across the North Pacific from more than one stock. The pelagic squid fishery was started by Japan in 1978. It does not exploit the same stocks as are taken in the hand harpoon fishery. Additional Dall's porpoises are killed in smaller numbers in the large-mesh drift net fishery off Japan for tunas and billfishes (L.L. Jones, pers. comm.). The total take from these populations is, therefore, somewhat less than 1% of the

¹⁵ Initial draft by R.L. Brownell, Jr.
