The reaction of three bottlenose dolphins to a gillnet was observed in February 1986 (Hatakeyama and Ishii, 1987). As shown in Fig. 6, three dolphins were held in a net enclosure which was partitioned equally with a salmon gillnet (45m long, 3m deep, 115m mesh size). They could move freely to other areas either by passing through spaces at both ends of the gillnet or passing under the gillnet or the floating pier. To more easily observe dolphin behaviour at night, a small flashing buoy (15cm in length, 7.5cm in diameter) was attached to one animal. The flash interval was 3sec. The behaviour was recorded on video tape.

Fig. 6. Layout of the gillnet, pier, boat and dolphin to observe bottlenose dolphin's behaviour to the gillnet.

Three situations were considered: (1) when they were swimming freely under ordinary conditions (day and night); (2) when they were chased; and (3) when they were feeding on fish attached to the gillnet.

Fig. 7 shows the frequency distribution of distances between the gillnet and the dolphins. Dolphins seldom went closer than 1m to the gillnet. For the experiment with chased dolphins, the length (*R*) of the rope between the edges of the pier and gillnet was varied from 0 to 10m. With *R*=5 or 10m, the dolphins passed easily under the rope ('a' in Fig. 6). When *R*=0m, on most occasions the dolphins passed the boat many times ('c'); on one occasion they passed under the gillnet ('b').

For the 'feeding' experiment, weak cotton thread was bound around the tail of 25–28cm mackerels, *Pneumatophorus japonicus japonicus*, and they were hung from the floatline at the side of area B and kept at a depth of 0.5 to 1m. Even when the dolphins were hungry, they fed on the fish attached to the gillnet without getting entangled. They were conducting careful echolocation with a horizontal shake of their heads.

In all categories, the dolphins fully detected the existence of the gillnet and did not get entangled in the gillnet.

Fig. 7. Distribution of distances between the dolphin and gillnet.
*Distance ranging from N-1 to N(m) is regarded as N(m).

Fig. 8. Side view of the gillnet in the experimental pool.

Reaction of harbour porpoises to gillnets in a darkened pool
Since salmon gillnets are set from evening to the following morning, it is important to observe the reaction of animals to gillnets in a darkened pool; in 1987, this was done for two harbour porpoises using a nightscope in front of the glass window (Hatakeyama *et al.*, 1988).

Fig. 9. Patterns of harbour porpoise's behaviours near the gillnet.

¹ Start time. ² The net was completely set in the pool. ³ One porpoise got entangled.

All mercury lamps over the experimental pool were turned off. The underwater irradiance was 1.4lux. vertically and 0.9lux. horizontally and conditions were such that nearby netting at a distance of about 2m could be seen dimly by the naked human eye accustomed to the darkness. The salmon gillnet was cut and remodelled to a small-sized gillnet (4m in height, 15m in length) as shown in Fig. 8; there was some space between the rope and net.

Reactions to the gillnet were categorised by pattern (Fig. 9, Table 5). The animals passed between the rope and net eight times and made nine U-turns immediately in front of the net. One porpoise approached the net at a right angle, 4mins 22secs after the net had been set. Whilst turning counter-clockwise immediately in front of the net, its caudal fin became entangled in the middle of the net.

The maximum detection ranges of harbour porpoise for the leadline and netting were estimated to be 9m and 2m, respectively, from an echo level and corrected auditory threshold. The echo level was calculated by taking account of distance-related variations in the areas of the reflecting portions. The auditory threshold of 68dB at 130kHz for a sound of 1.5sec (Andersen, 1970a) was corrected for the pulse width (43µs) of clicks emitted by harbour porpoises.

These estimated detection ranges are based on simplified models of the gillnet and reflection mechanism, and from the auditory characteristics of a dolphin from another family. Gillnets set in the sea will change their configurations in a complex three-dimensional manner. It is clear that further studies are required on the reflection of the ultrasonic pulse waves and the Dall's porpoise's ability to detect the gillnet. However, it should be noted that the echolocation ability of the Dall's porpoise will be better than that of the harbour porpoise because the source level, pulse width and frequency of its clicks are more suitable for echolocation.

RESPONSES TO SOUND WAVES AND OBJECTS

It is important to observe the response of porpoises to a variety of sound waves and objects in order to examine the likely success of different active and passive methods to prevent their incidental catches.

Dall’s porpoise on the high seas

Sound projection experiments in the Bering Sea

Although it is difficult to make detailed observations of the behaviour of Dall’s porpoises around a vessel in open seas and thus to evaluate quantitatively their responses to ultrasonic pulses, we attempted to do this as little or no such information exists.

The following ultrasonic pulses were projected toward Dall’s porpoises which approached the stationary salmon research vessel in the Bering Sea: pulses with frequencies of 75, 115 and 143kHz in July 1983 (Hatakeyama and Shimamura, 1984) and randomly generated 20–50kHz pulses in July 1984 (Taketomi *et al.*, 1985). The specifications of the pulse generators are listed in Table 6.

Swimming behaviour was observed in relation to the ultrasonic beam of the transmitter hung at the side of the vessel (Fig. 10). Results from the 1983 experiments suggested that the response to the 115kHz pulses was strongest. When the source level was 196dB or more, they made a quick U-turn as they became aware of the beam even at distances of 20 to 40m. It appeared that the porpoises regarded the beams as barriers.

At 143kHz, with a fixed sound source level of 210dB and varied pulse width of 100µs to 50ms, the animals showed avoidance responses more frequently to the greater pulse width. Responses to 75kHz pulses were the weakest but frequent avoidance occurred at a source level of 228dB.

In the experiments using randomly generated 20–50kHz pulses, reaction frequently entailed avoiding the ultrasonic beams or making a sudden dive when entering the beams.

Sound projection experiments in the Okhotsk coast off Hokkaido

A series of experiments were carried out in the Okhotsk Sea off east Hokkaido (Taketomi *et al.*, 1985; Ishii *et al.*, 1986). The following types of sound wave were projected toward Dall’s porpoise resting at the surface as the boat (about 2GRT) approached: ultrasonic pulses of 24 or 50 kHz and randomly generated 20–50kHz pulses in August 1984 and ultrasonic pulses of 24kHz and a vocalisation of killer whale in August 1985 (Table 6).

A total of 14 trials was conducted, two with 50kHz pulses, two with killer whale sounds, three with randomly generated 20–50kHz pulses and seven with 24kHz pulses. In addition 21 control trials were conducted in which no sounds were emitted while the boat approached. Transmission loss of sound pressure is calculated for each type of sound wave and shown in Fig. 11.

If Dall’s porpoises were found 2–3km from the boat, they were slowly approached up to 500–600m. In general, they showed two types of reaction to the boat at this

Table 6

Fig. 11. Sound pressure of each sound projected to Dall's porpoise as a function of distance.

distance when no sound was emitted: either to remain at the sea surface or to suddenly dive and disappear. When ultrasonic pulses were emitted from distances of 100–700m, the animals immediately became disturbed and swam rapidly away, splashing at each surfacing. No escape response was apparent during the killer whale sound experiments; after 2–3 minutes the animals swam away.

A captured live Dall's porpoise in a pool

Response to sound waves

Hatakeyama and Shimizu (1985) reported the observed responses of a Dall's porpoise captured in May 1984 to sound waves. The animal did not respond to potential food items thrown into the pool (anchovies, *Engraulis japonica* (about 7cm in length) or sardines, *Sardinops melanosticta* (about 20cm in length)) either as prey or merely as a source of underwater sound as the fish hit the water (when anchovies were thrown in the source level ranged from 140 to 150dB and the spectrum peak was between 1 and 3kHz).

Low frequency sounds (the source level was 171dB at the depth of 50cm and the spectrum peak was between 2 and 2.5kHz) were produced by striking the inner wall of the concrete pool (7x5x3m) six times but the porpoise did not seem to be frightened and did not change its swimming behaviour.

These experiments suggest that the Dall's porpoise is not sensitive to low frequency sound waves at pressure levels of up to about 170dB.

Randomly generated ultrasonic pulses 20 to 50kHz were projected twice toward the Dall's porpoise, with the sound pressure adjusted to 178dB at the position of the porpoise. The animal was clearly disturbed and this was indicated by: (1) an increase of four times its 'normal' respiration rate; (2) changing from its 'normal' circular swimming pattern; (3) constantly swimming at the surface to avoid the pulses.

Experiments were also conducted on the animal live-captured in 1986 and kept in the pool (5.1x5.7x2.0m) of the National Fish Farming Centres. Ultrasonic pulses ranging from 20 to 143kHz were projected towards the animal from a distance of 2m. The sound pressure (*Pt*) at which responses began was examined in 10dB increments (Hatakeyama *et al.*, 1987). The animal had floats on either sides of his body and in the absence of sounds swam slowly around the pool in a clockwise direction. When the pulses were emitted, two types of response were noted: movement to avoid the sound and irregular breathing or the emission of sounds in the air.

Fig. 12. Sound pressure (*Pt*) where Dall's porpoise began to respond to supersonic pulses. Auditory thresholds of Dall's porpoise and other species. From Awbrey *et al.* (1979).

The *Pts* at a pulse width of 1ms and the estimated auditory threshold (Awbrey *et al.*, 1979) of Dall's porpoise are shown in Fig. 12. The *Pts* between 20 and 100kHz range from 122 to 130dB and this sound pressure is approximately 70dB higher than the auditory threshold. The *Pt* increases drastically to 158dB at 143kHz and the auditory threshold deteriorates in a similar way. As the pulse width is reduced by a factor of about 10 (e.g. 10–1ms or 1–0.1ms at 143kHz) the *Pt* increases by 10dB, similar to the case of bottlenose dolphin (Johnson, 1967). The audible frequency range of the Dall's porpoise is similar to that for the bottlenose dolphin and harbour porpoise.

Responses to objects

When a white nylon rope (10mm in diameter) was stretched on the water surface of the pool (7x5x3m), the porpoise swam in a circle with its head up furiously blowing up in the air with splashing sounds on one side of the rope. It did not attempt to dive under the rope. The animal appeared to be both aware and cautious of the rope. No reaction was observed when the rope was stretched 10cm above the water surface.

In experiments where nylon monofilaments (0.6 or 1.2mm in diameter) were hung at intervals of 35 or 70cm, as the diameter of the threads became larger and the interval became smaller, the porpoise was more aware of the existence of the threads and the time it took to swim between the threads became longer. Since the porpoise emitted few clicks while passing through the interval, recognition of the existence of the threads seemed largely to have been visual (Hatakeyama and Shimizu, 1985).

SOUND GENERATORS

Specifications of sound generators

Specifications of all sound generators are listed in Table 7. The four types of sound generators (SG-1 to 4) were constructed on the basis of the frequency components of clicks and responses to ultrasonic pulses (National Research Institute of Fisheries Engineering, 1982; Hatakeyama, 1983; 1986).

Table 7
Specifications of sound generators tested in the actual fishing ground.

Type	Frequency (kHz)	Source level (dB)	Directivity (°)	Waveform				Size (mm)		Weight (kg)	Power supply	Life time (days)	Test year
				τ	t	t'	T	D*	L*

SG-4	20-50	186	360-60	1-109ms	10-226ms	9-110ms ⁴	6s	380	797	20	Battery 12Vx2 ⁵	1	1985-1989

¹ 4 pulses in 16 sec. in every 4 min. ² Horizontal x vertical. ³ 47 pulses in 0.6 sec. in every 3 sec. ⁴ Pulses and FM sounds in 1 sec. in every 6 sec. ⁵ 300-400 times rechargeable battery. Discharge and charge once a day. D = Maximum diameter; L = length.

Given the lack of available data in 1981, SG-1 was developed by the marine mammal project team on the basis of the whistle of bottlenose dolphin.

SG-2 and 3 took into account information obtained in 1983 concerning the frequency components of clicks emitted by the Dall's porpoise. SG-2 emitted 145kHz ultrasonic pulses repeatedly with a constant period. Its pulse width (50ms) was 1,000 times greater than that of clicks made by Dall's porpoises to stimulate their auditory sense with the duration time (energy quantity) and to attract their attention by disturbing their echolocation. SG-3 emitted 135-150kHz pulses similar to those used in echolocation by Dall's porpoises, by changing the pulse interval. SG-4 (manufactured in 1985) emitted random ultrasonic pulses and FM continuous waves of 20 to 50kHz which had been found to affect Dall's porpoises in a series of three experiments in 1984.

The electronic circuit of SG-1 was installed in a plastic case whilst those of the other sound generators were installed in buoys (Fig. 13).

Results of tests in the mothership fishery

The four types of sound generators were tested in the mothership salmon fishery and the results from 1983 to 1986 are shown in Table 9 (Kumagai *et al.*, 1984; Ogiwara *et al.*, 1985; 1986; 1987; Snow, 1987).

Decrease rates (DR) of the entanglement for SG-1 to 3 were 3-16%, smaller than expected. The DR for SG-4 was 19% in 1985. SG-1 was not used after 1985 given its low DR and difficulty of use.

Fig. 13. Sound generator (SG-2, 3 and 4).

In the experiments using SG-4 (Hatakeyama, 1986; 1987; 1988), there was a concentration of the entanglement in that portion of the gillnet where no sound generator was attached and the sound wave was weak. A total of 3-4 SG-4s per net were attached to positions either near both ends of the gillnet or on one half of it. The horizontal distribution of the entanglement is given in Table 8.

Porpoises incidentally taken were concentrated in sections 7-9. The CPUEs for the horizontal sections 1 to 6 which appeared to be within sound range and for the

horizontal sections 7–9 at which the sound pressure was weak were calculated (Table 10). The former were much smaller than the latter. Given the relatively small sample sizes involved, it is not appropriate to statistically analyse the data. The purpose of the experiment was to determine whether the approach was considered worthy of further attention, and this is clearly the case.

Effective range of SG-4

The effective sound pressure of SG-4 was examined under conditions where Dall’s porpoise was facing the sound generator (Hatakeyama *et al.*, 1987). The sound pressure (*P*_t) at which Dall’s porpoise began showing a response was 126dB. Since the increase step of sound pressure in the experiment was 10dB, the true value of the *P*_t was in the range of 116 to 126dB. The frequency characteristics of the projector rendered the sound pressure to be a maximum at 35kHz. The auditory threshold (TH) at 35kHz was

estimated to be 51dB by Awbrey *et al.* (1979). The TH represents the sound pressure at which Dall’s porpoise would barely hear the sound wave whereas the *P*_t represents the sound pressure at which Dall’s porpoise would show an external response. There presumably is an intermediate sound pressure (*P*_c) that would draw the Dall’s porpoise’s attention to the sound.

The effective range was obtained on the points of intersection between an attenuation curve of the sound and above parameters as shown in Fig. 14 and Table 11 (Hatakeyama, 1987). Dall’s porpoises were observed to jump and flee when the sounds were projected from distances up to 700m. The effective range based on the value of *P*_t is 440–740m and this upper limit is close to the experimental value (700m).

	Sea state 3 3,800
	Sea state 6 3,300
Pc	1,900
Pt	440-740

GEAR MODIFICATION

Gillnets with air-tube nylon threads

Awbrey *et al.* (1979) recommended that attempts be made to weave air-filled line into the net in order to increase the net target strength and thereby decrease mortality. Accordingly, the marine mammal project team conducted an experiment using air-tube nylon threads (outer diameter about 0.6mm; ratio of inner to outer diameter about 0.5). The TS of the gillnet with three air-tube threads was larger by 3 to 4dB than that of the ordinary net.

The project team monitored the incidental take and calculated its decrease rate (DR), comparing CPUE (number of incidental take/net) of the modified net with that of the standard unmodified net (Kumagai *et al.*, 1984; Ogiwara *et al.*, 1985; 1986; 1987; Snow, 1987). Four types of modified nets were used: 3 air-tube threads in the central portion (AT-1); 5 air-tube threads in the central portion (AT-2); 3 air-tube threads in the upper third of the net (AT-3); and 3 multi-filament threads in the central portion (MT-1). The results from 1983 to 1986 are listed in Table 9. The DRs of AT-1 to 3 were in the range of 8 to 20%.

Multi-filament thread has a higher (about 10dB) target strength than nylon monofilament and the obtained DR was 28%. Two statistical tests were used to examine the results: a test using entanglement frequency rate (U Test) was used for those cases where the sample size was small, e.g. for AT-1; a test using frequency distribution of the entanglement (χ^2 test) was also used. A significant difference (1% level) was found for 1985 and 1986 (Table 9). In addition, since 1984, the sample size has become sufficient to compare CPUEs for the two types of gillnets using the t-test; significant differences were found for 1985 and 1986 at the 1% level (Snow, 1987).

Gillnets equipped with reflectors

A total of 13 operations were conducted by a research vessel from 2–28 June 1986 with a set of 135 tans (1 tan=45m) of gillnet (Hasegawa *et al.*, 1987). Gillnets of five types were used. Types A to D were equipped with reflectors such as vinyl string, rope and sheets of blister plastic packaging material (Fig. 15). Type E, the control, comprised ordinary nets.

The target strengths of these objects are larger than that of the netting by 20 to 40dB, if the porpoises approach the net at a right angle. However, when they approach it at a diagonal angle, the reflected waves have a tendency to decrease abruptly. The mean values of the numbers of salmon caught per tan were 3.4 in type A (total length (TL) = 195 tans), 3.5 in type B (TL = 260 tans), 3.3 in type C (TL = 260 tans), 3.4 in type D (TL = 195 tans) and 3.7 in type E (TL = 845 tans). Although the values for the modified nets were smaller than for the control net, they were not significantly different.

Fig. 15. Schema of experimental gillnet with reflectors.

A total of five Dall's porpoises became entangled during the 13 operations, 1 in type B net, 2 in type C net and 2 in type E net. It was assumed that the vertical ropes had no alerting effect on Dall's porpoise. Given the small sample sizes it is not surprising that no significant differences were apparent between the modified and unmodified nets. If this approach is to be pursued, the experimental procedures must be greatly enlarged.

CONCLUSION

It is very difficult to successfully live-capture a Dall's porpoise. In addition, although we eventually succeeded in live-capturing two Dall's porpoises with purse-seines, we did not succeed in feeding them.

Dall's porpoises in the Bering Sea emit short high frequency (135–149kHz) pulses with pulse widths of 50–60μs and source levels of 165–175dB re 1μPa. When chased toward gillnets in open sea, they changed their swimming direction in front of the net, either swimming along it or diving and passing under it. This fact shows that they have a highly resolute echolocation ability and normally can avoid getting entangled in gillnets during the daytime.

Measured target strengths of a float, leadline, lead and netting were –25, –33, –39 and –55dB, respectively. The rough estimates of their detection ranges for the leadline and netting were found to be 30 and 8m, respectively.

Responses to sounds showed that Dall's porpoises are insensitive to low frequency (<3kHz) sounds with a sound pressure of up to 170dB, but are noticeably sensitive to ultrasonic pulses of 20 to 143kHz. Responses to objects suggested that they are aware and cautious of a rope on the water surface.

Four types of sound generator (SG-1 to 4), air-tube threads and reflectors such as rope were tested aiming to reduce the incidental catch. The decrease rates (DR) of the entanglement for the sound generators except SG-4 were 3 to 16% and the DR of the gillnet with three air-tube threads in its centre portion was 8 to 20%. As for SG-4, there was a concentration of entanglements in the portion of the net where it was not attached.

Although the numbers of salmon caught per unit length (tan) for nets with reflectors were smaller than that for the ordinary net, there was no significant difference between them. A total of 3 Dall's porpoises became entangled in the nets with vertical ropes. The vertical ropes probably have no alerting effect.

Although the harbour porpoise can detect netting at a short distance, one porpoise became entangled in a gillnet in a darkened pool. Judging from the waveform characteristics of clicks, the echolocatory ability of the harbour porpoise is worse than that of the Dall's porpoise. Bottlenose dolphins fully detected the existence of the gillnet and did not get entangled either at night or during the day.

From visual experiments with white whales, it was found that the netting is more easily recognised than the thread and that there are colour differences in recognition ability. The eyes of Dall's porpoises were examined and compared with those of bottlenose dolphins. The histological characteristics were similar. Neither the distribution of cells nor the mean ratio of the density of photoreceptors to that of ganglion cells were significantly different.

A number of questions concerning Dall's porpoises must be clarified in the future, including the following.

- (1) How frequently and 'seriously' do they conduct echolocation during the day and night in the open seas?
- (2) Which members conduct echolocation when swimming in a group?
- (3) Do they respond to sounds such as alarm or distress calls emitted by other porpoises?
- (4) At what distance can they recognise the net by eyesight at various light levels?
- (5) When do they 'sleep'? At what depth and speed do they swim while sleeping? What are their sensory contacts with the environment at night?

Items (1) and (5) can be examined with a radio telemetry system. If the sensitivities of their auditory and visual organs are weak during sleep, a passive method will not be effective in reducing their entanglement rates and strong stimuli will be required to awaken them. If they swim near the water surface at night, especially during sleep, nets set a few meters below the water surface should be effective.

ACKNOWLEDGEMENTS

We are grateful to S. Yajima and the late T. Koyama (former staff members of National Research Institute of Fisheries Engineering) for their instructions and valuable suggestions for this study. Y. Maniwa (180 Totsuka-cho, Totsuka-ku, Yokohama City, 244 Japan) and M. Furusawa (National Research Institute of Fisheries Engineering) kindly reviewed the present manuscript. G.P. Donovan and two anonymous reviewers are thanked for their helpful comments.

We would like to thank the staff of the Kamogawa Sea World, Japan Marine Fishery Resource Research Center, Akkeshi Station of National Fish Farming Centers for Culture-based Fisheries, Oarai Aquarium, Ozuchi and Utoro Fisheries Co-operative Associations and Tanaka and Tachibana Fisheries Cos. for their help in capturing and feeding Dall's porpoises. We would also like to thank the crews of *Wakatake maru*, *Hoyo maru* No. 12, *Kuromori maru* No. 38 and several catcher boats of Japanese mothership salmon fisheries for their assistance in obtaining data on the actual fishing ground.

Sonar Detection of Gillnets by Dolphins: Theoretical Predictions

Whitlow W.L. Au

Hawaii Institute of Marine Biology, Marine Mammal Research Program, PO Box 1106, Kailua, Hawaii 96734, USA

ABSTRACT

The detection and avoidance of gillnets by echolocating dolphins is examined by using the generalized sonar equation along with target strength values of nets and dolphin sonar detection data. Acoustic reflection data were obtained for several types of nets and associated gear by ensonifying them with simulated bottlenose dolphin sonar signals. Threshold detection ranges corresponding to a 90% probability of detection were calculated as a function of a dolphin's peak-to-peak source levels for: (a) monofilament gillnet used in the salmon mothership fishery, (b) Macah tribal cord setnet, (c) a twisted polyester rope 'poly rope' and (d) household light switch chain.

From calculations based on the measured ability of Atlantic bottlenose dolphins (*Tursiops truncatus*) to detect targets in noise, detection ranges for a monofilament drift gillnet should vary from 1.2m for a source level of 140dB re 1 μ Pa to 25m for a source level of 190dB. The Macah tribal cord setnet should be detected at least twice as far as the monofilament gillnet. The results indicated that most dolphins should be able to detect a monofilament gillnet at sufficiently long ranges to avoid entanglement. The sonar detectability of nets can be enhanced considerably by attaching poly rope or light switch chain on the nets. Some reasons as to why dolphins get entangled in nets which they should be able to detect with their sonar are discussed.

KEYWORDS: INCIDENTAL CAPTURE; FISHERIES; BEHAVIOUR; ATLANTIC BOTTLENOSE DOLPHINS; DALL'S PORPOISE; HARBOUR PORPOISE; SPINNER DOLPHINS; FALSE KILLER WHALE; ACOUSTICS

INTRODUCTION

Coastal and high seas gillnet fisheries result in the incidental take of large numbers of small cetaceans and the global extent of such takes is described in IWC (1994). Dall's porpoise (*Phocoenoides dalli*) are incidentally taken in high seas salmon and squid driftnet fisheries (Jones, 1984; 1988). Dall's porpoises and harbor porpoises (*Phocoena phocoena*) are also caught in coastal salmon gillnet fisheries in Alaska (Matkin and Fay, 1980) and Washington (Gearin *et al.*, 1990). Harbor porpoises are incidentally taken in gillnets off California (DeMaster *et al.*, 1985; Peltier *et al.*, 1993) and in waters off Maine (Read and Gaskin, 1988). Bottlenose dolphins (*Tursiops* sp.) and spinner dolphins (*Stenella longirostris*) were caught by gillnets in the northern Australian seas (Harwood *et al.*, 1984). Thousands of small cetaceans die annually in coastal driftnets off Sri Lanka (Leatherwood, 1994). These references are but a few examples of the pervasive problem of incidental take of small cetaceans by gillnets throughout the world. Nearly every species of small cetacean is affected. If gillnet fisheries are to continue to be used in cetacean habitats, methods to reduce or eliminate entanglement are urgently needed.

Dolphins possess a sophisticated sonar system that should assist them in detecting and avoiding nets. Yet the continual problem with entanglement has led some to assume that gillnets, especially those constructed of nylon monofilament lines are 'acoustically invisible'. However, Au and Jones (1991) clearly showed that monofilament gillnets will reflect acoustic energy and that an echolocating dolphin should be able to detect a monofilament gillnet at a sufficient range to avoid entanglement. In this study, the biosonar net detection problem will be examined in a different manner to that of Au and Jones (1991) and the maximum detection ranges of nets and associated gear will be calculated as a function of the dolphin sonar source level. The Atlantic bottlenose dolphin (*Tursiops truncatus*) will again be used as the model. Reliable target detection and related acoustic data exist for only a few cetacean species such as the bottlenose dolphin (Au, 1988b) and the

false killer whale (*Pseudorca crassidens*; Thomas and Turl, 1990). Unfortunately, few echolocation data exist for some of the phocoenids such as the Dall's and harbor porpoises, two species that are commonly caught in gillnets.

TARGET STRENGTH MEASUREMENTS

Target strength measurements were performed at the Naval Ocean Systems Center Hawaii Laboratory test pool using a monostatic echo measurement system that transmitted a broadband dolphin-like echolocation signal. Details of the measurements are given by Au and Jones (1991). The simulated dolphin echolocation signal resembled the sonar signal of the bottlenose dolphin, having a peak frequency (frequency of maximum energy) of 122kHz and a 3dB bandwidth of 37kHz. The transducer had a 3dB beam width of approximately 8° in the horizontal plane and 13° in the vertical plane. At the measurement distance of 2.4m, the effective area covered by the transducer's beam was rectangular, 0.34m by 0.55m. The nets were laid out with a minimum of tension applied so that their shapes were not rigid but resembled wavy curtains.

Target strength can be defined in several ways when dealing with short broadband signals such as dolphin echolocation signals. Target strength is often determined by using the peak-to-peak values of the incident and reflected sound pressure levels, and is denoted as TS_{pp} here. However, if an energy detection scheme is used to process echoes then target strength needs to be defined as the ratio of the incident and reflected energy flux density, and is denoted as TS_e . Au *et al.* (1988) have shown that the bottlenose dolphin processes sonar echoes like an energy detector with an integration time of approximately 264 μ s. Therefore, the received energy flux density should be integrated up to 264 μ s, resulting in a third target strength definition, TS_u , applicable to *T. truncatus*. All three target strengths will be given since it is not clear which is most applicable to other species of dolphins. Although the animal's bandwidth for the detection of click signals is not

known, the critical ratio measured with narrow band signals may be used as an estimate. The critical ratio measurements of Johnson (1968) and Au and Moore (1984) indicate that bottlenose dolphins process narrowband sounds with a filter having a Q (ratio of center frequency to bandwidth) of about 12.

Fishing equipment investigated

Three nets/fishing gear will be considered in this study, along with a household light switch chain.

- (1) *Commercial monofilament gillnet* used in the salmon mothership fishery, constructed of 0.49mm diameter nylon monofilament lines with a 10cm mesh size (distance between parallel lines of the webbing).
- (2) *Macah tribal setnet* used for salmon fishing in the state of Washington, constructed of 0.97mm diameter twisted (3 strands of 0.25mm diameter) cord with a 20.3cm mesh size.

- (3) *Poly rope*, 0.635cm diameter twisted polyester rope.
- (4) *Household light switch chain* consisting of chrome plated nickel beads, 0.3cm diameter spaced 0.4cm apart, center to center.

Target strength results

Waveforms and frequency spectra of echoes from the commercial monofilament gillnet are shown in Fig. 1, for different angles of incidence. The echo waveforms are relatively complex with many highlights, at all angles of incidence. With such complex echo structures, TS_e and TS_{tt} will generally be higher than TS_{pp} because the echo is considerably longer than the projected signal. Target strength varied little with angle of incidence. This probably was a result of the net being suspended like a wavy curtain which produced relatively similar echoes for different angles of incidence. The Macah tribal setnet also had similarly complex echo structures with little variation in target strength with incidence angles between 15 and 45°.

Fig. 1 Echo waveform and frequency spectra of acoustic reflections from the nylon monofilament gillnet for angles of incident of 0, 15, 30 and 45°. The target strength based on peak-to-peak amplitude (TS_{pp}), energy in a 1ms window (TS_e) and energy in the 264μs integration window of *Tursiops truncatus* (TS_{tt}) are also included.

Target strength values for the nets and gear are presented in Table 1. The monofilament gillnet had the lowest target strength making it the most difficult object to detect. The Macah tribal setnet had the higher target strength of the two nets. The echo waveform for the poly rope and the light switch chain, which were dangled vertically in front of the transducer, consisted of a single click resembling the incident signal. Therefore, the three types of target strength were the same for the associated gear. The unsoaked poly rope had the highest target strength. When the rope was left in the water for 24hrs, air bubbles trapped between the fibers dissipated and the target strength decreased by about 6dB. The target strengths of the rope and light switch chain were at least 20dB greater than the monofilament gillnet. This means that the acoustic reflectivity of a monofilament gillnet can be increased substantially by attaching objects such as the poly rope or light switch chain to it.

Table 1
Target strength (dB) of the gillnets and associated gear.

Net type	Incident angle	TS_{pp}	TE_e	TS_{π}
Commercial gillnet	0°	-58.8	-52.6	-54.0
	15°	-62.4	-55.2	-58.6
	30°	-60.2	-54.5	-57.3
	45°	-60.2	-53.7	-58.3
Makah tribal setnet	0°	-36.7	-36.2	-36.2
	15°	-49.3	-43.6	-43.7
	30°	-55.8	-47.7	-49.4
	45°	-56.1	-46.8	-49.8
Poly rope (unsoaked)	0°	-25.8		
Poly rope (soaked)	0°	-33.0		
Light switch chain	0°	-36.5		

Target strength for harbor porpoise signals

The sonar signals of small cetaceans from the phocoenid family (Kamminga and Wiersma, 1981; Evans *et al.*, 1988; Hatakeyama and Soeda, 1990) and the genus *Cephalorhynchus* (Dawson, 1988; Evans *et al.*, 1988; Dawson and Thorpe, 1990) are considerably different to those used by bottlenose dolphins (Au, 1980), white whales, *Delphinapterus leucas* (Au *et al.*, 1987) and the false killer whale (Thomas and Turl, 1990). The sonar signals of these small cetaceans tend to have narrower bandwidths, longer durations, higher peak frequencies and lower amplitudes. Examples of echolocation signals for the bottlenose dolphin and some of the smaller odontocetes are shown in Fig. 2. Note how much shorter the bottlenose dolphin signal is compared with the other signals. The reflection of a harbor porpoise sonar signal from the gillnet can be estimated mathematically by calculating the transfer function of the gillnet and convolving it with the signal of interest. Au and Jones (1991) performed this calculation for a Dall's porpoise signal. The monofilament gillnet echo for the *Phocoena* signal shown in Fig. 2 is presented in Fig. 3 for a 0° incident angle. There is little difference in the target strength based on energy between the results shown in Figs 1 and 3. The structure of both echoes is equally complex with many highlights. The frequency spectrum of the echo obtained with the *Phocoena* signal is narrower because of the narrower bandwidth of the *Phocoena* signal.

Fig. 2. Examples of sonar signals of (a) bottlenose dolphin (Au, 1980), (b) Commerson's dolphin (Evans *et al.*, 1988), (c) Dall's porpoise (Hatakeyama and Soeda, 1990), (d) harbor porpoise (Kamminga and Wiersma, 1981), (e) Hector's dolphin (Dawson, 1988).

Fig. 3. Calculated reflection from the monofilament gillnet for the harbor porpoise signal shown in Fig. 2d.

PREDICTION OF BIOSONAR DETECTION RANGES OF GILLNETS

The simplest and most accurate way of predicting the ranges at which echolocating dolphins can detect gillnets is to use target detection data obtained under controlled conditions and extrapolating the data for different conditions. Unfortunately, there are few data on biosonar detection in noise except for *Tursiops truncatus* (Au, 1990). The target sensitivity of *Tursiops* has been measured by three equivalent methods: (1) the range of a 7.62cm diameter water-filled sphere was increased until the dolphin could no longer detect it (Au and Snyder, 1980; Murchison, 1980); (2) a 7.62cm sphere was used at different target ranges and the amount of masking noise was increased until the dolphin could not detect the target (Au and Penner, 1981; Turl *et al.*, 1987); and (3) an electronic simulated target was fixed at a range of 20m and its target strength progressively decreased until the dolphin could not detect it (Au *et al.*, 1988). The results of all of these studies are summarized in Fig. 4 with the percent correct response plotted against the received echo energy-to-noise (E/N) ratio. The echo energy used in Fig. 4 was calculated with the click signal having the maximum energy for each experimental trial. The solid curve is the best-fit 3rd order polynomial curve and the dashed lines indicate the signal-to-noise ratio needed for the dolphin to achieve a 90% correct response performance (approximately 14dB).

Fig. 4. Target detection capability of *Tursiops truncatus* from five studies (Au and Snyder, 1980; Murchison, 1980; Au and Penner, 1981; Turl *et al.*, 1987; Au *et al.*, 1988). The solid curve is a 3rd order polynomial fit to the data.

The dolphin target detection performance shown in Fig. 4 can be used to estimate the detection range for a gillnet by using the sonar equation. The noise-limited form of the sonar equation modified for dolphin sonar signals can be expressed in dB as (Au, 1988a):

$$DT_E = SE - 2TL + TS_u - (NL - DI_R) \quad (1)$$

echo energy noise energy

here: DT_E = detection threshold; SE = source energy flux density; TL = one way transmission loss; TS_u = target strength based on energy with *Tursiops*' integration time window; NL = noise level; and DI_R = receiving directivity index.

Although SE is used in the sonar equation, peak-to-peak sound pressure level (SL) is more commonly used in describing the levels of dolphin signals. Au (1988a) derived a simple relationship between SE and SL by expressing the signal as $A \cdot s(t)$ where A is the peak amplitude and $s(t)$ is the waveform function ($|s(t)| \leq 1$), so that

$$SE = SL - 6 + 10 \log \left(\int_0^T s^2(t) dt \right) \quad (2)$$

The log integral term for a typical *Tursiops* signal in Kaneohe Bay is approximately -52dB. Therefore, $SE = SL - 58$ dB for *Tursiops*.

The one way transmission loss can be expressed simply as the spherical spreading loss plus an absorption term,

$$TL = 20 \log R + \alpha(f_p)R \quad (3)$$

where: R = target range in metres and $\alpha(f_p)$ = the absorption coefficient evaluated at the peak frequency of the dolphin sonar signal.

For short ranges (<25m), absorption losses will be small and can be ignored.

The received directivity index in the sonar equation was determined by Au and Moore (1984) and their results are shown in Fig. 5 with the received directivity index plotted as a function of frequency. The directivity index was found to vary with frequency according to the equation:

$$DI_R = 16.9 \log f(\text{kHz}) - 14.5 \text{ dB} \quad (4)$$

The sonar equation may be used to calculate the ranges at which an echolocating *Tursiops* should be able to detect a monofilament gillnet 90% of the time. I will assume that the typical deep water noise spectral density shown in Fig. 6 is applicable. For sea state conditions between 0 and 3, the noise at 120kHz is at the thermal limit and is equal to 27dB re $1\mu\text{Pa}^2/\text{Hz}$ (Albers, 1965). The noise then increases linearly to 33dB for sea state 6. Substituting $SE = SL - 58$ (from Equation 2) into Equation 1, $DT_E = 14$ dB (from Fig. 5), and $DI_R = 21$ dB (from Equation 4), we obtain the following equation:

$$40 \log R = \begin{cases} SL + TS_u - 79 & \text{SS 0-3} \\ SL + TS_u - 84 & \text{SS 6} \end{cases} \quad (5)$$

Fig. 5. Receiving directivity index as a function of frequency for *Tursiops truncatus* (Au and Moore, 1984).

Fig. 6. Deep-water ambient-noise levels for sea states 0 to 6 (Albers, 1965).

The 90% probability of detection range for *Tursiops truncatus* emitting signals with different peak-to-peak source levels are shown in Fig. 7 for sea states between 0 and 3. Equation 5 was used to generate the curves shown in Fig. 7. The calculated results indicate that if *Tursiops* emitted signals with a source level of 140dB re 1μPa, it should be able to detect a monofilament gillnet at a range of at least 1.2m, and for a source level of 190dB the detection range should increase to at least 25m. The detection ranges for the Macah tribal setnet are also shown in Fig. 7. Since the Macah tribal setnet had a higher target strength than the monofilament gillnet, its detection ranges were correspondingly greater. These detection ranges are sufficiently long for a swimming echolocating dolphin emitting signals with source levels of 155–160dB to detect a gillnet in time to avoid the net.

Fig. 7. Predicted biosonar detection of gillnets and associated gear by a *Tursiops truncatus* as a function of the peak-to-peak source levels. The detection range for the light switch chain (LSC) and the Macah tribal setnet (MTS) at 0° incident angle is identical.

The detection ranges for the poly rope and the light switch chain are also shown in Fig. 7. The target strengths used for both objects were obtained at normal incident where the reflection is highest. The amount of reflection will drop off substantially as the angle of incident deviates from the normal incident. However, the use of the normal

incident value for poly rope and light switch chain interwoven vertically, horizontally and diagonally, into a gillnet seems appropriate. Both of these items will not be taut but will follow the geometry of the net, and will take on an undescriptive, irregular and slack geometry. An echolocating dolphin will most likely scan a net from various aspects as it swims and will probably experience many occasions in which the rope or chain within the sonar beam will be nearly perpendicular to the beam resulting in relatively high-amplitude echoes. Therefore, the detection range of a gillnet can be increased substantially by attaching poly rope or light switch chains to the net.

Tursiops typically emit signals with source levels in the vicinity of 220dB in detection experiments performed in Kaneohe Bay (Au, 1980) and so the low source levels used in Fig. 7 are extremely conservative for *Tursiops* but may be more in line with phocoenids. Hatakeyama and Soeda (1990) recorded source levels of 165–170dB re 1μPa for Dall's porpoises in the open ocean, and 152–157dB in a tank. They also reported source levels close to 160dB for three *Phocoena phocoena* in a tank. With a source level of 160dB, a dolphin should be able to detect a monofilament gillnet at a range of 4m and a Micah tribal cord setnet at 7 to 13m. For a given peak-to-peak source level, some of the smaller cetaceans (signals shown in Fig. 2) may be able to detect a gillnet at roughly 20 to 30% longer ranges than *Tursiops* because they typically emit longer signals containing on the order of 5dB more energy.

DISCUSSION AND CONCLUSIONS

The target strength measurements and sonar detection range calculations indicate that echolocating *Tursiops* and other odontocetes should be able to detect gillnets at long enough ranges to avoid entanglement. This conclusion is supported by observations and experiments performed by Hatakeyama and his colleagues in Japan (see review by Hatakeyama *et al.*, 1994). Hatakeyama *et al.* (1986) found that a white whale had a 50% detection range of 5.5m with a salmon gillnet used as the target. The animal used relatively low amplitude clicks of approximately 182–189dB re 1μPa in this tank experiment, which is considerably lower than 210–225dB for a white whale measured in Kaneohe Bay (Au *et al.*, 1987). Hatakeyama and Ishii (1987) constructed a net enclosure in a cove that was partitioned with a salmon gillnet to house three bottlenose dolphins. Night observation of one of the dolphins with a flashing marker light attached to it indicated that it did not approach closer than 3–5m from the gillnet. Hatakeyama and Soeda (1990) observed Dall's porpoises around a salmon research vessel in the Bering Sea as gillnets were being retrieved. They saw two Dall's porpoises out of three in a group dive and pass under the gillnet and reappear on the other side. However, the third one became entangled in the net. They also twice observed a Dall's porpoise passing through a 1.5m wide, 1.0m high hole of a damaged gillnet without changing its swimming speed of 3–4ms⁻¹. On another occasion they found a school of Dall's porpoises along the coastal area of east Hokkaido and set a gillnet (1,300m long, 6m deep). The porpoises were chased toward the gillnet with four boats. Upon approaching the net the porpoises changed direction and swam along the net or dived and passed under the net. In one case, two porpoises out of a group of three dived suddenly when they were about 4 to 5m from the net and surfaced about 10m on the other side. The third animal swam into the net and broke through it. Hatakeyama and

Soeda (1990) concluded that Dall's porpoises can detect gillnets by echolocation and can also distinguish holes within nets. Hatakeyama and Soeda (1990) also observed the behavior of harbor porpoises in a tank that was partitioned with a salmon gillnet. Nightscope observation of the harbor porpoises suggested that they could detect the presence of the net and initially avoided it. However, when they became accustomed to the net, they became careless and some became entangled. Although many of the observations are anecdotal and each observation means little by itself, taken together they tend to support the notion that gillnets are detectable by echolocating dolphins.

Since this analysis and field observations indicate that echolocating dolphins should be able to detect gillnets at sufficient ranges to avoid them, why then do they still become entangled? This question is a puzzling one and has been addressed by other investigators (Awbrey *et al.*, 1979; Dawson, 1994; Goodson *et al.*, 1994). I would like to suggest a number of possibilities.

- (1) Pelagic dolphins may not echolocate while transiting a body of water. In the open ocean, there seems to be little need for dolphins to echolocate except to detect prey and possibly to avoid predators. However, little is known about how odontocetes utilize their sonar in the wild.
- (2) The problem may be in the difference between detecting and perceiving an obstacle. Although the nets are detectable, the echoes will be relatively weak, and a dolphin may not perceive the net as an obstacle but as a penetrable entity. Dolphins probably encounter sources of volume reverberation that are penetrable, such as the deep scattering layer, and may not perceive gillnets as harmful obstacles. In the open ocean, the concept of a barrier is probably foreign to a dolphin. Attaching more acoustically reflective items such as poly rope or light switch chains on a net may help to make a net seem more impenetrable. However, Hembree and Harwood (1987) have experimented with the use of metallic bead chain on gillnets and found them ineffective in reducing the incidental take of *Tursiops truncatus* and *Stenella longirostris* in Australian waters. The results in Fig. 7 (the light switch chain was similar but not identical to those used by Hembree and Harwood, 1987) indicated that *Tursiops* should be able to detect the metallic bead chains at tens of metres.
- (3) In some circumstances dolphins may be feeding on prey that inhabit the same general location where fishermen typically set driftnets (Ellis, 1989) and may be too distracted by prey to notice the presence of gillnets or may not be able to distinguish between the sonar reflections from prey and gillnets (Awbrey *et al.*, 1979; Evans *et al.*, 1988). Cockcroft (1990) indicated that *Tursiops* that are caught in shark gillnets used to protect swimmers in South Africa, seem to be aware of the presence of these nets, judging from their normal swimming patterns around them. Nevertheless, when they forage for food, they seem to become oblivious to the nets and are sometimes caught. An analysis of stomach contents indicated that most of the captured dolphins had almost full stomachs, implying that capture occurred either during or subsequent to feeding.
- (4) The presence of entangled fish and aggregations of free swimming fish in the immediate vicinity of a gillnet

may prevent dolphins from acoustically sensing the presence of the net. The sonar returns from free swimming and entangled fish may mask the presence of gillnets, since the echoes from the nets will be much smaller than echoes from the fishes. For example, from the expression of fish target strength given by Love (1971), a 40cm long salmon will have a target strength (frequency of 120kHz) between -26 and -33dB, considerably greater than the target strength of a gillnet.

- (5) The disturbances caused by entangled, struggling fish may actually attract dolphins to a net. As dolphins approach a net to investigate the cause of the commotion, the entangled fish may also distract them from sensing the presence of the gillnet.

In searching for viable solutions to the incidental gillnet capture problem, we should perhaps concentrate in areas other than the animal's sonar detection capabilities. Although only thoughtful speculations on why dolphins seem not to detect gillnets are presented here, some of these speculations should be seriously considered in future research. There is a need to obtain better understanding of the dynamics involved with the incidental catch problem. Why do dolphins swim close to gillnets? How do they typically get entangled? What percentage of dolphins swimming toward a gillnet actually become entangled? What is the role of fish and other marine life already entangled or entrapped by gillnets in attracting porpoises to the nets? Part of the entanglement problem may involve the presence of large quantities of entangled marine life which may attract dolphins to gillnets. Therefore, it may be difficult to discourage dolphins and porpoises from approaching these nets.

ACKNOWLEDGEMENTS

The Potential for Reducing Entanglement of Dolphins and Porpoises with Acoustic Modifications to Gillnets

Stephen M. Dawson

Department of Marine Science, University of Otago, P.O. Box 56, Dunedin, New Zealand

ABSTRACT

To reduce incidental catch of cetaceans in gillnets, two forms of acoustic modifications are reviewed here; one to make gillnets more reflective to cetacean sonar, and another using active sound emitters in nets to alert cetaceans to the presence of nets. A review of the literature shows that neither strategy has proven indisputably effective. Air-tube nets and multifilament nets used in the North Pacific Japanese driftnet fishery for salmon have caught fewer Dall's porpoises than equivalent standard gillnets. However, results were not consistently significant over several years, and have not been confirmed by a thorough study of modified gillnets in another driftnet fishery. Studies examining effects of adding sound emitters to gillnets have also proven inconclusive. Further, there appear to be serious problems with the logical basis for acoustic net modification strategies. I argue that such strategies are not likely to achieve the reductions in cetacean bycatch that are required to conserve several dolphin and porpoise species and propose alternative methods which are likely to be more effective.

INTRODUCTION

'In marked contrast to the improving prospects for the great whales, the status of many smaller cetaceans has continued to deteriorate over the last two decades' (Brownell *et al.*, 1989, p.5; and see Perrin, 1988). In part this is due to their incidental capture in gillnet fisheries (for a recent compilation of estimated catches, see IWC, 1994). Incidental catch of cetaceans in gillnets appears to be a generic problem inherent in all forms of gillnetting. Oceanic driftnet fisheries kill many thousands of cetaceans annually (e.g. Jones, 1984; Harwood *et al.*, 1984; Harwood and Hembree, 1987). Large incidental catches also occur in coastal gillnet fisheries for groundfish (e.g. Pilleri, 1971; Harrison *et al.*, 1981; Gaskin, 1984; Peltier *et al.*, 1993; Read and Gaskin, 1988; Dawson, 1991a; Brownell *et al.*, 1989). Such coastal fisheries may have a greater impact than oceanic fisheries because they kill coastal cetaceans which often have more restricted distributions than their oceanic relatives (Dawson, 1991b). The Gulf of California harbour porpoise, *Phocoena sinus*, ostensibly the rarest marine cetacean, appears threatened with imminent extinction by entanglement in gillnets (Barlow, 1986; Silber, 1988; Brownell *et al.*, 1989; Vidal, 1995).

There have been many proposals to reduce incidental catch of cetaceans by modifying gillnets. Several of these are based on the concept of modifying gillnets acoustically, so that dolphins and porpoises can detect them and hence avoid entanglement. In this paper I will briefly review the results of experiments testing these modifications, discuss some of the difficulties with the concepts and make some specific recommendations for the management of cetacean bycatch problems. Statistical tests used here are tests of proportion (Neter *et al.*, 1988) or G tests with Williams' correction (Sokal and Rohlf, 1981).

CONSTRAINTS ON POTENTIAL MODIFICATIONS

Modifications must be practical to be adopted in commercial gillnet fisheries. The conditions described below must be met.

- (1) *The modifications must have reasonable longevity under commercial fishing conditions.* For acoustic reasons, air-containing structures (as long as they are of reasonable size; Pence, 1986) are ideal to increase the reflectivity of nets to sonar. As they have a very different density to the surrounding water, they reflect sonar pulses better than any solid object of similar size. However, because they lack internal support, air-containing structures are usually less robust than solid ones and hence are more easily damaged. Also, unless rigid they are likely to crush at depth, becoming less effective as reflectors. Air-filled plastic tubing (8mm) in gillnets did not function as intended because it filled with water after compression by the net hauler (Hembree and Harwood, 1987). Similarly, panels of plasticised aluminium foil incorporated into the net matrix were found unsuitable as sound reflectors because seawater dissolved the aluminium layer when the plastic layer was damaged (Peddemors *et al.*, 1991).
- (2) *The modified gillnets must be safe to handle.* Peddemors *et al.* (1991) found that netting braid incorporating a double strand of 0.16mm diameter stainless steel braid became too brittle to handle safely. This is likely to occur in any method involving the addition into nets of wire filaments which are large enough to be detectable by cetaceans (Busnel and Dziedzic, 1966).
- (3) *To avoid compromising the economic efficiency of gillnetting, the net modifications must be reasonably lightweight and inexpensive.*
- (4) *Net modifications must not decrease catch rates of target species below an economic level.* For example, Hembree and Harwood (1987) found that nets set 4.5m below the surface caught significantly fewer cetaceans than standard nets, but that the modified nets also caught about 25% fewer fish. The gillnetting industry is unlikely to accept these costs willingly.

EXPERIMENTS TESTING ACOUSTIC MODIFICATIONS TO GILLNETS

Modifying gillnets by increasing their target strength

Most gillnets are made from nylon monofilament. This material is almost the same density as seawater and gives a poor sonar echo (i.e. has low target strength; Pence, 1986). Prompted by this observation, many authors have assumed or suggested that entanglement occurs because the animals' sonar *cannot* detect the net (Ohsumi, 1975; Awbrey *et al.*, 1979; Hatakeyama, 1986a; Hembree and Harwood, 1987).

On the assumption that increasing the target strength of gillnets will decrease incidental catches, Japanese workers have experimented with two types of passive modifications to gillnets. In the first (AT-1), three air-tube threads were intertwined into the central band in an otherwise standard gillnet (Snow *et al.*, 1988). These hollow threads were 0.5mm in diameter with a 0.25mm internal air space. Between 1981–6, mean incidental catch rates in these air-tube nets were about 21% lower (range = 6 to 48%; Ogiwara, 1986) than catches in standard nets. This reduction seems surprising, considering that the air-tube nets have a target strength only 3–4dB higher than standard monofilament (Hatakeyama, 1986a). The AT-1 nets showed significantly lower catch rates in four of the six seasons tested. This inconsistency is possibly explicable by the marginal nature of the increase in target strength. Neither increasing the number of air-tubes to five (AT-2) nor concentrating the air-tubes in the top third of the upper portion of the net (AT-3) resulted in lower catch rates than in AT-1 nets (Ogiwara, 1986).

A second type of modification has been tested since 1986. In these nets (MT-1), three multifilament threads were intertwined into a central band of an otherwise standard gillnet. Although Snow *et al.* (1988) do not give the plane in which target strength was measured, they state that multifilament thread had a target strength about 10dB higher than standard monofilament. In both the 1986 and 1987 trials, multifilament nets had marginally lower catch rates than air-tube nets, but the difference was not significant in either season ($z[1986] = 0.6$; $p = 0.27$; $z[1987] = 1.06$; $p = 0.14$; test of proportions; data from Ogiwara, 1986; Snow *et al.*, 1988). Data from adjacent sets provide a stronger test, but were available only from the two month study of 1987. A paired-sample *t* test comparing 88 pairs of adjacent air-tube and multifilament nets showed that multifilament nets caught significantly fewer (28%) porpoises ($p < 0.01$; Snow *et al.*, 1988). Catch rates of the two net types were significantly different in June ($z = 3.7$; $p < 0.001$), but not in July ($z = 0.96$; $p = 0.17$).

If multifilament threads are easier for porpoises to detect than air-tube threads, one would predict fewer entanglements in the modified portions of multifilament nets than in corresponding portions of air-tube nets. Only the 1987 data were available to test this idea. The vertical distribution of entanglements was significantly different between the two net types ($G = 16.3$; $p < 0.001$; 2×3 *G* test); paradoxically, the multifilament nets caught more porpoises in their central portions than did the air-tube nets (Hatakeyama, 1988; Snow *et al.*, 1988).

In summary, the Japanese AT-1 air-tube nets appeared to reduce entanglement by about 21% over standard nets. However, the reduction was variable among years and not consistently significant. Multifilament nets also produced inconsistent results, but appeared to have lower catch rates than air-tube nets. However, more porpoises were caught

in the modified portions of MT-1 nets than in corresponding sections of air-tube net, suggesting that the benefit of multifilament is yet to be established clearly.

After finding that captive, blindfolded, bottlenose dolphins (*Tursiops truncatus*) reacted strongly to 4mm chrome-plated nickel bead chain, Hembree and Harwood (1987) used this material to modify nets used in the Taiwanese drift gillnet fishery in northern Australian waters. In their 1984 trials, alternating half and full-length pieces of bead chain were woven vertically into the net every 8m. During the next season bead chain was woven into the mesh as nine 3m diagonals per 15 x 15m net panel. In neither season did the net modifications significantly reduce the number of dolphins caught. The 1985 trials produced the unexpected result that the modified nets caught more dolphins than the control nets (Hembree and Harwood, 1987).

The Japanese results, and those of Hembree and Harwood (1987) are somewhat in conflict. Bead chain has a much higher target strength than air-tube thread or multifilament thread (Au and Jones, 1991), and yet the bead chain did not reduce entanglement while the air-tube threads did (at least in four of six seasons). There are three reasonable interpretations of this result. (1) Increasing the target strength of gillnets is less effective in reducing entanglement than the Japanese studies suggest. (2) Target strength increases quoted above may represent the best case, measured with a sound source perpendicular to the modification material. An echolocating animal approaching from other angles is likely to perceive a lesser target strength. Hence, the modifications above, from an acoustic point of view, have not been ideal (Goodson *et al.*, 1994) and this may have contributed to the inconsistency of effectiveness. (3) There is something radically different between the sonar capabilities of bottlenose and spinner dolphins, *Stenella longirostris* (the major catch off Northern Australia) and Dall's porpoise, *Phocoenoides dalli*.

There are some valuable lessons to be learned from the approach of Hembree and Harwood (1987). Their 1985 trials are the only passive net modification trials which have used a balanced design with equal numbers of control and experimental net panels. This balance was achieved by using nets with alternating 1km long modified and unmodified sections. Balanced design helps strengthen the power of statistical comparison. Also, Hembree and Harwood's (1987) study was conducted on a scale which was large enough to be useful. Several smaller-scale studies have involved too few entanglements to allow statistical comparison of modified and unmodified nets (Hasegawa *et al.*, 1987; Peddemors *et al.*, 1991). This is unavoidable where the entanglement problem is localised and the total number of animals involved small (Peddemors *et al.*, 1991). However, in the North Pacific driftnet fishery for salmon the total number of porpoises caught is large and despite the extra expense, studies of adequate design and scale could have been conducted. For example, the goal of Hasegawa *et al.* (1987) was to assess the catch rate of four types of modified net against a control, unmodified net. However, they studied only 13 setting operations in which the amount set of each net type was unbalanced (195–260 tans for experimental nets; 845 tans for standard net (1 tan = 50m)). It is not surprising that the total number of porpoises caught was small (5) and that there was no significant difference between catches in modified nets (3) and those in unmodified nets (2). Studies like this can do little to clarify the value of gillnet modifications.

Unfortunately, this is not an isolated case in tests of the effectiveness of net modifications (Silber *et al.*, 1994) or sound emitters (Hatakeyama, 1986b; Hatakeyama, 1987) in reducing incidental catch.

The influence of active sound emitters in gillnets

Sound emitters appear to be of marginal benefit, if any. When sound emitters were added to AT-1 nets, there was no significant decrease in catch rates in any of the years tested (Ogiwara, 1986; Hatakeyama, 1988; Snow *et al.*, 1988).

If sound emitters reduce incidental catch, one would expect fewer entanglements in regions of the net near emitters than in regions further away. As indicated above, attempts to make such comparisons have been frustrated by small sample sizes and unbalanced designs. Data are available for only 13 entanglements from 1985 (Hatakeyama, 1986b) 8 from 1986 (Hatakeyama, 1987) and 12 from 1987 (Hatakeyama, 1988; Snow *et al.*, 1988). The 1985 and 1986 data suggested that the emitters may have an effect, but in 1987 the entanglement rate in sections of the net near emitters (<55 tan) was not significantly different from that in sections further away.

Even if sound emitters reduced catches of dolphins and porpoises it is extremely unlikely that it would be practical in the foreseeable future to place them in all gillnets. Devices currently available are large, heavy (Hatakeyama, 1986a), relatively expensive (Ogiwara, 1986) and require regular recharging (Hatakeyama, 1988). As Peddemors *et al.* (1991) point out, metal devices, whether electronic or not, are vulnerable to corrosion. Further, as high-frequency sounds attenuate quickly in water, there would need to be many emitters spaced along the net (Awbrey *et al.*, 1979). Their comment that 'The cost and complications of active devices would preclude their proper use and maintenance.' (1979, p. 36) is still accurate today. This applies not only to set-up and operating costs, but also to costs of enforcement, as an observer scheme would be necessary to ensure that fishers use the devices as intended (Gaskin, 1984).

LOGICAL PROBLEMS WITH ACOUSTIC MODIFICATIONS TO GILLNETS

Increasing the target strength of gillnets

I. The assumption that nets are difficult to detect

The strategy of increasing target strength to reduce entanglement is largely based on the assumption that the sonar systems of dolphins and porpoises are incapable of detecting unmodified nets, or at least have difficulty in doing so (Ohsumi, 1975; Awbrey *et al.*, 1979; Gaskin, 1984; Hatakeyama, 1986a; Hembree and Harwood, 1987). At face value this assumption seems fair, but data on the sonar capability of dolphins and porpoises and observations of their behaviour near nets suggest that entanglement does *not* result from an inability of the sonar system to detect nets (Au and Jones, 1991; Dawson, 1991b; Au, 1994). Similar phenomena are observed in insectivorous bats, which despite their remarkable sonar ability are routinely caught in mist nets for study and marking by researchers.

Dubrovskiy reported that the harbour porpoise, *Phocoena phocoena*, can detect nylon filaments of 0.1mm diameter (Dubrovskiy, pers. comm. in Evans *et al.*, 1988). Even so, harbour porpoises are routinely entangled in gillnets made of nylon several times that diameter (0.8mm;

Gaskin, pers. comm.). Au (1994) has shown that bottlenose dolphins should be able to detect gillnet webbing made of 0.49mm diameter monofilament at long enough ranges to avoid entanglement. However, that species is occasionally entangled in shark nets of coarse 3mm multifilament braid (Peddemors *et al.*, 1991), which would be much easier to detect. A net's detectability is enhanced by the knots between the meshes (Pence, 1986). Furthermore, the floats along the top of a groundfish gillnet should be easily detected by even a crude sonar system (Awbrey *et al.*, 1979; Pence, 1986; Ogiwara, 1986). If cetaceans can detect the nets which entangle them, entanglements are most likely to result from one or more of three factors: (a) the animal is not making sonar pulses at the time of entanglement and hence is not aware of the net's presence; (b) the animal is aware of the net but fails to perceive it as something to avoid; or (c) the animal is aware of the net and the danger it poses, but simply makes a (fatal) mistake.

II. How much of the time do cetaceans use their sonar?

Increasing the target strength of a gillnet is irrelevant if the animals are not making sonar pulses when they encounter nets. If cetaceans only echolocate when they need to, i.e. when feeding or trying to localise objects, they are likely to be silent most of the time. Species which remain in relatively small areas for extended periods (such as Hector's dolphin, *Cephalorhynchus hectori*; Slooten and Dawson, 1988) would seem to have no need to constantly interrogate their environment with sonar as they would be thoroughly familiar with it. Neither would oceanic species cruising in open areas where they do not expect an obstacle. No study has yet quantified what proportion of time free-ranging dolphins and porpoises spend echolocating. This would be a difficult task because of the narrow emission field of these animals (Au *et al.*, 1978; 1986; 1987) and the inherent directionality of high-frequency sounds¹. During my recordings of free-ranging Hector's dolphins (Dawson, 1988; Dawson and Thorpe, 1990; Thorpe and Dawson, 1991) sounds were not recorded every time a nearby dolphin was oriented at the hydrophone, suggesting that they were not always vocalising.

III. Perceptual problems

When using sonar, cetaceans probably have a 'search image' of what they expect to encounter. It is possible that sonar reflections from airfilled net modifications might mimic a fish's swimbladder, and attract cetaceans to nets. In other cases, foraging dolphins may disregard echoes from a net as being from non-prey, and hence become entangled (Awbrey *et al.*, 1979; Evans *et al.*, 1988). Observations of insectivorous bats confirm that echolocating animals are not always able to detect obstacles when chasing prey. Evans *et al.* (1988) described these bats as having a detection system which is open for prey detection but closed for obstacle avoidance.

¹ Quantification of the time dolphins spend silent could be possible using small event recorders which store the time of occurrence of each of a free-ranging dolphin's high frequency sonar pulses. In a study such as the long-term study of bottlenose dolphins in Sarasota Bay (e.g. Wells *et al.*, 1987) in which dolphins are routinely caught, examined and released, an event recorder could be attached to a dolphin's melon with a suction cup and recovered when it detaches for downloading of its data.

The rate at which clicks are repeated is probably a significant factor in gillnet detection by dolphins. Dolphins normally space their clicks apart so that the previous pulse's echo returns before the next pulse is emitted (Au *et al.*, 1982; for review see Turl and Penner, 1989). When searching for a target they 'range-gate' using a click repetition rate suited to detecting a target within an expected range (Au *et al.*, 1974; Turl *et al.*, 1987; Goodson *et al.*, 1994). Once a target is detected, echolocating animals typically increase their click rate as they approach the target (Watkins, 1980: i.e. range and click rate are matched). In both the searching and target-locked phases, objects outside the (expected) range of the target are unlikely to be easily perceived. This suggests that dolphins, like bats, may not perceive obstacles (gillnets) while chasing prey.

Echolocating dolphins and porpoises may not interpret echoes from gillnets (modified or not) as representing an impassible obstacle. Cetaceans, especially oceanic species, live in an environment in which barriers are rare. Also, they routinely encounter sources of volume reverberation which are passable (e.g. the deep scattering layer), and may interpret the reflections from gillnets similarly (Au, 1994). Further, even if they perceive gillnets as dangerous obstacles, some entanglements will occur because cetaceans make mistakes. Human car accidents are analogous in that although drivers know the dangers, accidents still happen at a high rate.

Active sound emitters

To be effective in reducing entanglement rates, sound emitters could work if (a), (b), or (c) (below) were true.

(a) *The sound is sufficiently aversive to scare cetaceans away from nets.* It seems likely that any low frequency sound sufficiently aversive to scare cetaceans away from nets would also decrease fish catches. That 'tuna bombs' are used to herd dolphins shows that high-level explosive sounds are aversive to dolphins. However, such sounds are rich in low frequencies which are readily perceived by fish. Sounds of sufficiently high frequency to be inaudible to fish are unlikely to be perceived by dolphins as inherently aversive.

(b) *The sound is effective at both attracting the attention of nearby cetaceans and encouraging them to use their sonar to carefully examine their environment.* Implicit in this idea is the assumption that cetaceans might investigate the source of sound and discover the gillnet in the process. It would seem paradoxical to attempt to reduce entanglement by encouraging cetaceans to investigate the source of the danger.

(c) *The sound is effective as a warning which cetaceans associate with the danger of gillnets.* However, 'warnings' involve learned behaviours which, in the absence of sophisticated communication between individuals, will only be apparent to those who experience both the danger and the warning sound, and survive to associate the two. According to Awbrey *et al.* (1979, p.2) the 'low incidence of net damage unrelated to porpoise deaths would be evidence that encounters are usually fatal'. In addition, if the danger is not clearly perceived and associated with the sounds, cetaceans might be expected to quickly habituate to the emitters' sounds (Gaskin, 1984). Randomising the sounds used (Hatakeyama, 1986b) might prevent habituation, but it may also prevent association of any particular sound with the danger of gillnets.

Habituation to the sounds is a general problem in each of these hypotheses, and even if the emitters are successful in

making cetaceans aware of the presence of gillnets, cetaceans may not perceive gillnets as an impassable barrier (see III above).

Additionally, there are cases in which marine mammals appear to feed directly on fish caught in gillnets, or on the scavengers of gillnetted fish. In Canadian waters, harbour porpoises appear to be attracted to gillnets to feed on hagfish, which are scavengers of gillnet-caught fish (Gaskin, pers. comm.). In this situation, attaching sound emitters to nets could have the effect of 'ringing the dinner bell'.

CONCLUSIONS

To maintain current dolphin and porpoise populations, acoustic modifications to gillnets need to be shown to result in unequivocal and large reductions in cetacean bycatch. It must be stressed that even statistically significant reductions in catch rates may be insufficient to stem population declines. Most dolphins and porpoises have relatively low reproductive rates (Gaskin *et al.*, 1984; Perrin and Reilly, 1984; Reilly and Barlow, 1986; Slooten and Lad, 1991) and some stocks or species appear to have suffered population declines as a result of gillnet entanglement (Gaskin, 1984; Read and Gaskin, 1988; Dawson and Slooten, 1993). Potential gillnet modifications have now been tested for over ten years. No study has demonstrated that they achieve unequivocal, large reductions in catch rate of cetaceans. This fact must surely argue against the continuation of gillnetting in areas where entanglement rates remain high.

Obvious differences exist among the sonar signals of different odontocete species (Au, 1994), yet no species common in intensively gillnetted areas appears able to avoid entanglement completely. The generality of the problem across many different gillnet fisheries suggests that the answer does not lie in detailed investigations of the interactions present in each. I suggest that the problems discussed above and elsewhere (Awbrey *et al.*, 1979; Au, 1994; Au and Jones, 1991; Dawson, 1991b) are likely to apply in most, if not all, situations in which odontocetes are incidentally caught in gillnets.

Management action required

As a top priority it is essential that the status and reproductive rates of incidentally caught species be assessed as soon as possible. Such data could be used to determine acceptable catch levels for gillnet fisheries. Decisions about whether to continue the fishery should be based on the need to prevent further declines of cetacean stocks or species rather than on the economic needs of gillnet fisheries.

From these arguments, I believe there are two reasonable courses of action.

- (1) Abandon acoustic gillnet modification experiments because of their poor prospects for success and in their place initiate time/area and/or gear restrictions to achieve the necessary reductions in incidental catch.
- (2) If, despite the arguments above, it is believed that acoustic gillnet modifications still hold promise (Goodson *et al.*, 1994), conduct one more set of experiments for a limited time, perhaps over three seasons. These experiments should test only the modification which is most promising (by acoustical and practical criteria; Goodson *et al.*, 1994). The experiments should be of balanced design, preferably

using alternate modified and unmodified panels (Hembree and Harwood, 1987). Power analysis, based on the reduction in catch necessary to avoid population decline, should be used to determine an appropriate scale for the experiments (Fairweather, 1991). If the experiments fail to demonstrate an unequivocal reduction in catch rate to, or beyond, the required level, acoustic gillnet modifications should be either abandoned or used only in conjunction with time/area and/or gear restrictions.

ACKNOWLEDGEMENTS

Ideas presented here have been developed and refined in discussions and correspondence with many people. I am especially grateful to Elisabeth Slooten, Whitlow Au, Larry Field, Steve Leatherwood, Doyle Hanan, David Gaskin, Dave Goodson, Linda Jones, Frank Awbrey, Jon Lien, Robert Jackson and William Thorpe. The manuscript was improved by reviews from Whitlow Au (Naval Ocean Systems Center, P.O. Box 997, Kailua, Hawaii 96734), Scott Kraus (New England Aquarium, Central Wharf, Boston, Massachusetts 02110-3309), Steve Leatherwood (IUCN/CSG, 728 Solana Circle East, Solana Beach, CA 92075) and two anonymous reviewers.

ABSTRACT

Thousands of porpoises die annually in monofilament gillnets. Simple net modifications may alleviate the problem. In June through August 1988, we quantified harbour porpoise (*Phocoena phocoena*) reactions to weighted vertical lines suspended from corklines. If effective in deterring porpoises, vertical lines might be threaded into gillnets to reduce entanglement rates. No structure deflected all porpoise groups, but strands consisting of small metallic spheres and surgical tubing turned a greater proportion of porpoises than did polypropylene line verticals. Although the structures may not be useful in reducing cetacean mortality in gillnets, the experiment may have merit in identifying areas for continued research in attempts to reduce cetacean entanglement in gillnets.

KEYWORDS: INCIDENTAL CAPTURE; HARBOUR PORPOISE; BEHAVIOUR; ACOUSTICS; VISION; FISHERIES

INTRODUCTION

Porpoises (family Phocoenidae) are vulnerable to entanglement in monofilament gillnets because their distributions overlap those of commercial fisheries. Thousands of porpoises die annually due to entanglement in set and drift gillnet fisheries. For example, throughout the 1980s, an average of 2,300 Dall's porpoises (*Phocoenoides dalli*) died each year in drift gillnets (Jones *et al.*, 1986), although incidental catches of this species have declined in recent years (Hobbs and Jones, 1993). Harbour porpoise (*Phocoena phocoena*) annual mortality on the California coast was estimated to be between 200–400 individuals from 1983–1986 (Hanan *et al.*, 1987), and Read and Gaskin (1988) concluded that incidental mortality in gillnets may seriously threaten the harbour porpoise population on the Atlantic coast of North America. Gillnet entanglement most affects coastal species and populations that are small or have limited distribution. For example, the vaquita (*Phocoena sinus*), one of the rarest cetaceans, continues to die in gillnets in unknown numbers (Silber, 1988; Vidal, 1995).

There have been few published accounts of experiments aimed at reducing cetacean entanglement through net modifications. Air-filled nylon tubing has been incorporated into gillnets in an attempt to reduce the incidental catch of Dall's porpoises in North Pacific salmon fisheries (Snow *et al.*, 1988), but these efforts were ineffective in reducing incidental entanglement (Jones, 1984). Hembree and Harwood (1987) performed open

ocean trials of modified nets and examined changes in dolphin mortality rates and fish catch rates. The two materials used, air-filled tubing and metallic bead chain, both yielded inconclusive results with respect to cetacean entanglement rates. The bead chain, although promising in one trial, yielded no significant difference in dolphin mortality in a second trial.

Our objective was to study porpoise reactions to vertical lines in the water column and to identify economical and readily accessible materials that, when incorporated into gillnets, might deter porpoises. The study was based on the findings of Norris and Dohl (1980) who determined that spinner dolphins (*Stenella longirostris*) did not swim between vertical 30m lengths of 6.35mm diameter polypropylene line suspended from the surface. This apparatus was called a 'hukilau'. When the distance between verticals was increased incrementally from 1 to 6m, spinner dolphins continued to avoid swimming through the hukilau.

We theorised that harbour porpoises, like spinner dolphins, might avoid swimming through hukilaus. If effective in deterring porpoises, vertical lines could be threaded into gillnets without a concomitant reduction in target species catch levels. This paper reports on our initial testing of porpoise responses to hukilaus of various materials and configurations; it quantifies porpoise reaction to hukilaus in Monterey Bay, California in the summer months of 1988.

METHODS

Two corklines 120m in length were constructed with 9.53mm diameter yellow polypropylene line, strung with either 7.0 x 7.5cm styrofoam floats or 5.5 x 9.5cm plastic floats at roughly 10–15cm intervals. Suspended verticals, 10m in length, were attached to the corkline. The lines were held vertical in the water column with 3–4 links of

Fig. 1. Schematic representation of experimental apparatus. Weighted vertical lines that consisted of three types of material were suspended from corklines to the sea floor.

6.35mm chain at the bottom and roughly 1.5m from the bottom (Fig. 1).

Five variations on this structure were used: (1) a corkline with nothing attached; (2) a corkline with 6.35mm polypropylene line verticals spaced 1.5m apart; (3) a corkline with 6.35mm polypropylene line verticals 3.0m apart; (4) a corkline with 10m verticals of surgical tubing tied to rope 3.0m apart; and (5) a corkline with 10m verticals of 4.76mm diameter bead chain (strands of metallic spheres) 3.0m apart.

Surgical tubing (interior diameter of 3.18mm and 0.79mm walls) was used in an attempt to utilise air trapped in water, to reflect underwater sound. The tubing was knotted at the ends and at roughly 1–2m intervals to hold air when submerged. However, parts of the tubing collapsed and fused following extended exposure to salt water, sunlight and water pressure, and it probably did not hold air for the duration of the study period. Bead chain was selected based on the gillnet trials by Hembree and Harwood (1987). It was suspended without polypropylene line and without weights because it was sufficiently dense to hang straight in the water column.

Corklines and hukilaus were placed roughly perpendicular to the shoreline at two observation sites in water 8–10m deep. They were held in place by 5–22lb Danforth anchors; two anchors at each end on 12.7mm diameter nylon or polypropylene line (Fig. 1). To render the structures more visible to boat traffic, 45.72cm diameter orange polyvinyl floats were secured at each end of the corkline. A red flag extending 0.75m above the water's surface was also attached to the corkline.

Observations of porpoises were conducted from bluffs overlooking Monterey Bay (Fig. 2). The sites, located at Sunset and Manresa State Beaches were 67.5 and 22.4m above mean sea level respectively. They were operated (simultaneously on 24 days) from 25 June to 26 August 1988. Each configuration remained in the water from 13–37 days and a minimum of 25 hours of observations was conducted per variable (Table 1). Porpoise movements were plotted with two theodolites: a *Leitz* DT20E and *Pentax* TH-10WA.

Wind speed and direction, sea state (Beaufort scale), cloud cover and visibility were estimated at the outset of observations, and when changes occurred in conditions. All observations were conducted when sea state was ≤ 3 , 96.6% were conducted when the sea state was ≤ 2 and the mode was sea state 1.

Porpoises were usually abundant within the study area which allowed us to concentrate on those in the vicinity of experimental apparatus. From computer-generated plots of theodolite data, we assessed porpoise behavioural response to the experimental gear. In 52 cases, porpoises clearly responded by swimming through (Fig. 3a) or by avoiding (Fig. 3b) hukilaus. However, in some cases ($n=30$) it was not possible to definitively ascertain porpoise reaction to the structures. In analysis, we used only those cases for which we were certain about the porpoise's reaction to the gear. The 'closest observed approach' to the gear was measured as the closest surfacing to the gear, even though we were unable to quantify the possibility that they may have proceeded closer to the gear by travelling underwater.

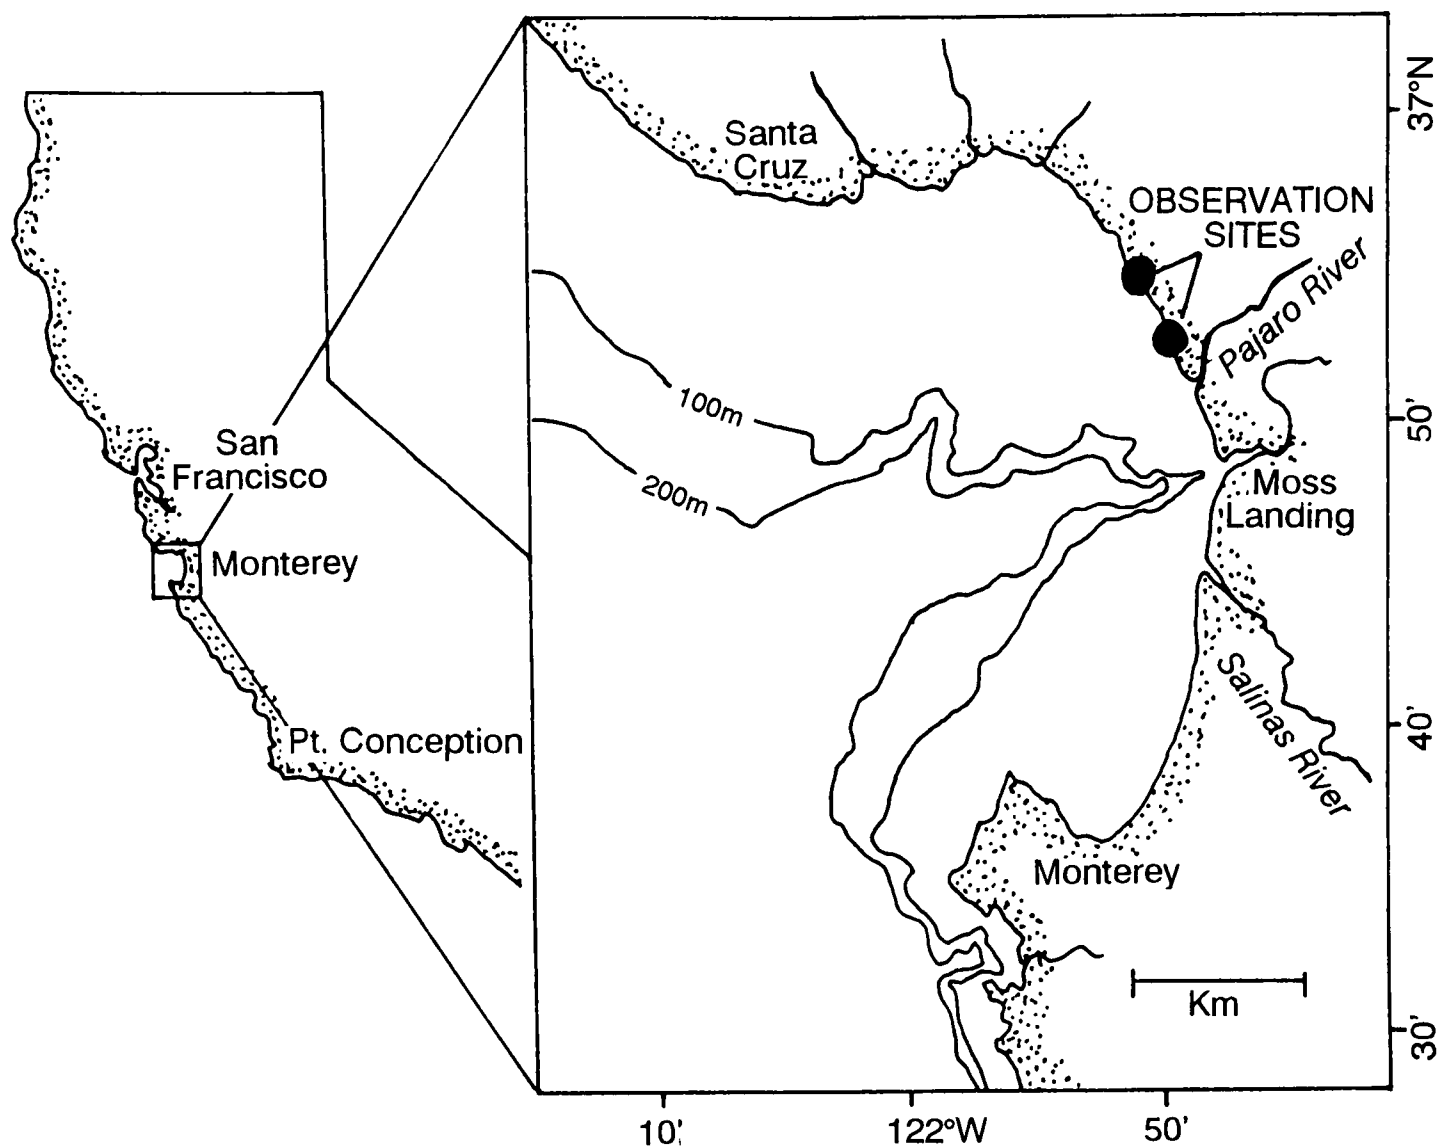

Fig. 2. Study area where harbour porpoise observations were conducted in Monterey Bay, California.

Table 1
Deployment schedule of experimental structures
and hours of observation.

Variable	Period	Obs. days	Total obs. hrs.
Cork line	25 Jun - 11 Jul	11	37.5
Polypropylene 3.0m	11 Jul - 23 Jul	9	28.8
Surgical tubing 3.0m	06 Jul - 11 Aug	27	83.7
Polypropylene 1.5m	23 Jul - 11 Aug	10	31.5
Bead chain	11 Aug - 25 Aug	11	25.0
Total:		68	206.5
Mean:		13.6	41.30
SD:		7.54	24.14

A log likelihood ratio test (and Yates continuity correction statistic where appropriate) was used to determine if the number of porpoise groups that altered course differed between configurations. An analysis of variance (ANOVA) was used to determine if differences existed in the distances that porpoises turned from each experimental configuration. A Student's t-test was used to determine if differences existed in the size of groups swimming through versus those swimming around the gear, and the size of groups that swam within 50m of the gear relative to those whose closest approach exceeded 50m.

RESULTS

Although the number of porpoise groups that encountered the experimental gear was relatively small, the proportion that responded by turning differed with each configuration. All of the structures turned some porpoise

Fig. 3. Plots of porpoise response to experimental structures in Monterey Bay. Example of a porpoise group that swam through bead chain verticals on 14 August 1988 (a), and a porpoise group that altered course relative to surgical tubing verticals on 13 July 1988 (b).

groups, but no structure deflected all groups (Fig. 4, Table 2). There was a significant difference ($G=33.86$, 4 df, $p < 0.001$) in the proportion of porpoise groups that swam through the five structures. Although some groups were turned by polypropylene hukilaus (vertical lines at 1.5 and 3.0m intervals), porpoises swam through them 68.2% ($n=22$) of the time (Table 2). The number of groups that altered course in response to polypropylene line did not differ significantly ($G=0.0217$, 1 df, $0.75 < p < 0.90$) from the number of groups that responded in a similar manner to the corkline alone. There was no significant difference ($G=0.113$, 1 df, $0.50 < p < 0.75$) between the proportion of groups that turned from bead chain versus surgical tubing hukilaus. Only 25.0% ($n=3$) of the groups that encountered bead chain and surgical tubing hukilaus swam through them, and there was a significant difference ($G = 6.102$, 1 df, $0.005 < p < 0.01$) between the number of groups that turned away from these hukilaus relative to all other hukilaus. On two occasions (both were polypropylene hukilaus) porpoises initially turned from the hukilau and subsequently swam through it. Several groups milled near the corkline and two groups swam under it repeatedly.

Although dive times and respiration intervals were not quantified, groups which swam close to the experimental gear ($<30\text{m}$) appeared to dive for longer periods or interrupted patterned surfacing sequences relative to those

Table 2

Harbour porpoise reaction to experimental structures in Monterey Bay, June through August 1988.

Variable	<i>n</i>	Swam through	Altered course	Response uncertain
Cork line	26	11	7	8
Hukilaus				
Polypropylene				
1.5m	22	10	4	8
3.0m	13	5	3	5
Bead chain	6	1	4	1
Surgical tubing	15	2	5	8

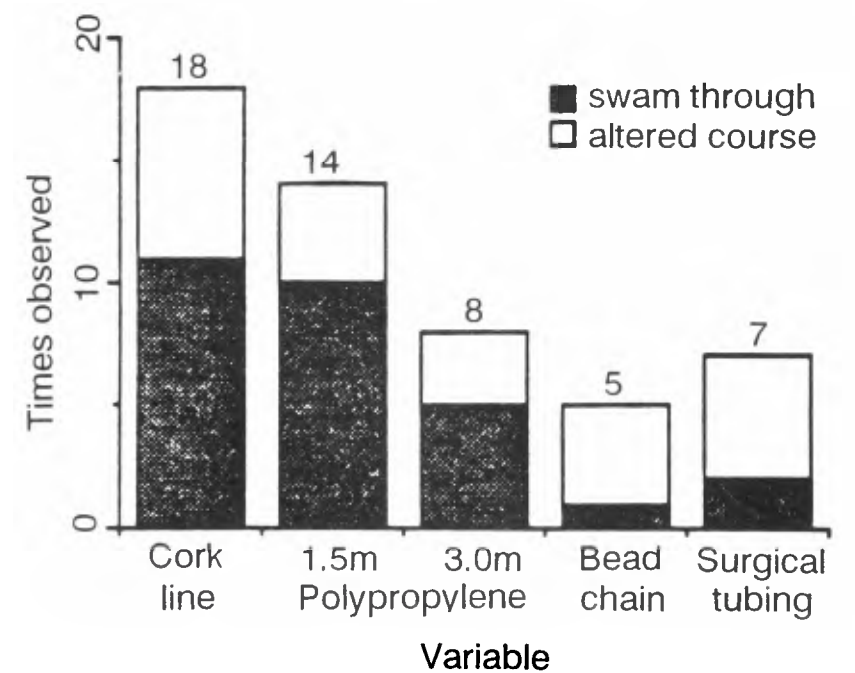

Fig. 4. Number of porpoise groups that swam through or altered course relative to each experimental variable.

which did not encounter the structures. This may have been a period in which they explored the apparatus. The mean closest observed approach was greatest for bead chain, least for surgical tubing, and intermediate for corkline and polypropylene hukilaus (Fig. 5), however these data were not significantly different ($F=1.178$, 4 df, $p=0.3576$).

Fig. 5. Mean closest observed approach of porpoise groups relative to each experimental variable. One standard error is represented.

Water clarity measurements, using a secchi disc within 20m of the experimental gear, ranged from 2.8 – 7.0m (mean = 4.4 ± 1.53 (SD)m, $n = 7$). The degree of water clarity that we observed near the hukilaus was likely adequate for porpoises to see the structures. Therefore, the porpoises' reaction to the gear (their tendency to avoid or swim through it) probably was not dependent upon their capacity to visually detect the gear.

The mean size of groups that swam through the experimental gear (4.6 ± 5.80 (SD) individuals, $n = 29$) did not differ significantly ($t = -0.206$, 42 df, $p = 0.838$) from those that altered course or swam around the gear (4.3 ± 2.23 (SD) individuals, $n = 23$). However, there was a significant difference ($t= -2.382$, 77 df, $p = 0.020$) in mean group size between groups that approached within 50m (4.6 ± 4.52 , $n=44$) of hukilaus as compared to those whose closest approach exceeded 50m (6.9 ± 3.77 (SD), $n = 35$). It is possible that large porpoise groups possessed greater 'sensory awareness' and the ability to locate the gear was enhanced by cumulative abilities of large groups. Larger groups were more readily seen at greater distances than smaller groups, which may reflect a bias toward large groups being seen more often than smaller groups farther from the experimental structures.

DISCUSSION

Incidental mortality in gillnets poses an actual or potential threat to many cetacean populations worldwide and, in many settings, few alternatives are available to reduce

cetacean mortality in gillnets (IWC, 1994). Our work was undertaken to assess porpoise reaction to a particular type of net add-on or modification that might reduce incidental mortality by deterring porpoises from nets. We showed that some porpoises avoided vertical lines in the water column, although the variables that we tested were not completely effective in deterring porpoises.

Polypropylene vertical lines were no more effective in turning porpoises than was the corkline alone. Polypropylene line is a common material in coastal marine environments where humans are present (e.g. anchor lines). Familiarity with polypropylene line may increase the likelihood of porpoises approaching the material and may account for the lack of response to the corkline alone and to the polypropylene verticals. In contrast, those porpoises that avoided polypropylene hukilau may have been responding merely to the corkline component of the hukilau. Bead chain hukilau may have turned a higher proportion of porpoises than did other hukilau because it was a less familiar material than the other hukilau. In addition, bead chain hukilau may have possessed acoustic properties which not only caused a greater proportion of porpoises to avoid this material, but also to change direction at slightly greater distances relative to other hukilau. Because the surgical tubing did not hold air as intended, it probably reflected very little sound, such as porpoise echolocation signals. However, the tubing turned a relatively high proportion of porpoises. The tubing was used in conjunction with polypropylene and it may have represented a more obvious and unfamiliar material than did polypropylene alone.

Unlike harbour porpoises, spinner dolphins would not swim through hukilau (Norris and Dohl, 1980). However, spinner dolphins are a pelagic species and are likely to respond to obstructions that are uncommon in their habitat. In contrast, harbour porpoises frequent coastal waters where they are likely to encounter structures in the water column such as pier pilings, kelp and anchor lines. In addition, groups of harbour porpoises typically average less than ten individuals, whereas spinner dolphin groups may contain tens or hundreds of individuals; greater distances between vertical lines may be needed to allow spinner dolphin schools to pass than is required for harbour porpoise schools.

The issue of gillnet mortality is biologically and sociologically a complex problem and a debate exists regarding solutions to high cetacean mortality in gillnets (IWC, 1994). Some researchers advocate a total elimination of gillnets (Dawson, 1991), others recommend fishery closures by location or time, while some believe that it is possible to render the nets less destructive through modifications (for example Goodson *et al.*, 1994).

Clearly more work is needed to address this problem and attempts to reduce cetacean entanglement almost certainly lie in a multi-faceted approach in which several avenues are pursued simultaneously. Restricting the use of gillnets by degree (e.g. time and area closures), the use of alternative fishing techniques, net modifications and total bans should all be considered depending upon the region, the fishery and the marine mammal species involved. Reasons for cetacean entanglement may vary with fishery, net type, means and timing of net deployment, mesh size and target species, and the social structure and behaviour of incidentally captured species.

We believe that in many cases, the abolition of gillnets may be the only solution. However, moratoria on gillnets will encounter resistance due to the detrimental economic

impact on fishermen. In addition, in many remote locations enforcing bans on gillnet use will be extremely difficult. It is not reasonable to assume that gillnets will be eliminated in all regions in the foreseeable future, and because cetaceans continue to die, alternatives should be explored in the interim.

Further experimentation on gillnet modifications that reduce cetacean mortality should be considered, particularly if moratoria are not possible. However, gear modifications should not be necessarily regarded as solutions, but as potential short-term means of lowering cetacean mortality rates while more far-reaching and effective solutions are sought. Reductions of even small percentages in entanglement rates could benefit affected populations until permanent solutions are found. For example, in the Gulf of California, where vaquita incidental mortality is high relative to the population size, laws banning the use of gillnets have existed since 1975, but the practice continues unchecked due to a lack of resources to adequately enforce the laws (Vidal, 1994). Attempts to implement additional or more stringent laws are not likely to reduce the amount of gillnetting activity. However, by instituting a programme involving simple modifications that lower entanglement levels, it may be possible to mitigate the impact of incidental mortality, while other people work simultaneously toward the elimination of this fishing practice. Net modifications that reduce but do not eliminate porpoise entanglement rates should not be pursued *in lieu* of the possibility of substituting the use of gillnets with safer fishing methods, but they might provide relief to porpoise populations while more permanent solutions are sought.

ACKNOWLEDGEMENTS

We are grateful to those who assisted in the field work, including S. Beavers, M. Greenburg, T. Jefferson, P. Leiberg, J. Macias, M. Newcomer, A. Rennelson, R. Sanders, T. Silber, M. Smultea, K. Urian, D. Waples and R. Wells. We thank F. Spear and the personnel at Sunset and Manresa State Beaches and California Department of Parks and Recreation for allowing us to use the parks for observation sites. The California Department of Fish and Game allowed us to borrow anchors and other hardware and B. Wursig provided theodolites. We are grateful for analysis provided by E. Carlson and D. Waples. We thank the Marine Mammal Commission and the Homeland Foundation for financial support. The study was conducted under scientific permit No. 530 issued by the National Marine Fisheries Service. The paper benefitted from comments by M. Newcomer, T. Jefferson, S. Kraus, B. Wursig, K. Norris and an anonymous reviewer.

ABSTRACT

The entanglement and drowning of large numbers of the smaller cetaceans in gillnets is a matter of international concern and necessitates research to identify techniques which will minimise such incidental catch. In attempting to explain the behaviour of animals immediately prior to net entanglement in modern driftnets we need to understand the ability of the animal to detect and assess the threat. A non-intrusive study of the behaviour of a solitary wild *Tursiops truncatus* (using sonobuoys) has examined several natural behaviour patterns classified respectively as: foraging, travelling and resting. This paper examines some specific acoustic behaviours which were observed to be employed by this free ranging animal. The interpreted behaviour of this dolphin is seen to further complicate the problems of gillnet perception. No simple solution appears to exist, but for those animals which are actively echolocating the authors believe the best chance of net avoidance requires that the net be detectable near the animal's maximum searched range. The target tracking behaviour employed during fish interception suggests that diffuse obstructions, i.e. gillnets, that can only be detected at lesser ranges, are likely to be ignored. Design parameters for passive enhanced echo reflectors which are orientation independent and optimised for dolphin sonar signal characteristics are discussed in detail.

KEYWORDS: INCIDENTAL CAPTURE; BOTTLENOSE DOLPHIN; ACOUSTICS; BEHAVIOUR

INTRODUCTION

The incidental capture of cetaceans in fishing gear is recognised as the major threat to their populations in many parts of the world (IWC, 1994). Attempts to reduce incidental catches have been hindered by a lack of knowledge as to why cetaceans become entangled. This can be oversimplified as a question of 'detection' (they do not know the net is there) or 'classification' (they know it is there but do not recognise it as a threat). Many of the early attempts to modify fishing gear were based on an assumption that the problem was one of detection. Given that dolphins used echolocation it was concluded that the solution was to make nets 'louder'. These attempts rarely considered the detection capabilities of dolphins, their behaviour, the acoustic properties of water or the acoustic properties of the gear.

In this paper we examine these factors and use the information to consider ways of enhancing the detectability of gillnets in a manner that takes into account the physiology and behaviour of dolphins.

PHYSIOLOGICAL AND BEHAVIOURAL CONSIDERATIONS

Most studies of the acoustic capabilities of cetaceans have been of captive animals, for obvious reasons. However, while this is of value in providing baseline data, it is important to study the acoustic behaviour of animals in the wild in order to better address problems, such as gillnet entanglement, that face them in their natural environment.

A common difficulty encountered when carrying out acoustic studies of animals in the wild is that of isolating and identifying the individual sound sources within a group. Studies of a single wild animal, which exhibits

repeatable patterns of behaviour, greatly simplifies the problems of classifying activity and correlating the associated sound emissions (Goodson *et al.*, 1988; Goodson and Datta, 1992).

The study animal

The solitary bottlenose dolphin (*Tursiops truncatus*) resident close to Warkworth harbour entrance at Amble by the Sea (Northumberland, UK) has been extensively studied since 1989 (Bloom, 1990; 1991). The animal is a mature male of approximately 20 years (this estimate is based on the dolphin's size, condition, visible tooth wear and apparent lack of tongue papillae – Kastelein and Dubbeldam, 1990). Conveniently, the animal normally remains within sight of shore inside a relatively small, well defined home range which is less than 1km square. Brief excursions outside this favoured area do occur, usually while providing an escort to local fishing boats as they approach or depart from Warkworth harbour. Increasing social interaction between the dolphin and humans, especially with divers, occurred after the first year of study but this modified behaviour is ignored here. Night-time foraging patterns of behaviour seem to be consistent, especially when interference due to human activity is absent.

Equipment

Sonobuoys (modified type SSQ41a) were employed to monitor the dolphin's acoustic emissions continuously during 24 hour intensive study periods. The available sonobuoy signal bandwidth was extended upwards to 40kHz and the low frequency response below 50Hz restricted for this application. The signal bandwidth in practice was restricted by the use of the original 'bender' hydrophones. Although sensitive, these hydrophones

possess a rippled frequency response above a nominal 2kHz resonance and are therefore unsuitable for determining signal power spectra or examining precise pulse wave shape. Precision hydrophones (B&K 8104s and Universal Sonar D/70s) were occasionally used but their deployment for directly wired wideband recording is limited by the weather and turbulent water conditions close to the pierheads. As a result sonobuoy radio telemetry provided the bulk of the data.

AOR Ltd AR-2002 and Yaesu FT9600 communication receivers were used to receive the sonobuoy signals. Simultaneous recordings from each deployed sonobuoy were made on separate channels of a wideband Racal Store 4D instrumentation recorder at 19cms⁻¹ (37kHz bandwidth). A VHS Camcorder was deployed at the pier and operated by the observers. An additional sonobuoy communication receiver assisted the pierhead observers and supplied underwater sounds to the video camera sound track. Handheld VHF radio transceivers were used to coordinate observers, mobile activity, boat handling and the recording/control vehicle (Base) throughout the 24 hour watch periods. The sonobuoy (with a long-life battery pack) deployed at sea was moored between two small surface floats and kept on station by a double anchor system (to avoid entangling the hydrophone). The inshore sonobuoy was deployed 40m clear of the south pierhead and moored using a rope loop with a pulley at the seaward end attached to an anchored surface float. The inshore end was attached to the pierhead and could be controlled by the observers. This technique provided for sonobuoy recovery and replacement if required and allowed the hydrophone position to be optimised without needing a support boat. Subsequent analysis of the instrumentation recordings was aided by a Loughborough Sound Images (LSI) speech work station.

Summary of the animal's behaviour

During 1989 and 1990, the positions of the animal within its home range were logged, during daylight hours, by local observers. In addition, four intensive 24hr studies were carried out in order to acquire data under both winter and summer conditions. Bloom (1991) reported that typically during these 24hr study periods, the animal exhibited behaviour patterns loosely classified as foraging (53%); resting (22%); play or other behaviour (12%). The animal was out of observation range for 13% of the total period. This summary is based on 96 hours of observation, sampled at 15 minute intervals.

Acoustic behaviour – resting

A navigation buoy marking the outfall of a sewer pipeline some 500m offshore (Fig. 1) appeared to be used by the animal as a reference point during resting. The animal spent significant periods circling near it, exhibiting a regular breathing pattern. Sonobuoys deployed nearby registered no echolocation 'click trains' or 'whistle' sounds while the animal was near. A very occasional 'loud click' was the only sound noted which might possibly be classed as a bio-sonar emission from the dolphin (Goodson *et al.*, 1988).

Echolocation behaviour – travelling

The sonobuoy sensitivity is such that good detection of click train emissions could be obtained at ranges in excess of 500m when the animal was orientated towards the hydrophone. At ranges of <100m, the low directivity of the low frequency spectrum sampled ensured that clicks were detectable even when the animal was swimming away

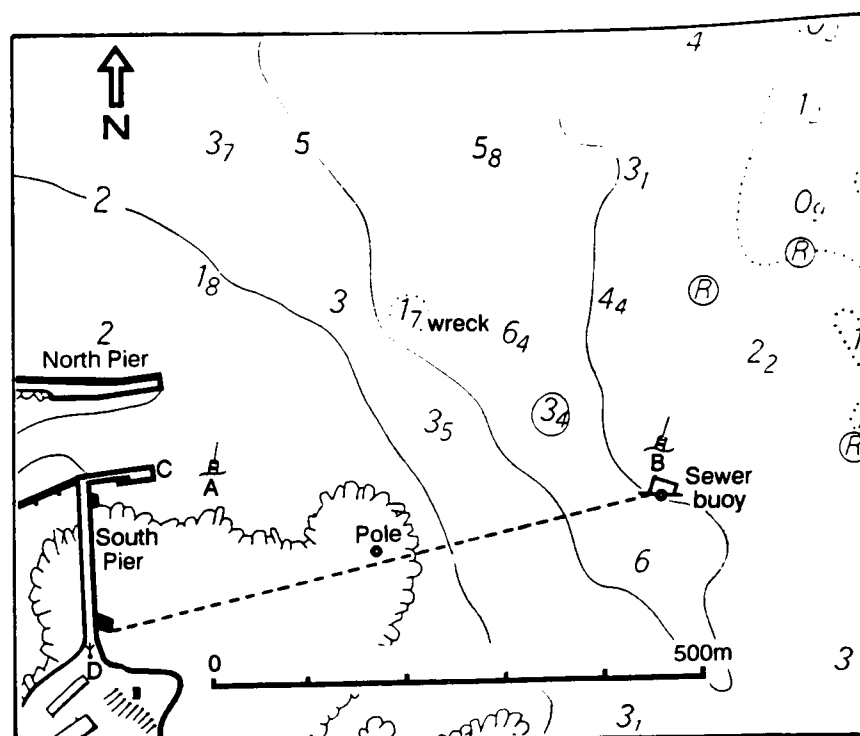

Fig. 1. The Amble dolphin's home range close to Warkworth harbour. A & B – sonobuoy positions; C – south Pierhead observers; D – base station for telemetry reception.

from the hydrophone. The relative amplitude of the clicks and their reverberation components also provided clues to changing orientation.

Sonobuoys were deployed at the sewer outfall and close to the end of the south pier. On a number of occasions the animal was timed travelling underwater quickly (8–10ms⁻¹) and directly between these two sonobuoy locations, which were about 500m apart. Echolocation signals were rarely evident in this fast travel mode. This 'quiet' travel behaviour was typical and noted in a variety of sea states, in both winter and summer, and in conditions of poor water visibility and fading evening or dawn light. No evidence was found to support the view that the dolphin employs its active sonar as a navigational aid within this home range.

The preferred foraging zone

The river at Amble passes into the sea between two parallel (concrete and stone) breakwater piers, some 68m apart, which define the harbour entrance. The area immediately outside and between the breakwater arms appears to be a prime foraging area. Sonobuoy deployment 40m seaward of the end of the south pier permitted continuous monitoring of the dolphin's sonar emissions. Observers based on the south pier head were well placed to monitor the dolphin's fishing activity, much of which occurred within 100m of their position. Even in total darkness, the animal's blow could usually be heard at this range while the radio receiver relayed underwater sounds from much greater ranges.

Fish entering or leaving the river must pass between the two piers of the harbour breakwater. Severe tidal scouring effects exist close to the north pier which has been undermined. A sand 'bar' causing a small step discontinuity in the seabed exists between the seaward ends of the piers. The average tidal range is 4.5m and the minimum water depth, measured at the bar, is less than 1m at spring low tides.

Echolocation – search patterns

The animal's search pattern was dominated by a slow, relatively loud click emission typically transmitted at a rate varying between 12 and 16Hz. In rough sea conditions or when the animal chose to fish between the pier heads, the click rate was noticeably faster, up to 25Hz. In contrast, in

calm quiet conditions when the animal was swimming clear of both piers, the slowest repetitive emission rate recorded was 8Hz. These slow repetition clicks were employed over long periods (hours) at a time. They were initiated at the start of a dive and were the emission pattern to which the animal returned after interruptions by other acoustic activity. These pulse trains exhibit a characteristic slightly irregular interval with each sequence settling to, and varying about, the nominal rate (Fig. 3a). The presence of this type of sonar emission has been used to classify 'foraging' behaviour. Foraging activity could occur during any tidal state, although the ebb tide appeared to be favoured. It was rare for the dolphin to fish close to the harbour mouth at low water. Extended periods of fishing activity frequently occurred at night.

There was a short pause after taking breath before these slow sonar transmissions resumed, suggesting that the animal dived to a preferred depth and levelled out parallel to the bottom before initiating a long range search transmission. During this activity, the animal frequently resurfaced in the same position and on the same heading as the preceding dive. The underwater search strategy would seem to be the repetition of a particular underwater manoeuvre.

Changes in the peak received signal intensity were minimised by the sonobuoy's reverberation gain control (RCG) circuitry, but cyclic variations in the relative strength of the inter-click reverberation components suggest that the animal may have been circling slowly on or near the bottom, presumably sweep-searching a large sector. Alternatives to this normal circling pattern included patrolling a path across the harbour mouth some 10 to 20m outside the pier heads and a 'figure of eight' pattern executed between the harbour pier walls. These patterns have been reported independently by divers near these locations.

Interaction with fish

The sudden cessation of the slow 'foraging' clicks and the initiation of a rising pitch 'mewing' sound (Goodson *et al.*, 1988) appears to characterise detection of a target fish and initiation of a chase sequence. After such sounds the animal was occasionally observed to surface holding a relatively large fish in its mouth. On several occasions the dolphin has also been seen to play with a fish, either 'herding' it along the surface or by throwing it into the air (Fig. 2). Salmon, sea-trout, herring, mackerel, cod, coalfish, flatfish (dabs or plaice) and dogfish are among species that have been tentatively identified as prey by both pierhead observers and divers.

Although the transition from the 'foraging' clicks to 'mewing' sounds may occur as a progressive increase in click frequency, it is more common for the foraging click sequence to terminate abruptly and after a brief silent period (some 200 millisecs) for 'mewing' to commence. The perceived pitch of this signal rises and may vary before terminating, either in silence or in an immediate resumption of the slow loud clicks.

Echolocation signals – interpretation

The inter-click period is presumed to define the maximum range being actively searched, as the next transmitted pulse must tend to desensitise the receiver and thus effectively terminate detection of weak echoes returning from greater ranges. If strong long range echoes originating from an earlier transmission are detected then the target range perceived will be ambiguous. The maximum range searched by this animal in ideal conditions is therefore believed to be less than 94m (from the occasional 8Hz repetition rate noted in calm conditions). The slow click repetition rates normally employed suggest that this dolphin was rarely interested in searching for prey much beyond about 60 to 70m, coincidentally the width of the Warkworth harbour entrance. This is also close to the maximum range achieved by trained animals searching for a -35dB target close to the seabed (Murcheson, 1980).

'Mewing' comprises a rapid sequence of discrete clicks emitted in a regular and precisely timed sequence (e.g. Fig. 3b). These rapid clicks appear to be repeated at intervals closely related to the two way sound propagation time between the animal and the target of interest and can be seen to represent the maximum rate at which echo data from the target can be acquired. By concentrating directly on the target range, this technique will effectively mask multipath secondary echoes of the target and also reject much of the echo clutter returned from greater ranges than that of the fish. The consistent range/time interval relationship appears to break down at very short ranges (<1m) but this may well be due to physiological factors controlling the maximum rate of click generation. *T. truncatus* is rarely observed to click at rates much above 1kHz.

Published studies of range locked behaviour (Au *et al.*, 1974; 1982; Turl *et al.*, 1987) are confined to constrained or stationary animals. It is worth considering whether the unrestrained forward motion of a wild animal during target interception should be considered as a parameter affecting the acoustic behaviour and, in particular, the reported variations in latency.

Fig. 2. Throwing a fish (salmonid) into the air.

Fig. 3. Inter-click period (instantaneous frequency) plotted against time. (a) Foraging clicks 'unlocked' variable 12 to 20Hz. (b) Target interception phase, starting to 'mew'.

During a typical fish chase sequence, the pitch of the 'mew' increases as the dolphin rapidly shortens the range during interception. Short periods of almost constant pitch are occasionally observed which could suggest that, having achieved a close range, the animal may be content to tire its prey (fish muscle exhaustion tends to occur suddenly, leaving the fish helpless in the path of the dolphin). Alternatively, it seems probable that when intercepting a large target fish with a swimbladder, the increasing click rate employed as the range shortens will match and stimulate a resonant response in the swimbladder. The peak click rate then employed may thus reflect target size rather than range parameters. The subsequent reaction of the targeted fish is unknown but repetitive stimulation of the Mauthner escape reflex through swimbladder transduction is unlikely to aid the fish's ability to escape (Canfield and Eaton, 1990).

Unsuccessful chase sequences or target rejection are assumed to have occurred if 'mewing' stops and foraging clicks are abruptly resumed. The frequency of the 'mew' occasionally fell slightly before terminating. There is of course no reason why the ingestion of very small fish should necessarily interrupt the sonar transmissions. In chase sequences known to be successful, i.e. where a fish was brought to the surface within sight of observers, the sonar transmissions appeared to terminate at capture, the abrupt cessation of the 'mew' occurring at the highest frequency.

Long range 'foraging' clicks exhibit relatively loose timings and the instantaneous rate often seems varied cyclically about a nominal range (Fig. 3a). In contrast, 'mewing' comprises click sequences with precisely timed click intervals. Plots of inter-click period/time profiles (Fig. 3b) can be used to identify segments of acceleration, deceleration or constant swimming velocity relative to a target.

Selecting segments of constant gradient as indicative of a constant velocity allows the relative dolphin/fish velocity to be estimated; the Amble dolphin's swimming speeds during target interception were typically 5ms^{-1} terminating in a brief burst at higher speed (up to 8ms^{-1}).

In some of the data analysed, the dolphin appeared to employ an intercept behaviour built up from segments of nominally constant swimming velocity. If this 'stepped velocity' behaviour is non-accidental, it may be a technique employed to simplify the moving target interception problem.

Echolocation behaviour – implications

The detection and active tracking of a target by a dolphin is characterised by a range locked transmission, i.e. as the echo from the target is detected, the next click transmission occurs. The interclick period normally reflects accurately the range to the target at any instant and the increasing frequency as the dolphin closes with a target gives the observer a reliable indication of distance until the target is very close to the animal. At ranges less than 2.5m the range/frequency relationship ceases to be linear and it is unusual to observe click rates which peak at much above 1kHz, so the effort or usefulness of this information rate is assumed to be rarely needed.

One important benefit of a range locked transmission rate is the effective suppression of over-range target information and multipath 'echo clutter'. The transmission of the succeeding click immediately on receipt of an echo ensures that the echo-receptor is desensitised. A latency period will follow in which the receptor recovers. The perception of any over-range target during an active fish chase would appear to necessitate a very strong echo from the secondary target.

Dolphin sensory perception during fishing activity

The two senses which are usually assumed to predominate during fish hunting activity are hearing (sonar) and vision, with the former clearly the more important. Other senses such as chemoreception, may play a part in long range detection but are not believed to offer more than 'present/absent' clues, although it is not inconceivable that fish or shoals of fish might be tracked by taste. As noted above, at ranges greater than about 100m, the presence of gillnets will provide no warning clues to an animal swimming on a collision course. Underwater vision, even in ideal conditions, will not be able to detect netting until significantly closer than 20m. At night or in 'normal' sea conditions, animals will probably not see a net until collision is imminent. Sound detected in the passive sense may provide coarse hydrographic orientation and position clues to a travelling animal, especially in shallow coastal waters. However, gillnet 'self noise' (i.e. noise generated by the drifting netting due to sea state disturbance) will be at low levels and will probably be masked in most conditions by the background ambient seastate noise; it would be interesting to compare statistics of incidental catch in relation to sea state. The assumption must be then that few clues to a drifting gillnet position will be given to a

passively listening animal. The sense most likely to detect the presence of a net as an obstruction is therefore the active sonar 'echolocation' mode employed by the animals, especially when foraging.

Dolphin sonar – resolution

Bottlenose dolphins project their broadband transient clicks from the melon (Wood, 1964; Norris and Harvey, 1974; Romanenko, 1974). This anatomical feature functions as an acoustic lens of limited aperture and as a result the projected signal is spectrally dispersed in both azimuth and elevation. The energy distribution within a *T. truncatus* high source level transmitted pulse has been shown by Au (1980) to peak spectrally near 120kHz within a tight (10°) conical beam. The dispersive effect of the melon's limited acoustic aperture means that lower frequency components progressively dominate as the observation point is moved off axis (Au, 1980; Watkins, 1980). The projected acoustic 'directivity' pattern can be pictured spatially as a graded series of concentric conical beams of increasing included angle but dominated by progressively lower frequency and lower amplitude spectral components. If the dolphin's angular perception is based solely on the transmitted signal beamwidth, then the animal should have difficulty resolving target position in azimuth or elevation to better than 10° (unless the dolphin ignores the human convention of half-power beamwidth and successfully discriminates echo intensity variations significantly smaller than -3dB). However, trained animals have consistently displayed an ability to discriminate angular position in both azimuth and elevation to better than 1° (Renaud and Popper, 1975; Floyd, 1988). The receptor mechanism by which this angular resolution is achieved is unclear and not explained by the traditional hypothesis based solely on the cochlea response to a fatty tissue sound conduction pathway along the lower jaw. An alternative echo receptor hypothesis, optimised for high frequency echo-reception within the near field, is modelled in Goodson and Klinowska (1990).

It is evident from physical acoustic principles that, regardless of the receptor mechanism employed, the animals angular discrimination of very small objects must utilise the high frequency spectral components contained within its transmission. This perception can therefore only function within the very narrow 'spotlight' beam projected forward along the swim axis. Searching behaviour in dolphinarium experiments supports this, as head swinging actions are employed while swimming towards and discriminating between spatially separated target positions. Once the required decision has been made, the animal points its beak accurately towards the selected target for the final approach phase. For an optically masked target (TS=-41dB) the data acquired during the early learning phase of using three captive bottlenose dolphins an experiment suggested that they left their final discrimination decisions to about 2.5m range (Goodson, unpub. data).

The limiting factors affecting detection of very small sonar targets relate to the target's physical size, geometry and the insonifying wavelength. Progressively reducing the target's dimensions to below 1 wavelength of the incident sound, results in the back scattered echo energy returned towards the source becoming very small (Fig. 4). For very small targets the animal's perception will therefore be limited to the centre line of the transmit axis. Larger targets may be perceived in off-axis positions as the outer conical zones of the transmitted beam are defined by lower

frequency and lower power components. If a recording of a sequence of clicks made by the animal as it scans its sonar transmissions across a hydrophone, is slowed down by a large factor (16:1), then the human ear can perceive a significant shift in the apparent pitch of the individual dolphin click. This azimuthal shift in pitch may well provide the initial centring clues during target acquisition. At short ranges, the perception of a phase difference between the echo received by the left and right receptors must explain the ability of an echolocating dolphin to track an elusive fish target down to the capture point in total darkness. The lack of head scanning movements when a dolphin is in the final 'locked on' (mewing) phase of a fish chase and the animal's apparent ability to react to the target's sudden direction changes without employing head scanning actions, would seem to support this (Goodson, unpub. data).

Fig. 4. Acoustic backscatter from a rigid sphere, as a function of the insonifying wavelength (after Clay and Medwin, 1977).

THE PROPERTIES OF GILLNETS

The deployment of gillnetting made from modern polymer materials is an efficient method of fish capture which, although intended to discriminate its target species by choice of mesh size, also indiscriminately captures much larger species through entanglement. Gillnets can be exploited by a wide range of fisheries, from relatively small scale inshore artisanal to large scale off-shore operations. The technique has proliferated throughout the world during recent years and is rapidly replacing traditional fishing methods. The nets are frequently deployed at night in order to capture fish which approach the surface nocturnally. Before the UN ban on large-scale pelagic driftnetting came into force in 1992, vessels in the Tasman Sea albacore tuna fishery each deployed long lengths of gillnet, typically 39km per boat, which hung below the surface in a curtain some 10-15m deep (Coffey and Grace, 1990). Alternatively, in shallow water much smaller nets may be permitted to sink close to the seabed (Karlsen and Bjarnason, 1987). A wide variety of cetacean species are taken as incidental catches and those that escape may only do so after causing significant damage to the nets (IWC, 1994). It seems probable that many of these animals are captured during their own foraging. In a large number of cases the netted animal is unable to break away and once entangled, suffocates. From the fisherman's perspective,

the damage to expensive netting and the associated down time is significant (Lien *et al.*, 1988) and an economic incentive exists to employ methods which minimise the problem.

The Target Strength of gillnet webbing

The Target Strength (TS) of various gillnet materials* have been assessed by Au (1994), by Hatakeyama *et al.* (1994), by Pence (1986) and for tuna purse seine nets by Leatherwood *et al.* (1977). The quoted results differ depending on methodology and materials and the highest values assessed result from insonification normal to the plane of the deployed webbing. Insonification at other angles results in reduced echostrengths and for an azimuth change of 15°, Au (1994) determined a reduction in the perceived TS of 3.8dB. Although he did not examine the worst approach angle scenario, his measurements imply that the peak TS value should be reduced by some 7.6dB in order to allow for a dolphin/net interception along combined azimuth and elevation angles exceeding 15° from the normal. For monofilament gillnet webbing, Au (1994) measured a peak TS value of -58dB. For net detection estimates, the use of the peak value is likely to mislead and a worst case TS value (-66dB) needs to be considered as the general case. Hatakeyama and Soeda (1990) refer to directivity data (provided by Pence) which indicates that small changes in azimuth angle (3–4°) at frequencies of 150kHz and 170kHz should result in a reduction in the perceived TS by 10dB. Thus the 'worst case' TS estimate of -66dB (for a monofilament salmon gillnet with animals intercepting the plane of a net at angles other than 90° in both azimuth and elevation) may still be an overestimate.

In this context it may be argued that foraging animals must spend a significant proportion of each dive projecting their echolocation signal for maximum range in the horizontal plane. However, the actual angle of incidence of a horizontally projected signal at the gillnet interface may not be normal in the elevation plane, as strong thermal gradients near the surface will modify the incident angle at the net by refraction. This effect is likely to be pronounced in tropical waters and may result in diurnal changes in the bycatch. In addition (for moored nets), tidal displacement will deflect the plane of the net from the vertical.

THE NET DETECTION PROBLEM

Given that the acoustic reflection characteristic of the unmodified gillnet webbing is inadequate for long range detection, an estimate of the increase in TS theoretically needed to alert dolphins can be made from the foraging behaviour and targeted prey of the animals at risk. From observations of the (Amble) dolphin's sonar behaviour and from consideration of the size of the larger fish observed caught by this animal, we can deduce that swimbladdered fish, with a TS in the order of -35dB (re a 2m radius sphere; Foote, 1980) are frequently sought, and are believed to be detectable at ranges between 60 and 70m.

Using the basic sonar equations (Urlick, 1983; Au, 1994) to predict the spreading and attenuation losses due to range for a monostatic sonar functioning at 120kHz, we can

* When measuring Target Strength (TS) the target dimensions need to be fully insonified by the sonar beam. If the target's dimensions exceed the beam width, as in a fishing net, the echostrength becomes range dependent. Unless the measurements conditions are fully specified the TS values, conventionally assumed to be in dB re a 2m radius sphere, are not comparable.

demonstrate that the equivalent detection range of an unmodified gillnet (TS = -66dB) when compared with a targeted large fish (35–40cm salmon nominal TS = -35dB) at 70m range will be less than 12m.

Knowledge of the actual source level employed and of the animals detection threshold in noise is not essential for this comparison, given that the ability to detect fish of this TS at the stated range has been observed.

Since the prior detection of a fish and the initiation of interception sonar behaviour is believed to exclude the detection of over-range targets, even assuming the simplest scenario the problem of dolphin/net detection cannot be solved unless the net position is always perceived before the fish is detected! That this assumption may be simplistic is witnessed by the (unique) South African shark net bycatch problem (Cockcroft and Ross, 1991; Peddemors *et al.*, 1991), where prior knowledge of the net position could be presumed. However, it may be argued that for the (Amble) dolphin at least, any enhancement of the gillnet TS to a value that is less than about -35dB will be ineffective in the presence of fish. For other animals at risk, the maximum size of fish prey regularly taken can be used to establish a minimum TS value that must be matched or exceeded by the gillnetting if its position is to be detected before that of a fish.

Of course, detectability alone is not enough to ensure that animals avoid entanglement. The echoes from the net obstruction once detected must also be classified as an impenetrable barrier to be avoided. The characteristic distributed echo returns from a curtain of gillnet webbing will appear diffuse and may easily be classified by the animal as penetrable volume reverberation, as would similarly distributed echo returns from seaweed, algae blooms or even the bubble wakes left from passing boats.

Although the addition of reflecting objects to a gillnet to achieve the 'minimum' TS criteria described is possible, net handling imposes serious operational constraints. The physical size of these additional devices, their spacing, shape and buoyancy all need to be considered (Goodson *et al.*, 1994).

Some assumptions about dolphin behaviour and net perception

- (1) Dolphins in a resting mode appear to swim relatively slowly (0.5 to 1.5ms⁻¹) and seem to only maintain minimal active monitoring of their immediate environment. Although the evidence is slight, our observations suggest that the occasional loud click thought to be emitted by the dolphin may be intended to maintain a position check. 'Dozing' dolphins sometimes appear slow in reacting to rapidly approaching boats on a collision course.
- (2) When travelling fast (5 to 8 ms⁻¹) in known territory, the dolphin does not appear to employ its active sonar; our evidence suggests that active sonar is only used when foraging. Human fishing activity (an occasional bottom set cod net) within the Amble dolphins home range did not result in any reported interactions. The animal was aware of the deployment of the net and presumably treated it as part of its 'normal' environment. Seal/net conflicts in the same general area are a regular complaint of the local fishermen.
- (3) While foraging actively for food, the sonar range examined is probably defined by the anticipated prey behaviour and the balance of effort required to intercept, *versus* the size of the reward. The slow click rates employed by our study animal suggest a 60–70m

maximum search range. Although acoustic searches beyond this range for large targets may well be possible in good acoustic signal/noise conditions, the effort involved in capturing large fish targets detected at extreme ranges is probably uneconomic.

- (4) Observed behaviour patterns suggest that the dolphin is searching a large volume of water by swimming slowly in a circular pattern while clicking at these slow repetition rates. From the estimated sizes of the largest fish seen to be caught, the probability of *T. truncatus* detecting a large (TS = -35dB) fish at the maximum range in mid-water is quite high. Target detection frequently occurs at ranges less than the search range maxima, suggesting that the animal is turning onto the bearing of a fish at closer range.
- (5) The final attack phase is usually fast (some chase sequences last less than 4 seconds) with maximum speeds estimated at about 8ms⁻¹. Much longer sequences can occur with inter-click intervals which suggest quite short dolphin/target ranges. These seem to indicate that the target fish may be detectable but less accessible due to the seabed topography. Initial target detection commonly occurs at ranges well under the search maxima.
- (6) The dolphin's echo-perception, exploiting its own high frequency signal components, does not appear to be degraded by high levels of low frequency noise. Off-line spectrographic analysis of the recorded signals demonstrated that the dolphin's fishing activity frequently continued while a fishing boat, entering or leaving harbour, passed at very close range, as the presence of foraging click signals is clearly discernible extending well above the relatively low frequency ship noise spectrum (Mitson, 1989).

IMPLICATIONS FOR PASSIVE ACOUSTIC NET MARKERS

Sonar perception of a fish target is not believed to be impaired in the presence of a competing (or cooperating) dolphin sonar. The lack of *a priori* knowledge of the echo/source timing precludes other animals acquiring range information from such echoes. The sharp directivity of the transmission and the apparent focussing of attention to the precise target range during a chase/interception 'mew' can be seen to be an excellent technique to reject such interference. Gillnet detection as a byproduct of a second animal's signal echoes is thus not likely.

Attempts to enhance a gillnet's TS by the addition of simple sound scattering mechanisms such as ropes or 'bead chain' (e.g. Hembree and Harwood, 1987; Dawson, 1994) have not been very effective. However, the mechanisms employed so far are ostensibly inefficient as most of the incident echolocation energy is dispersed omnidirectionally. Strong specular echo returns can only be produced from target dimensions which exceed several wavelengths of the incident sound. The very high TS's measured by Au (1994) for 'light switch chain' (-36dB) and for 'poly rope' (-33dB) are the peak values which are specific to vertical deployment with horizontal insonification at one (2.4m) range. At all other angles of incidence the proportion of energy reflected back towards the source from a line reflector (long thin cylinder) is much lower (Urlick, 1983; Hatakeyama *et al.*, 1994). The TS is also dependent on range as the length of target insonified

by the transmitted beamwidth changes. These factors may partially explain the disappointing second year results noted by Hembree and Harwood (1987) when their 'bead chain' was deployed diagonally within the net structure.

Clearly if a significant proportion of the intercepted acoustic energy is reflected back directly towards the source, independently of the approach angle, then the perceived echostrength will remain consistently high. However, most simple shapes, large enough to return specular reflections, involve flat reflecting facets which are highly orientation and wavelength sensitive and these will rarely be positioned to reflect echoes back directly towards the approaching animal.

Reflecting shapes which return the intercepted radiation back along a reciprocal bearing can be constructed, e.g. the radar 'diamond' commonly found on navigation buoys and small boats effectively increases the TS detected by a ship's radar. However, the acoustic equivalent of an idealised 'corner reflector' has several design parameters which need to be taken into account if the result is to be efficient.

Target Strength – directivity

The strength of echo returned by a target depends on several factors, the most important being the shape and size of the target, the material of its construction and the intensity of insonification and its angle of incidence. The smaller the target, the less the returned energy. However, as the target's size in cross-section becomes $<1\lambda$ of the incident sound, the echo strength returned decreases quickly (λ = the acoustic wavelength in the medium). Small gas bubbles can exhibit resonant peaks in some circumstances and may be an exception to this generalisation. Since λ for sound in seawater at the peak frequency of 120kHz is 12.5mm, this represents a minimum target dimension for *T. truncatus* below which the intercepted energy will be scattered rather than reflected.

The reflecting target's dimensions must be evaluated in terms of the wavelength (λ) of the incident acoustic wave (see description in Clay and Medwin, 1977; Urlick, 1983). As a simple guide, if the re-radiating target cross-section equates to a flat disk of single λ diameter, the reflected energy will be re-shaped as a spreading cone some 60° wide together with lower intensity side lobes (note that when the echoes are perceived by a monostatic sonar, this angle appears to be 30°!) For smaller target dimensions, the reflected energy is scattered over wider angles and tends towards an omnidirectional distribution. For larger apertures, the width of the reflected cone of sound will be progressively narrowed and hence more intense (for a 2λ diameter aperture the cone becomes 30° etc.) Conventional acoustic engineering utilises 'wave numbers' ($k=2\pi/\lambda$) to simplify the problems of estimating TS variation with size in a given medium. When the wave number defined by the surface dimensions (radius= a) and $ka>5$, then the object is assumed to reflect 'geometrically'. When $ka<5$, 'Rayleigh' scattering effects dominate. Diffraction effects result in a rippled amplitude response as the dimensions approach $ka=1$ and these less predictable sizes are normally to be avoided (Fig. 4).

The most predictable reflecting shape, which has frequency independent characteristics and a consistent TS independent of the incident angle, is a large sphere, but attempting to obtain large TS's by increasing size will rapidly lead to net deployment problems. However, some non-spherical target shapes can offer significant size advantages.

Cylinders of significant length (with a diameter where $ka > 1$) will only return strongly directional echoes towards the source if the incident wave approach angle is normal to the straight cylindrical surface. However, the energy is spread omnidirectionally in the other plane by the circular cross-section. To be effective this shape would require accurate vertical deployment within the net structure and even so, unless the animal approached horizontally, the perceived returns would be minimal.

Thin cylinders ($ka < 1$), i.e. ropes or bead chains, are much less effective, as the sub-wavelength cylindrical cross-section is a Rayleigh scatterer and the specular return due to the length insonified is sharply directional.

Flat disks deployed in the plane of the vertical net wall suffer the same disadvantage, in that the maximum return only occurs for incident signals normal to the surface. Although these reflections are relatively intense, in a practical deployment they cannot be assumed to occur towards the approaching animal (there is a special case where $ka = 1$ which, although inefficient, may be considered a useful economic option).

It should be clear from these examples that the angle of incidence to a reflecting surface is critical.

Acoustic impedance

The target material affects the percentage of energy reflected *versus* that transmitted. Most animal and fish tissues are relatively transparent to sound, and more incident energy passes through the target than is reflected. The best sound reflection will occur from materials with a ρc value very different to water, e.g. a gas bubble reflects incident energy well (ρc is an expression of acoustic impedance and is the product of ρ , the density and c , the sound velocity for the material.)

Synthetic net materials, especially the monofilament varieties, are relatively transparent to sound. Traditional net materials, twisted from natural fibres, tend to trap significant quantities of air which are retained for quite long periods of immersion and hence exhibit much higher TS's. Fish TS in the swim bladder species is dominated by the bladder gas bubble (Foote, 1985). For species without a swim bladder, the bone skeleton may reflect sound better than the flesh, but as the proportion of bone is small, the overall TS of such fish is significantly lower. Molluscs such as squid and octopus are predicted to have low TS's relative to body size.

Efficient sound reflecting materials must exhibit a significant mismatch in acoustic impedance when compared to water; both very dense materials and very low density materials can be good reflectors.

Dense materials such as rock or metal with high ρc values reflect echoes which are in-phase with the insonifying signal. In contrast, gas-filled objects (including foamed plastics) are classed as 'pressure release' and produce echoes characterised by a phase reversal between the incident sound and its echo, a perceptual detail that a dolphin may be capable of exploiting when classifying targets as potential food. Evidence that a dolphin can detect the difference between an initial 'rarefaction' and a 'compression' pulse is reported by Ridgway *et al.* (1981). The possibility that echoes from gas bubble filled objects could be perceived as 'food like' and therefore act as 'attractors' must be considered.

A further disadvantage of gas-filled objects is the difficulty of ensuring accurate shape retention with increasing water pressure. Thin-walled plastic tubes, balls

etc., all tend to collapse or deform badly with hydrostatic pressure and predictable reflection characteristics cannot be assumed.

Any material selected for deployment at sea must be examined for its longevity in saltwater corrosive conditions. Most metals are very susceptible to electrolytic corrosion and connections made with dissimilar conductive materials can result in very rapid dissolution.

Deployment – reflector distribution

The distribution pattern of any deployed reflectors must also be considered. It is desirable that the dolphin perceives the enhanced net as a continuous barrier rather than a series of minor obstructions. Experiments with spinner dolphins, using net crowding techniques, have shown that escape apertures less than 1m x 1m in size seriously deterred the animal from attempting to pass through (Perrin and Hunter, 1972). If this factor can be transposed to distributed point reflectors, then an equivalent distribution density of 1m⁻² provides a useful starting point for experimental evaluations.

The TS of reflectors must to be as high as possible in order that the barrier created can be perceived in the presence of fish targets. However, physical size, shape and total mass must be compatible with net handling. Specifically the shape chosen must pass through net handling gear without damaging the net to which it is attached. Similarly the attached device must be retained on the net efficiently without creating entanglement problems in storage. The total mass of the reflectors must not seriously alter the net buoyancy or behaviour when the net is set. The distributed pattern of reflectors must not impair the primary function of the net which is to catch fish. Finally, the extra cost of net modification must be seen to balance the significant down time losses currently incurred through net damage.

Preferred echo-enhancing shapes (Fig. 5)

One practical option is to create a disk reflector surface as a segment taken from a larger sphere i.e. a bi-convex lens shape. The surface curvature must be selected to return the echo into a suitably restricted range of approaching angles. The device must be mounted in the plane of the net and will then generate quite large TS's without excessive physical dimensions. This reflector will be least effective at grazing angles of approach to the net.

A corner reflector 'diamond' shape, with included 90° facets is probably the most efficient relatively simple shape. Almost all the incident energy is double reflected back into the approaching dolphin's path. However, the angular shape may be incompatible with net handling operations, although it could be deployed in fixed gear and in beach protection 'shark nets'.

Reshaping a sphere into a faceted polygon can offer some enhancement if the size is carefully optimised: if the facet size is small ($ka < 1$) there is no advantage, as the object behaves as a sphere of the same overall size; if very large, then the echo return pattern will possess deep nulls between peaks.

A cast metal 'icosahedron', with the faceted sides replaced with corner reflecting recesses, is an effective and compact target. However, in this context, the shape complexity may make mass production uneconomic.

A simpler shape with few of the perceived disadvantages of the previous examples, is the 'bi-conic' or 'diabolo'. This in effect is a cylindrical corner reflector constructed from two conical 90° sections mounted point to point.

Fig. 5. Strong echo forming target shapes which return significant energy directly back towards the source.

Reflections are returned towards the source by double reflection as from a line reflector, energy in the other plane being spread cylindrically. These shapes may be made compatible with net handling and a variety of mass production techniques appear possible and requires more detailed study.

An additional reflection mechanism offering a high TS for a given size is the 'focussing sphere' (Folds, 1971). This device comprises a thin wall spherical metal shell containing a high density liquid filling (SG 1.8 – 1.9) with a high sound propagating velocity. The sphere size and the liquid filling are selected to bring the incident (planar) wave front to a focus on the back wall of the sphere where total reflection occurs. The liquid lens then refocuses the returning echo back along the incident path. For a given size, this device can offer the strongest echo return towards the source, but the TS is frequency dependent. The concept of liquid filled spheres as net markers does not lend itself to practical deployment in a fishing industry context and in any case the liquid fillings, some based on CCl_4 , could involve handling problems.

Target dimensions

The dolphin 'click' signal comprises a relatively wide band transient pulse with a duration of less than 1ms. When this transmission is sampled on-axis, its energy spectrum is observed to peak near 120kHz, within a 10° (-3dB) beamwidth, (Au, 1980). If the signal is sampled outside this angle, the spectral peak is observed to fall as a direct result of the limited acoustic aperture of the melon. Measured at 60kHz, the projected beamwidth will be approximately 20° wide. Since an animal's acoustic sensitivity is best between 60 and 80kHz and still excellent at 120kHz (Johnson, 1966; Seeley *et al.*, 1966), it would seem a desirable compromise that echo-reflecting net markers should provide enhanced echo returns at all these frequencies.

Fig. 6 compares the computed maximum TS's predicted for a range of dimensions, with a 60kHz insonification, for some of the shapes discussed. These were based on formulae listed by Urick (1983) and from J. C. Cook (pers. comm).

For a nominal TS of -35dB at 60kHz, the computed size for each shape will be:

Sphere = 7.1cm diameter	($ka > 5$)
Corner reflector = 2.3cm sides (4.6cm dia.)	($ka > 2$)
Diabolo = 5.6cm diameter	($ka > 5$)

Clearly other target shapes can be considered, especially as the conventional design requirement of a constant TS with angle can be relaxed in this application. However, a successful net marking reflector must meet not only the acoustic but also mechanical and economic criteria to be acceptable to the fishing industry.

This above discussion has concentrated on passive reflectors with dimensions optimised for detection at the maximum foraging ranges searched by the smaller delphinoids. The concept is unlikely to be as effective for the larger echolocating animals as their echo-perception is assumed to exploit much lower spectral components. To be effective for these, the passive reflectors would need scaling in size but this is likely to exceed the mechanical limitations imposed by commercial net handling.

Fig. 6. Computed TS for a range of sizes, $a=1\text{cm}$ to 5cm at an insonifying frequency of 60kHz.

CONCLUSIONS

The sense most likely to perceive a fishing net obstacle is the dolphin's active sonar but this is only likely to be in operation when the animal is foraging for food. At other times, active sonar cannot be assumed to be a factor. If a dolphin is fishing and has already detected and locked its sonar repetition frequency onto the range of a target fish, then echoes from greater ranges are suppressed and perception of a fishing net prior to entanglement is unlikely unless the TS of the net is enhanced very significantly. Advance warnings from echoes generated by other dolphins in close proximity are unlikely to provide any interpretable information about the obstacle's presence.

Increasing the gillnet TS by the addition of wires, ropes or thin 'bead chain' will be ineffective if these devices are intercepted at incident angles other than normal. True vertical deployment of these acoustically 'thin cylinders' is essential if the technique is to be of benefit. Enhanced echo reflector shapes can be designed to return strong specular echoes directly towards the approaching animal and such devices are more likely to be perceived independently of the azimuth/elevation angles of approach. The distribution of reflecting devices along the net may need to approach a 1m² pitch spacing if the echo structure is to be classified as an impassable barrier by the animal.

In order that an animal can perceive the net position before locating a fish, the gillnet TS needs to be increased to be at least as detectable as the maximum size fish prey normally taken. The stomach contents of autopsied bycatch victims should be examined in an attempt to obtain this information for all vulnerable animal groups.

If the reflecting surface of the TS enhancer is manufactured from a pressure release material, single surface reflections may be perceived as 'food-like' and could act as attractants. The same effect may occur with time as the captured target species accumulate in the net. The mass, buoyancy and shape of the added reflectors need considering carefully as these parameters will affect the deployed behaviour of the gillnet and its handling during deployment and recovery.

The passive reflector target shapes which seem worthy of practical evaluation should include the 'diabolo', 'diamond' corner reflector and derivatives of these. In practice, however, any design which demonstrates a measurable reduction in cetacean bycatch must also satisfy additional mechanical and economic parameters imposed by the commercial gillnet fishery if it is to be accepted without legislation.

Additional economic and ecological incentives in favour of significantly increasing the fishing net TS can be found in the context of lost netting. Lost fishing gear, particularly bottom set nets, continue to fish for long periods as 'ghost' nets, the recovery of such gear is likely to be simplified if the nets can be more easily located by a ship's echosounder.

Goodson *et al.* (1994) describe how the principles described in this paper were put into practice in the development of a prototype modified net and in initial field trials.

ACKNOWLEDGEMENTS

ABSTRACT

Field trials to examine the behaviour of wild bottlenose dolphins in the presence of passive acoustic deterrents supported in a surface set gillnet configuration were carried out in September 1991 and 1992 in the Moray Firth, Scotland. Leading animals were tracked using electronic theodolites as they interacted with these barriers which were placed across their regular travel paths. Underwater acoustic behaviour was recorded from hydrophones via radio telemetry. Avoidance behaviour was consistently initiated at ranges greater than 50m and occasionally greater than this. On only two occasions behaviour that might have resulted in entanglement was observed. In addition a sea trial using commercial tuna gillnet gear was undertaken in which a sidescan sonar was used to evaluate the acoustic detectability of both modified and unmodified components. The potential of passive acoustic deterrents for the reduction of cetacean bycatches in commercial fisheries is discussed.

KEYWORDS: INCIDENTAL CAPTURE; FISHERIES; NORTH ATLANTIC; BOTTLENOSE DOLPHIN; ACOUSTICS

INTRODUCTION

The problem of incidental catches of marine mammals (and indeed other non-target species) in fishing gear is well known (IWC, 1994). As discussed in Goodson *et al.* (1994), one approach to the problem has been to investigate ways of making nets more apparent to the animals. Although a number of attempts to increase the acoustic detectability of fishing nets have been made, the methods employed have been largely ineffective in achieving a reduction in cetacean bycatch (see review by Dawson, 1991). In general, the techniques employed did not consider the wavelength-dependent resolving power of dolphin sonar signals, the directivity of the reflectors or the behaviour-related restrictions imposed by the animal. Furthermore, the problem is now seen to include target classification, i.e. it is not simply a problem of detection (Au and Jones, 1991; Au, 1994). In other words, it may be difficult for dolphins to interpret weak diffused echoes from nets as a life-threatening hazard, when experience has taught them that similar volume scattered echoes, returned by algae or by entrained air bubbles, are penetrable zones to be ignored, especially when a discrete fish target can be detected on the far side (Goodson, 1992; 1993).

As described in Goodson *et al.* (1994), our approach differs significantly from these earlier attempts in that we seek to enhance the detectability of the fishing net under all conditions to a level at least equivalent to that of the larger prey sought by the foraging animal. This objective cannot be achieved by simply altering the dimensions, material or other base characteristics of the gillnet mesh, as the reflectance of the webbing structure is primarily limited by its geometry (assessed in wavelength terms). Even if the

webbing were to be constructed from a perfectly reflecting fibre material, the overall Target Strength (TS) enhancement that could be achieved is unlikely to exceed 10dB above that of unmodified monofilament nylon. Goodson *et al.* (1994) estimated that enhancements greater than 25dB may well be required. To achieve such improvements, the devices added need to be efficient acoustic reflectors returning echoes directly back towards the source (analogous to 'cat's eyes' road markers which reflect car headlights back to the driver). Some limitations of dolphin sonar in the context of net-like targets and parameters to be considered when attempting to apply acoustic engineering techniques to the design of efficient passive acoustic reflectors have been discussed elsewhere (Goodson, 1990; Goodson *et al.*, 1991; 1994; Goodson and Datta, 1992).

Whilst an efficient reflector design must be optimised to suit the characteristics of the individual odontocete sonar, a consideration of the wavelengths involved suggests that a common solution for the delphinid species similar to the bottlenose dolphin (*Tursiops truncatus*) and for the smaller phocoenids seems to be practical. In summary then, to at least have the possibility of success in addressing the bycatch problem, the following acoustic characteristics would be required of a sonar reflector:

- (1) echoes from the approaching animal's sonar must be reflected directly back towards the animal, regardless of its approach direction in either azimuth or elevation;
- (2) the device must be large enough (in acoustic terms) to intercept and return a specular echo with sufficient energy to become a more detectable target than the

- largest fish normally foraged for – the individual devices should be detectable at the maximum search range of the animal;
- (3) the reflecting devices must not generate echoes which can be incorrectly classified as 'food-like' or the devices may function as attractors;
 - (4) the distribution of the devices across the face of the net must be perceived (at close range) as an impenetrable barrier.

These minimum parameters have been quantified, largely through detailed studies of wild bottlenose dolphin foraging behaviour, and several physically small prototype reflectors have been engineered which appear to meet these requirements (Goodson *et al.*, 1994). For a bottlenose dolphin foraging in relatively shallow water, a reflector with a TS of approximately -35dB (reference a 2m radius sphere) appears to be optimum.

This approach has been used to identify a commercially available device which possesses acoustic and mechanical characteristics that meet many, but not all, of the parameters needed by an optimised reflector. The present paper describes a series of experiments that have been devised in which the distribution of these devices, supported within a simulated surface gillnet configuration, could be closely studied in interactions with wild bottlenose dolphins. These experiments are similar in concept to those described by Silber (1994). However, our approach also includes the monitoring of cetacean echolocation signals underwater in the vicinity of the barriers, video recordings and a high order of achievable precision in the electronic theodolite tracking technology (Mayo and Twigg, 1993). The preliminary results presented here confirm that the devices tested function effectively to deter echolocating bottlenosed dolphins at ranges in excess of 50m and occasionally from as far away as 170m. These initial experiments allow interaction data to be obtained at a faster rate than can be achieved in a commercial fishery and without placing the animals at risk of entanglement. At this stage the experiments were not designed as statistical tests of efficiency but were rather qualitative studies to determine the value of continuing the current line of research.

The practical problems that fishing nets modified with this reflector technique may cause to commercial fishermen have also been examined in a short sea trial off Cornwall, in which an experimental net was shot and hauled and examined with a side scan sonar for its acoustic detectability.

MATERIALS AND METHODS

Wild dolphin interaction trials held in the Moray Firth

The site chosen for the first field test carried out in September 1991 was the Moray Firth, NE Scotland. This was chosen for a number of reasons. The bottlenose dolphins in the area are already being studied and a catalogue of approximately 150 photo-identified individuals has been compiled (Wilson *et al.*, 1992). Although not used in the trials described here, the potential to identify individual animals may be important for future work. Animals are regularly sighted within 200–600m of shore near the entrance to the Cromarty Firth, where there is good visibility from adjacent 50m cliffs and the seabed in the zone of interest is flat (hard sand) with a minimum water depth of 7m. A larger scale experiment was carried out in the same area in September 1992.

Equipment and procedures

As shown in Figs 1 and 2, in 1991 a single barrier, consisting of a buoyant head-rope from which thin rope tails were attached, was deployed perpendicular to the shore, across the predicted path of the dolphins. The acoustic reflectors were attached at 2m intervals to the rope tails, which were spaced 2m apart. The head-rope was 200m long, half unchanged and half supporting a grid of reflectors, comprising an obstruction 100m x 7m deep.

In September 1992, a larger scale experiment was carried out using two 200m long barriers of reflectors distributed on a 2m x 2m spacing. On the last two days of the two week study concluded with one barrier reconfigured with a reduced numbers of reflectors (6m x 2m spacing).

Details of the differences between the 1991 and 1992 trials are illustrated in Fig. 1 and Table 1.

A detailed list of equipment for both years is given in Table 1. The experiment extended that described by Silber (1994), with the dolphins being tracked by their surfacing positions using an electronic theodolite (with data logger), and underwater acoustic activity monitored with sonobuoys. The theodolite employed was also capable of working as a distance measuring device and in this mode the instrument could be used to accurately measure its own height above sea level. Subsequent measurement of horizontal and vertical angles enabled the Northings and Eastings of each surfacing position and of the head rope barrier, to be calculated and plotted. The precise times of these readings were also recorded. As only one theodolite of this type was available it was usually not possible to track more than the leading animal(s) from each passing main group, even when several distinct sub-groups were present. To back up the theodolite readings, two video cameras and voice-logging recorders were used. The underwater sounds, received from the sonobuoy hydrophone by radio telemetry, were recorded on a four-track instrumentation machine, together with timecode and a voice log. A second receiver simultaneously fed the telemetry to an R-DAT digital recorder. In general, observations could be maintained only between dawn and dusk, as the team was too small to provide full 24-hour cover.

Initial handling trials at sea

A short sea trial took place in Cornwall in June 1992, where both modified and unmodified panels of gillnet were shot and hauled in order to evaluate handling problems. Additionally the acoustic detectability of echo-enhanced net panels was compared with equivalent un-modified sections at different ranges and angles using a 100kHz sidescan sonar.

Equipment and procedure

A short sea trial to discover any practical problems associated with using modified nets was arranged with the support of the Sea Fish Industry Authority on board a UK gillnet fishing vessel, the 15.25m (overall length) *Britannia V* (FH 121). A test net, based on a commercial tuna net, was prepared (Table 2, Fig. 3). The reflectors had been prepared, by a commercial twine manufacturer, within a mixed fibre flat braid. This technique was chosen with a view to ease of handling and reducing the likelihood of 'buttoning', which would cause adjacent layers of netting to catch together. Braiding also avoids the torque effects that occur in a conventional rope when under tension.

Mesh
Twine size: 210/18 (420 tex) ¹ red nylon multifilament
Mesh size: 168mm stretched (6.625 inches)
Panel
Mesh long: 588
Mesh deep: 125.5
Stretched panel length: 100m
Rigging
Ranging ratio (E) 0.55
Staple settings: 2 full meshes onto the staple length
Staple length: 197mm (7.375 inches)
Set depth: 17.8m
Set length: 55m
Flotation: one polyurethane 350g buoyant float every 1.1m (44 inches)
Leadline: No. 4 reinforced, runnage 11kg/100m
Prototype Acoustic Reflectors
Target strength: nominal -35dB (ref. 2m radius sphere) rigged in a 2 x 3m grid across the face of the net
Reflectors: plastic, elliptical, air-filled, 20g weight in air, 20g lift in seawater (nominal); length 67mm, maximum diameter 33.5mm, axial hole 10mm internal diameter
Attachment sheath; braided polyethylene/polypropylene/worsted twine composition; runnage 35.3g/m
Reflector vertical spacings (from headrope downwards): 3m, 6m, 9m, 12m, 15m
Reflector string horizontal spacings: every 2m along the net.

¹ 210/18 is a Denier notation for twines.

The prototype devices employed (small ellipsoid shaped pressure release reflectors) were applied to two of four panels of an experimental 240m long 'tuna' drift net and were distributed in a 2 x 3m grid pattern across the face of the net (see below). The study included the use of a *Waverley 3000* towed sidescan sonar to examine the effectiveness of the modified net as an acoustic barrier. The sidescan sonar equipment operated at 100kHz, i.e. with a wavelength λ of 15mm in seawater. At this frequency the sonar has a broadly similar resolution to that of the bottlenose dolphin. The animal's resolution is limited by the highest frequency response in its audiogram, i.e. for the bottlenose dolphin around 120kHz to 130kHz, (Johnson, 1966) and by the presence of these frequencies as spectral components within its sonar transmissions, (Au, 1980). The sidescan sonar operated at a Source Level of 227dB reference 1 μ Pa which is very close to the maximum reported for a bottlenose dolphin (Au, 1980). However, it is important to appreciate that the dolphin's sonar functions as a forward looking (10°) spotlight system whereas the sidescan generates two very narrow vertical 'fan' beams ($1.5^\circ \times 50^\circ$) which are projected at 90° to each side of its track. The sidescan image is built up on a paper record from successive transmissions as the tow fish, several metres below the surface, follows its parent vessel's course (Fig. 4).

Fig. 3 illustrates the net configuration employed in the gillnet trial. The first pair of 55m long panels were modified with a grid of acoustic reflectors spaced apart 2m horizontally and 3m vertically. A 10m wide gap was deliberately inserted as a potential 'passing place' between these. The remaining pair of panels were also separated by a 10m gap and the two 120m sections butted together. The reflectors in braided tubes formed vertical 'strings' attached to both headline and leadline. The complete net assembly, with marker dahn buoys attached by short bridle ropes to each end, was shot in very calm conditions in 50m water depth where it drifted throughout the period of study. The sidescan sonar was deployed 50m behind the vessel and a series of runs made with the tow-fish deployed between 15 and 20m depth at different ranges and angles to the experimental net.

RESULTS

Moray Firth

September 1991

Control sightings and recordings, made before the barrier was deployed (e.g. Fig. 5), confirmed that dolphins passing in small groups, and in loose associations of up to about 30 animals, did swim parallel to the cliff, in both directions, at a predictable distance offshore ($2\frac{1}{2}$ days of observation, an average of about 30 animals per day). The presence of a moored sonobuoy close to this track line had no discernible effect of the passing animals' behaviour (which was usually travelling). As the barrier was first deployed on the afternoon of 27 September, a group of dolphins approached. There was considerable acoustic activity and all the animals diverted to avoid the barrier, taking an inshore passage very close to the edge of the kelp (Fig. 6). Late the following morning the inshore anchor of the barrier dragged, but for the first afternoon and most of the next morning animals were observed passing, in both directions, between the inner end of the barrier and the shore in a narrow zone of very shallow water. After some difficulty in obtaining stable moorings closer to shore, the barrier was finally repositioned during the morning of 29 September to obstruct the inshore passage.

Fig. 4. Diagram of sidescan sonar examining net.

Fig. 5. The passage of the leading animal (direction shown by arrow, surfacings by triangles, the line represents minimum distance between surfacings) of a group of five bottlenose dolphins (including one accompanied by a calf) before deployment of the headline barrier. Deployment of the sonobuoy is clearly not associated with any deviation in the line of travel. The solid dots show the positions of buoys marking crab pots.

Fig. 6. The passage of the leading animal of a group of 8-10 (including 2 juveniles) after deployment of the headline barrier; Squares indicate surfacings. Although the initial approach is exactly on the line shown in Fig. 5, there is a clear deviation inshore to avoid the barrier.

Fig. 7. The passage of a pair of animals leading the first sub-group of the second main group on 30 September 1992, after final deployment of the headline barrier closer inshore. (For further explanation, see Fig. 5. Surfacing positions shown here by crosses.)

Fig. 8. Passage of a single animal, a trailing member of the second main group on 30 September 1992, first sighted 55 m from the headline barrier. Note that in this figure the arrow only indicates the general travel direction. (See text, Fig. 5, Fig. 9 and Table 3 for further explanation.)

Fig. 9. Time between surfacings of the animal from Fig. 8. Surfacing positions, minimum calculated speeds and times between surfacings are tabulated in Table 3.

In the early afternoon of the final working day (30 September), two distinct main groups of about 30 animals, each with several sub-groups, were observed sequentially passing the outer end of the barrier over about an hour. The track of a pair of animals leading the first sub-group of the second main group is shown in Fig. 7. After tracking this pair through the test zone and while other sub-groups were still passing, a single animal was seen to surface some 55m from the centre of the barrier. The subsequent track of this animal is plotted in Figs 8 and 9. It retreated, initially at a speed of about 3–4ms⁻¹, to a distance of 170m. This apparent retreat from the barrier was interrupted several times, with the animal backtracking briefly while swimming at much slower speed (Table 3). It finally altered course to join the track of the rest of the group and, closely following this, swam past the outer end of the barrier. Then, as had been observed for the previous passing groups, the single animal appeared to investigate the back of the barrier before leaving the area, continuing along the usual line of passage. The similarity between these two main tracks can be seen by comparing Figs 7 and 8. It has not been possible to establish from the photographic evidence whether the same or different animals passed during the days of the experiment. It is possible that some individual identification information may be obtained from analysis of ‘signature’ whistles. However, from the experience of the photoidentification team (Wilson, pers. comm.), it seems likely that the groups were different.

Subsequent analysis of the recorded underwater sounds demonstrated no obvious echolocation activity which can be assigned to the approaching single dolphin until seven seconds before the first surface plot made as it retreated.

At that time a burst of clicks at a repetition rate indicative of target detection at 20m range is apparent. Slow motion replay of the video record shows that at the first surfacing position the animal is swimming rapidly away from the barrier. This is the single recorded close approach to the barrier made during the study period, although a large number of animals (50 or more during daylight hours) passed the site each day.

September 1992

Pre-trial observations were carried out for several days prior to barrier deployment but poor weather resulted in few dolphins being seen (less than two per day on average). For the seven days the barrier was in place, on a typical day, two large (12–20 animals) groups and several smaller groups (<6 animals) would be seen. As in 1991, the reflectors appeared to be detectable to the dolphins at ranges in excess of 50m and were consistently avoided (Fig. 10). Figs 11 and 12 demonstrate composites of tracks taken by the lead animals and by close knit groups. The avoidance behaviour is clear. It is worth noting that a single animal was observed and tracked as it 'crashed' the barrier at slack water whilst apparently travelling on an intercept course towards a group which had safely passed around the end of the barrier a few minutes before – the animal in question was not echolocating and emerged from the barrier at high speed (6 ms^{-1}). The risk of entanglement therefore appears to remain high for a few non-echolocating 'stragglers' especially when these appear to be travelling in a low state of alertness. For the last two days of this trial the outer barrier had two out of three reflector string supports removed and the low density 6m x 2m distribution that resulted continued to generate avoidance behaviour although it seemed that detection/avoidance behaviours around this modified structure were initiated at shorter ranges. This spacing factor was examined in more detail in the 1993 trial (see Goodson and Mayo, *In press*).

Handling trials

Irrespective of their success or otherwise in reducing incidental catches of marine mammals in gear, the application of acoustic devices to commercial fishing nets may create practical problems for fishermen e.g.

- (1) the increase in the volume of the modified net may overfill a standard net storage bin;
- (2) the handling of the net during deployment, recovery and during transfer between net pounds on board ship may be impaired;
- (3) the change in buoyancy caused by the reflectors may affect the deployment of the net in the water.

In fact during the field trials, the method of attachment of the reflectors functioned reasonably well during shooting and recovery although a potential for snagging may exist. The braided tubing was chosen to support the reflectors as this does not twist under tension and was intended to smoothly guide the devices while shooting to reducing the likelihood of the reflectors catching into adjacent net layers. However, the wetted braid tube trapped air bubbles which were slow to disperse and the consequent additional buoyancy hindered the net from quickly achieving its correct fishing geometry. The presence of trapped air in the braided tubes also appeared to temporarily enhance the acoustic TS. The most significant handling problems occurred while transferring the wet net after recovery

between the net storage 'pounds' preparatory to re-shooting the net. Some improvement in the attachment method will be necessary before this technique can be applied in a large scale commercial test but the mounting problem can be reduced with a minor design change incorporated in the device moulding.

Fig. 10. Detection and avoidance behaviour, 1992 (see text).

Fig. 11. Composite 1992 tracks – Ebb tide.

Sidescan sonar images

The (unusually) flat calm trial conditions were favourable for the sonar study and in these conditions the side scan images revealed considerable detail. The sonar images all clearly resolved the acoustically modified panels even though one of these panels remained incorrectly deployed (folded) for much of the study period. Fig. 13 shows a typical sidescan sonar image and the annotations indicate a number of interesting features.

Fig. 12. Composite 1992 tracks – Flood tide.

The headline was the most detectable component in these very calm test conditions. However, in rougher seas, wave troughs will form which will mask the headline and its echoes from a horizontal (dolphin) sonar operating near the surface.

When viewed at 30m range, i.e. by a sonar towed parallel to the net, the echo component of the leadline/footrope is easily detected. However, the leadline constitutes a long 'thin cylinder' target structure and this strong echo (produced by the ensonified length dimension) is very directional. At all other angles, the detectability of the leadline component falls rapidly as the reflections are then directed elsewhere!

Very fine bubbles, created by the vessel's propeller, are driven several metres deep producing an acoustically opaque cloud which persists for quite long periods. An identical effect spread throughout the water column occurs when high sea states start to entrain air at the breaking wave crests. Such an acoustic 'fog' can severely impair the detection range of a small odontocete's sonar.

The reflector enhanced panels generate very detectable echoes and in-fill the vertical plane of the net between headline and leadline. By contrast the unmodified net

segments appear completely transparent, even at short range, with no detectable echoes returning from this 18m deep net curtain.

The 10m wide passing places (net 'ends') are defined by the 4mm polypropylene vertical cords.

DISCUSSION

Moray Firth trials

The tracks reconstructed seem to indicate that whilst most animals approaching on a potential collision course detected the barrier and changed course at ranges greater than 50m, a few leading animals became aware of the barrier position at a maximum range of 150 to 170m – a much greater range than predicted. Two factors may help to explain this.

(1) The dolphins were approaching in a direction normal to the plane of the barrier. At a range of 170m a 10° beamwidth will excite nearly simultaneous echoes from the reflectors spread along approximately 30m of the barrier, which effectively increases the TS. This would not be the case if the animals approached from a more oblique angle, as the multiple echoes then arrive sequentially.

(2) The quiet sea (Sea State 2 or less) provided excellent acoustic conditions and the flat sandy seabed contributed little confusing reverberation.

The single animal discussed for 1991 may have been travelling in a low-awareness or resting state. Whether its behaviour was triggered by the acoustic activity of other animals beyond the barrier, or by one of the random loud clicks that have been occasionally noted from other resting animals, has not yet been established. However, if a real gillnet without reflectors had been in the position of the test barrier, this individual seems a likely candidate for entanglement. The single animal that 'crashed' the barrier in 1992 would either have become entangled or broken through the net. Supplementary methods of attracting such animals' attention would still be needed if mortalities are to approach zero, even if the overall approach ultimately proves successful.

One potential problem we had anticipated was that as the simple ellipsoid (air filled) reflectors under test produce 'soft' pressure release echoes, they might have appeared food-like and attracted dolphins. No such attraction phenomena was observed in either year and it is clear that the animals were able to classify these target echoes as 'alien' and took early avoiding action.

Fig. 13. Sidescan sonar images of the acoustic enhanced net (left) and the unmodified net (right). A=headline, B=leadline/footrope, C=aeration, D=enhanced panels, E=unmodified panels and G=gaps.

We recognise that the data obtained in these first field tests have limitations. Clearly the sample size is as yet rather small. In both years, at least one animal may have become entangled had 'real' modified nets been used. The concept of a 'control' needs refining and improved experimental design is required if one is to be able to prove that the observed 'capture' rate with a modified net is significantly lower than one would have expected from an unmodified net. Similarly, the behaviour of the animals was generally 'travelling' rather than 'foraging', which may also affect capture rates. Further trials are needed to investigate these aspects. In addition of course, particular problems (e.g. with respect to species and area) may require particular solutions: no single method is likely to solve every bycatch problem. Eventually, the only true test is application in a real fishery.

However, having said this, these were intended to be preliminary studies and the results appear promising and exceeded our expectations. Although the protocol employed needs further refinement, it is clear that the technique generates detailed interaction data at rates far faster than in conventional fishery monitoring and without any risk to animals.

Sea handling trials

The sonar images obtained, typified in the examples given in Fig. 13, demonstrate that the difference in acoustic detectability between the modified and un-modified panels is very marked and that the reflector modification effectively infills the 18m deep 'gap' between the headline and leadline.

It should also be noted that an approaching dolphin can only resolve small objects within the 10° wide 'spotlit' zone directly ahead of its path. During its approach it cannot acquire a comprehensive picture of the whole structure, as provided by these sidescan images, each of which took several minutes to scan at this resolution. At any instant the dolphin can only resolve targets that are contained in range by the time interval between its 'clicks' and in angle by the very narrow ensonified cone (beam) projected ahead. Only the highest frequency part of the dolphin's transmission spectrum (the very short wavelength signal components) are capable of resolving the acoustic dimensions of the larger supporting component parts of a fishing net and in most sea state conditions and from most approach directions even these may be missed.

CONCLUSIONS

The trials in the Moray Firth during 1991 and 1992 have demonstrated that the passive acoustic marking technique has the potential to deter small echolocating odontocetes from passive gillnets. The test on a Cornish commercial fishing boat demonstrated that when the devices are attached to a fishing net they function to effectively infill the relatively transparent zone between headline and leadline. The mechanical method of attachment to the nets needs improvement and alternative more efficient reflector designs will need to incorporate a safe/simple method of fastening them directly to the net mesh. For evaluation at sea, especially in an offshore fishery, accurate underwater tracking techniques are required (Woodward *et al.*, 1993) in order to localise positions and plot the underwater tracks of approaching cetaceans in relation to the fishing net.

Behaviour changes induced by potential deterrent modifications need rapid evaluation (in relatively small scale comparative tests) if the current reliance on gross 'body count' bycatch statistics is to be avoided in the short term.

ACKNOWLEDGEMENTS

The support of the Commission of the European Communities through the Eurogroup for Animal Welfare, the Conservation Foundation, the Co-operative Wholesale Society, Racal Group Services and Racal Recorders Ltd., Sokkia (UK) Ltd. and of visitors to the UK dolphin centres at Windsor Safari Park and Flamingo Land, is gratefully acknowledged. We also thank our team colleagues and especially the large number of volunteers whose assistance made the intensive field studies possible. We particularly appreciate the co-operation of Ben Wilson and colleagues at the University of Aberdeen Field Station in Cromarty (including use of their survey boat *Tursiops*), Billy Frazer and the staff of Dolphin Ecosse, as well as the help and support of many other local people in Cromarty and the surrounding area. The support of the sea trial by the Sea Fish Industry Authority, Leach and Turner Fishing Gear, and by the master and crew of the MFV *Britannia V*, as well as the help and advice of Julian Swarbrick and the loan of the sidescan sonar equipment by the Defence Research Agency (Bingleaves). The supply of Life-Ex sonobuoys by RAF Kinloss is also acknowledged with many thanks.

Developments on Issues Relating to the Incidental Catches of Cetaceans Since 1992 and the UNCED Conference

G.P. Donovan

International Whaling Commission, The Red House, 135 Station Road, Cambridge, CB4 4NP

ABSTRACT

Developments on issues relating to cetaceans and gillnets since 1992 are summarised. The most significant is the successful ban on pelagic driftnetting. Incidental catches by European Union vessels using driftnets are discussed. More effective enforcement of the EU ban on nets over 2.5km is required in both the eastern North Atlantic and the Mediterranean. The situation in the Mediterranean is serious and warrants immediate action. Some progress has been made in addressing issues related to the harbour porpoises in the North Atlantic. The situation of the vaquita remains extremely serious. New information on bycatch levels and/or new fisheries where cetacean bycatches have been identified is summarised. In general, the situation remains much as it did in 1992 – in almost no fishery can the impact of bycatches be assessed. Ways in which this may be remedied are discussed. In particular, the need to provide financial and practical support to developing countries is stressed.

KEYWORDS: INCIDENTAL CAPTURE; SMALL CETACEANS-GENERAL; LARGE WHALES-GENERAL; REVIEW; HARBOUR PORPOISE; VAQUITA; STRIPED DOLPHIN; MEDITERRANEAN; NORTH ATLANTIC; SOUTH PACIFIC; SOUTH ATLANTIC; NORTH PACIFIC; FISHERIES.

INTRODUCTION

The two Reports included at the beginning of this volume were accepted by the member governments of the International Whaling Commission (IWC) and submitted as part of the IWC's contribution to the United Nations Conference on Environment and Development held in Rio de Janeiro in 1992. The purpose of this short paper is to summarise developments concerning the issue of cetaceans and gillnets since those reports were written. Much of the information here is taken from the papers published in this volume.

PELAGIC DRIFTNET FISHING

Perhaps the most significant progress since the Workshop concerns high seas driftnet fishing, which was identified as a serious threat to cetaceans (e.g. Hobbs and Jones, 1993; IWC, 1994c). In 1990, the IWC endorsed Resolution 44/225 of the UN General Assembly, which among other things called for a review of the best available scientific data on the impact of large-scale pelagic fishing, noting the contribution that the Scientific Committee Workshop would make to this review (IWC, 1991a). Partly as a result of the Workshop, the UN adopted Resolution 46/215 on 20 December 1991. The active parts of this Resolution called for nations to ensure that:

- (1) pelagic driftnet fishing effort should be reduced by half by 30 June 1992;
- (2) driftnet fisheries should not expand into new areas;
- (3) a moratorium on pelagic driftnet fishing should be implemented by 31 December 1992.

As reported by Nagao (1994), Japan ceased driftnet fishing in summer 1990 for all areas outside the Pacific and on 1 January 1993 for the Pacific. This was accompanied by enforcement and compensation measures. The Republic of Korea suspended such fishing from 30 November 1992 and China, Taiwan ordered vessels to surrender their driftnets by 1 January 1993. Both countries encouraged compliance with the ban by assisting with refitting fishing vessels as well as using patrol vessels to enforce it.

Despite occasional breaches (3 Chinese vessels were prosecuted by the Chinese authorities and one Honduran flagged vessel was seen but not apprehended), the moratorium appears to be holding (Anon., 1994).

DRIFTNET FISHING BY COUNTRIES OF THE EUROPEAN UNION (EU)

Eastern North Atlantic

In accordance with the UN Resolutions noted above, the EU adopted measures to phase out pelagic driftnetting. Initially, it was intended to limit driftnets to a maximum of 2.5km both within and outside EU waters but a request from France resulted in the eastern North Atlantic French albacore fishery being allowed to use nets of up to 5km in length until 31 December 1993, subject to the results of a scientific evaluation of the ecological impact of the fishery.

Although French vessels dominate this fishery (46 vessels in 1992 and 64 in 1993 – Goujon *et al.*, 1993), Irish vessels (about 5 in 1991 and 1992, about 18 in 1993 and 1994 – S. Berrow, pers. comm.) and British vessels (6 in 1993) also operate in the same area.

In response to the EU decision, France carried out a study to examine the impact of the tuna fishery on common dolphins, *Delphinus delphis* and striped dolphins, *Stenella coeruleoalba* (Goujon *et al.*, 1993). In the area surveyed, Goujon *et al.* estimated an annual fishing mortality of around 0.7% for common dolphins and 1.6% for striped dolphins.

Irish vessels carried observers to monitor the fishery in 1991 and 1993, and the Irish South and West Fishermen's Organisation has funded a pilot study to examine the ecological risk in the tuna fishery; preliminary analyses suggest that the Irish fishery has a much lower catch rate per km than the French (Berrow, pers. comm.).

The results of the French study are difficult to interpret, particularly for the striped dolphins. Whether the populations are thought to be able to sustain incidental catch levels depends on what assumptions are made about dolphin population dynamics (see below), the geographical range of the population and, in particular in this case, the vital rates of striped dolphins (Goujon *et al.*,

1993). The EU has decided not to renew the French exemption and now no EU registered vessel may carry more than 2.5km of gillnet (Article 9a, No. L42/18).

This regulation has led to a number of claims and counter claims about vessels from various EU countries using illegal nets in 1994. It is clear that monitoring and enforcement methods require strengthening.

Mediterranean

Despite the controversy over 'illegal' use of driftnets in the eastern North Atlantic, it is the situation in the Mediterranean that gives greater cause for concern.

Large numbers of cetaceans are known to be taken in driftnet fisheries in the Mediterranean, particularly in the fishery for swordfish and albacore. IWC (1994c) commended Italy for banning this fishery from 30 July 1990 and encouraged other Mediterranean states to do the same. However, since then the situation has become complex and confusing, with a number of 'relaxations' and 'rebannings' by both the Government and Administration Courts (Aguilar and Silvani, 1994; Di Natale and Notarbartolo-di-Sciara, 1994). It should be remembered that irrespective of national legislation, EU states should not be using nets >2.5km but nets of 10–12km are still being used. In fact the situation in the Mediterranean may even be worse now than in 1990; over 800 vessels from Italy (600+) and Morocco (200+) in particular are still operating. Although no good estimates of bycatches exist, prior to 1990 the Italian bycatch alone was thought to number several thousand animals (Di Natale and Notarbartolo-di-Sciara, 1994). In view of this, the Scientific Committee has again repeated its concern about the situation in the Mediterranean, particularly for the striped dolphin (IWC, 1995).

It is clear that immediate action is required. A first step would be for EU countries to ensure that EU regulations are met. In addition, the Action Plan for Cetaceans established by the 1991 meeting of the Barcelona Convention should be enacted as soon as possible (Di Natale and Notarbartolo-di-Sciara, 1994).

INCIDENTAL CATCHES OF HARBOUR PORPOISES

The harbour porpoise (*Phocoena phocoena*) appears to be one of the most vulnerable species to capture in fishing nets (IWC, 1994c). Indeed, phocoenids in general are often caught (e.g. Corcuera, 1994; Goodall *et al.*, 1994; Lal Mohan, 1994; Jefferson and Curry, 1994; Van Waerebeek and Reyes, 1994a; c) and, as discussed below, the vaquita, *Phocoena sinus*, is probably the world's most endangered cetacean (e.g. Vidal, 1995). There is some speculation that this vulnerability may partly reflect the nature of their echolocatory abilities when compared to delphinids (e.g. IWC, 1994c).

The Scientific Committee drew attention to catches of harbour porpoises on both sides of the North Atlantic at the Workshop and the UNCED review. Since then it has emerged that, for some countries, much larger catches occur than envisioned in 1990 (e.g. Denmark, see Lowry and Teilmann, 1994). Although some nations have increased their efforts to try and estimate bycatch levels in North Atlantic fisheries (e.g. see Berrow *et al.*, 1994; Lowry and Teilmann, 1994; Read, 1994), even where there are schemes, they are inadequate. Few reliable estimates derived from scientifically designed observer programmes exist, despite resolutions accepted by consensus in the IWC (e.g. 1994a) that such work should be given high priority.

There are however, some positive signs that Governments are beginning to recognise that the harbour porpoise/fishing gear problem must be addressed.

In the western North Atlantic, recent information on the harbour porpoise bycatch problem was considered at a Workshop to assess the status of harbour porpoises in those waters (Palka, 1994). Only for the US Gulf of Maine are bycatch estimates and population estimates available (Read, 1994). A series of recommendations for action and research based on the Workshop Report are given in IWC (1995). Recent US legislation requires that annual incidental catches of harbour porpoises must be significantly reduced to 1% or less of the estimated population size in the near future and a workshop to assess the potential of gear modifications to reduce bycatches in the sink gillnet fishery was held in September 1994 (Frady *et al.*, 1994).

In July 1994, a multi-national survey of the North Sea and adjacent waters was undertaken, although the results are not yet available (Anon., 1994). This should provide a useful baseline for any evaluation of the impact of incidental captures on harbour porpoises in the region, particularly the Celtic Shelf (Berrow *et al.*, 1994) and the central North Sea (Lowry and Teilmann, 1994).

In September 1994, the first meeting of ASCOBANS (Agreement on the Conservation of Small Cetaceans of the Baltic and North Seas) took place (ASCOBANS, 1994). The range states agreed to a Resolution that defined a conservation and management plan for the region, including the reduction of direct and indirect interactions with fisheries (estimation of reliable bycatch numbers and research on gear and fishing method modifications are part of this).

VAQUITAS IN THE GULF OF CALIFORNIA

The vaquita has the smallest range of any marine cetacean, being restricted to the Upper Gulf of California (Vidal, 1995), and probably numbers only a few hundred animals (Gerrodette *et al.*, 1995). Despite a number of attempts to protect these animals from incidental catches, mainly in an illegal fishery for the endangered sciaenid fish, the totoaba, incidental catches still occur. On 10 June 1993, the Government of Mexico declared the Biosphere Reserve of the Upper Gulf of California, a move commended by the Scientific Committee (IWC, 1995). However, evidence of continuing incidental catches (D'Agrosa *et al.*, 1995) has led the Committee to recommend that further action to eliminate bycatches be taken urgently, if the extinction of the vaquita is to be avoided.

NEW INFORMATION

The Workshop has served to encourage a number of studies to improve our knowledge of bycatch levels. In many of these cases the work has been carried out in difficult conditions and without government support. For example, a considerable amount of new information is available from Central and South America. In several cases these studies identified new areas/fisheries (e.g. Félix and Samaniego, 1994; Haase and Félix, 1994; Siciliano, 1994; Zavala-González *et al.*, 1994) or improved our knowledge of existing interactions (e.g. Corcuera, 1994; Lescrauwaet and Gibbons, 1994; Van Waerebeek and Reyes, 1994c).

Although almost all the new information refers to smaller cetaceans, two previously unknown areas where large whales are taken in nets have been documented:

minke whales off Peru (Van Waerebeek and Reyes, 1994b); and sperm whales off Ecuador (Haase and Félix, 1994).

DISCUSSION

While there has clearly been some progress in addressing questions related to fishery/cetacean interactions, it is also clear that much work remains to be done.

Assessing the impact of bycatches

Several pieces of information are required if a quantitative assessment of the impact of bycatches on cetacean populations is to be made: reliable estimates of bycatch numbers; knowledge of stock identity and migration; reliable estimates of abundance. All these are difficult (and expensive) to obtain. Together they will provide us with an estimate of bycatch levels as a proportion of current population size. However, the interpretation of this remains problematic for a number of reasons associated with our lack of knowledge of the dynamics of small cetacean populations (e.g. Reilly and Barlow, 1986) i.e. what level of takes might be sustainable. Such knowledge is also required if attempts are to be made to relate current abundance to 'initial' abundance. Finally, this information needs to be considered in the context of other factors affecting the population (e.g. direct catches, habitat loss/degradation).

A number of attempts to obtain more reliable estimates of bycatch numbers have been made since the Workshop. Generally, to have any chance of success they require observers on vessels; if the cetaceans have an economic or subsistence value to the fishermen (i.e. they bring a substantial percentage of the animals to shore), monitoring of ports may be sufficient. It should not be impossible to use observers on either all, or a representative sample of a fleet in commercial fisheries, although this has rarely been done (e.g. Berrow *et al.*, 1994; Lennert *et al.*, 1994; Lowry and Teilmann, 1994). However, it is almost impossible where large numbers of small vessels are involved, for example in the many artisanal fisheries of the developing world. Other methods, such as questionnaires and interviews are difficult to interpret (e.g. Lien *et al.*, 1994) but may give some idea of the problem.

It is important to recognise that for almost all fishery/cetacean interactions we have, and probably will continue to have, only rough (usually minimum) estimates of bycatch levels (IWC, 1994c – Table 1).

The question of stock identity is a persistent problem in cetacean studies (e.g. Donovan, 1991; Perrin and Brownell, 1994) and our knowledge of small cetacean stock structure is poor for almost all areas and species. Despite the progress made in biochemical techniques (e.g. IWC, 1991b) there are no simple unambiguous ways to address this problem. It is important that a suite of techniques are used (Donovan, 1991) and that information on movements is also obtained.

The question of estimating the abundance of cetaceans has been more thoroughly addressed in recent years and guidelines for conducting surveys have been developed (e.g. Hammond, 1986; Hiby and Hammond, 1989; IWC, 1994b). However, such work is expensive. For example, the survey of the North Sea and adjacent waters carried out in July 1994 cost over £1,000,000. At present we have few reliable estimates of abundance for cetaceans affected by fisheries (IWC, 1994c – Table 1), particularly for developing countries.

It is unlikely that funding research on these three subjects will be allocated high priority in developing countries given their economic situation. It is important that Government and non-governmental agencies from the 'developed' world offer financial and logistical support for such studies to be carried out, particularly where the impact of bycatches is suspected to be high. In this regard it should be noted that many of the projects identified in the IUCN Action Plan for Cetaceans (Reeves and Leatherwood, 1994) address research relevant to bycatch problems.

Management actions

It is clear that in almost all cases it is impossible at present to determine reliably the impact of bycatches on cetacean populations; it is equally clear that action to reduce bycatches should not wait until it can be shown with certainty that levels are unsustainable.

Although there are some indications that passive and active acoustic modifications may eventually result in a reduction in bycatches in some fisheries (e.g. Goodson *et al.*, 1994; Lien *et al.*, 1994), it seems unlikely that any simple and effective gear modifications will be available in the near future.

One approach that has potential in some areas is a change of gear type e.g. from gillnets to longlines (Van Waerebeek and Reyes, 1994c; Corcuera, 1994). However, it is important to monitor the effect of such changes for several reasons. Firstly, cetaceans are only one part of the ecosystem – changing gear or methods may reduce cetacean bycatches but increase bycatches of other species (such as turtles, fish and sea birds) to unsustainable levels (e.g. see Joseph, 1994). Secondly, there is evidence from Venezuela, French Guiana and Ecuador that longline fishermen use dolphin meat as bait (Van Waerebeek and Reyes, 1994c; Félix and Samaniego, 1994). Finally, the new gear or method may also result in incidental catches or, in the case of longlines for example, direct kills by fishermen who observe cetaceans stealing fish from them.

A number of countries have taken legislative action since the Workshop (e.g. Philippines – Dolar, 1994; USA – Read, 1994; Peru – Van Waerebeek and Reyes, 1994c). However, it is clear that such action is only of value if it is enforced. The case of Peru provides a good example of this, as illustrated by Van Waerebeek and Reyes (1994c). The Government of Peru banned the capture and trade in small cetaceans in December 1990 but, in the absence of enforcement, the main effect appeared to be to make it more difficult to obtain information on catch levels, rather than a reduction in catch levels. A more recent law (August 1994) that elaborated enforcement measures and responsibility appears to be having more effect (Van Waerebeek, pers. comm.).

A number of lessons can be learned from the Peruvian experience. The most obvious is that while it is relatively easy to pass legislation and even to stress the need for enforcement, actually enforcing the law can be logistically very difficult, particularly in the case of fisheries involving large numbers of artisanal vessels in developing countries. It is not immediately obvious how this can be remedied. However, it is important that monitoring of the situation continues after legislation is passed (e.g. in the Philippines, where similar legislation was passed in 1992 – Dolar, 1994). Another factor that is relevant here is the need for education (e.g. Lescrauwaet and Gibbons, 1994); fishermen are more likely to obey a law if they can understand the need for it.

Several authors have stressed the need for the financial and subsistence needs of the fishermen to be taken into account when attempting to reduce bycatches. With the exception of 'deliberate' incidental catches (where the cetaceans have an economic or subsistence value), many fishermen see incidental catches of cetaceans as having a negative impact on their fishing, and may well be pleased to change the gear and/or operation if they can maintain their income (e.g. Corcuera, 1994; Crespo *et al.*, 1994).

CONCLUSIONS

Although some progress has been made, a considerable amount of work remains to be done. Incidental capture in fishing gear is probably the most serious threat to cetaceans today. The recommendations of the Workshop remain valid and it is to be hoped that Governments who have endorsed those recommendations in the context of the IWC and UNCED, do more than pay lip service to them. It is particularly important that financial and logistic assistance is provided to developing countries.

In closing, I would particularly like to stress certain points raised in the Workshop report.

- (1) Fishing communities should be made aware of the reasons behind calls for a reduction in bycatches and become involved in the process of finding solutions.
- (2) Research should focus on those fisheries where urgent action is required (as identified in the Workshop Report).
- (3) Potential solutions must be evaluated in the context of all marine species, not only cetaceans.
- (4) There is no universal cause or solution to the incidental capture of cetaceans in fishing gear. Each case should be evaluated in the light of local conditions.

ACKNOWLEDGEMENTS

I would like to thank a number of people who provided information and ideas for this update including Simon Berrow, Bob Brownell, Phil Hammond, Bill Perrin, Martin Hall and Andrew Read. In particular I would like to express my admiration for the scientists who have worked under extremely difficult conditions to obtain information on bycatches, particularly from South America, and who responded so positively to my unreasonable requests to publish their papers in an unreasonably quick time. Finally, I would like to thank Finn Larsen, Phil Hammond and Andy Read for their review of this manuscript.

Résumés

SECTION 1. PAPERS PRESENTED TO THE MEETING BUT NOT PUBLISHED. COPIES OF THE FULL PAPERS CAN BE OBTAINED AT COST FROM THE IWC SECRETARIAT.

SC/O90/G1. MORTALITY OF DOLPHINS IN SHARK GILLNET FISHERIES OFF URUGUAY. *Ricardo Praderi, Museo Nacional de Historia Natural Casilla de Correo 399, Montevideo, Uruguay.*

In the artisanal shark fisheries along the Uruguayan coast, sporadic accidental catches of small cetaceans have been recorded. The main species involved are: *Phocoenaspinnipinnis* (Burmeister's porpoise) and *Tursiops truncatus* (bottlenose dolphin). But, due to the kind of nets used (gillnets), a considerable number of *Pontoporia blainvillei* (franciscana) also die every year. In studying the incidental mortality of the franciscana, two factors are considered: fishing effort and types of nets used. The type and scale of fishing operations is, without doubt, the main determinant factor of the number of dolphins caught in nets. It is contingent upon climatic conditions, a factor which considerably limits the number of days suitable for fishing. The economic conditions of fishermen are also significant, because, in the absence of prior successful fishing, fuel and salaries are limited to the maximum. The type of nets employed is important in incidental mortality, because the nets with the largest mesh, used to catch large sharks, accounted for the largest number of dolphins killed (55% of the total) whereas the other two types of net used combined resulted in 45% of mortality. [24pp.]

SC/O90/G4. DRIFTNET FISHING IN THE SOUTH ATLANTIC. *Roger Krohn, Zoology Department, University of Cape Town, Rondebosch 7700, South Africa.*

Drift- and gillnetting by Japanese, Korean and China, Taiwanese fishing fleets has caused a large decline in the stocks of albacore (*Thunnus alalunga*), as well as large scale mortality of non-target species in the South Pacific. The first direct evidence to show that this activity has now extended its range to include the South Atlantic Ocean is presented. [6pp.]

SC/O90/G12. A REVIEW OF ENTANGLEMENT OF SMALL CETACEANS IN GILLNETS AND THE GILLNET FISHERIES OF THE INDIAN COAST. *R.S. Lal Mohan, Research Centre of Central Marine Fisheries Research Institute, West Hill, Calicut-673 005, India.*

The smaller cetaceans, *Stenella longirostris* (spinner dolphin), *Delphinus delphis* (common dolphin), *Tursiops truncatus* (bottlenose dolphin), *Sousa chinensis* (humpback dolphin) and *Neophocaena phocaenoides* (finless porpoise) get entangled in gillnets operated along the Indian coast. The Ganges river dolphin (*Platanista gangetica*) is a casualty in the nets operated in the rivers Ganges and Brahmaputra. Most of the entanglements occur along the southwest coast of India. The recent development of gillnets, mode of operation, structure of the nets, types of crafts and gear employed, species of fishes caught and the economics of the fishery are discussed. The important gillnet fisheries of India like pomfret fishery, shark fishery, skate and ray fishery, scombroid fishery, mackerel fishery, whitebait fishery, polynemid fishery, catfish fishery, oil sardine fishery, lesser sardine fishery, hilsa fishery, riverine catfish fishery and prawn fishery are described. Recommendations are made to try to make gillnet fisheries less harmful to dolphin populations. [70pp.]

SC/O90/G14. POSSIBILITIES OF REDUCING INCIDENTAL CATCH AND MORTALITY OF MARINE MAMMALS IN DRIFTNET FISHERIES. *Joel Prado and Andrew Smith, Fishing Technology Service, Fisheries Industries Division, FAO of the UN, Rome, Italy.*

The entanglement of cetaceans in fishing gear has been known for many years, but prior to the use of nylon twine in the fishing industry in the late 1950s it was not considered to be a problem. At this point driftnets and gillnets increased their efficiency by up to 50% and other species were sought which had not been traditionally fished by driftnets. Relatively recently this led to a high-seas development of gillnet fisheries for tuna, salmon and squid. Although the tuna and squid stocks are not considered overfished, the gillnet fishery for salmon has been subject to management measures agreed at an international level for a number of years. The international negotiations with regard to these measures have been very difficult, with each country trying to represent a number of vested interests. The problem of the catch of cetaceans is therefore only one factor in a complex controversy on high-seas gillnetting. Notwithstanding the demand for the banning of drifting gillnets on the high seas and the regulation of these nets in EEZs, it has got to be considered that during the last decade many developing countries have started fishing with driftnets for species which they had not previously harvested. Pragmatically, one has to consider not only what happens on the high-seas but also within areas under national jurisdiction where the management of the fisheries is vested in the coastal state and where the coastal state determines the allowable catch of the living resources in its exclusive economic zone. Therefore, in the context of good fisheries management practices, gillnetting does not pose a problem with regard to overfishing and the solution to the problem of the incidental catch of mammals will lie in seeking methods whereby the reduction of the amount of cetacean entanglements in the nets can be achieved. Although it is accepted that 'prevention is better than cure' it is proposed that an effective strategy for tackling the problem will contain elements of both. [12pp.]

SC/O90/G17. ENVIRONMENT, ACOUSTICS AND BIOSONAR PERCEPTION. OPTIMISING THE DESIGN OF PASSIVE ACOUSTIC NET MARKERS. *A.D. Goodson, Sonar and Signal Processing Group, Electronic and Electrical Engineering Department, Loughborough University of Technology, LE11 3TU, UK.*

The associated symposium paper 'Enhancing the acoustic detectability of fishing nets' (SC/O90/G16) discussed the foraging behaviour leading to fish detection and the extraction of target range parameters from recordings of the sonar emissions of a solitary *Tursiops truncatus*. The concept of increasing the target strength of fishing nets by adding simple sound scattering mechanisms has been investigated in recent years by a number of researchers. However, the methodology employed to date has not resulted in significant reductions in the incidental catch of cetaceans. These workshop notes attempt to examine some

environmental acoustic factors which could affect behaviour and consider the design of passive markers optimised for detection by the small delphinoids. [5pp.]

SC/O90/G18. REVIEW OF CETACEAN NON-ACOUSTIC SENSORY ABILITIES. Margaret Klinowska, *Research Group in Mammalian Ecology and Reproduction, Physiological Laboratory, University of Cambridge, Downing Street, Cambridge, CB2 3EG, UK.*

This review provides a more detailed background to the discussion in SC/O90/G19 of the ways in which non-acoustic sensory abilities and behaviour might be exploited to prevent cetacean entanglement. [39pp.]

SC/O90/G19. SOME NON-ACOUSTIC APPROACHES TO THE PREVENTION OF ENTANGLEMENT. Margaret Klinowska, *Research Group in Mammalian Ecology and Reproduction, Physiological Laboratory, University of Cambridge, Downing Street, Cambridge, CB2 3EG, UK* and A. David Goodson, *Sonar and Signalling Research Group, Electronic and Electrical Engineering Department, Loughborough University, Loughborough, LE11 3TU, UK.*

The non-acoustic senses are reviewed for their potential to provide additional practical ways to prevent the entanglement of cetaceans in fishing nets and other gear. Two general approaches emerge. The first involves modification of gear deployment. It would apply to animals using environmental information such as the geomagnetic field, currents, temperature or salinity gradients as a travel cue, and simply consists of orienting the gear parallel to the environmental cue providing the travel path instead of across it. It should not be difficult, expensive or disruptive, to collect the extra data required to test this approach during routine fishery monitoring. However, if the target species of the fishery should happen to be using the same travel cues as the cetaceans, reorientation of gear will not be practical. Nevertheless, this approach deserves serious consideration, because it is easy to test, and if effective, would not be difficult or expensive for well-equipped modern fisheries to implement. The second approach involves gear modification. Increasing the visibility of gear underwater might be useful in some restricted circumstances, and it may even be worth exploring whether improving visibility above water would be helpful. Although little is known of the role chemoreception plays in cetacean food finding and social behaviour, it is a sense which can be invoked from a distance in water. Natural fibre nets, traditionally treated with a variety of oils, tars, etc., would be likely to leave a distinctive 'trail' in the water. The contents of any nets would be likely to provide a trail of excreta and other substances. Urgent investigation is required to elucidate the role such cues may have in attracting or alerting cetaceans to nets, because such broadcast chemical signals could well negate any other efforts to prevent entanglement. [7pp.]

SC/O90/G23. SOURCES OF A GLOBAL REVIEW OF MORTALITY OF CETACEANS IN PASSIVE FISHING NETS AND TRAPS. Aleta A. Hohn and William F. Perrin, *Southwest Fisheries Science Center, National Marine Fisheries Service, PO Box 271, La Jolla, CA 92038, USA.*

This provides a list of sources that may be useful during the IWC Workshop on Mortality of Cetaceans in Passive Fishing Nets and Traps. These sources include references pertaining to the species and numbers of cetaceans incidentally caught, types of gear, mitigation methods tried or suggested, coastal fisheries operating and possibly catching cetaceans even if such reports of incidental catches do not currently exist, and other potentially relevant papers. We have tried to include references on incidental mortality in passive gear from all regions of the globe where information exists. Generally, the list has been restricted to recent documents, within the past 10 years or so. Unpublished material has been included because much of it is very recent or contains details or information not otherwise available. All of the sources listed will be accessible during the workshop. [16pp.]

SC/O90/G25. CETACEAN MORTALITY IN PASSIVE FISHING NETS AND TRAPS IN THE BALTIC SEA: A REVIEW. Carl Chr. Kinze, *Zoological Museum, University of Copenhagen, Universitetsparken 15, DK-2100 Copenhagen O, Denmark.*

The dominant cetacean of the Baltic Sea is the harbour porpoise (*Phocoena phocoena*), and interactions between cetaceans and fisheries hence are almost totally with this species. A further 19 species have been reported occasionally from Baltic waters, usually in the westernmost part and may potentially become entangled in fishing gear. Since the end of the second world war, the harbour porpoise in the Baltic appears to have undergone a significant decline and in recent years the species has become very scarce in the Baltic proper. Amongst other factors, entanglements in passive fishing nets and traps has been mentioned as a cause of the decline. Harbour porpoises are or have been caught in gillnets and pond nets all over the Baltic Sea. Set gillnets are widely applied in Danish, Swedish and German waters whilst salmon drift nets are in use in the Baltic proper. Taking into account, however, the present distribution of the harbour porpoise in the Baltic Sea, incidental catches may only have an impact on the species in the westernmost parts of these waters, i.e. mainly in the Danish, German and Swedish parts of the Kattegat and the Belt Sea. [22pp.]

SC/O90/G26. REVIEW OF GILLNET AND TRAP FISHERIES IN THE BRAZILIAN REGION. Graciela Cannella and Alfredo Ximenez, *Laboratorio de Mamíferos Aquáticos e Ictiologia de la Universidad Federal de Santa Catarina, Caixa Postal 5132, Campus Universitario 88049 Florianópolis, SC, Brazil.*

This paper provides information on gillnet and trap fisheries that characterise each region of the Brazilian coast and on their impact on the marine mammals that frequent these areas. Artisanal fishing represents 50–60% of the total national fishing yield and is particularly important in the north and northeast regions. The southeast region concentrates most on industrial fisheries and together with the south has the highest fishing potential of the country. Different problems resulting from overfishing, fish handling, pollution, etc. are described. The impact of fishing activity on marine mammal populations cannot be assessed at present, given the lack of data. [39pp.]

SC/O90/G27. FRESHWATER DOLPHIN/FISHERIES INTERACTION IN THE CENTRAL AMAZON (BRAZIL). Vera da Silva and Robin C. Best*, *Laboratorio de Mamíferos Aquáticos, Instituto Nacional de Pesquisas da Amazonia (INPA), C.P. 478, 69011 Manaus, Amazonas, Brazil.*

The Amazonian freshwater dolphins, *Inia geoffrensis* (boto) and *Sotalia fluviatilis* (tucuxi), have been little studied and their actual populations and status are still unknown. As part of a general study of the biology and conservation of the aquatic mammals of the Amazon region, the Instituto Nacional de Pesquisas da Amazonia (INPA), in Manaus has undertaken a study of these two dolphins. The increasing fisheries pressure in the Amazon has greatly augmented the potential for dolphin/fisheries interactions which could adversely affect the status of the dolphins, both through higher rates of incidental mortality in fishing gear, and through direct competition for certain fish species. This paper summarises data for 67 dolphins (33 *Inia* and 34 *Sotalia*) collected between May 1979 and March 1984 in the central Amazon region. This collection is the result of our contacts with local, and our institute's fishermen and is by no means a quantitative sampling of all dolphin mortality for this region. [11pp.]

* Robin C. Best died on 17 December 1986. He was a Research Associate of the Vancouver Public Aquarium.

SC/O90/G30. INFORMATION ON FISHERIES OF PAKISTAN. Mohammad Sadiq Niazi, *Deputy Director, Marine Fisheries Department, Government of Pakistan, Westwharf, Fish Harbour, Karachi-74000, Pakistan.*

Pakistan is located in Asia having India to its east and Iran to the west, and the northern Arabian Sea to its south. It has a coastline of about 1,050km and has an Exclusive Economic Zone (EEZ)

extending offshore to 200 n.miles (370km). The marine environment of Pakistan has been divided into two maritime provinces, viz. Sind maritime region and Baluchistan region. The former area, stretching about 350km, has Karachi harbour as its main base. It is characterised by a broad continental shelf (extending about 110km out from the coast to a depth of 200m), a coastline marked by the numerous small creeks and deltas of the Indus river, and by a muddy, easily trawlable bottom. The Baluchistan coastline, which extends some 700km, is characterised by a number of bays (Sonamiani, Ormara, Pasni, Gwadar, Jiwani) and the absence of any substantial river systems. The continental shelf of the Baluchistan coast is narrow (15 to 50km) and falls off steeply into very deep water. It has a comparatively hard bottom which makes it very difficult for bottom trawling. The shelf area is estimated to be about 35,740km² in Sind and 14,530km² on the Baluchistan coast (50,270km² total). [8pp. + Addendum 26pp.]

SC/O90/G31. FISHING OPERATIONS AND DEATH OF MARINE MAMMALS IN THE WATERS OFF KAMCHATKA. V.N. Burkanov, Kamchatka Department of Nature, Pacific Geographic Institute, Far East Branch of the USSR Academy of Sciences.

The Kamchatka region is one of the richest in the world. Throughout the year Soviet, Japanese, North Korea and China, Taiwanese and US vessels intensively harvest fish and other food species there. Numerous marine mammals are present including five Phocidae (*Phoca largha*, *Pusa hispida*, *Eryghothus barbatus*, *Histiophoca fasciala*, *Phoco vitulina richardi*), two Otariidae species (*Eumetopias jubatus*, *C. ursinus*), walrus (*Odobenus rosmarus*), sea otter (*Euchydra lutris*) and no less than 20 cetaceans (Cetacea). Species interactions between man and marine mammals during fishing give rise to serious potential problems of which little detail is known for Kamchatka. This paper attempts to give a general outlook on the impact of different fishing patterns on marine mammals. [3pp.]

SC/O90/G32. DOLPHINS IN THAILAND. Suraphol Sudara, Chulalongkorn University, Bangkok, Thailand.

Ten species of dolphins have been recorded in Thai waters, both in the Gulf of Thailand and in the Andaman Sea. Order Odontoceti (toothed whales): (1) *Sotalia plumbea* (Thai name: white-grey loma); (2) *S. borneensis* (Thai name: white loma of the south sea); (3) *S. chinensis* (Thai name: loma of the north sea); (4) *Steno bredanensis* (Thai name: spotted loma); (5) *Stenella malayana* (Thai name: bottlenose Malayan loma); (6) *Delphinus delphis* (Thai name: common bottlenose loma); (7) *Tursiops truncatus* (Thai name: bottlenose, short mouth loma); (8) *Orcaella brevirostris* (Thai name: bowl head, dorsal fin loma); (9) *Neophocaena phocaenoides* (Thai name: bowl head, smooth back loma); (10) *Stenella longirostris* (spinner dolphin). [3pp.]

SC/O90/G33. A REVIEW OF GILLNET AND TRAP FISHERIES IN MICRONESIA AND THE CENTRAL PACIFIC. Eugene T. Nitta, NMFS, Southwest Region, Pacific Area Office, 2570 Dole Street, Honolulu, Hawaii 96822-2396, USA.

Numerous variations of gillnet and trap fisheries occur throughout Micronesia and in Hawaii. The levels of effort and techniques are dictated in large part by the physiography of the islands or atolls where the fisheries occur. Conditions such as the width of the reef flat, whether or not there is a lagoon, depth of the waters immediately seaward of the fringing reef, and currents and tides are all considerations in the selection and use of gear. These fisheries are now conducted with modern gear such as monofilament nets and lines, steel rebar and wire screening, outboard motors, fibreglass and aluminium boats and scuba; a significant change from traditional gear made almost entirely from natural materials. In many locations the distinctions between recreational, subsistence and commercial fishing by gillnet and/or traps are difficult to make because of the lack of formal markets or infrastructure, nonreporting of mixed subsistence and commercial

catches and the continuation of some semi-traditional or cultural practices involving the sharing of catches, subsistence or otherwise. Commercial landings data, therefore, probably do not accurately reflect the true scale of local gillnet and trap fisheries in many areas of the Pacific. Cetacean interactions with gillnets and traps in what would be considered inshore reef fisheries in the central and western Pacific are rarely, if ever, reported. Gear set on the reef flats nominally separates most cetacean species from these fisheries. On occasion groups of small whales or dolphins become disorientated and trapped inside stoll lagoons and are sometimes taken for food in some areas of Micronesia. There are unconfirmed reports of humpback whales carrying away inshore gillnets in Hawaii over the past few years. This is in contrast to the reported high rates of incidental catch of cetaceans and other marine species in the high seas drift gillnet fisheries in the North Pacific and South Pacific regions. [38pp. + Revision 5pp.]

SC/O90/G35. DRIFTNET FISHERIES AND THEIR IMPACT ON NON-TARGET SPECIES. Simon P. Northridge, Marine Resources Assessment Group, 8 Princes Gardens, London, SW7 1NA, UK.

The major driftnet fisheries of the world are reviewed in terms of the numbers of vessels fishing, area and season of operation, major commercial species landed, and in a few cases in terms of fishing effort. Gear types are described and estimates of the amounts of netting deployed are made. The accidental captures of non-target species are described where they are known, and some indications of catch rates by species are also given. In some instances, broad estimates of total catches by species for individual fisheries are also given. Populations of non-target species which might most be at risk from entanglement in drift nets are discussed. Driftnet fisheries which have been little documented but which might be considered as potentially detrimental to individual species are also identified. [100pp.]

SC/O90/G36. REVIEW OF THE INCIDENTAL CATCHES OF CETACEANS IN JAPAN. Teruo Tobayama, Kamogawa Sea World, Kamogawa-shi, Chiba-ken, 296 Japan, Yoshio Inagaki and Masahiro Ryohno, Hiyoriyama Marine Park, Toyooka-shi, Hyogo-ken, 669-61 Japan and Kenji Hiratsuka, Kamogawa Sea World, Kamogawa-shi, Chiba-ken, 296 Japan.

Data on incidental catches of cetaceans in Japanese waters from 1970-1989 were gathered from 25 aquaria in Japan in 1990. In the last 20 years, a total 352 animals from 18 species caught incidentally were observed by aquaria. These were mainly caught by set nets (81%), seine nets (8%) or gillnets (7%). Major species were *Lagenorhynchus obliquens* (47%), *Neophocaena phocaenoides* (21%), *Grampus griseus* (7%), *Phocoena phocoena* (6%), *Tursiops truncatus* (5%) and *Balaenoptera acutorostrata* (4%). [6pp.]

SC/O90/G37. LARGE SCALE TRAP NET FISHERY IN JAPAN. Tooru Sakuma, Japan Fisheries Agency, Kasumigaseki, Chiyodaku, Tokyo, 100 Japan.

This paper summarises the large scale trap net fishery in Japan. These can be divided into two types: 'salmon' (operating in Hokkaido, mainly September to October); and 'other' (operating year round along the coast of the other Islands) that take sardines, atka mackerel, scombrids and other species. [3pp.]

SC/O90/G38. THE GROUND FISH GILLNET FISHERY IN THE GULF OF MAINE: FISHING GEAR AND METHODS. Stephen C. Drew, MBO, Box 936, Manomet, Massachusetts 02345, USA.

This paper describes the gear and operations of the Gulf of Maine groundfish gillnet fishery. Monofilament gillnets with stretched mesh size ranging from 5.5 to 9 inches (140-229mm) are set on the bottom and anchored at both ends. Such nets commonly present a profile from eight to twelve feet in height. Several sections of net, each net 300 feet (91.5m) long, are joined end-to-end to make 'strings'. The length of a string of gear generally ranges from 1,500 to 3,600 feet (457-1,100m), with some strings over 6,000 feet

(1,830m). In common practice, one boat may fish 30 to 70 nets, divided among 3–6 strings. The species most often targeted are cod, pollock and spiny dogfish (on a seasonal basis). Nets which target flatfishes are rigged to fish with the headline on the bottom and the float rope 2–3 feet above the bottom, with the net webbing slack. A few multifilament and multimonomofilament nets are also used. Over 150 vessels participate in this fishery on a year-round or seasonal basis. Most vessels fall into the 35–55 foot (11–17m) length range, fishing one-day trips, leaving their nets in the water and attempting to haul them on a daily basis when weather permits. Nets which target flatfish are often soaked longer, since these species live longer while entangled. A minority of gillnetters fish farther than 40 miles from shore, making trips lasting two to eight days, hauling their nets daily and bringing the catch ashore at the end of each trip. [4pp.]

SC/O90/G39. DISCUSSION PAPER ON MANAGEMENT OPTIONS TO CONTROL MARINE MAMMAL MORTALITY IN PASSIVE FISHING GEAR. *James M. Coe, NMFS, Alaska Fisheries Science Center, 7600 Sand Point Way NE, Seattle, WA 98115, USA.*

Public and political expectations have often clashed with industrial, managerial and biological views and capabilities over controlling the fisheries bycatches of a wide range of species. Domestic and international attention to this problem is increasing as the real or perceived value and wastage of living marine resources increases. This paper discusses some general features of the fisheries resource management process and makes some recommendations in hopes of provoking vigorous discussion of the priorities and practicalities of marine mammal bycatch control. Bycatch is the collection of non-target species caught but not retained in any fishery. Bycatch may be unharmed, injured or dead when discarded. It includes both commercial and non-commercial fish and shellfish, marine mammals, birds, turtles and invertebrates. Bycatch is a fact of life for most fisheries. It typically becomes a management issue when a second or third party attaches some value to the discarded animals. The higher the value, the more likely some authority will be created or invoked to justify management actions to control, reallocate, or eliminate the bycatch. The legal notions of property, due process, and reasonableness are ever present in the application of these authorities. Marine mammals have virtually zero commercial value to passive gear fishermen. As bycatch they are cumbersome, aggravating and occasionally dangerous. On the other hand, a significant segment of the population attaches considerable value to marine mammals, wishing to protect them from harm in fisheries through statute and regulation. By establishing an economic consequence to the taking of marine mammals in the act of fishing, some control may be exercised over that taking. This type of artificial valuation of marine mammals *will* be necessary if their bycatch in passive fishing gears is to be reduced or eliminated. This implies the creation of authority permitting governmental agencies to apply appropriate measures. This type of authority varies widely around the world as does the value people and cultures attribute to marine mammals. Within the US Exclusive Economic Zone (EEZ), the Marine Mammal Protection Act and the Endangered Species Act provide this authority under certain conditions. On the high seas, this type of authority is absent except as extended through bilateral or multilateral agreements. Energetic international debate is developing over the ways and means to manage the resources of the high seas, focusing on bycatch in large-scale driftnet fisheries. [10pp.]

SC/O90/G40. MITIGATING CETACEAN MORTALITY IN FISHERIES: APPROPRIATE ALTERNATIVES. *Ronald Joel Smolowitz and Clifford Goudey, Massachusetts Institute of Technology, Center for Fisheries Engineering Research, Mass., USA.*

The United States has a commercial fishing industry that is very important to its economy. Concerns about marine mammals have the potential of significantly impacting commercial fishing. Efforts

are underway to develop cetacean-saving gear so that fisheries can be conducted without harming cetacean populations. Gear development proceeds best when the fishermen are economically motivated to innovate to solve the problem. Proper motivation can result in the most economically efficient solution. [11pp.]

SC/O90/G41. INTERACTIONS BETWEEN THE NEW ENGLAND SINK-GILLNET FISHERY AND THE HARBOR PORPOISE, *PHOCOENA PHOCOENA*. *P. Michael Payne and Charles T. Yustin, Manomet Bird Observatory, PO Box 936, Manomet, Massachusetts 02345, USA and Gregory Power, NMFS, Northeast Fisheries Center, Woods Hole, Massachusetts 02543, USA.*

Under the 1988 reauthorisation of the Marine Mammal Protection Act the New England sink-gillnet fishery was classified as a Category I fishery. This was due to a known, but not yet quantified, bycatch of harbor porpoise (*Phocoena phocoena*) by gillnetters in the Gulf of Maine. In August 1989 the National Marine Fisheries Service/Northeast Fisheries Center initiated sea sampling aboard vessels participating in this fishery. Sea sampling effort was distributed according to fishing effort by region and season. Sea samplers observed gillnetters on 234 days during this study period on approximately 80 different vessels. The percent coverage represented by this level of sampling effort (number of days sampled per month/the total number of days fished in the fleet per month) by DSSP samplers ranged from <1.0% of total fleet effort during each month, June through August, to approximately 3.2% coverage (September). Most fleet effort (therefore sea sampling effort) occurred in NMFS/NEFC Fishery Statistical Areas 513 and 514 located from approximately Muscongus Bay to Cape Cod in the western Gulf of Maine. From August 1989 to July 1990 sampling occurred on 158 sea days, and monthly sea sampling effort ranged from 4 days per month (July 1990) to 30 (September 1989) in these two areas. Fifteen harbor porpoise were taken between October 1989 and April 1990. All documented harbor porpoise takes occurred in NMFS Fishery Statistical Areas 513 and 514. There were no porpoise captured from June through September 1989 or from May to July 1990. The seasonal take in NMFS Statistical Areas 513–514 is consistent with known movement patterns of harbor porpoise. Harbor porpoise move north, out of the western Gulf of Maine into the Bay of Fundy-eastern Scotian Shelf region from early-summer through autumn, then back through the western Gulf of Maine during late-autumn and spring. The lack of incidental take in remaining areas of the Gulf of Maine may reflect sampling effort disjunct from known harbor porpoise concentrations in the Gulf of Maine. [29pp.]

SC/O90/G43. HIGH SEAS DRIFTNET FISHERIES OF THE NORTH PACIFIC OCEAN. *Linda Jones, Michael Dahlberg and Shannon Fitzgerald, NMFS, Alaska Fisheries Science Center, 7600 Sand Point Way NE, Seattle, WA 98115, USA.*

This paper reviews high seas driftnet fisheries in the North Pacific. For each of the fisheries it provides a summary of the available information on the following: flag state; ports; target species; regulations on fishing season and area; vessels and crew; fish handling methods; gear; operation details; economics and history; catch and effort data; interactions with cetaceans. The fisheries reviewed were for squid, albacore and salmon. [35pp.]

SC/O90/G44. FACTORS IMPORTANT IN INITIAL EVALUATION OF THE BIOLOGICAL SIGNIFICANCE OF CETACEAN BYCATCH. *T.D. Smith, G.T. Waring and T.W. Polacheck, Northeast Fisheries Center, Woods, Hole, Massachusetts, USA.*

This paper examines the information needed to evaluate the biological significance of cetacean bycatches and compares this with the data that are frequently available so that possible

systematic biases in the appraisal of the biological significance can be anticipated and corrected for where possible, and so that statistical precision can be measured where possible. Such factors are considered here for data on bycatch rates, total fishing intensity, and population size. The interrelation of these data sources in the comparison of bycatch level and population size is then discussed. Examples are drawn from the tuna purse seine fishery in the eastern tropical Pacific (ETP) and the bottom-tending gillnet fishery in the Gulf of Maine (GOM) and nearby waters. [36pp.]

SC/O90/G45. [NOTE TO PARTICIPANTS] *John LaGrange, Captain, 'Cloud Nine', 533 North Rios Avenue, Solana Beach, CA 92075, USA.*

This note was presented by the captain of a gillnetter. He discusses the measures that were successfully used to reduce gray whale captures in nets, including closed areas and seasons and modifications to gear. He recognised that the solution for other species is not so simple, given the different behaviour, size and knowledge of other species. Some measures that may help are discussed including limiting total gear and suspending nets some distance below the surface. Problems and methods of reducing caught animals are described. [5pp.]

SC/O90/G46. GILLNETS AND MARINE MAMMALS. *K.S. Norris, Institute of Marine Sciences, University of California, 100 Shaffer Road, Santa Cruz, CA 95060, USA.*

Possible ways in which marine mammal bycatches can be reduced can be classified as: (a) behavioural solutions; (b) gear-related solutions; (c) operations related solutions and (d) regulatory related solutions. Only the first two are discussed.

Behavioural solutions. If a marine mammal is patrolling a net to take trapped fish from it, it automatically is placed at risk. Even if the animal is somehow warned of the danger involved it may be attracted to the nets because easy food lies there for the taking. Warning a marine mammal away from a net is not likely to be enough, although it might help avoid kills of animals blundering into undetected nets. A first step is to determine how the marine mammal in question becomes entangled. Second, it will be useful to keep in mind the sensory capabilities of the animals' being trapped, as opposed to the kinds of signals that may be produced by a drifting net. Not all odontocetes echolocate equally well. Delphinids in general, produce broad band clicks arranged in trains, while the phocoenids, such as the Dall's porpoise, produce very different rather narrow band signals at very high frequencies. Dall's porpoise signals have been called 'black and white sonar' as compared to the richer signals of the delphinids. Their signals are expected to be useful at short ranges; a few dozen yards, as opposed to the delphinid clicks that may be useful at hundreds of yards. Phocoenid clicks may not be useful for fine discrimination but may well be good enough to discriminate prey species. The dolphins and porpoises that produce the narrow band high frequency clicks are uniformly species that live in murky water environments. The high frequency of these signals is above the hearing of their prey so they can echolocate with impunity, in terms of alerting prey to their presence. Other senses should also be considered such as vision, touch and manoeuvrability. Knowledge of the diurnal behavioural cycle may be useful. Marine mammals have preferred times for various activities in their lives such as sleep, feeding, etc. If nets fish for more than 24hrs, a consideration of these is restricted in its usefulness, i.e. one cannot design a netting system that avoids marine mammal activity. What one can do is to learn during what activity period most marine mammal kills occur, and this might be tied to behavioural state. Such information might help define the causes of kills.

Gear-related solutions. If marine mammals blunder into nets it would be useful to warn them of the net's presence. However, a 'warning' might be an attractant into danger because the net might

represent a source of food and the warned marine mammals might rush in. Behavioural observations are needed about how marine mammals regard these nets. Do they seek them, or avoid them? How do the different species that are taken react? Use of passive or active acoustic devices may be useful. If a net food is the same size range as the normal food of the marine mammal concerned there will be an attraction for the marine mammal. Therefore, if mesh size is regulated to exclude the major marine mammal foods (i.e. by use of meshes too large to take such food) the attraction should be reduced and we should be dealing with incidental take related to nets undetected by the marine mammal. In this case, a different set of solutions is indicated than if active attraction is involved. An assessment of the food types utilised by a given marine mammal species is needed. How does what the mammal eats match the kinds of fish the net takes or releases? [4pp.]

SC/O90/G48. A REVIEW OF GEAR AND ANIMAL CHARACTERISTICS RESPONSIBLE FOR INCIDENTAL CATCHES OF MARINE MAMMALS IN FISHING GEAR. *Dawn Nelson, Memorial University of Newfoundland, Department of Psychology, St. John's, Newfoundland, Canada, A1B 3L1.*

World-wide incidental capture of marine mammals in fishing gear is a serious problem. Bycatch seriously affects some populations; losses to fishermen are, in some instances, substantial. Because of the extent of the problem, there have been many studies which have attempted to alleviate it. This paper provides an overview of these studies and their findings. Biological factors which influence entrapment of marine mammals include: (1) species distribution; (2) seasonal and migratory movements; (3) various behavioural traits; (4) sensory capacities and (5) attention and searching images. While additional information is needed on all of these factors, the most promising area in which solutions may be found and which requires the most investigation is that of attention. This biological trait interacts with a number of gear characteristics including: (1) target traits and strength; (2) location of sets and (3) rigidity and rigging characteristics. Solutions to bycatch problems for marine mammal populations and fishermen can be found by cooperative investigations involving both gear technologists and marine mammalogists. [26pp.]

SC/O90/G49. RESPONSES OF NAIVE, CAPTIVE DOLPHINS TO PROTOTYPE WHALE ALARMS. *Dawn Nelson, Dolphin Research Center, Grassy Key, Florida and Memorial University of Newfoundland, Department of Psychology, St. John's, Newfoundland, Canada and Jon Lien, Ocean Science Centre and Memorial University of Newfoundland, Department of Psychology, St. John's, Newfoundland, Canada.*

Every year, thousands of cetaceans worldwide become entangled in fishing gear. One possible explanation for this phenomenon is that certain types of gear may be difficult for cetaceans to detect. If this is the case, then enhancing the detectability of a net should cause a decrease in the number of entrapments. One possibility is to place sound generators onto fishing gear. Such devices need not frighten cetaceans away, but merely serve to inform them that there is something in their vicinity. It is thought that after encountering 'alarms' on nets, cetaceans will associate the alarm noise with the presence of a net and will stay away. Preliminary work with various types of alarms in Newfoundland waters indicated that the costs of humpback whale (*Megaptera novaeangliae*) collisions with fixed fishing gear were less when alarms were placed on the gear, possibly indicating that the whales were indeed attempting to avoid the nets. The purpose of this study was to discover what initial reactions captive dolphins might have to a novel sound generator. In order for the alarms to

be most effective, cetaceans should initially be both curious and wary of them, so that they will approach cautiously and discover the net without becoming entangled. [10pp.]

SC/O90/G51. REACTIONS OF HUMPBACK WHALES TO NOVEL SOUNDS: CURIOSITY AND CONDITIONING. *Jon Lien, Ocean Studies Centre and Department of Psychology, Memorial University of Newfoundland, St. John's, Newfoundland, Canada, A1C 5S7; Amy Verhulst, School of Oceanography, University of Rhode Island, Narragansett, Rhode Island, USA; Tim Huntsman, Whale Research Group, Memorial University of Newfoundland, St. John's, Newfoundland, Canada; Janice Jones, Environmental Studies, Oberlin College, Oberlin, Ohio, USA and Rosie Seaton, Biopsychology Programme, Memorial University of Newfoundland, St. John's, Newfoundland, Canada.*

Add-on acoustical devices, which produce biologically novel sounds, have been proposed as a means of alerting cetaceans to the presence of cryptic fishing gear. To accomplish this, there are two prerequisites: the whale must notice the sound and learn it is associated with nets. Experiments during the summer of 1990 were designed to evaluate the reactions of humpback whales to sounds from devices developed as net 'alarms'. In the first experiment, two underwater acoustical 'alarm' devices were installed in a small bay where humpback whales were plentiful. Positions of the devices were marked with buoys which could be observed from shore. Movements of the whales in relation to the alarms were measured from shore by a theodolite. Throughout the observations, alarms were switched on and off; the observers did not know which were activated, or when. Results indicate that humpbacks closely approached alarm positions when they were producing sounds; approaches were not as common when the devices were off. The second experiment paired the presentation of these same sounds with a standard biopsy procedure used to obtain skin and blubber samples from individually identified whales. Humpbacks were photographed for individual identification and were later biopsied with or without sound; behaviours observed were recorded. Later, individuals were approached a second time with and without the sound. Behaviours observed in both approaches were compared. Individual reactions to biopsies vary as do the reactions to later presentations of sounds alone. Circumstances prevented completion of this experiment; results presented will evaluate the humpbacks short-term memory for novel sounds when they are paired with more meaningful stimuli. [13pp.]

SC/O90/G53. THE FRENCH ALBACORE TUNA FISHERY IN THE NORTH ATLANTIC. *J. Bonnemains and M. Kanas, Robin des Bois, 15 rue Ferdinand-Duval, 75004 Paris, France.*

The French albacore tuna fishery in the North Atlantic uses driftnets 4.35 miles long and 49.5 feet deep and is currently practised by 37 ships of less than 82.5 feet in length roughly between June 15 – September 15 of each year. This fishery began in 1986 with 2 vessels. Testimonies by crew members as well as observers from IFREMER (French Research Institute for the Exploitation of the Sea) during the 1988–90 fishing seasons have contributed to the Robin Des Bois' study which is based on an observer report from a fishing trip of average duration between July 31 – August 15, 1990. Estimates of the number of dolphins taken incidentally each year by this fleet have not been disproved by Robin Des Bois' observers. The question remains as to whether certain indications of abundance can permit us to claim that this incidental take does not pose a threat to regional populations. There is a need for systematic studies which suspend nets below the surface for an entire fishing season by 1 or more boats, as similar studies in the South Pacific have had encouraging results. The French albacore tuna fishery – a small-scale artisanal fishery – needs to be part of a European regulated fishery so as to avoid proliferation of the number of vessels, collapse of resources and increasing numbers of marine mammal takes. [9pp.]

SC/O90/G56. HEALTH STATUS AND BYCATCH OF HARBOUR PORPOISE (*PHOCOENA PHOCOENA*) IN DANISH WATERS. *B. Clausen, National Environmental Research Institute, Moerkhoej Bygade 26, H, DK-2860 Soeborg, Denmark.*

The report summarises available information on the health status and bycatch of harbour porpoise (*Phocoena phocoena*) in Danish waters for the last 50 years and the conclusions which may be drawn hereupon. In general it is not known how much the stock of harbour porpoise in Danish waters has decreased, but we know that there has been a migration of large numbers of harbour porpoise in and out of the Baltic Sea. This migration seems more or less to have stopped after the second world war, but before the intensive fishery started. Further, the area of distribution of harbour porpoise in the inner Danish waters seems reduced. Recent sightings from 1983–1989 do not indicate changes in the population during this period. Necropsis of harbour porpoise caught in poundnets from 1960 to 1970 revealed heavily parasitised animals. Animals caught alive in poundnets usually die due to lungworm infestation if not dewormed shortly after capture. Various information on heavy metals and chlorinated hydrocarbons have caused concern for the health and especially reproduction among marine mammals. Finally, information has been received that harbor porpoise are often incidentally caught in Danish waters. Therefore, there have been investigations conducted in order to assess: (1) whether changes in the population size have occurred; (2) the health status of the population; (3) whether it is just the sick animals which end up in the fishermens net; (4) the levels of toxichemicals, and the possible influence of pollutants on the reproduction and (5) the impact of the bycatch. SC/O90/G58. PRELIMINARY REPORT ON THE JAPANESE FISHING EXPERIMENTS USING SUBSURFACE GILLNETS IN THE SOUTH AND THE NORTH PACIFIC, 1989–1990. *Shigeo Hayase and Yoh Watanabe, National Research Institute of Far Seas Fisheries, 7-1 Orido, 5 chome, Shimizu-shi, Shizuoka 424, Japan and Takashi Hatanaka, Japan Marine Fishery Resource Research Center.*

In order to develop fishing methods and techniques for avoiding or reducing the incidental takes of non-target species including cetaceans without the reduction of target species, the Fisheries Agency, Government of Japan, conducted the following two types of fishing experiments. (1) Experimental trials were conducted from November 1989 to March 1990 in the Tasman Sea and east of New Zealand setting 178mm large mesh gillnets both at the surface (about 900 tans/operations) and at 2m below the surface (100 tans simultaneously) for comparing the fish and dolphins catches between two different fishery gears. (2) During 4–31 May 1990, trials were conducted on the Japanese squid fishing ground in the North Pacific by seven Japanese commercial squid driftnetters, using surface gillnets (subsurface nets at average 2m) (88 tans). All data used were obtained through radio communications. In the experiment in the South Pacific, 57,940 tans of surface gillnets and 6,898 tans of subsurface gillnets were deployed. The CPUEs (catch in number/1000 tans) on albacore, the target species, were 533.8 in the surface net, and 644.5 in the subsurface net, respectively. Thus the result indicated that there was no significant difference in albacore catch rates between the surface and subsurface nets. A total of 97 common dolphins, 17 striped dolphins, and 9 other cetaceans were caught by the surface nets. Only one Baird's beaked whale was caught by the subsurface nets. In the experiment in the North Pacific, 124,881 tans of surface nets and 16,021 tans of subsurface net (8,751 at 1m, 7,270 at 2m) were deployed, respectively. CPUEs (kg/1,000 tans) on neon flying squid were 1,330 for the surface net and 1,310 for the subsurface nets (2m). This result indicated that there was no significant difference in squid catch among these three types of fishing operation. A total of 44 dolphins (CPUE: 0.35 individuals/1,000 tan) by surface nets; 3 dolphins (0.34) by 1m nets and one dolphin (0.14) by 2m were caught. This suggests that alternative fishing methods submerging nets below the surface may be more or less effective in reduction of cetacean catch rate. Although

these trials are preliminary, the results suggest that subsurface gillnets may be effective for reducing cetacean bycatch while maintaining catch rate of target species at almost the same level as with surface net. Further extensive trials will be required to confirm these results. [11pp.]

SC/O90/G59. ENCOUNTERS WITH GILLNETS: PRELIMINARY RESULTS FROM A SIMPLE MODEL AND SIMULATION OF THE PROBABILITY OF ENCOUNTERS WITH LONG PELAGIC DRIFTNETS BY CETACEANS.

Gordon R.V. Anderson, Australian National Parks and Wildlife Service, PO Box 636, Canberra City, ACT 2601, Australia.

Scattered observations on the distribution of entanglement sites of small cetaceans in long pelagic driftnets show non-random distributions along the net, with higher frequencies of entanglement toward the ends of the nets than in the central areas in some sets of observations. Explanations for the observed differences have included attraction of cetaceans to the net-end buoys and locating gear or differential soak times for nets shot and hauled from the same end. The preliminary results of a simple model and computer simulation of encounters of small cetaceans with a gillnet are described. The model: a two dimensional model of a single 50km driftnet; soak time of 10 hours; dolphin movement on random headings each ten minutes from a randomly assigned starting point, travelling at 100 to 2,000m/10 minutes, density of animals 100 per 50km by 200m strip parallel to the gillnet axis, strips from 0 to 20km, with equivalent density in

quadrants beyond net ends. Simulations were run for swimming speeds of 100 to 2,000m/10 minutes in increments of 100m/10 minutes, with variance estimated from ten replicates for each speed. For the area beyond the net ends, 10 replicates were run for each swimming speed. Initial results indicate that for the area perpendicular to the net, the probability of encounters along the net is not uniform, with progressively greater differences between encounter rates in the central sections and the ends of the net with increasing swimming speed. For even quite modest swimming speeds, there is a significant chance of encountering the net for animals many kilometres away when the net is set and a significant encounter rate well into the soak period. There is also a probability that an animal well beyond the end of the net when it is set may move far enough during a ten hour soak time to encounter the net. Encounters along the net for animals moving from the areas beyond the net ends show strong peaks towards the ends of the net; the peaks spreading along the net with increasing swimming speed. Those peaks are strong enough to mask the lower probability of encounter towards the ends of the net for animals from the areas along the nets. The combined distributions for all areas fished by a net show strong peaks towards the net ends, with the form of the distribution dependent on swimming speed. While pelagic species of small cetaceans may travel considerable distances at speeds of 10 knots or more, foraging and resting movements may be very much slower. For inshore species, sustained speeds of 2–5 knots are reported commonly, although the horizontal distance covered in any 10 minute period may give a lower overall speed. (For a speed of 5 knots, the distance travelled in 10 minutes is approximately 1,300 metres). [7pp.]

SECTION 2. ABSTRACTS AS INCLUDED IN THE SYMPOSIUM BOOKLET (EXCLUDING THOSE WHERE A FULL PAPER WAS SUBMITTED AND MADE A DOCUMENT FOR THE WORKSHOP). ABSTRACTS ARE IN ALPHABETICAL ORDER BY AUTHOR.

PRELIMINARY REPORT ON DEATH OF CETACEANS IN GILLNETS IN NORTHEASTERN VENEZUELAN WATERS.

Ignacio Agudo, Fundacetacea Fundación Venbezolana para la Investigación, Defensa y Conservación de Mamíferos Cetáceos y Afines, P.O. Box 1273, Carmelitas, Caracas 1010, Venezuela.

In Venezuelan waters between 9°55'–11°25'N and 61°50'–64°30'W, local fishermen use gillnets 50–200m long and 5–12m deep constructed of 8–13cm-mesh webbing (Mihara *et al.*, 1971; MAC, 1982). In February 1987, 1,537 nets were reported operating in the area. Morro de Puerto Santo of August 26 1988 reported the sale of six dolphins to the crew of a shark-fishing boat. The dolphins were cut into pieces and placed in refrigerated storage for use as bait on bottom longlines. The skulls were obtained and have been placed in the Estación Biológica Rancho Grande (EBRG). The six dolphins were identified as *Stenella frontalis* (EBRG 16884, 16889), *S. longirostris* (EBRG 16885, 16886, 16887) and *S. clymene* (EBRG 16888). According to preliminary reports, since the beginning of 1988 deaths of cetaceans in gillnets have been very frequent. They have been used both for bait and for human consumption (Dollinger, 1985). In addition to the above three species of *Stenella*, cetaceans involved include *Delphinus delphis*, *Tursiops truncatus*, *Sotalia fluviatilis* and *Balaenoptera* sp. There have been no systematic efforts to determine capture rates, total mortality, species composition or impact of the incidental kills on the cetacean populations.

INCIDENTAL CAPTURE OF SMALL CETACEANS ON THE COASTS OF RIO DE JANEIRO, ESPIRITU SANTO AND BAHIA STATES, BRAZIL. L. Capistrano, R. Ramos and A.P. Beditto, Fundação dos Estudos do Mar (FEMAR) World Wildlife Fund-US Project No. 3807, Rua Marques de Olinda, 18, Botafogo – Rio de Janeiro, Brazil 22.230.

Between October 1988 and September 1989 we surveyed approximately 1,400km of the Brazilian coast from the village of Parati in the north (23°13'S, 44°43'W) to Santa Cruz de Cabralia in the south (16°13'S, 39°04'W). Fishing activities occur throughout the area surveyed. The main types of gear used are gillnets, seines, trawlnets and handlines. According to the fishermen, small cetaceans are incidentally captured in gillnets and seines in almost all of the places visited. The animals are generally used for fishing bait; an exception is the village of Regência (19°40'S, 39°45'W), where they are used for human consumption. We collected 25 small cetaceans at three localities (Atafona 21°37'S, 41°01'W, Regência and Conceição da Barra 18°30'S, 39°45'W); 21 were from gillnets and 4 from strandings. Of these, 17 were of the marine form of *Sotalia fluviatilis*, 7 were *Pontoporia blainvillei* and one was unidentified. The gillnets varied from 146–2,000m in length and 2–10m in depth. Mesh size ranged from 3–20cm. Because of the very long coastline involved and the brief period of time available for the survey, no attempt has been made to assess the impact of the incidental kills on the dolphin populations.

DOLPHIN CATCHES IN TAIWAN. Che-Tsung Chen, National Taiwan Ocean University, 2 Pei Ning Road, Keelung 20224, Taiwan.

There is a long history of catches of marine mammals in Taiwan. The primary species has been *Tursiops truncatus*, caught by gillnet, purse seine, drag net, drives using nets, tuna longline, troll line and harpoon. The main landing ports have been Peng-Fu, Suao and Tung-Kang. The meat is sold locally for human consumption at an attractively low price. At Peng-Fu the

fishermen use nets in a drive fishery to encircle the dolphins and hold them in inshore areas for sale to oceanaria in Taiwan and abroad. In recent years, about 60–100 dolphins have been captured during their annual migration in February. Local fishermen report that dolphins often interfere with hook-and-line fisheries, scaring the fish away and removing hooked tuna. Some dolphins are harpooned by fishermen when they follow the fishing vessels. Recommendations are made for future conservation and management of dolphins in Taiwanese waters.

BIOLOGICAL, ENVIRONMENTAL AND PHYSIOGRAPHIC FACTORS IMPLICATED IN THE INCIDENTAL CATCH OF BOTTLENOSE AND HUMP-BACKED DOLPHINS IN GILLNETS. V.G. Cockcroft, Port Elizabeth Museum, PO Box 13147, Humewood 6013, South Africa.

On the east coast of South Africa, gillnets are set to catch and deplete the numbers of sharks which may interact with bathers. Although the annual incidental catches of bottlenose and hump-backed dolphins (32 and 8, respectively) in these nets are low, neither population seems capable of sustaining such mortality and both appear to be in danger of local extinction. An analysis of biological, environmental and physiographic data for each animal captured provides some insights into the reasons for the incidental capture of these dolphins. The biological characteristics of the catch of the two species were generally distinct, although a few commonalities were evident. The majority of captures were single events, but mother and calf pairs of both species were often captured, although much more so for bottlenose dolphins. Most captured dolphins had almost full stomachs, implying that the capture of individuals of both species occurred either during or subsequent to feeding. Environmental parameters generally appeared to have no influence on captures. However, for the majority of captures of both species, current direction on the day of capture was different to that normally prevailing, possibly resulting in local prey movement and abundance. None of the physiographic factors analysed seemed to have an influence on capture. These results suggest that both bottlenose and hump-backed dolphins are captured during or immediately subsequent to feeding and although the exact mechanisms of capture are unknown, it is feasible that inattentiveness during or following feeding may result in capture. In conclusion, these data infer that efforts to prevent incidental captures should concentrate at the species level. Additionally, as both cetaceans and fisheries harvest in areas of relative prey abundance, it may be difficult to minimise captures without modifying fishing gear.

CAPTURE OF SMALL CETACEANS IN GILLNETS OFF THE PROVINCE OF SANTA CRUZ, ARGENTINA. R.N.P. Goodall and M. Iniguez, 3410 Ushuaia, Centro Austral de Investigaciones Científicas, Tierra del Fuego, Argentina. P. Sutton, Fundación Vida Silvestre Argentina, Buenos Aires, Argentina.

The Province of Santa Cruz, Argentina (46°S to 52°20'S) has some 1,000km of coastline facing the southwestern South Atlantic, with low areas at the mouths of rivers and streams interspersed with long stretches of high cliffs. The province is sparsely populated, with few large towns. In the southern part of the province, fishing takes place sporadically during summer months with fixed gillnets set in the tidal zone perpendicular to shore for coastal fish. During brief coastal surveys in 1983 and 1986, we found 31 Commerson's dolphins (*Cephalorhynchus commersonii*) taken in nets at Bahia Laura, San Julian, Bahia Media Luna, Angelina and Cabo Buen Tiempo. Remains of Peale's dolphins (*Lagenorhynchus australis*) and spectacled porpoise (*Australophocaena dioptrica*) could have come from net fisheries. Coastal fishing with gillnets set from small beaches is common in the northern part of the province and in rivers such as the Rio Gallegos. One or more captures are known from Bahia Laura, but no recent cetacean mortality has been reported from Puerto Deseado, the largest port, where nets evidently are not set if dolphins are present. At least 20 ocean-going vessels of over 30m in length are based in Puerto Deseado and a few leave from the ports of Santa Cruz and San Julian. These work over the continental shelf with mid-water or bottom

awl nets for shrimp, abadejo (*Genypterus blacodes*), merluzas (hakes, Merluccidae) and others. In some of these fisheries, especially for abadejo in mid-water trawls, cetaceans are taken incidentally; the species involved to date are *C. commersonii* and *L. australis*. Monitoring for incidental catch in this province began only recently and the data are far from complete.

ASSESSMENT OF THE IMPACT OF DRIFTNET FISHING ON OCEANIC ORGANISMS: TASMAN SEA, JANUARY 1990, THE RESULTS OF THE GREENPEACE EXPEDITION. Michael R. Hagler, Greenpeace Ocean Ecology Campaigner and Leader of the Tasman Sea Driftnets Expedition, Private Bag, Wellesley Street, Auckland, New Zealand.

While numerous scientific observer programs had documented the devastating toll being exacted by driftnets on marine wildlife in the North Pacific, no data existed at all on their impact in the Tasman Sea or South Pacific region. Concerned about this lack of data, Greenpeace launched an expedition into the area during the 1989/90 albacore tuna fishery season. Driftnet fishermen in the Tasman laid an average of 40km per boat, per night between January 12 and 21, 1990. Japanese vessels deployed an average of eight individual nets, five kilometers in length, end to end: Taiwanese vessels deployed an average of five individual nets, eight kilometers in length, end to end. These nets were laid north/south across the expected easterly migration path of albacore tuna. Quantitative catch data were recorded for 23 complete nets and part of two additional nets of nine different days. Data recorded were fishing activities carried out between approximately [3?] to 41°S, and 156° to 161°E. Total net length surveyed for quantitative catch data was 126km, or an estimated 1.6% of the total length of driftnets deployed during this period. Eighteen nets were surveyed during net haulage; seven were surveyed during net soakage. Total catch records for nets which were quantitatively surveyed included 1,419 tuna (albacore and skipjack), 5 sunfish, 6 sharks, 7 billfish, 7 dolphins and 31 miscellaneous animals. A rare southern bottlenose whale was found entangled in an additional net. On the basis of mean calculated catch rates, twenty driftnet vessels in the Tasman Sea were predicted to have caught between some 780,000 to 900,000 tuna, 3,000 sunfish, 4,000 sharks, 3,000 billfish, 6,400 dolphins and 20,000 Ray's bream during the 3 month season. In the case of marine mammals, one dolphin was caught per 113 tuna, or per 11km of net during the net haulage (using calculated means). A major concern raised by this investigation was the apparent extent of 'high grading' (discarding of damaged target species) by Japanese driftnet vessels. These data fully support reports that this fishing practice is directly responsible for an unacceptable number of marine mammal deaths in the Tasman Sea and that it presents a hazard to non-target animals such as sharks and sunfish.

INCIDENTAL TAKE OF CETACEANS BY FISHING ACTIVITIES IN THE NEARSHORE WATERS OF THE NORTHEASTERN US, 1975–1989. Scott D. Kraus, New England Aquarium, Central Wharf, Boston, MA 02110, USA. Colleen Coogan, National Marine Fisheries Service, 1 Blackburn Drive, Gloucester, MA 01930, USA. Patricia M. Fiorelli, New England Fishery Management Council, 5 Broadway, Saugus, MA 01906, USA.

A total of 428 cetacean entanglements have been documented from 1975 through 1989 in the nearshore waters of the Gulf of Maine and the New York Bight. Gillnets, lobster gear, weirs and seines are the primary sources of entanglement. When the documented entanglements are analysed by species, mortality rates are inversely correlated with the size of the animals involved. In harbor porpoise encounters with gillnets, mortality exceeded 99%. The reported minke whale entanglement mortality is 64%, for humpbacks it is 12% and for finback whales 0%. These figures are probably overestimates of large whale mortality per entanglement, since some whales are likely to escape before they are discovered in fishing gear. In right whales, for example, 58% display scars indicative of entanglement at some time in their lives, but only three are known to have died incidental to fisheries activities (Kraus, 1990). However, because

most entanglement reporting has been opportunistic the total number of entanglements is probably far larger than the 428 reported here. Further data from the NMFS marine mammal exemption program are not included here. For harbor porpoise, extrapolations from a limited systematic study conducted by Dr. James Gilbert in the early 1980s, combined with a review of the published literature, suggests that nearly 1,000 harbor porpoise are taken from the Gulf of Maine annually. This represents about 6.5% of the highest estimate of 15,300 for the Gulf of Maine harbor porpoise population (Read and Gaskin, 1988). Significant life history changes in the Bay of Fundy population indicating a serious population decline (Read and Gaskin, 1988) combined with this estimate suggest that the Gulf of Maine harbor porpoise population is being threatened by the gillnet fisheries of both the US and Canada.

MORTALITY OF HARBOUR PORPOISES IN THE SWEDISH GILLNET FISHERY. Ingalill Lindstedt, Institute of Marine Research, PO Box 4, S-453 00 Lysekil, Sweden.

Data on the mortality of harbour porpoises (*Phocoena phocoena*) in fishing gear in Sweden in the years 1988-1990 are presented. In June 1988, a collection of harbour porpoises found dead in Swedish waters was started. Animals killed in the Swedish fishery as well as animals that have died of other causes are taken to the Museum of Natural History in Goteborg where they are examined. Data on the location of the catch, the kind of fishing gear used, etc. are obtained from the fishermen. During the first two years of this project 272 animals were collected of which 137 (50%) were found in fishing gear, of these 116 (85%) were from the coastal gillnet fishery. Currently most of the harbour porpoises incidentally killed in the commercial fishery are collected, this is supported by interviews among fishermen. The findings have been evaluated in terms of distribution of different kinds of fishing gear, seasonal and geographical distribution and sex and age of the animals. All major types of gillnets used in the Swedish fishery were represented, but most of the animals were taken in large mesh nets, (70-170mm) set for cod (*Gadus morhua*), pollack (*Pollachius pollachius*) and dogfish (*Squalus acantias*). Fishery statistics indicate that large meshed nets show the highest catch per unit effort. Most animals were taken in nets set at 10 to 60 meters. Few animals were taken in driftnets, probably because the fishery with large mesh driftnets for salmon largely occurs in the Baltic Sea where the harbour porpoise nowadays is rare. The number of animals caught in the gillnet fishery shows a peak in April, most probably reflecting the migratory behaviour of the species as well as seasonal changes in the fisheries involved.

SURVEY OF INCIDENTAL NET CATCHES OF MARINE SOTALIA FLUVIATILIS, PONTOPORIA BLAINVILLEI AND OTHER SMALL CETACEANS IN BRAZIL. Liliane Lodi and Salvatore Siciliano, Projeto Baleia Jubarte, Parque Nacional Marinho dos Alborhos, Praia do Kitongo s/no., Caravelas, Bahia, Brazil 45.900. Monica Borobia, St. Lawrence National Institute of Ecotoxicology, 310 Avenue des Ursulines, Rimouski, Québec, Canada, G5L 3A1.

Unknown numbers of small cetaceans are killed annually by net entanglement in fishery operations in Brazil (Lodi and Capistrano, 1990). As a preliminary assessment of the nature and magnitude of catches, specimens were collected opportunistically from Pará (01°00'S 48°30'W) to São Paulo (25°15'S 48°00'W) States and available information compiled from the literature. Marine tucuxi (*Sotalia fluviatilis*) and the franciscana (*Pontoporia blainvillei*) appear to be the most common species incidentally caught in gillnets (of various dimensions) from coastal artisanal fisheries throughout most of their range in Brazil. To date, 90 *Sotalia* are known to have been taken incidentally by 22 fishing villages in the surveyed region, with 73% of these catches from

1986-1990. Twenty-nine franciscanas were captured by three fishing villages between 1984-1988, from Espírito Santo (19°38'S 39°49'W) to São Paulo (24°43'S 47°33'W) States. Sex ratios for *Sotalia* (n=54) and *Pontoporia* (n=23) were similar, being approximately 1:1. Catches for both species were higher during the austral summer, with adult *Sotalia* (87%, n=45), and juvenile and subadult *Pontoporia* (62.5%, n=24) predominating. Other species identified from bycatches were the rough-toothed dolphin (*Steno bredanensis*) (n=3), the common dolphin (*Delphinus delphis*) (n=2), one false killer whale (*Pseudorca crassidens*) and one spotted dolphin (*Stenella frontalis*), all from the coast of Rio de Janeiro State. Target fish vary regionally, but the main species include mullet (*Mugil* spp.), croaker (mainly *Micropogonias furnieri*), weakfish (*Cynoscion* spp.) and marine catfish (Ariidae). Captured dolphins are stored and sold to serve mostly as bait for local shark fisheries (mainly Carcharhinidae) but in poorer villages for human consumption. From the coasts of Pará to São Paulo, at least 83 fishing villages operate gillnets year round. In spite of its low sampling effort our survey indicates that *Sotalia* and *Pontoporia* are highly vulnerable, especially considering the rudimentary nature of some fisheries. The impact of such interactions on dolphin populations, of yet unknown size, requires further evaluation for the achievement of sound management and conservation policies.

PROPOSAL FOR COLLECTION OF INFORMATION ON THE VAQUITA (PHOCOENA SINUS) FROM FISHERMEN IN THE GULF OF CALIFORNIA. Roman G. Maldonado, Coordinator of Nature and Exact Sciences, University Iberoamericana, Mexico Parq. Ave. No. #403, Z.C. 22200, Beaches of Tijuana, B.C., Mexico.

The production and distribution of a simple brochure will provide an opportunity for fishermen to cooperate in efforts to preserve the vaquita. The fishermen may see the porpoise during or apart from fishing operations and potentially can collect data useful for scientific investigations. The brochure should include at least: (1) a complete description of the characteristics of the vaquita, including external proportions, with photographs; (2) a map showing all previous records; (3) a description, with illustrations, of the various types of nets in which the vaquita may be entangled; (4) a list of the kinds of observations of appearance, behaviour and fishery interactions that will be useful for research. The goal of this program, in addition to collection of data, will be to educate the fishermen and make them part of the program to save the vaquita.

ACCIDENTAL CATCH OF SOTALIA BRASILIENSIS IN SOUTHEAST BRAZIL. Emygdio L.A. Monteiro Filho, Departamento de Zoologia, Instituto de Biologia, Campinas, SP, CP 6109, Cep. 13.081, Brazil.

The estuarine complex of Cananéia is a mangrove region of high fertility, located in the south of the state of São Paulo, Brazil (25°01'S, 47°55'W). In this region, the local fishermen utilise two principal methods of fishing: the waiting net, which is extended in certain areas, although this method of fishing has not been used frequently; and the 'cercos' which is a fixed trap set in all seasons of the year in some mud banks, within the tidal range. *Sotalia brasiliensis* is frequently found in this habitat where it feeds in the surroundings of the mud banks. In 1984 a young female was found (approximately four months old) which had been killed in a waiting net in the mouth of a river. In 1989, young dolphins were found twice inside the 'cerco', with sufficient space for swimming and diving. In these occasions, the two dolphins were withdrawn from the 'cerco' with the help of a special net and subsequently were returned to the sea without any injury. However, these accidents in this region are rare and only one of the methods utilised (waiting net) may be harmful to the dolphins, although, without danger to the stock population.

REACTIONS OF BOTTLENOSE DOLPHINS DURING THE FIRST ENCOUNTERS WITH MONOFILAMENT GILLNETS.

Dawn Nelson, *Biopsychology Programme, Memorial University of Newfoundland, St. John's, Newfoundland, Canada and Dolphin Research Center, Grassy Keys, Florida. Jon Lien, Ocean Sciences Centre and Department of Psychology, Memorial University of Newfoundland, St. John's, Newfoundland, Canada.*

Reactions of captive bottlenose dolphins that had no previous experience with monofilament gillnets were recorded by underwater video camera. The dolphins were released in a familiar enclosure which contained a single gillnet. Trials continued for one hour. Later, latency of first behaviours directed toward the net, type and frequency of behaviours were scored from analysis of the videotape. Each animal was tested at least twice. In this presentation, videos of the dolphins' reactions to nets were shown. The relationship of behaviours during first encounters with gillnets to entrapment and net mortality will be discussed. Often the incidental entrapment of young dolphins in gillnets is considered the result of a failure to detect or pay attention to nets. This study suggests that exploratory behaviours and attention actually directed toward nets is responsible for many gillnet entrapments.

AN UPDATED WORLD REVIEW OF INTERACTIONS BETWEEN MARINE MAMMALS AND FISHERIES.

Simon P. Northridge, *Imperial College Centre for Environmental Technology, Marine Resources Assessment Group Ltd., 8 Princes Gardens, London, SW7 1NA, UK.*

This review is presented as an update to a previous work (Northridge, 1984) on interactions between marine mammals and fisheries. Each of the FAO statistical areas of the world oceans are treated in turn and published information for each area is used to collate an updated account of the ways in which marine mammals and fisheries interact. Particular attention is paid to the accidental capture of marine mammals in fishing gear and some new fisheries with potentially significant impacts on marine mammal populations are noted.

REFERENCE

Northridge, S.P. 1984. World review of interactions between marine mammals and fisheries. *FAO Fish. Tech. Pap.* 251.

ACCIDENTAL CAPTURES OF MARINE MAMMALS BY FISHERIES IN BRITISH WATERS WITH PARTICULAR EMPHASIS ON GILLNET FISHERIES.

Simon P. Northridge, *Imperial College Centre for Environmental Technology, Marine Resources Assessment Group Ltd., 8 Princes Gardens, London, SW7 1NA, UK.*

Records of accidental captures of marine mammals in British waters have been collected from a wide variety of sources. Such records indicate that accidental captures of marine mammals have occurred over a long period of time and in a wide variety of fisheries. Catches are reviewed by fishing method. Trawlers are economically the most important part of the fishing fleet in Britain and these vessels evidently catch a number of marine mammals every year. Although gillnet fisheries are economically far less important, the numbers of boats employing gillnets is very large. Accidental captures of marine mammals in these fisheries are discussed on a regional basis. Certain areas and types of gillnet fisheries appear to catch significantly more marine mammals than others. The reasons for this are discussed and recent trends in gillnet fisheries in Britain are reviewed in terms of changes in vessels size distribution and fishing effort by region.

DOLPHIN DETERRENTS TESTED IN SHARK NETS OFF NATAL, SOUTH AFRICA.

Vic Peddemors, *Natal Sharks Board, Private Bag 2, Umhlanga Rocks, 4320, South Africa. Vic Cockcroft, Port Elizabeth Museum, PO Box 13147, Humewood, 6013, South Africa.*

Shark nets are permanently set off 44 beaches on the Natal coast to protect bathers from shark attacks. Although these nets have proved very effective in preventing shark attacks, they have also

caught a substantial number of harmless animals, including dolphins (Cockcroft, 1990). Concern for the effect of these incidental shark-net captures on populations of *Tursiops* and *Sousa* led to experiments with dolphin deterrent devices in the nets. These deterrents included both active and passive devices which were manufactured as cheaply as possible to enable future mass production if the tests proved successful. (1) Active devices emitted sounds and were of three types: (a) *clangers*: hollow copper cylinders with a pendulum suspended underwater and set in motion through wave action; (b) *rattles*: loose metal balls rolling with wave action inside the plastic net floats; (c) *bell buoy*: a floating 7kg gas bottle with a pendulum suspended inside the sealed cavity and activated through wave action. (2) Passive devices did not produce audible signals: (a) *plasticised aluminium foil*: 25cm squares attached to 4m intervals along the net centre; (b) *aluminium disc*: 23.5cm diameter flat discs were attached to net ends; (c) *stainless steel twine*: a double strand of 0.16mm diameter stainless steel twine was included in the braid of a new net. 2(a) and 2(b) were intended to act as possible visual and echolocatory stimuli, whereas the braid was to act as an echolocatory stimulus. Dolphin behaviour did not change when in the vicinity of the nets containing the active devices, however, the net containing the rattles caught a juvenile dolphin after 15 days and a humpback dolphin was caught 300m from the bell buoy. Although shark catches did increase during the period of experimentation in the net containing clangers, the rattles and bell buoy appeared to cause no change to the shark catch rate. Electrolytic reaction between salt water and the aluminium foil resulted in clear plastic panels where sealing had broken. The aluminium discs tarnished (reducing visual stimulus), caused minor entanglements and cut the nets. No dolphin movements were observed around the nets during these two experiments and no shark or dolphin catches occurred. The stainless steel twine was not affected by corrosion but broke during normal net handling, resulting in numerous steel burrs which rendered the net unmanageable. These operational problems and an extremely low annual CPUE for dolphins led to the discontinuation of these experiments. Results from this work suggested that more data should be obtained regarding factors influencing the dolphin catches before continuing attempts to deter dolphins from these nets. Subsequent behavioural observations indicate that the dolphins are normally aware of the presence of the nets, suggesting that a form of distractant behaviour exists during capture. This usually takes the form of feeding behaviour, however, spontaneous behaviour such as play may be important, especially during the captures of younger animals. Experimentation has therefore started using nets of varying mesh sizes in an attempt to reduce catches of smaller/younger animals. This represents the first approach at modifying net selectivity rather than attaching possible deterrent devices to nets, although this is possibly not directly applicable to the problem of incidental captures elsewhere. The international lack of success with deterrent devices suggests that *ad hoc* experimentation of this type should be reduced in favour of gaining a better understanding of the species interacting with the fishery. It is also the authors' opinion that cheap, homemade devices would probably be insufficient to warn dolphins of nets and that electronic acoustic devices would be more effective.

STATUS AND CONSERVATION OF SEA DOLPHINS ALONG THE EAST COAST OF ANDHRA PRADESH, INDIA.

Rayavarapu J. Rao, *School of Zoology, Jiwaji University, Gwalior, 474 011, India.*

An investigation was carried out during the months of May and June, 1990 to study the mortality of dolphins in fishing nets in the coastal belt of Andhra Pradesh near Kakinada. Data were also collected from the Fisheries Department, A.P. It was reported by the fishermen that dolphins (*Tursiops aduncus*), vernacular name:

Gadumi, Torra) were occasionally caught in the gillnets. According to them sightings of dolphins are occasional and usually dolphins are sighted during October-April in groups of 6–10 animals. Along with sea turtles (*Lepidochelys olivacea*), dolphins were also killed along the east coast due to gillnet operation (Rao, 1985; Silas *et al.*, 1983). Fishermen reported that earlier dolphins were not used for any purpose: however, these days they use the flesh of dolphins as bait for sharks, which is a growing fishery on this coast. Fishermen also sell dolphins as food. The price for one dolphin varies from Rs500 to 1,000 (US\$30–60). According to the reports given by the Fisheries Department, a total of 7,892 fishermen using 1,973 boats operate gillnets along this coast. Each gillnet measures 30–40m in length and 12m in width, with a mesh size of 15–25cm. Detailed information on dolphin mortality rate along this coast is not available. It was learned that no measures are taken by the gillnet operators to avoid incidental catch of dolphins. It is suggested that a conservation programme for the protection of dolphins be started along the coast, where a sanctuary was created in 1978 for the conservation and management of the saltwater crocodile (*Crocodyles perosus*). Incidental catch of whales along this coast in gillnets has not been reported.

A TANGLED WEB: HARBOUR PORPOISES AND GILLNETS IN THE BAY OF FUNDY. Andrew Read, Department of Zoology, University of Guelph, Guelph, Ontario, Canada, N1G 2W1. Laurie Murison, Grand Manan Whale and Seabird Research Station, PO Box 129, North Head, Grand Manan, New Brunswick, Canada, E0G 2M0. Per Berggren, Department of Zoology, University of Stockholm, S-10691, Stockholm, Sweden. Thomas Woodley, Andrew Westgate and David Gaskin, Department of Zoology, University of Guelph, Guelph, Ontario, Canada, N1G 2W1.

We have been studying incidental catches of harbour porpoises (*Phocoena phocoena*) in the Bay of Fundy gillnets since 1985. Each summer harbour porpoises and groundfish move into the Bay of Fundy where the porpoises become entangled in gillnets set for the groundfish. In this paper we briefly review the fishery, the nature of the entanglement process, the effects of these incidental catches and explore potential resolutions to the problem. The gillnet fishery in the western Bay of Fundy is relatively small, composed of between 19 and 28 vessels each season. Typically, each fisherman use 15 webs (183 × 3.65m each) of 15cm mesh monofilament net, anchored on the bottom in depths of 35–100m (Read and Gaskin, 1988). The nets are usually set in the morning and retrieved the following day. Indirect evidence suggests that porpoises are entangled while the nets are on the bottom. We have received very few reports of live porpoises recovered from gillnets; most of the 300+ specimens we have examined exhibited rigor mortis and damage by benthic scavengers. In addition, many porpoises have remains of hagfish (*Myxine glutinosa*) in their stomachs, suggesting that the porpoises are feeding on hagfish that are themselves foraging on fish in the nets. It is unclear whether or not the porpoises can detect the nets. Preliminary evidence indicates that rates of incidental mortality from all gillnet fisheries, including those of the Gulf of Maine, lie between 2 and 10% per year. It is unlikely that the population can sustain such incidental catches, given their low potential for increase (Woodley and Read, 1990). Harbour porpoises have virtually disappeared from some areas in the Bay of Fundy in which they were formerly abundant, perhaps due to a decrease in total population size. There have also been changes in life history parameters, such as a decrease in age at sexual maturity and an increase in calf size, that are consistent with a reduction in density (Read and Gaskin, 1990). There are several

potential resolutions to this problem, including area closures, gear modification, or elimination of the fishery. We suggest that the most efficient solution to this particular conflict is to replace gillnets with other, more selective forms of fishing gear such as longlines.

THE IMPACTS OF PASSIVE NETS AND TRAPS ON THE GANGETIC DOLPHIN. Tej Kumar Shrestha, Royal Nepal Academy of Science and Technology and Department of Zoology, Kirtipur Campus, Kathmandu, Nepal.

Gillnetting is widely practised in the hydrographically unique mountain rivers of Nepal. Both fishermen and the susu (*Platanista gangetica*) rely on food from the rivers for survival and therefore interact in many ways. In the present paper, design and construction of various kinds of driftnets and gillnets are described. Entangling properties of the nets and their impacts on breeding and calving populations of dolphins are evaluated. Synthetic twine is widely used in the nets; this may be deadly, because it is not easily detected visually or acoustically by dolphins in the murky run-off waters generated by the annual monsoon (May-July). Dolphins are an indirect target of such fishing efforts and their populations are often negatively affected by interactions with fisheries. The fishermen compete for limited fish resources. In the process, dolphins become entangled in gillnets or are otherwise harvested inadvertently. The low water of winter attracts commercial gillnet fishermen, who use stretched gillnets and capture juvenile dolphins. Gillnets are often stretched across the river at night to capture everything that passes, placing them in direct competition with the dolphins. An estimate of mortality of juvenile dolphins and endangered game fish is made. Incidence of entanglement and effects of stranding events are evaluated. Possible ways and means to reduce dolphin kills in nets are discussed, including recommendations for regulation of mesh size. The dead and dying dolphins are retrieved immediately. Their eyes, foetuses and genitalia are used by folk healers as charms and in medicines. The need and opportunity for educating the riverside people about the value of the endangered dolphin are highlighted and suggestions are made for effecting fishing regulations and enforcement.

FRESHWATER DOLPHIN/FISHERIES INTERACTIONS IN THE AMAZON REGION (BRAZIL). V.M.F. Da Silva and R.C. Best*, Laboratorio de Mamíferos Aquáticos, Instituto Nacional de Pesquisas da Amazônia, (INPA), Brazil.

An analysis of the relative importance of different types of fishing gear in Amazon dolphin mortality based on samples of 33 *Inia geoffrensis* (boto) and 34 *Sotalia fluviatilis* (tucuxi) revealed the lampara seine was most lethal (82.8%) for *Inia*. Whereas, drifting (38.3%) and fixed gillnets 35.3% were the major contributors in *Sotalia* mortality. These three types of gear accounted for a total of 97% of all *Inia* captures and 88.2% of *Sotalia* incidental captures. The use of nylon gillnets in fisheries in the Amazon, although recent, is widespread throughout the whole region, with increasing fisheries pressure and the potential for dolphin-fisheries interaction is much greater. Competition between man and dolphin for commercial fish is still minimal in the Central Amazon. Food habits analysis have shown that only 43% of 53 identified prey species are of commercial value and that the dolphins generally prey on size-classes of fish below the size-classes of commercial interest. Interviews with fishermen in the boats, in the fishmarket and in the shops supposedly selling

dolphin products were conducted in an attempt to quantify the overall incidental kill attributed to commercial fisheries operations. The results showed that in the Central Amazon dolphin catches are incidental and only a very small number of these carcasses are used for commercial purposes.

INCIDENTAL CATCHES OF SMALL CETACEANS IN DRIFTNETS DURING SALMON TAGGING EXPERIMENTS IN THE NORTHWEST ATLANTIC. Garry B. Stenson and Dave G. Reddin, Science Branch, Department of Fisheries and Oceans, PO Box 5667, St. John's, Newfoundland, Canada, A1C 5X1.

We examined incidental catches of cetaceans in surface driftnets used to obtain salmon (*Salmo salar*) for tagging experiments. From 1965 to 1989, 29 cruises with a total of 5,365nm-hrs (nm*hr) of fishing effort were undertaken in offshore areas from the southern Grand Banks of Newfoundland to West Greenland. In addition, 12 cruises totalling 887nm*hr of fishing effort, occurred in inshore areas around Newfoundland and Labrador between 1969 and 1981. Data on the species and numbers of individuals caught, dates and locations of capture and catch per unit fishing effort were obtained using trip summaries and onboard observations. Although earlier sets used multifilament gillnets, monofilament nets with mesh sizes from 102 to 140mm were used for the majority of sets. Four species of small cetaceans were identified as bycatch. Harbour porpoise (*Phocoena phocoena*) were the most frequently caught species in all areas except for the Labrador Sea, where white-sided dolphins (*Lagenorhynchus acutus*) were more common. Long-finned pilot whales (*Globicephala melas*) and common dolphins (*Delphinus delphis*) were also caught. Low numbers (1–3) of harbour porpoise were regularly caught in the West Greenland, Grand Banks and inshore areas. Occasional large catches occurred in some sets. CPUE averaged 0.008/nm*hr inshore (spring and summer), 0.01/nm*hr in West Greenland (summer), 0.03/nm*hr on the Grand Banks (spring) and 0.14/nm*hr in the Newfoundland Basin (spring). Although considered primarily an inshore species, harbour porpoise were found in waters of all depths, including the deep waters (>2,000m) of the Newfoundland Basin and Labrador Sea. White-sided dolphins were caught sporadically (6 trips only) but in larger groups than harbour porpoise. CPUE varied from 0.04–0.05/nm*hr in the Newfoundland Basin (spring) and Labrador Sea (summer) to 0.004/nm*hr on the Labrador Shelf. White-sided dolphins tended to be caught in warmer waters and along the shelf edge. None were caught inshore, in West Greenland, or on the Grand Banks proper. Catches of all species varied greatly along years and were highly skewed. No animals or seasonal trends were obvious although the large number of cetaceans caught during the only major trip to the outer slope of the Grand Banks in May suggest that this may be an important area for all four species.

ENTANGLEMENT OF TWO HUMPBACK WHALES AND ONE GRAY WHALE IN PASSIVE FISHING GEAR IN SOUTHEASTERN ALASKA. Janice M. Straley, Glacier Bay National Park and Preserve Gustavus, Alaska 99826, USA. C. Scott Baker, Victoria University, Wellington, New Zealand.

In August 1986, a humpback whale (*Megaptera novaeangliae*) calf (defined as a whale less than one year old and accompanied by another, larger whale, presumed to be the cow) was observed towing fishing gear in Frederick Sound. The gear consisted of 100m of small diameter, green, polypropylene ground line, trailing a large, 1m diameter, fluorescent-pink bag buoy attached to a 2m tall, weighted aluminium flag pole. This type of gear is used in long-line bottom fishing in southeastern Alaska. The pod consisted of the cow, calf and a companion. To disentangle the whale, the pole and buoy were cut loose and the ground line was reeled in and cut off in 8m sections. It was not obvious where the line was attached to the whale, it was assumed to be around the tail stalk. All but 5–8m of line was removed. This procedure took

about three hours. All three whales stayed together during this time, not diving or fluking. The pod was then observed for 20 minutes and behaviour appeared to resume to normal. In July 1988, a 16m, gray whale (*Eschrichtius robustus*) became entangled and died in a gillnet set at the mouth of the East Alsek River. The net was set in accordance with state law. The whale was presumed to be feeding in shallow water, nearshore on a rising tide. It apparently became entangled in the haul out line of the set gillnet on the outgoing tide. The whale appeared to have been in good health. The entanglement occurred near the tail as there was no gear or scarring on the body of the whale. In August 1988, a humpback whale calf was observed towing a yellow, 1/2m diameter float in Icy Strait. The calf was accompanied by a larger whale presumed to be the cow. The whales were approached and the line disentangled in a similar manner described above. The fishing gear consisted of 160m of small diameter, green, polypropylene ground line. Entangled with this line were ground line snaps, circle hooks and salmon trolling gear (flashers and hoochies). This whale had apparently caught other fishing gear while towing this longline gear. This cow and calf were seen subsequently throughout the summer season. The two humpback entanglements occurred in gear left after a fishing opener. This could have been avoided by stricter regulations on gear removal. The gray whale entanglement and death could have been avoided by a closer watch by the regulatory agencies. It is known that gray whales feed close to shore and there were observations of grays and humpbacks feeding in the area prior to the incident. The biology and behaviour of individual cetacean species needs to be considered when establishing guidelines for reducing entanglement and developing methods for disentanglement in passive fishing gear.

THE SOUNDS OF SILENCE: ACOUSTICS OF FISHING NETS AND BAIT. Sean Todd, Biopsychology Programme, Memorial University of Newfoundland, St. John's, Newfoundland, Canada, A1B 3X9 and C-CORE (Centre for Cold Ocean Research and Engineering), Memorial University of Newfoundland, St. John's, Newfoundland, Canada. Jacques Guigne, C-CORE, Memorial University of Newfoundland, St. John's, Newfoundland, Canada. Jon Lien, Ocean Sciences Centre and Department of Psychology, Memorial University of Newfoundland, Canada.

A series of experiments were conducted to determine acoustic signatures of fishing gear and fish schools. The objective was to determine those signals which would be available to cetaceans in locating such objects and the acoustic interactions between fish and fishing gear. Sounds from different types of nets were measured in a flume tank under different water flows. Nets vary considerably in the noise they produce. Field data on number of the entrapments of humpback whales correlates inversely with noise of fishing gear. Acoustic signatures of a bait fish, capelin, were obtained for schools of different sizes and sex compositions in both laboratory and field tests. The presence of bait modifies and reduces noise associated with nets and may make them more difficult to detect. Complex fishing gear, such as traps, were studied as they filled with target species such as codfish. Sounds produced by this gear were also modified by the presence of fish. Sounds produced by fishing gear may be an important factor in determining the frequency of entrapment of at least some cetaceans, but the acoustic characteristics of fish in the nets modifies sound of the nets. Thus entrapment frequency is a function of net acoustics and how well the net is fishing.

ESTIMATE OF VAQUITA, *PHOCOENA SINUS*, MORTALITY IN GILLNET FISHERIES IN THE NORTHERN GULF OF CALIFORNIA, MEXICO. Peggy T. Turk Boyer, The Intercultural Center for the Study of Deserts and Oceans, 2601 E. Airport Road, Tucson, AZ 85706, USA. Gregory K. Silber, Institute of Marine Sciences, University of California, Santa Cruz, CA 95064, USA.

The vaquita, *Phocoena sinus*, is vulnerable to the point of extinction. While the species apparently suffers substantial mortality in gillnets, the magnitude of incidental mortality and its

impact on the population are not known. We interviewed fishermen in an attempt to determine fishing effort in the northern Gulf of California and to quantify vaquita mortality levels in gillnets. Though some problems are inherent to these types of data, the information can guide management decisions until more complete studies on incidental mortality are conducted. A total of 70 fishermen were interviewed from three communities in the northern Gulf of California. Gillnet fishermen reported capturing 22 vaquita, at a rate of 0.05 vaquita/fisherman/year resulting in an overall mortality estimate of 32.3 ± 14.1 (95% CI) vaquita/year. This estimate may represent as much as 10% of the entire vaquita population. The majority of vaquita (90.1%) were caught in the most frequently used nets which consisted of 25.4–30.5cm mesh. Ninety-five percent of the vaquita were captured in water depths between 9 and 50m and mean depth was $24.9 \pm \text{SD } 17.61\text{m}$. The greatest fishing effort and 75.0% of the porpoise captures occurred in March through June corresponding with the northward migration of totoaba (*Cynoscion macdonaldi*). The taking of totoaba is prohibited by law. In addition to vaquita, 43.5% of the fishermen reported capturing sea turtles, 32.6% caught sea lions, 28.3% caught common dolphins and 21.7% caught bottlenose dolphins. Of all reported incidental catches of reptile and marine mammal species, 95.7% occurred in 25.4–30.5cm mesh gillnets. We recommend that gillnetting activities in the northern Gulf of California be ceased immediately. If complete moratoriums are not feasible, restrictions should be considered with respect to mesh size, fishing location, water depth or season.

INCIDENCE OF GEAR ENTANGLEMENT FOR RESIDENT INSHORE BOTTLENOSE DOLPHINS NEAR SARASOTA, FLORIDA. Randall S. Wells, Conservation Biology Department, Chicago Zoological Society, Brookfield, IL 60513, USA. Michael D. Scott, Inter-American Tropical Tuna Commission, c/o Scripps Institution of Oceanography, La Jolla, CA 92038, USA.

Bottlenose dolphins residing in the shallow inshore waters along the central west coast of Florida are exposed to gear from a variety of commercial fishing activities, including gillnets, trammel nets, purse seines and crabtraps. We have found evidence of apparent gear entanglement on 11.0% of the 146 dolphins we have handled during our capture, sample, mark and release efforts during 1975–1990. Evidence of apparent entanglement includes direct observations, as well as records of cuts and scars around the torso, fins and gape of the mouth that match the diameters of lines commonly used in fishing gear. Mortality from entanglement with fishing gear, however, appears to occur infrequently. Only one of the resident dolphins is known to have died directly from entanglement during 1975–1989. A subadult male entangled in a beach-set pompano gillnet during a squall in 1976. Two other entangled dolphins would probably have died save for human intervention. One 9 month old female entangled in a mullet gillnet was released unharmed by our research team. A 7 year old male became tangled in a crabtrap floatline; the trap and float were cut free by boaters. A minimum estimate of the annual mortality rate due to entanglement is 0.001 ± 0.0011 (1 confirmed mortality during 898 animal years), but could have been 0.003 ± 0.019 (3

mortalities) if human rescue had not occurred. These mortality rates are minimum estimates because not all dolphin carcasses may have recovered or have shown signs of entanglement. Annual loss from the approximately 100 residents of the Sarasota population due to natural in incidental fishery mortality and emigration averaged 0.189 for young of the year and 0.038 for older animals (Wells and Scott, 1990). A disproportionately high number of subadult dolphins were involved in entanglement. At least 9 of 16 apparent entanglement records involved subadults; the scarring on the remaining adults occurred at an undetermined age.

FIRST EVALUATION OF THE INTENTIONAL AND ACCIDENTAL CATCH OF CETACEANS AT SANTA CATARINA ISLAND, BRAZIL. Alfredo Ximenez, Laboratorio de Mamíferos de Universidade Federal de Santa Catarina, Caixa Postal 5132, Campus Universitario, 88049 Florianópolis, SC, Brazil.

Until 1985, the level of mortality of cetaceans caused by fishing activities in Santa Catarina State was unknown. In that year a program began which included collection, preparation and conservation of stranded specimens all along the littoral (172km) of Santa Catarina located between the parallels 27°10' and 27°50'S and the meridians 48°25' and 48°35'W. Between February 1985 and June 1990, 40 specimens have been obtained showing marks of gillnets and mutilation. One intentional take of *Pontoporia blainvillei* was recorded. The following species were stranded and collected: *Steno bredanensis*, *Sotalia fluviatilis*, *Tursiops truncatus*, *Stenella frontalis*, *Delphinus delphis*, *Pseudorca crassidens* and *Balaenoptera acutorostrata*. Also collected was the head of a specimen identified as *Tursiops truncatus* but the morphology of its skull shows combined characters of both *Tursiops* and *Steno*; this suggests that the specimen is an intergeneric hybrid that should be the central point for further studies. Artisanal fishing is developed in the region in ancient traditional communities that use several kinds of nets with mesh size between 40mm and 200mm. The impact of this kind of activity on the cetacean population still remains unknown. Nevertheless a well directed study could yield valuable information in the future.

* Correspondent: caleb.phillips@ttu.edu

The biology of the Steller sea lion (*Eumetopias jubatus*) has been the subject of intense scientific investigation. This is primarily due to the rapid decline of population size in the western part of the species' range since the 1970s and the subsequent Threatened and Endangered species listings that had direct impact on the management of one of the world's largest fisheries. The Steller sea lion has emerged as an indicator species representing the environmental health of the North Pacific Ocean and Bering Sea. In this study, to better understand the historical processes that have culminated in the extant populations of *E. jubatus*, a large genetic data set consisting of 3 mitochondrial regions for >1,000 individuals was analyzed from multiple phylogeographic and demographic perspectives. The results describe the role of climate change in shaping the population structure of *E. jubatus*. Climatically associated historical processes apparently involved differential demographic responses to ice ages (and putative glacial vicariance) dependent on population size. Ice ages during times of small effective population size promoted restricted gene flow and fragmentation, and ice ages occurring during times of large population size promoted gene flow and dispersal. These results illustrate that effective population size has a profound effect on how species respond to climate change, an observation with obvious implications for large mammals and endangered species under the present conditions of imminent anthropogenically caused climate change. In addition, the results confirm previous observations of strongly biased historic and contemporary gene flow involving dispersal from west to east. Furthermore, phylogenetic patterns in combination with available fossil data suggest the potential of an Asian origin of *E. jubatus*. The results of this study provide a detailed scenario for the history that has shaped contemporary populations of *E. jubatus*.

Key words: climate change, demography, environment, long-term effective population size, phylogeography

© 2011 American Society of Mammalogists

DOI: 10.1644/10-MAMM-A-305.1

An intensive research effort into the biology of the endangered Steller sea lion (*Eumetopias jubatus*) has resulted in significant advances in our understanding of the evolutionary history, population structure, demographic trends, physiology, ecology, and evolution of this species (Baker et al. 2005; Bickham et al. 1996, 1998; Harlin-Cognato et al. 2006; Hoffman et al. 2006, 2009; Kenyon and Rice 1961; Loughlin et al. 1987, 1992; O'Corry-Crowe et al. 2006; Phillips et al. 2009a, 2009b; Trites and Donnelly 2003). For example, population genetic and phylogenetic investigations have demonstrated clear population structure at rookery, region, and stock levels, with phylogenetic delineation increasing at broader geographic groupings (Baker et al. 2005; Bickham et al. 1996, 1998; O'Corry-Crowe et al. 2006). In addition, a population decline of >80% resulted in listing the western stock as endangered under the United States. However, the eastern stock has maintained stable numbers over recorded time

but still retains a threatened listing. The determination of major coincident patterns in genetics, morphology, and demography recently has led to the formal description of these 2 forms as the subspecies *E. j. jubatus* (consisting of the Asian and western stocks) and *E. j. monteriensis* (eastern stock—Phillips et al. 2009a; Fig. 1). Refining our understanding of the processes that ultimately led to the current population structure can enhance our existing knowledge of mammalian evolution and guide the future management of Steller sea lions in the North Pacific and Bering Seas. As a result of extensive research conducted to support Endangered Species Act listing, we have a relatively broad understanding of many aspects of the biology and life-history characteristics of *E. jubatus* and a preliminary

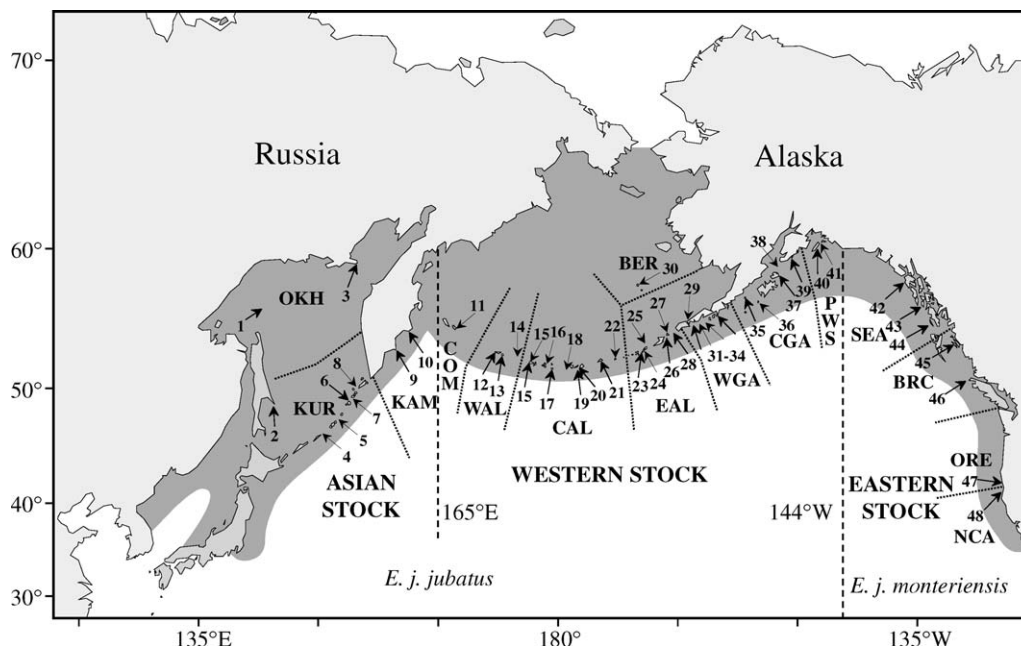

FIG. 1.—Map of the distribution of *Eumetopias jubatus* and recognized subspecies. Abbreviations for the regions are as follows: OKH = Sea of Okhotsk, KUR = Kuril Islands, KAM = Kamchatka Peninsula, COM = Commander Islands, WAL = western Aleutian Islands, CAL = central Aleutian Islands, EAL = eastern Aleutian Islands, WGA = western Gulf of Alaska, BER = Bering Sea, CGA = central Gulf of Alaska, PWS = Prince William Sound, SEA = southeastern Alaska, BRC = British Columbia, ORE = Oregon, NCA = northern California. Rookeries included in this study are indicated by arrows and numbered following Appendix I.

understanding of how the evolutionary history of the species has influenced observed contemporary genetic patterns. Given the distribution of *E. jubatus* around the North Pacific Rim (within a region where glacial movement has been particularly dynamic throughout the Pleistocene—Mann and Peteet 1994; Fig. 1) and the dependence of *E. jubatus* on linearly distributed rookeries for breeding and birthing (many of which are within areas known to have been covered by ice during previous glacial maxima—Grosswald and Hughes 2002; Mann and Peteet 1994; Westgate et al. 2001), the hypothesis of Harlin-Cognato et al. (2006) that genetic patterns are in part the result of phylogeographic occurrences driven by climatic change (changes in the extent of ice cover, glacial vicariance, and sea-level changes) is reasonable. Furthermore, the presence of a detailed and accurate phylogeographic history encompassing the entire range of *E. jubatus* is necessary to provide evolutionary context for the life-history characteristics documented in other studies.

The well-defined population model of *E. jubatus* is characterized by rookery dependence with high female philopatry. This information, in combination with a thorough genetic sampling of individuals through years of fieldwork, is useful for interpreting genetic patterns from a population genetics or phylogeographic perspective. In addition, a detailed working hypothesis of global climatic history based on ice core data (Loulergue et al. 2008) provides logical a priori phylogeographic expectations and a potential to build accurate phylogeographic inferences about *E. jubatus*.

We used a large genetic database of *E. jubatus* of >1,000 individuals (approximately 1.63% of the female population from 79% of known rookeries). Sequence data are taken from

2 mitochondrial genes, cytochrome *b* (*Cytb*) and nicotinamide adenine dinucleotide dehydrogenase 1 (*ND1*), and the hypervariable region 1 (HVRI) of the control region. Evolutionary signal is maximized from this data set by recovering cryptically recurrent substitutions from HVRI data (Phillips et al. 2009b). The end result is a robust and highly resolved genetic data set. Multiple analytical approaches have been used to test the major hypothesis that climate change has shaped contemporary genetic patterns of diversity and divergence in *E. jubatus*. These analyses help develop a long-term perspective on gene flow and elucidate the geographic center of origin of the species.

MATERIALS AND METHODS

Sampling and molecular methodologies.—All tissue samples used in this study were hind-flipper punches taken from pups biopsied at natal rookeries a few weeks after birth and were obtained in accordance with guidelines of the American Society of Mammalogists (Gannon et al. 2007) under Marine Mammal Protection Act permit 782-1532-02. Sampling included specimens from 48 of 61 total known breeding rookeries distributed across the North Pacific Rim (Fig. 1). Because of strong natal philopatry observed in *E. jubatus*, this sampling strategy leads to a high probability that pup haplotypes observed at rookeries are the result of breeding at that particular rookery.

Sequence data for the complete *Cytb* (1,140 base pairs [bp]) and HVRI (238 bp) for 1,021 individuals were available from previous studies (Baker et al. 2005; Harlin-Cognato et al. 2006; Phillips et al. 2009b). In addition to these *Cytb* and

HVRI data, at least 1 individual representing each observed HVRI/*Cytb* haplotype combination also was sequenced for the entire *ND1* gene (957 bp). Because a large proportion of total observed HVRI/*Cytb* composite haplotypes were observed at a low frequency ($69\% \leq 5$ observations), the sample subsets of individuals for *ND1* likely provided an accurate overall depiction of the distribution of *ND1* haplotypes and provided a reasonable alternative to sequencing all 1,021 samples for *ND1*. Polymerase chain reactions for *ND1* were performed as described by Baker et al. (2005) using primers LGL 287 (CCTACGTGATCTGAGTTCAGACC) and LGL 563 (GG-TATGAGCCCGATAGCTTA) with thermal profiles consisting of an initial denaturing cycle of 95°C for 5 min followed by 32 cycles of 95°C for 30 s, 50°C for 30 s, and 72°C for 2.5 min. For sequencing, internal sequencing primers Ejub-ND1-434seq(F) (CCATTATTCTCCTGTCTCAGTAC) and Ejub-ND1-636(R) (GGCCTGCTGCATATTCTACG) were used with a 50°C annealing temperature. Reactions were cleaned by centrifugation through Sephadex G-50 columns and then sequenced on an ABI 3730 platform (Applied Biosystems, Warrington, United Kingdom).

The *ND1* sequences were aligned in Sequencher 4.8 (GeneCodes Corporation, Ann Arbor, Michigan) and examined for the presence of insertions–deletions and stop codons in the coding region to check for any signs that nuclear inserts had been sequenced incidentally. A neighbor-joining tree was constructed in PAUP* version 4.0b10 (Swofford 2003) to identify all unique *ND1* haplotypes.

Data matrices construction and selection.—To maximize phylogeographic signal from the mitochondrial DNA (mtDNA) data set an approach involving the concatenation of HVRI and coding region sequences, followed by the preferential weighting of coding region data and subsequent phylogeny construction, was used—similar to that of Bandelt et al. (2002)—to characterize HVRI recurrent substitution. Characterized recurrent substitutions were incorporated into the data matrix as pseudo positions at the end of the file, and the original position was removed. Phillips et al. (2009b) demonstrated little indication of recurrent substitution in mtDNA coding regions of *E. jubatus*, justifying the application of this strategy. Using this method basal tree structure was determined largely by coding region data, areas unlikely to be subject to homoplasy at the taxonomic level and lineage age considered here, and resolution at more terminal branching was improved by the disclosure of recurrent substitution within HVRI. To confirm the appropriateness of this method an Approximately Unbiased (AU) test was performed. In this test phylogenies constructed from genetic data matrices that were either extended to describe recurrent substitution at HVRI, were not extended to express this variation, or did or did not include the *ND1* data (included as a variable here due to the nonexhaustive sampling strategy for this gene) were produced and then compared for explanatory power given each data matrix, following the methods outlined by Shimodaira (2002). The input phylogenies for this assessment were generated in MrBayes version 3.0 following all program

TABLE 1.—Results of Akaike information criterion selected best-fit models of nucleotide substitution for each gene. α = gamma distribution shape parameter. HVRI(*Cytb*) refers to the hypervariable region 1 (HVRI) sequence extended to express recurrent substitution identified by cytochrome *b* (*Cytb*) weighting during neighbor-joining tree construction. Similarly, HVRI(*Cytb*/*ND1*) refers to the HVRI sequence extended to express recurrent substitution identified by *Cytb* and nicotinamide adenine dinucleotide dehydrogenase 1 (*ND1*) weighting during neighbor-joining tree construction.

Gene	Best-fit model	α
HVRI	HKY + I + G	0.8905
<i>Cytb</i>	HKY	Equal rates
<i>ND1</i>	HKY + I	Equal rates
HVRI(<i>Cytb</i>)	HKY	Equal rates
HVRI(<i>Cytb</i> / <i>ND1</i>)	HKY	Equal rates

author implementation specifications (Ronquist and Huelsenbeck 2003) and using the best fit model of evolution for each gene determined by the Akaike information criterion in ModelTest 3.7 (Posada and Crandall 1998; Table 1). For the AU test site-wise log-likelihoods for each nucleotide position in each data matrix were calculated independently given each phylogeny. Log files containing site-wise log-likelihood values served as input for the program CONSEL (Shimodaira and Hasegawa 2001) where the AU test was performed and the confidence set ($\alpha = 0.05$) was obtained.

Phylogeographic methods.—The complete single-locus nested clade phylogeographical analysis (NCPA) procedure conducted in this study followed the methodologies outlined in several other studies as follows. A haplotype network was constructed in TCS version 1.3 (Clement et al. 2000) following the rules of parsimony using the data matrix previously selected through AU testing. Next, the network was nested into clades following the nesting algorithm described by Templeton et al. (1987), Templeton and Sing (1993), and Crandall (1996). Testing for significant associations (χ^2) of clades with geography was performed in the program GeoDis by conducting 10,000 random permutations of clades (genetic variation) among sampling locations (rookeries—Posada et al. 2000; Templeton and Sing 1993). Geographic distances used were calculated as dispersal distances along the continental shelf, rather than great circle distances, to depict more accurately probable dispersal patterns in *E. jubatus*. Along-shelf dispersal distances (measured as distance between rookeries passing through any intermediate rookeries) are likely most appropriate because dispersal among rookeries by *E. jubatus* is thought to largely be confined to productive continental shelf waters, and great circle distances (point-to-point measurements around a sphere) would, in some instances, imply long dispersal routes through deep oceanic waters. Significant results from the GeoDis analysis were interpreted using the most recent inference key (made available 15 December 2008).

To cross-validate NCPA statistical significances an analysis of variance (ANOVA) was performed for each clade that returned a significant NCPA test statistic. For this analysis

each haplotype/nested clade was treated as a group and the nesting clade as the population to which the groups belonged. Covariance components were calculated from the observed distribution of haplotypes/nested clades among each rookery. Significance was determined by randomly permuting the geographic distribution of groups among each respective population for 1,000 iterations and recalculating the test statistics for each iteration to obtain the null distributions.

Additionally, data on methane concentration recovered from ice cores with dense coverage extending 800,000 years ago were incorporated for comparison with dated significant single-locus NCPA inferences. This data set consisted of 2,103 data points with an average time resolution of approximately 380 years (Loulergue et al. 2008). Because methane is a globally mixed and long-lived greenhouse gas, it is considered a valuable indicator of climatic oscillation (Houghton et al. 2001). In the North Pacific Ocean climatic oscillations clearly have promoted the advance and retreat of glacial bodies that likely have modified biotic distributions (Grosswald and Hughes 2002; Mann and Peteet 1994; Westgate et al. 2001). If demographic events inferred by single-locus NCPA within *E. jubatus* are largely the result of glacial vicariance, we would expect global methane values (i.e., climate) at the time of these events to correlate with single-locus NCPA derived inferences in a meaningful way. Because preliminary analysis verified the normality of the methane data (Kolmogorov–Smirnov test; $D = 0.068$, $P > 0.99$), and because sample size was large, significance of this relationship was assessed through a 2-tailed Z-test by treating methane concentrations at estimated dates of demographic events as random samples from a normally distributed population of values.

Because preliminary analysis of single-locus NCPA results indicated sequestering of the same demographic inference type into distinct temporal clusters, the probability of such a pattern arising by chance was assessed as a binomial probability. Eighteen unique inference outcomes exist in the most recently revised inference key. Therefore, the probability of success (i.e., obtaining any 1 specific inference in a single trial) was $1/18 = 0.0556$, and the probability of failure to obtain any 1 specific inference in a single trial was $17/18 = 0.9444$. The exact binomial formula is $P(k \text{ out of } n) = n!/[k!(n - k!)](p^k)[q^{(n-k)}]$, where n is the number of trials, k is the number of successes, p is the probability of success on a given trial, and q is the probability of failure on a given trial.

To date historical events inferred by single-locus NCPA for this assessment divergence dating using BEAST version 1.4.8 (Bayesian evolutionary analysis sampling trees—Drummond and Rambaut 2007) was carried out as described below for the Bayesian phylogeny, except with monophyly constraints added to ensure tree topology matched that observed in the haplotype network. Monophyly constraints were expressed in the starting newick tree used to initiate the analysis.

Divergence dating and Bayesian phylogeny estimation within the lineage of *E. jubatus* were performed simultaneously in the program BEAST. The basal position of *Callorhinus* within the family Otariidae, the sister relationship

of the Arctocephaline clade to the *Otaria*, *Zalophus*, *Eumetopias* clade, and the *Zalophus*–*Eumetopias* split are well supported (Arnason et al. 2006; Higdon et al. 2007) and are the 3 node date priors included in this study. Multiple studies have assigned divergence dates within the family Otariidae, with dates estimated from fossil evidence representing a hard lower bound (Marshall 1990) and multiple molecular date estimates producing a range of values. For example, although the oldest available *Eumetopias* specimen (potentially an extinct form) recovered suggests a minimum *Zalophus*–*Eumetopias* divergence of 2 million years ago (mya—Repenning 1976), molecular dates for this split are 4.5, 6, and 8 mya, depending on the estimation algorithm and the loci included (Arnason et al. 2006; Higdon et al. 2007). As a conservative measure—conservative in that older molecular-based divergence estimates imply a greatly reduced rate of sequence evolution in otariids, which is not likely given the observed sequence diversity within *Eumetopias*—the dates estimated by Higdon et al. (2007), based on a 50-gene supertree that provided the most recent molecular dates, were used as date priors in this study (*Callorhinus* divergence, 8.2 mya; Arctocephaline–*Otaria*, *Zalophus*, *Eumetopias* clade split, 5.2 mya; and *Zalophus*–*Eumetopias* split, 4.5 mya).

Initial divergence dating within the *Eumetopias* lineage was performed using the 2 coding regions (*Cytb* and *ND1*), with each partition receiving its own model of DNA evolution as previously determined through model testing. In this analysis all codon positions were included. However, dates estimated from the inclusion of only 1st and 2nd codon positions gave very similar node dates, indicating that homoplasy at coding regions within the family Otariidae was not heavily influencing divergence estimation (data not shown). All program operations for this analysis strictly followed the program author guidelines. Dates estimated for the time to most recent common ancestor and the next most basal set of divergences within the *Eumetopias* lineage were recorded and retained as node date priors in a 2nd BEAST analysis to estimate dates of the more terminal nodes using only HVRI data. The objective of dating basal nodes with coding region data and terminal nodes with HVRI data was to partition substitutions from the 3 genes into areas of the tree where they retain the most phylogenetic information. From the final tree file the maximum clade credibility tree was obtained using TreeAnnotator (part of the BEAST package). In addition, because previous studies have demonstrated that the *Eumetopias* phylogeny contains substantial information about population history, a Bayesian skyline plot allowing for 5 discrete changes in population size was constructed using standard Markov chain Monte Carlo sampling procedures to estimate posterior distributions of theta ($\theta = N_{ef}\tau$, where N_{ef} is female effective population size and τ is generation length) through time using a flexible demographic model and directly from the sample of gene sequences (Drummond et al. 2005). Five demographic changes were allowed to identify historic demographic changes while at the same time not over-parameterizing the analysis. A generation time for *E. jubatus*

TABLE 2.—Approximately Unbiased (AU) test (Shimodaira 2002) of topological congruence based on site-wise log-likelihoods of 4 molecular data matrices for reciprocal gene trees. The tree receiving 1st-position ranking for each comparison is demarcated by bold and italicized numbering. See text for definition of acronyms.

of 10 years was assumed for this estimation (Calkins and Pitcher 1982; York 1994).

RESULTS

Gene variability, recurrent substitution, and data matrix selection.—Approximately 1.6 million sequenced base pairs (bp) were included in this study. We identified 18 *Cytb* and 82 HVRI haplotypes from 1,021 individual *E. jubatus* (Appendix I). The *Cytb* network (not shown) contained no reticulations and consisted of 2 halves that largely describe the 2 previously identified subspecies. The halves of the cladogram are separated by an inferred haplotype and 2 amino acid changes. Conversely, the network produced from the 82 observed HVRI haplotypes (not shown) contained numerous reticulations. We sequenced 202 individuals, including at least 1 representative of all HVRI/*Cytb* composite haplotypes, for the 957 nucleotides of *ND1*, revealing 11 haplotypes (see Appendix II for accession numbers). A parsimony network constructed from these haplotypes included 1 inferred haplotype and no reticulations (not shown). In summary, relationships among haplotypes within the *Cytb* and *ND1* data sets were resolved although they exhibited only broadscale geographic resolution provided by the moderate number of observed variable sites (19 in *Cytb* and 12 in *ND1*). Conversely, the HVRI data set contained 41 variable sites within 238 bp; however, the frequency of reticulations throughout the network prevented an accurate depiction of the evolutionary relationships among haplotypes. The frequencies of all composite 3-gene mitochondrial haplotypes are described in detail in Appendix II.

Character changes mapped onto a neighbor-joining tree constructed from preferential weighting of *Cytb* and *ND1* recovered 86 substitutions at 19 sites within HVRI, a 30% increase in the number of recurrent substitutions that otherwise would be detected by character mapping using only the HVRI data. Furthermore, results of the AU test based on site-wise log-likelihood scores selected the phylogeny constructed from *Cytb*, *ND1*, and HVRI extended to express all of these 86 substitutions as the optimal for describing 3 of 4 data matrices (Table 2). Notable is the observation that the phylogeny produced from the most simplistic data set (that including *Cytb* and HVRI) was best explained by the most complex data set (that including *Cytb*, *ND1*, and HVRI extended to express identified recurrent substitutions, termed HVRI(x)/*Cytb*/*ND1* in Table 2). As a result, this data matrix was used for downstream phylogeographic analyses.

Phylogeographic and phylogenetic patterns.—The haplotype network constructed from the final data matrix generally maintains a network structure consisting of basal haplotypes that are frequent and widely distributed and terminal haplotypes that are sequestered geographically and occur in lower frequency relative to interior haplotypes (Fig. 2). From this network the divergence between subspecies is clearly demarked, although *E. j. monteriensis* is distributed across 2 parts of the network that are separated from each other by 2 widely distributed and 3 inferred haplotypes. An additional characteristic of this network is that, except for 1 instance, range-wide haplotypes (those observed in all 3 stocks) are sequestered to regions of the network otherwise consisting exclusively of haplotypes of *E. j. jubatus*. Of these range-wide haplotypes, their occurrence in *E. j. monteriensis* (eastern stock) is rare (6 of 7 of these haplotypes occur fewer than 4 times in *E. j. monteriensis*) and is restricted to southeastern Alaska (the westernmost region of *E. j. monteriensis*).

Eighteen demographic events were detected by single-locus NCPA, consisting of 5 contiguous range expansions, 5 instances of restricted gene flow with isolation by distance, 5 inferences of restricted gene flow or dispersal but with some long-distance dispersal, 2 past fragmentation or long-distance colonization events (or both), and 1 inconclusive outcome (Table 3). The inference of restricted gene flow with isolation by distance obtained at the total-cladogram level describes the overall demographic phenomenon of population structure of *E. jubatus*. The inference of past fragmentation or long-distance colonization (or both) for clade 4-2 captures, in part, the ancient divergence between *E. j. jubatus* and *E. j. monteriensis*. The relationship between subspecies within clade 4-2 and at the total cladogram level corresponds to the general pattern observed in the Bayesian phylogeny describing the subspecies divergence (Fig. 3). Tests performed for clades 4-1 and 4-3 both returned an inference of restricted gene flow or dispersal but with some long-distance colonization. These 2 clades are the largest subspecies-specific groupings in the analysis, and their associated inferences correspond with previously identified dispersal trends in *E. jubatus* described by dispersal generally occurring among adjacent rookeries with potential for longer distance migration due to their high vagility. The remaining inferences were recovered throughout portions of the network that describe further variation within subspecies.

As would be expected under the assumption of a low error rate of NCPA, of the 18 clades indicated as having statistically significant geographic associations through NCPA, 10 also

FIG. 2.—Nested design of the statistical parsimony network constructed from the HVRI(x)/*Cytb*/*ND1* data matrix. Circles represent observed haplotype linkages, and the distributions and frequencies are indicated by coloring and size, respectively. Lines connecting haplotypes represent substitutions defining their relationships. Small black circles indicate inferred haplotypes. Reference Table 3 for information about dating and single-locus nested clad phylogeographical analysis (NCPA) results. See text for definitions of gene acronyms.

yielded significant ANOVA test statistics (Table 4). Of these 10 clades, all but 1 received inferences involving some type of long-range movement or dispersal of haplotypes (contiguous range expansion, past fragmentation or long-distance colonization [or both], or restricted gene flow with some long-distance dispersal; events promoting significant among-group variation). Conversely, of the 8 clades returning nonsignificant ANOVA test statistics, all but 2 of these (inconclusive outcome and contiguous range expansion) involved restricted gene flow often with isolation by distance (events that would hinder accumulation of intergroup variation).

The mean methane concentration at dates estimated for the time to most recent common ancestor of all significant single-locus NCPA inferences was 468.44 parts per billion by volume (ppbv). Although this value is irrespective of the 95% highest probability density intervals (HPDs) surrounding the mean divergence dates, this value was significantly different from a mean methane concentration over the last 800,000 years of 519.97 ppbv ($Z = 2.41$, $P = 0.015$). By contrast the mean methane concentration at estimated times for all other clades was not significant ($\bar{X} = 499.16$; $Z = 1.64$, $P = 0.10$). Furthermore, dates for significant demographic inferences show a pattern of temporal clustering that generally correlates with periods of low methane concentrations and time periods previously characterized as periods of glacial maxima. The inference returned at the total-cladogram level dates to within the 5th glacial maximum and all other inferences form 2 distinct

groupings most closely associated with the 2nd and 3rd glacial maxima (Rohling et al. 1998; Fig. 4). The HPDs for the date estimates are generally large and span the time frame of methane-inferred climatic oscillations. However, 1 SD from the mean dates generally resides within major climatic periods in which the mean is positioned. This important nuance justifies the overall confidence in the datings.

Comparing the patterns of demographic events with climatological cycling relative to estimated historic population sizes provided information on how the relationship between climate (glaciation) and population size potentially interacted to influence demography (Figs. 4 and 5). Notable is the observation that all inferences (6) clustering around the time of the 3rd glaciation describe processes involving restriction of gene flow. These 6 inferences refer to deeper clade nestings (3- and 4-step clades) and date to periods of low ancestral population sizes. The most common inference within this cluster was restricted gene flow or dispersal but with some long-distance dispersal, occurring 4 times. The binomial probability that 4 of 6 inferences within this time period would be the same by chance is 0.00013. In contrast, inferences clustering around the 2nd glaciation or earlier all refer to shallower nestings (1- and 2-step clades) corresponding to a time of population size increase in *E. jubatus*. In this cluster several inferences describe some sort of restricted gene flow; however, the most common type of inference within this cluster was contiguous range expansion, occurring 5 times.

TABLE 3.—Summary of significant results for the nested clade phylogeographical analysis (NCPA). Values within the D_c and D_n columns are distance (km), with an indication of whether each value was significantly large ($>$) or small ($<$), and its associated P -value. n.s. = not significant at $P = 0.05$. I – T = interior minus tips distance. Inferences were drawn from the key made available 15 December 2008. CRE = contiguous range expansion; IC = inconclusive outcome; RGF w/ IBD = restricted gene flow with isolation by distance; RGF/LDD = restricted gene flow or dispersal but with some long-distance dispersal; PF/LDC = past fragmentation or long-distance colonization (or both). Estimated dates are expressed as millions of years ago (mya).

FIG. 3.—Maximum clade credibility Bayesian phylogeny. Haplotypes are color coded by their observed distributions, and the black outgroup haplotype is *Zalophus californianus* according to Wilson and Reeder (2005). Nodes receiving a posterior probability support value of 0.5 or higher are indicated by small red stars. Significant nodes containing clades, where the sequestering of haplotypes into distinct geographic regions is observed, are numbered, and the estimated divergence date and 95% highest probability density intervals (HPDs) for these nodes are listed. Although posterior support for node 6 was below 0.5, this node is numbered for reference in the text.

The probability of such a chance occurrence is 0.00017. No significant demographic inferences were recovered in more recent times, around the last glacial maximum, a period in which population sizes were estimated to be highest.

The time to most recent common ancestor for *E. jubatus* (Fig. 3, node 1), based on coding region data and outgroup node priors from Higdon et al. (2007), was estimated at 0.360 mya (95% HPD = 0.145–0.876). The initial divergence from node 1 resulted in the sequestering of all exclusively *E. j. monteriensis* haplotypes into a single, yet polyphyletic, grouping (node 2). Terminal to node 2 were all 40 haplotypes exclusive to *E. j. monteriensis* and 22 exclusive to *E. j. jubatus*, with 8 and 12 of these exclusive to the western and Asian stocks, respectively. Within this grouping 2 major clades were identified, 1 of which (node 4) was comprised exclusively of haplotypes of *E. j. monteriensis*, except for 4 haplotypes observed only in the Asian stock. Node 6, being sister to node 3 (Fig. 3), retained the remaining haplotypes observed exclusively in *E. j. monteriensis* in addition to haplotypes occurring across the species’ distribution; however, the posterior probability of this node was <0.5. The basal clades terminal to nodes 4 and 6 consisted of haplotypes of *E. j. jubatus*.

On the other half of the phylogeny terminal to node 3 all but 5 range-wide haplotypes and 1 haplotype observed in the western and eastern stocks—3 of 48 occurrences of this haplotype were in the eastern stock—are haplotypes exclusive to *E. j. jubatus*. Although within this clade 11 haplotypes were observed throughout *E. j. jubatus*, 17 and 13 haplotypes were restricted to the western and Asian stocks, respectively. The divergence observed at clade 5 leads to 2 lineages, 1 of which contains haplotypes found either exclusively in the Asian stock or shared between the Asian and western stock, but none exclusive to the western stock.

Although posterior support for some nodes in this phylogeny was <0.5, the major phylogenetic pattern depicted supports

TABLE 4.—Results of ANOVAs for each clade receiving significant test statistics through the nested clade phylogeographical analysis (NCPA) statistical testing procedure. Descriptions of NCPA inference abbreviations are found in Table 3. *P*-values are for global F_{ST} calculated from the analysis, and significant statistics are bold and italicized. Significance was determined by 1,000 permutations of rookery occurrences of haplotypes among clades.

Clade	% variance among groups	% variance within groups	<i>P</i> -value _{d.f.}	NCPA inference

previously hypothesized relationships among the 3 stocks and the 2 subspecies. However, the current results both describe the early divergence in the species history between the 2 extant and currently recognized subspecies and also indicate a complex history leading to the current distribution of haplotypes. Moving from the base to the tips of the phylogeny of *E. jubatus*, clear patterns of lineage sorting at different stages of completion are observable. Although terminal to the initial divergence all haplotypes of *E. j. monteriensis* (eastern stock) are sequestered to node 2 (Fig. 3), it is not until about 200,000 years later at node 4 that a large group of haplotypes of *E. j. monteriensis* approach monophyly—1 Asian stock haplotype is within the eastern stock clade that is itself terminal to an exclusively Asian stock clade. The relationships among haplotypes terminal to node 6 present a pattern of less complete lineage sorting, with some tip clades exclusively *E. j. monteriensis*, with others still retaining many haplotypes of *E. j. jubatus*. Although node 6 was unsupported, a comparison of the completion of sorting between nodes 4 and 6 illustrates the stochastic nature of the lineage sorting process; although nodes 6 and 4 likely have similar coalescence times, sorting is closer to completion terminal to node 4.

DISCUSSION

In this study single-locus NCPA was used to draw inferences on population history. Multiple independent statistical approaches were used to validate the inferences returned by single-locus NCPA. ANOVA returned patterns of group (clade) significance that correspond to what would be expected given the types of demographic events returned for each clade; demographic events that promote significant among-group

variance allocation (those events that distribute genetic diversity among rookeries) were usually significant, and those demographic events that promote within-group variance retention were found most often to be nonsignificant. Furthermore, results from the single-locus NCPA, in combination with reconstructions of historical N_{ef} and ice-core inferred climatological cycling, suggest that the patterns of demographic events are related to the climate and population size at the time. The chance probability of such a pattern was assessed in this study by using *Z*-tests and binomial probabilities and found to be low. These combined statistical observations describe a pattern of phylogeography of *E. jubatus* that includes an interaction between population size, climate, and their dependence on linearly distributed rookeries.

Our results support the hypothesis that climate change has a major role in shaping the observed distribution of genetic diversity in *E. jubatus*. One of the major inferences pertaining to this hypothesis is that glacial vicariance has largely shaped the evolutionary history of *E. jubatus*. The observation that historic events related to restricted gene flow generally occurred during a time of low N_{ef} suggests that vicariance, in conjunction with genetic drift acting on low ancestral numbers of haplotypes, promoted geographic sequestering throughout portions of the distribution. In addition, inferences of occasional long-distance dispersal during this time potentially describe the species' ability to establish new territory via dispersal during a time of low N_{ef} and reduced competition for breeding territory. Conversely, all inferences of contiguous range expansion correlate with a population expansion as described by the Bayesian skyline plot (Fig. 5). This indicates that as N_{ef} increased the response to glacial vicariance changed. During this time the population of *E. jubatus* as a whole was expanding both in numbers and in range. Individuals would have been forced to disperse greater distances to find breeding territory as N_{ef} increased and glacial cover reduced the number of ice-free rookeries. Finally, the lack of significant demographic inferences recovered around the time of the last glacial maximum is likely the result of large, sustained N_{ef} , previous saturation of all suitable habitats, and perhaps a lack of phylogeographic resolution at this timescale.

In general, these results can be interpreted as descriptive of how abiotic factors can influence the evolutionary fate of a species. Specifically for *E. jubatus*, one of the results of this study is that relatively warm periods have promoted population expansion and dispersal by increasing available rookery habitat. Perhaps the most important aspect of the current results is the implication that future climate change has the potential to affect distributions and demography of contemporary populations of species in ways similar to that documented in this study. It is clear that climate change causes stress, including the necessity of finding new breeding sites, adapting to new food sources, and so on. It can be inferred from the present study that population size influences the capacity for dealing with such stressors, because the genetic signatures resulting from similar climatic patterns are distinctly different for large and small populations.

FIG. 4.—Histogram of methane concentration (in parts per billion by volume) over the last 500,000 years. The nonlinearity of the x axis is a result of heterogeneity of methane sampling over time (Louergue et al. 2008) and should be considered when interpreting this figure. Dates of time to most recent common ancestor for significant single-locus nested clad phylogeographical analysis (NCPA) clades are plotted onto this histogram, and the type of inference obtained for each clade is color coded. Small black hash marks above the histogram define point estimates for nonsignificant clades. Gray rectangles along the bottom of the histogram indicate time spans of 5 previous glacial periods, as defined by Rohling et al. (1998).

FIG. 5.—Bayesian skyline plot with mean population size and 95% highest probability density intervals (HPDs) plotted against time. As in Fig. 4, significant NCPA inferences are plotted and color coded.

Although the Bayesian phylogeny presented in Fig. 3 describes relationships among haplotypes similar to those presented in the haplotype network, this perspective provided additional insight into both historical and contemporary processes. This tree describes the ancient divergence between subspecies, with node 1 representing the base of the lineage of *E. jubatus* describing the initial documentable divergence 0.360 mya. Following from this estimation, during the 5th glacial period when population sizes were low, the distribution of *E. jubatus* was split by glacial vicariance into at least 2 disjunct populations initiating subspecific differentiation. The observation that 3 Asian stock haplotypes form the base of the large *E. j. monteriensis* clade terminal to node 4 describes an ancient “out of Asia” relationship between the extreme ends of the distribution of *E. jubatus* and indicates that Asian portions of the species’ range served as the source population for the eastward expansion. Although node 6 is unsupported, the relationship observed between sister clades here is similar to that observed at node 4, with an *E. j. jubatus* clade forming the base of a clade consisting largely of *E. j. monteriensis*. That no haplotypes were observed in the Asian stock and *E. j. monteriensis*, but not the western stock, indicates the lack of contemporary dispersal between the Asian stock and *E. j. monteriensis*. However, the observation that 6 of 7 range-wide haplotypes belong to *E. j. jubatus* clades does indicate recent directional dispersal from west to east. The oldest *Eumetopias* fossil was recovered from the Onna formation in Japan dated to the Pliocene about 2 mya (thought to represent an extinct member of the genus *Eumetopias*—Kaseno 1951; Mitchell 1968; Repenning 1976). This information, paired with the findings from the current study, indicates a potential geographic center of origin for *Eumetopias*.

In this study a novel method was used to account for generally cryptic recurrent substitutions. This improved resolution by decreasing the phylogenetic obscurity produced by homoplasy while improving confidence in branching order. Potentially, this approach is applicable to any phylogenetic analysis in which coding genes, or otherwise conservative loci, are used in combination with a more rapidly evolving locus in which recurrent substitutions produce homoplasy. In the event of evidence for coding region homoplasy, these regions should not be weighted to resolve hypervariable region recurrent substitutions. To determine the appropriateness of using this method several aspects of the data set should be considered. First, the estimated time to most recent common ancestor is an important parameter, because the greater the age of the lineage, the more time for homoplasy to accumulate in all regions. By using this information in combination with knowledge about the mutation rate of coding regions, network construction and evaluation (whether coding region-based networks contain reticulations), and consistency and homoplasy index calculations, a logical decision can be made regarding the use of this approach.

In summary, by the implementation of multiple statistical approaches to maximize genetic signal and draw evolutionary inferences, a strong, multifaceted perspective of evolutionary history of *E. jubatus* has been developed. This history reflects a major influence of climate change and glacial vicariance,

with demographic response contingent upon population size at the time. In addition, phylogenetic patterns indicate the direction of dispersal over evolutionary timescales and, paired with limited fossil data, present a hypothesis for the geographic center of origin of *E. jubatus* located in Asia. The results of this study can serve as a working hypothesis for future studies to develop a better understanding of the evolution of *E. jubatus*.

ACKNOWLEDGMENTS

We thank the many people who helped in obtaining tissue samples—especially V. Burkanov (coordinator for the collecting trips in Russia), T. Loughlin, and D. Calkins—and also the National Oceanic and Atmospheric Administration cruises in the Aleutians and the Gulf of Alaska and the Alaska Department of Fish and Game. K. M. Nichols, O. E. Rhodes, and J. A. DeWoody provided valuable insights and suggestions during the course of the doctoral studies of CDP. All sea lion tissue samples were collected under authorization of United States Marine Mammal Permits 358–1888 (Alaska Department of Fish and Game) and 782–1532 (National Marine Mammal Lab). Comments from 2 anonymous reviewers were very constructive and greatly improved this manuscript. This study was conducted as part of the doctoral dissertation of CDP at Purdue University. Funding was provided by the National Marine Fisheries Service, the Lily Endowment, and internal funds provided by the Department of Forestry and Natural Resources, Purdue University.

APPENDIX II

Frequency of HVRI/*Cytb*/*ND1* haplotype linkages across the 3 genetically identifiable stocks. The 1st series of letters in the name refers to the hypervariable region 1 (HVRI) haplotype name, the following number refers to the cytochrome *b* (*Cytb*) haplotype name, and the number after the N in each name refers to the nicotinamide adenine dinucleotide dehydrogenase 1 (*ND1*) haplotype name. GenBank accession numbers for HVRI haplotypes: AY340876–AY340937, FJ948491–FJ948546. GenBank accession numbers for *Cytb* haplotypes: DQ144995–DQ145021, FJ948486–FJ948490. GenBank accession numbers for *ND1* haplotypes: GQ477068–GQ477078.

Observations of Western Gray Whales by Ship-based Whalers in the 19th Century

Randall R. Reeves, Okapi Wildlife Associates, 27 Chandler Lane, Hudson, Quebec, Canada J0P 1H0 (rrreeves@okapis.ca)

Abstract

Animals belonging to the small, endangered population of western gray whales (*Echrichtius robustus*) are observed today primarily during the summer open-water season in feeding areas off the north-eastern coast of Sakhalin Island, Russia. The migration route(s) and wintering area(s) used by this population are largely unknown. Gray whales once had a fairly extensive distribution in the Sea of Okhotsk but little detailed information has been published on when and where they occurred. Open-boat, ship-based whalers from the United States and a few other countries conducted an intensive hunt for bowhead whales (*Balaena mysticetus*) and North Pacific right whales (*Eubalaena japonica*) in the Sea of Okhotsk from the 1840s to 1870s. According to entries in voyage logbooks, the American whalers regularly encountered (and sometimes hunted) gray whales in the far north-eastern corner of the Okhotsk Sea (Shelikhov Bay, Gizhiginskaya Bay and Penzhinskaya Gulf) between early May–late August. They also observed gray whales in summer along the northern coast of the sea (especially Tauskaya Bay), around the Shantar Islands, in Sakhalin Bay, off Cape Elizabeth at the northern tip of Sakhalin Island and along the west coast of the Kamchatka peninsula. No evidence was found in the logbooks studied of gray whales (and indeed of whaling effort) off north-eastern Sakhalin Island where most observations of gray whales occur in the present day.

Introduction

Recent and current interest in gray whales (*Eschrichtius robustus*) from the western Pacific (Korean-Okhotsk) population has centred on that population's endangered status and the ongoing threats to its survival and recovery. Specifically, there is concern about (a) the small number of whales in the population; (b) environmental degradation and disturbance from oil and gas development on the north-eastern Sakhalin Island shelf, the main area where the population is presently known to congregate in summer to feed; and (c) mortality of gray whales in Japanese waters, mainly in set nets.

The history of this population has been reviewed by Mizue (1951), Nishiwaki and Kasuya (1970), Brownell and Chun (1977), Omura (1988), Weller et al. (1999, 2002) and Kato and Kasuya (2002). In addition to those reviews, Henderson (1972, 1984, 1990) made reference to ship-based whaling on the western population during the 19th century, primarily by American and French whalers. In our recent studies of whaling history in the North Pacific, we have examined a sample of American voyage logbooks that contain substantial unpublished data on western gray whales. The present paper uses those data to

describe where and when western gray whales were observed by ship-based whalers during the 19th century.

The data confirm that in the past gray whales used various parts of the Okhotsk Sea, likely as feeding grounds and as routes to and from such grounds. Given the rapid proliferation of offshore oil and gas operations around the perimeter of the Okhotsk Sea as well as on the entire Sakhalin Shelf, understanding the historical (and thus both current and potential) summer range is essential.

Background

Offshore or ship-based whaling for gray whales along the Asian coast from southern China to Japan and in the Sea of Okhotsk has been less well documented than shore-based whaling there. Among the reasons for this difference is the death in June 1999 of David Henderson, who authored classic studies of the American pre-modern, ship-based fishery for *eastern* Pacific gray whales (1972, 1984) and was working on a similarly exhaustive study of the Okhotsk fishery for *western* Pacific gray whales (e.g. see Henderson 1984, p. 176, note 14; Kugler 1984, p. 157, note 6). Henderson (1972) provided only limited information on western gray whales although on his Map I, he offered an intriguing sketch of their distribution (Fig. 1). Henderson's 1984 book chapter (pp. 176-177) indicates that gray whales were not hunted by the American whalers in the Sea of Okhotsk until sometime in the 1840s and that catches of 6-7 whales per ship were being made by the 1850s. He judged that the total kill of gray whales in the Okhotsk Sea by the American fleet was probably similar to that in the Bering Sea and Arctic Ocean, i.e. a few hundreds (his estimate of total kill in the latter areas between 1845-1874, adjusted for hunting loss, was 539; Henderson 1984, p. 169). Some American whaling for gray whales continued in the Sea of Okhotsk until at least the mid-1880s (Henderson 1984, p. 177), by which time most of the remaining Arctic fleet was committed to the 'hazardous, though profitable, whaling in the Arctic [i.e. Bering, Chukchi and Beaufort seas]' (Clark 1887, p. 19). The Sea of Okhotsk was also a frequent destination of French whalers from the mid 1840s until perhaps the mid 1860s (Du Pasquier 1982, pp. 183, 192, 245-249; Kugler 1984, p. 152) and they probably took at least some gray whales although we have not found any direct evidence for this (Du Pasquier 1986, p. 274). At least three Russian whaleships (all originating from Finland) also visited the Okhotsk Sea in the 1850s (Clark 1887, pp. 206-207).

The Okhotsk Sea fishery for balaenids was most intensive from 1847-1867, with nearly 1,400 vessel-seasons, 90% of them from the United States and the rest from France, Bremen, Russia, and the Hawaiian Islands, and occasionally Great Britain, Norway, and Chile (Kugler 1984, p. 153). As an example of the intensity of this fishery, one ship's logbook reported that 65 other whaling vessels were in sight on 27 August 1854 in Shantar Bay (*Good Return*). In that same month, Lindholm (1863) counted 82 ships in the bay and on one day 363 whaleboats were in sight from his ship (*Storfursten Constantin*). Bowhead whales (*Balaena mysticetus*) and North Pacific right whales (*Eubalaena japonica*) were the principal targets and, according to Henderson's preliminary analyses (as reported by Kugler, *op cit.*), more than 15,000 bowheads and

2,400 right whales were killed and processed by the Okhotsk whalers in those first 20 years. The fishery continued until the 1890s.

Henderson's only publication containing data on western Pacific gray whales (apart from the few references to Okhotsk whaling in his 1972 book and his 1984 book chapter) was a short article on American whaling in southern China in the 1860s (Henderson 1990). There he recounted two voyages to the 'Chinese gray whale ground' in the winter of 1868-69 – by the New Bedford ships *Cornelius Howland* and *Onward*. Although they failed to strike any, the crews of these vessels sighted gray whales near the Chinese mainland coast at c. 25-26°N off the island of 'Hatan Ho Tan' (Haitan, Pingtan Dao, or Tao on modern maps, according to Henderson), in the middle of Taiwan (Formosa) Strait, and off the northern coast of Taiwan.

Materials and Methods

In addition to a search of the literature, we sampled whaling voyage logbooks from the Kendall Whaling Museum and Old Dartmouth Historical Society collections, both available at the New Bedford Whaling Museum library in New Bedford, Massachusetts. Okhotsk Sea logbooks were identified using library finding aids, *Whaling Logbooks and Journals* (Sherman et al. 1986), and *The History of the American Whale Fishery* (Starbuck 1878), as well as through references in logbooks to other vessels sighted or 'spoken' on the grounds. Data from the logbooks, including date, position, details concerning whale observations, and other vessels spoken, were entered into an Access database and plotted using ArcMap.

Frequently, the exact location could not be determined from the logbook and therefore it was necessary to estimate positions by interpolation and reference to landmarks. A particular problem encountered while working with this material was that place names used by the American whalers did not always correspond to the Russian names. For that reason, we compiled a gazetteer in the course of our logbook reading as a research tool. Sketch maps prepared by the whalers themselves were useful in that regard (Fig. 2). A composite map of the region was developed from a variety of sources (Fig. 3). When places are mentioned throughout the text of this paper, alternative names have been indicated in brackets.

The American whalers used several different terms to refer to gray whales, including ripsacks (rip sacks), musseldiggers (mussel diggers), devil fish, scraggs, scamperdowns, California grays, graybacks and California whales.¹ They called bowheads polar whales, steepletops, bowheads (bow heads) or often just whales (in most but not all instances, the species can be inferred from the context). Blue whales (*Balaenoptera musculus*) were consistently called sulphur bottoms (or sulfur bottoms). Right whales, humpback whales (*Megaptera novaeangliae*) and 'finback' whales (probably mainly fin whales, *B.*

¹ Henderson (1972, pp. 34-35; 1984, pp. 163-164) included mud digger, digger and hard head in the list of names used for the gray whale by American whalers, but we did not encounter these terms in our limited sampling of logbooks.

physalus, though this name also may have been applied to sei whales, *B. borealis*) were referred to as such.

Results

Our sample of logbooks included 21 multiyear voyages that visited the Okhotsk Sea one or more times, for a total of 43 ‘vessel-seasons’ in the Okhotsk. The ships were in the region for more than 5000 days, and daily positions have been determined or estimated for most of those days (Fig. 4). The sampled voyages spanned the period from 1847-1885 though the majority of them took place in the 1850s and 1860s. Logbooks of 14 voyages, including 24 vessel-seasons in the Okhotsk, contained references to sightings of gray whales. There was a total of 152 daily entries with observations of gray whales, including sightings, chases, strikes and captures (Fig. 5).

Occurrence

Citing early Russian literature, Yablokov and Bogoslovskaya (1984) described gray whales (and humpback whales) as having been “very common and even abundant in the coastal waters of the northern part of the Okhotsk Sea and off the western shores of the Kamchatka Peninsula.” They surmised (as did Tomilin 1957, p. 314) that gray whales migrated into the Okhotsk Sea from the Sea of Japan via both Tatar Strait (Tatarskiy Proliv) and La Perouse Strait. Indeed, American logbook data imply that gray whales at least occurred in or near La Perouse Strait in mid-June (e.g. some were sighted and chased there by *Cicero*, 16 June 1859, c. 46°N, 142°E). Vladimirov (2004) questioned the feasibility of gray whales entering (or leaving) the Okhotsk Sea via Tatar Strait ‘due to the small depths of the Amur Firth (2-3 m) ... which must be a natural obstacle for migrating animals’. In contrast, Rice and Wolman (1971, p. 20), citing Mizue (1951), suggested that all gray whales passed through Tatar Strait ‘as none was ever seen in La Perouse Strait’.²

Many voyages to the Okhotsk Sea originated in Hawaii and therefore the ships entered via the northern Kuriles (usually in the vicinity of Paramushir Island) and then worked northwards along the western shore of Kamchatka. According to Henderson (1972, p. 87, citing reports from *Fortune*, 6-8 June 1855, *Mary and Susan*, 19-30 August 1848 and *Montezuma*, 30 May and 29 September 1860), gray whales were observed mainly along the northern coast of the Sea of Okhotsk, and this is consistent with Yablokov and Bogoslovskaya (1984).

Gray whales were observed consistently by the American whalers in the southeastern portion of Shelikhov Bay (Zaliv Shelikhova) and in Penzhinskaya Gulf (Penzhinskaya

² From Mizue (1951, p. 79): “... it is reported by Mr. Tago that they reach Hokkaido or the western coast of Sakhalin in May or June and then through the Mamiya [Tatar] Channel go to the northern part of the sea of Okhotsk, where they seem to spend their summer. On their southwards migration they seem to take the same course as they come up north. It is not probable that grey whales pass through the Soya [La Perouse] Channel to the farther north, for fin and hump-back whales are captured there from the landstation in Hokkaido but not grey whales.”

Guba) from early May (earliest record 6 May 1885; *Mary and Helen II*) to the end of August (approximately 43 observations in our sample; Fig. 5). They were seen in Gizhiginskaya Bay (North-east Gulf) between mid-May and late August (approx. 46 observations, including a report of ‘thousands of devilfish but no bowheads’ in the logbook of the *Benjamin Cummings* on 3 June 1869) and in the vicinity of Magadan along the north-central coast of the Sea of Okhotsk (i.e. in Tauskaya Gulf/Guba, generally called Tausk or Taousk Bay) from at least early June to early July and from mid-August to mid or late September (approx. 19 observations). Gray whales were seen occasionally just east of Okhotsk City in the north-western Sea of Okhotsk (*Lancaster*, 12 September 1860; *Oliver Crocker*, 29 August 1861). There is little evidence that they still occur in any of those northern areas (Maminov and Blokhin 2004) although it is unclear how much search effort has been expended there at the appropriate times.

Only a handful of references to gray whales in the vicinity of the Shantar Islands were found in the logbooks: ‘a few rip sacks’ northeast of Big Shantar Island on 5 June 1860 (*Oliver Crocker*), ‘muscle diggers’ somewhere in the Shantars on 7 September 1855 (*Nassau*) and ‘Devilfish or Ripsack whales’ in Taylor’s Bay, off Ulbansky Bay, on 13 August 1885 (*Mary and Helen II*). Another sighting was recorded about midway between Ayan and the Shantar Islands on 14 June 1860 (*Lancaster*). Tomilin (1957, p. 314) cited Russian observations in Akademii and Ulbanskii bays. Also, in recent years a few observations have been reported in September in Tugurskiy and Ulbanskiy bays (Maminov and Blokhin 2004).

The American whalers observed gray whales, sometimes in sizeable concentrations (e.g., 20-30 seen in a day, references to “plenty” being seen), in Sakhalin Bay (Sakhalinskiy Zaliv) and off Cape Elizabeth (Mys Yelizavety) at the northern tip of Sakhalin Island (*Mary and Susan*, various entries between 18 August – 9 September 1848). A sighting of two gray whales in summer 2005 in Severnyy Bay (just south-west of Cape Elizabeth) (Tyurneva et al. 2006) demonstrates the continued use of that area by the extant population. Also, gray whales were seen in southern Sakhalin Bay in August 2000 (Maminov and Blokhin 2004).

Finally, American whalers sighted gray whales at least occasionally near the northern (Cape Huntsville, 58°05'N, 157°06'W; *Europa*, 17 May 1869), central (vicinity of Moroshechnoye, 55°51'N, 155°52'E; *Mary and Susan*, 13 July 1849) and southern coasts of western Kamchatka (51°16'N, 155°23'W; *Europa*, 14 September 1868). Although Blokhin (1996) reported that gray whales had not been seen along the western coast of Kamchatka in many years, one was reported in August 2000 at the mouth of the Bolshaya River (Vertyankin et al. 2004). In that regard, the logbook of *Mary and Helen II* refers to arrival at the Bolshaya mouth on 12 September 1885, the vessel having departed the Shantar Islands on 23 August bearing east “for ‘Bolshaya River’ for Right Whales”. The 13 September logbook entry states: “I am bound back to the west end of the Sea north of the Shantar Islands for I am convinced there are no whales to be seen about this locality or where I have been expecting to find ‘Ripsack Whales’ off the mouth of the ‘Bolshaya River’.” Having found neither right nor gray whales off Kamchatka, the *Mary and Helen*

II relocated to Tauskaya Bay, with the top of the logbook page for 19-20 September declaring, “In ‘Tausk Bay’ among the ‘Ripsack Whales’.”

In recent years sightings of gray whales have become regular in Olga Bay (between Cape Seniavin and Cape Kozlov) and Vestnik Bay (just north of Cape Lopatke, c. 51°35'N) on the south-eastern coast of Kamchatka (Vertyanin et al. 2004) and at least some of the individuals seen there have been photographically matched to individuals observed off north-eastern Sakhalin (Yakovlev et al. 2007).

We found no evidence beyond that presented by Henderson (1990) that American whalers observed or took gray whales in Chinese waters where sightings and a few strandings and kills were reported in the 20th century (Wang 1984; 1993, 1999; Zhu 1998; Blokhin and Blokhin 2006). However, our logbook sample included little coverage of whaling in those waters.

Removals

Our reading of logbooks thus far has not revealed any major inconsistencies with Henderson's (1984) findings as summarised above. Gray whales clearly were secondary targets and they were pursued mainly at times when the preferred bowheads and right whales were unavailable. For example, in 1859 the ship *Oliver Crocker* arrived in Tauskaya Bay at the end of May, with its first sighting of ‘mussel diggers’ reported on 3 June. Within a few days the boats were engaged in the pursuit of bowheads in the bay. Three were bomb-lanced and/or harpooned, but lost, between 6-10 June. By 15 June the run of bowheads had ended, and after a few more days the hunt for gray whales began. Between 19-30 June the *Crocker*'s boats were lowered daily and no fewer than nine gray whales were taken and processed. In addition at least two were lost when the harpoon drew or the line was cut. Two of the processed whales had sunk initially and, in both instances, were only recovered two days later. Three other ships were spoken in the bay during the second half of June – *L.C. Richmond*, *Robert Morrison* and *Cambria* – but it is unclear whether any of them took gray whales (the *Richmond* was seen taking a bowhead on 13 June; the *Cambria* reportedly had taken three bowheads that season as of 30 June). On 1 July the *Crocker* sailed towards the Shantar Islands where bowheads were plentiful and hunting for them resumed on 11 July. There is no further mention of gray whales that year in the *Crocker* logbook. Also, in the next two years, even though the *Crocker* followed a broadly similar itinerary, there is nothing in the logbook to suggest another episode of intensive gray whaling. Two were taken in North-east Gulf on 3 August 1861, the only day during the 1861 season when the logbook indicates the boats were lowered for ‘ripsacks’.

The ship *Europa* arrived in Gizhiginskaya Bay (North-east Gulf) early in the 1868 season, with its first bowhead sighting on 19 May. From then until 28 June, when the first bowhead was taken, only one more bowhead was seen by the crew (on 7 June), whereas gray whales (and ‘finbacks’) were seen often and the boats were lowered on at least three occasions with the explicit intention of hunting gray whales (none was taken by the *Europa* until 20 June). The logbook records that on 5 June 1868: “Lowered for Ripsacks

for the purpose of trying our new whaling guns, tried four shots and the irons would not enter the blubber.” In 1869 the *Europa* followed the same itinerary but had more success finding and taking bowheads, and there was only one brief lull (11-12 June) when attempts were made to take both gray whales and a ‘finback’. Later that season (26 July), the *Europa* ‘picked up’ and processed a dead gray whale found floating in Penzhinskaya Gulf between Ship Rock and Big Grampus Island and the log refers frequently to ‘ripsacks’ being observed (e.g. 17 August near Ship Rock, ‘...not seeing anything but Ripsacks’) but with only one more desultory attempt made to hunt them (27 August).

In 1885 the *Mary and Helen II* reached the north-eastern part of the Okhotsk Sea by the end of April and gray whales were sighted on 6 May and again on 20 May, by which time no bowheads had yet been seen. In fact, only one brief sighting of a bowhead was made before mid-June. Even though gray whales were seen many more times, the boats were not lowered to chase them (except on 21 June and 11 July ‘by mistake’) until the brief and intense episode in Tauskaya Bay in mid-September mentioned above.

Before the present study is considered complete, we expect to produce a quantitative estimate of the American catch of western gray whales, adjusted appropriately to account for hunting loss. For the present, we note the following catch information: 9 (plus 2 struck/lost) by *Oliver Crocker* in 1859 and 2 in 1861 (see above); 1 by *Florida* (15 bbl) (Williams 1964, pp. 185) and 1 by *South Boston* in 1861 (Williams 1964, p. 186); 4 by *California* in 1863 (Henderson 1972, p. 87); 1 each by *Endeavour*, *Rainbow* and *Europa* in 1867 (*Europa* 1867); 1 by *Europa* (salvaged) in 1869; and 4 by *Mary and Helen II* in 1885.

The estimated total landed catch of western gray whales by modern whaling and Japanese net whaling between 1890-1966 was 1,800-2,000 (Kato and Kasuya 2002). No other catches are known to have taken place during that time or since 1966 although some unreported catches may have been made by catcher boats from the People’s Republic of China or the Republic of Korea, neither of which belonged to the International Whaling Commission until 1980 and 1978, respectively. It is also possible that some catches were made by whalers from the Democratic People’s Republic of Korea or from Taiwan.

Discussion

Occurrence

Mizue (1951) analysed catch dates and positions for 545 gray whales in the ‘East Sea Area’ of Korea. The catches all occurred between November and May with a strong peak in December (63%) and January (22%). The infrequency of catches in other months from September through March apparently was not related to effort because, as Mizue (p. 76) points out, the same area was an important whaling ground for fin whales and ‘many catcher-boats work during the season, from September to March next year’ and so the whalers ‘would have certainly caught grey whales if they had seen them in the months of October, November, February and March’.

The speculation by Mizue (1951) that gray whales migrated northwards from Korea through the Mamiya Channel (Tatar Strait) in May or June and thence to summering grounds in the northern Sea of Okhotsk is not inconsistent with some of the American whalers' observations. It is unclear, however, whether Mizue was correct in his belief (shared by Andrews 1916, p. 210) that gray whales calved and mated in Korean waters. There is no reason to doubt that at least some of the whales migrated to as far south as 25°N along the Chinese mainland and moved through Taiwan (Formosa) Strait (Henderson 1990). Also, it is important to consider that Mizue's reasoning that gray whale females with large foetuses taken in mid-December off Korea were 'immediately before birth' and that 'delivery is made among the islands at the southern extremity of the Korean Peninsula' was without the benefit of Rice's (1983) analysis showing a 'prenatal diapause' in eastern Pacific gray whales such that foetal growth 'virtually ceases' during the final month of pregnancy and birth occurs between early January and mid-February (median 27 January). It is therefore plausible that the strong peak in occurrence of female gray whales in Korean waters from early December to early January (Mizue 1951, his Table 5) represents primarily a movement of migrating animals towards a destination farther south for parturition.

Based on the American whalers' observations summarised in this paper, gray whales were consistently observed in specific portions of the Sea of Okhotsk during the middle decades of the 19th century. Although most of the observations reported in the logbooks occurred on grounds where bowhead whales were the primary targets, some observations were also made on right whale grounds (e.g. on the Okhotsk side of Paramushir Island/Mys Lopatka, 51°16'N, 155°23'W, 14 September 1868, *Europa* 1867-1868). No sightings were reported on the north-eastern Sakhalin Shelf where western gray whales are observed most often today. However, none of the logbooks read for this study contained evidence that the American whalers visited that area (Fig. 4). The ship positions of whaling voyages into the Okhotsk Sea between 1844-1852 indicate some effort off the far northern, east-central and southern shores of Sakhalin but almost none along the north-eastern coast on or near the present-day feeding areas (Josephson et al. 2008). Lindholm (1863), a whaleman with much experience in the southern part of the Okhotsk Sea (particularly around the Shantar Islands), reported that gray whales were 'found in large numbers close to Cape Elizabeth [northern end of Sakhalin Island] and in the northern section of the sea during the summer'.

It is important to emphasize that the spatial and seasonal coverage of the Sea of Okhotsk represented by the logbooks was dictated primarily if not solely by the whalers' interest in catching bowhead whales and right whales though it was also influenced by the logistical constraints of sailing conditions, ice coverage and day length. It is fair to question whether the relative concentration of sightings of gray whales in the far north-eastern reaches of the sea (Gizhiginskaya Bay and Penzhinskaya Gulf ; Fig. 5) reflects relative density or is instead the result of a strong bias in search effort. It was not possible to address this issue rigorously given the biased nature of the effort data (the whalers went where they hoped to find bowhead whales and right whales) and the uncertainty about how consistently observations of non-target or secondary-target species like the gray whale were reported in the logbooks.

Removals

As indicated earlier, Henderson (1984) suggested that commercial ship-based whalers in the Sea of Okhotsk took about as many gray whales between the 1840s-1880s as were taken over roughly the same period in the Bering Sea and Arctic Ocean. Our findings are consistent with Henderson's suggestion. It is clear from the logbooks we read that gray whales were of little interest to the whalers during the early years of the Okhotsk fishery when bowheads and right whales were available in good numbers. In the 1840s and early 1850s, few masters bothered to lower the boats when gray whales were observed on or en route to the bowhead or right whale grounds. This seems to have begun changing by the mid 1850s when logbooks record gray whales being chased more often (e.g. *Gov. Troup*, 9 July 1854 near the Jamskiye Rocks [Yamske Islands]; *Cicero*, 16 June 1859 in La Perouse Strait).

Within a given voyage, particularly from the 1860s onwards, it was not unusual for the crew to pursue *eastern* gray whales in the Mexican lagoons or alongshore Baja California and California in the winter, and *western* gray whales in the Sea of Okhotsk in the summer. Kugler (1984, p. 153-4) referred to these as 'loop voyages', with the southern and northern components separated by visits to Hawaii and perhaps the Sea of Japan in the spring. Charles M. Scammon, for example, on the San Francisco ship *William C. Nye* during his last year as a whaling captain, sailed to the Okhotsk Sea for bowhead whaling in summer 1862 and then to Magdalena Bay for gray whaling in the following winter (Henderson 1972, pp. 86, 271).

The gray whale's reputation as a 'devilfish' is borne out by occasional statements in the logbooks. For example, when boats from the ship *Europa* (1866-1867) attacked a 'ripsack' in North-east Gulf on 19 August 1867, the bow boat 'got stove' after making the first strike, and then the other boats made the kill.

Conclusions

In the sample of logbooks examined, there was no evidence that American 19th century whalers visited the north-eastern coast of Sakhalin Island where gray whales have been studied intensively over the past decade. However, gray whales were observed regularly in certain other parts of the Sea of Okhotsk where the ship-based whalers hunted bowhead whales during the summer. They observed and hunted gray whales relatively often in the north-eastern corner of the sea, especially in Gizhiginskaya Bay (North-east Gulf) and Penzhinskaya Gulf. Gray whales were present in Gizhiginskaya Bay as early as mid-May when (or at least very soon after) the whalers arrived and gray whales continued to be observed there through the end of August. Good numbers also were observed in early June and as late as the third week of September in Tauskaya Bay (Magadan coast) and in late summer (mid-August to mid-September) in Sakhalin Bay off the north-western coast of Sakhalin Island.

The historical distribution of gray whales in the Sea of Okhotsk appears to have been much more extensive than it is at present although increased search effort at appropriate times in areas of historical occurrence is needed confirm their absence from such areas. Although not definitive, the information on western gray whales obtained from American 19th century whaling logbooks is of potential value in the following ways:

- To inform the timing and spatial coverage of modern survey effort.
- To support, in principle if not also in planning as to time and location, a satellite tagging and tracking programme to learn more about the movements of western gray whales.
- To contribute to an accurate reconstruction of catch history for input to population models.
- To provide a basis for formulating hypotheses regarding stock structure.

Acknowledgements

Most of the work reported here was funded by the Lenfest Oceans Program of the Pew Charitable Trust through Stanford University and we thank Steve Palumbi for his pivotal role in securing the grant. Library staff at the New Bedford Whaling Museum (specifically Laura Pereira and Mike Dyer) provided much assistance by helping us identify and gain access to relevant materials. Also, Judy Lund kindly shared her extensive knowledge of whaling history and checked several references for us.

FOREWORD

WHALES long remained among the world's least known mammals because their large size and oceanic habitat make them difficult to observe and collect. Individual whales cannot be observed repeatedly, therefore knowledge of most aspects of their life history must be deduced from data provided by examining large series of specimens. In the early decades of this century the expansion of the modern whaling industry with its efficient catcher boats and its mechanized shore stations and floating factory ships finally provided biologists the opportunity to undertake large-scale studies of whales. Concern for the future of whale stocks provided an incentive for government support of whale research. As a result, we have now learned more about the biology of the rorquals and the sperm whale than of most other species of wild mammals. Gray whale populations, however, had been depleted before this opportunity for research arose. Although field observations had provided a fairly detailed picture of the distribution, migration, and behavior of the gray whale, many important aspects of the species' biology—such as age and growth, reproduction, parasites, pathology, and population dynamics—remained virtually unknown.

Under the protection afforded by the 1946 International Convention for the Regulation of Whaling, the California gray whale stock has increased so much that a resumption of commercial exploitation has been considered. As the dearth of basic data on the biology of the species would handicap any efforts at rational regulation of the harvest, the Bureau of Commercial Fisheries in 1959 initiated a research program that included collecting small series of gray whales under Special Scientific Permits. Beginning in 1966, the number of animals taken annually was increased upon recommendation of the Scientific Committee of the International Whaling Commission, which has reviewed the work each year and provided much encouragement and advice. The data now available reveal the basic features of the ecology of the gray whale and provide a foundation for further studies on its population dynamics.

This study would not have been possible without the cooperation of the Del Monte Fishing Company and the Golden Gate Fishing Company of Richmond, California. John Caito and Charles Caito of Del Monte, and Robert Casebeer of Golden Gate placed the

facilities and crews of their whaling stations and catcher boats at our disposal for collecting and examining specimens. Kenneth C. Balcomb III, James Ekberg, Bernard Lenheim, and Toshio Kasuya (Ocean Research Institute, University of Tokyo), assisted in the examination of whales at the whaling stations. Margaret Anderson, Lawrence Dickson, Susan D'Vincent, Ekberg, James Houk, Hiroshi Kajimura, Lenheim, Donald Ramsey, Jeffrey Rochin, James Rote, Catherine Short, and Robert Strawn manned the counting stations. Lenheim, Ramsey, and Ancel M. Johnson conducted the transect cruises of the catcher-boat *Allen Cody*. Balcomb, Kasuya, Thomas J. McIntyre, Masaharu Nishiwaki (Ocean Research Institute), Daniel Lluich B., and Joaquin Arvizu M. (both with the Instituto Nacional de Investigaciones Biologico Pesqueras, Mexico) assisted in the whale-marking cruises. Ford Wilke, Johnson, and Lenheim assisted in the aerial surveys. Francis H. Fay, Arctic Health Research Laboratory, U. S. Public Health Service, provided a sample of the stomach contents of a gray whale killed near St. Lawrence Island, Alaska. Earl L. Bousfield, National Museum of Canada, identified the amphipods, provided information on the habits of benthic invertebrates, and made suggestions concerning the feeding behavior of gray whales. The following individuals identified other stomach contents or parasites: Martin W. Johnson and Margaret D. Knight, Scripps Institution of Oceanography (crab larvae); Josephine F. L. Hart, British Columbia Provincial Museum (cumaceans); Frank Bernard (ascidians and holothurians) and Cyril Berkeley (polychaetes and salps), Pacific Biological Station, Fisheries Research Board of Canada; Yuk-maan Leung and John L. Mohr, University of Southern California (cyamids); Kenneth M. Neiland, Alaska Department of Fish and Game (acanthocephalans and campulid trematodes); Robert L. Rausch, Arctic Health Research Laboratory (cestodes and notocotylid trematodes); John T. Davey, Commonwealth Bureau of Helminthology (nematodes). Daniel F. Cowan, Michigan State University, examined a pathological liver specimen. The late Gordon C. Pike, Arctic Biological Station, Fisheries Research Board of Canada, made the baleen tracings and allowed us to see his unpublished manuscript on gray whales taken off British Columbia. Unless otherwise noted, individuals mentioned above are present or former employees of the Marine Mammal Biological Laboratory, Bureau of Commercial Fisheries.

INTRODUCTION

IN February each year, pod after pod of gray whales departs from the tropical mangrove-fringed lagoons bordering Bahia Magdalena, from Laguna Ojo de Liebre in the heart of the Vizcaino Desert, and from other lagoons on the west coast of Baja California. Swimming slowly but steadily, they move northward along the coast; four months later the same whales may be surfacing and blowing among the ice floes of the Chukchi Sea. This migration is the longest performed by any mammal.

The gray whale, *Eschrichtius robustus* (Lilljeborg, 1861), is unique in other ways. It is the sole member of the family Eschrichtiidae and the most primitive surviving baleen whale. In structure it is remarkably similar to the extinct cetotheres, which were ancestral to all living baleen whales. The gray whale became extinct in the North Atlantic only a few centuries ago and is now a relict species confined to neritic waters of the North Pacific Ocean and adjacent waters of the Arctic Ocean (Fig. 1).

Because gray whales swim slowly and congregate in near-shore waters, they were easy prey to whalers. By the turn of the century, the species was almost extinct. Since 1946, the eastern Pacific stock has increased under the legal protection afforded by the International Convention for the Regulation of Whaling to the point that commercial utilization may again be advocated.

Gray whales are the only large whales that can regularly be observed in large numbers from shore. Their annual passage along the coast of California is one of the world's outstanding wildlife spectacles. Public interest in gray whales is increasing, and they have become an important tourist attraction in southern California. More than a million people visit Cabrillo National Monument on Point Loma, San Diego, each year to watch the migrating whales, and several sport-fishing companies in San Diego and San Pedro profitably operate "whale watching" cruises (Rice, 1961).

The abundance and accessibility of gray whales in their calving lagoons and along the coast is also attracting a growing number of experimental biologists, and there is cause for concern that, especially on the calving grounds, repeated harassment of gray whales

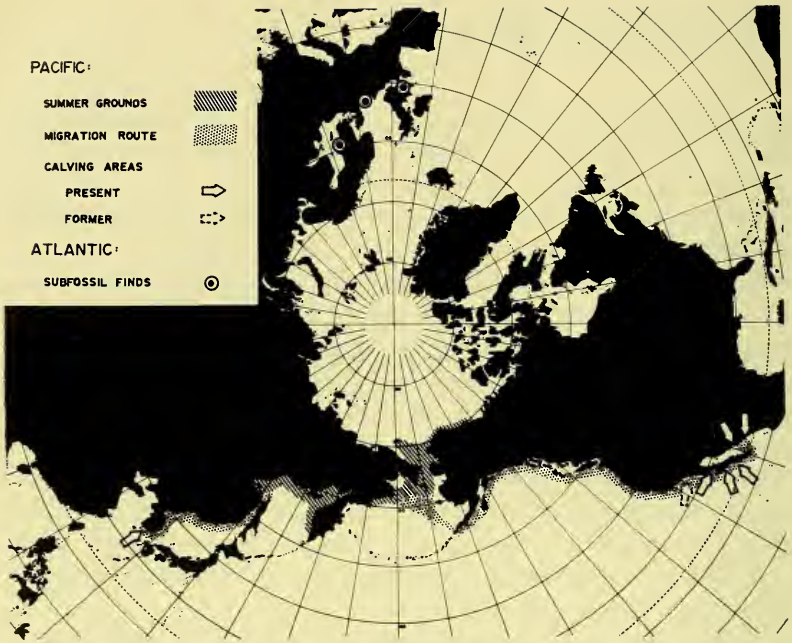

FIG. 1. Distribution of the gray whale. A few gray whales spend the summer in the migration area, especially along the coast of Washington and Oregon.

by investigators using small boats or aircraft in attempts to implant telemetering and tracking devices or drug darts may deleteriously affect reproduction (Schevill *et al.*, 1967; American Society of Mammalogists, 1967). Another threat to the survival of the gray whale is increasing industrial development and boat and ship traffic in the remaining calving lagoons (Marx, 1966). The species has long since been driven from San Diego Bay.

The gray whale is clearly an important species from the standpoint of basic scientific interest, esthetic appeal, and economic significance. If commercial exploitation is resumed it should be limited to the sustainable yield so that the scientific and esthetic values of the population may be preserved. A wise management program must be based on a sound knowledge of the biology of the species.

Beginning with Scammon's (1874) classic account, the gray whale has been the subject of many field observations (for example, Gilmore, 1960*a*, 1960*b*; Hubbs, 1959; Hubbs and Hubbs, 1967; Pike, 1962*a*). As a result, certain facets of its life history and ecology, such as distribution, migrations, and behavior, are better known than for other baleen whales.

Only five biologists have had the opportunity to examine series of gray whales. Andrews (1914) studied 23 specimens taken during southward migration and brought into the shore station at Ulsan, Korea, in January and February 1912. In his monograph he presented a historical review of earlier research on the species. Zenkovich (1934*a*, 1934*b*, 1937*a*, 1937*b*, 1937*c*) examined 104 gray whales aboard the Soviet floating factory *Aleut* during the summers of 1933 through 1936. Tomilin (1937) examined 54 specimens aboard the *Aleut* in August and September 1934. Unfortunately, neither Andrews, Zenkovich, nor Tomilin recorded reproductive information other than measurements of fetuses and condition of mammary glands. Pike (1962*a* and unpublished data) examined 10 northward migrating gray whales killed under a special scientific permit and brought into the shore station at Coal Harbour, British Columbia, during the first week of April 1953. Zimushko (1969*a*, 1969*b*) reported on 63 gray whales collected off the Chukotsky Peninsula in the summer and autumn of 1965 and 1966.

Few other original data based upon examination of dead gray whales have been published. Gilmore (1960*a*) and Eberhardt and Norris (1964) examined a number of dead calves at Laguna Ojo de Liebre, Baja California, and Maher (1960) reported on several whales killed by Eskimos at Barrow, Alaska.

Statistical data from commercial catches of gray whales in Baja California and in the Bering Sea were analyzed by Risting (1928). Unfortunately, his data are unreliable, because body lengths were estimated rather than measured (see Mackintosh and Wheeler, 1929, p. 273), and therefore the conclusions concerning fetal growth and size at sexual maturity are not valid. Mizue (1951) presented statistical data from gray whale catches in Korea.

The Bureau of Commercial Fisheries began a program of research on the species in 1952 under the leadership of Raymond M. Gilmore. During the first five years, the work consisted of field observations

and censuses designed primarily to determine the extent of the calving grounds and to document fluctuations in population size (Gilmore, 1960*a*, 1960*b*).

In 1958, responsibility for whale research was transferred to the Marine Mammal Biological Laboratory in Seattle, Washington, under the direction of the senior author. Beginning in 1959, small series of gray whales have been periodically collected to obtain basic data on all aspects of the life history and ecology of the species. Particular emphasis has been given to reproduction, growth, age, and population structure. As collections and observations had to be made incidentally to studies on rorquals and sperm whales, they have been mostly confined to the periods when the gray whales were on migration along the coast of California. This report presents the results of the study from 1959 through February 1970.

NOMENCLATURE

THERE has long been a controversy over the correct scientific name of the gray whale. *Eschrichtius robustus* (Lilljeborg, 1861) is used here for the extinct Atlantic and the living Pacific populations of gray whales following Cederlund (1939). As the data and conclusions of this author have been mostly ignored by subsequent workers, none of whom has contributed new evidence to refute his conclusions, it seems desirable to briefly review the nomenclature of the gray whale.

The generic name *Eschrichtius* Gray (1864) is now used by virtually all taxonomists. There are three available species-group names (Hershkovitz, 1966) that require consideration. These are, in order of priority: (1) *Balaena gibbosa* Erxleben (1777), based on the New England "scrag whale" described by Dudley (1725); (2) *Balaenoptera robusta* Lilljeborg (1861), based on subfossil skeletal remains from Gräsö, Sweden; and (3) *Agaphelus glaucus* Cope (1868), based on gray whales from the coast of California. Two questions must be resolved: (1) which of the first two names should be used for the Atlantic population, and (2) is the Pacific population taxonomically distinct from the Atlantic population?

The applicability of Erxleben's name *gibbosa* to the gray whale depends upon the identity of Dudley's "scrag whale." Dudley's (1725) brief description reads as follows: "The Scrag Whale is near a-kin to the Fin-back, but, instead of a Fin upon his Back, the Ridge of the Afterpart of his Back is scragged with half a Dozen Knobs or Nuckles; he is nearest the right Whale in Figure and for Quantity of Oil; his Bone is white, but won't split." The lack of a dorsal fin, knobs on the back, and white baleen are diagnostic of the gray whale. It seems improbable that Dudley's description of the scrag whale is inaccurate because all other large whales described by him are readily recognizable. On the other hand, there are minor discrepancies between Dudley's description of the scrag whale and the gray whale. For one thing, the oil yield is too high; Scammon (1874) stated that right whales yielded an average of 60 barrels, but that gray whales produced only 20 with a maximum of 60 or 70. For another, the number of knobs on the back is too few; gray

whales have nine to 14 knobs behind the dorsal hump, although the posterior knobs are weakly defined. These discrepancies might seem minor were it not for the fact that no other account of early whaling gives any indication of the occurrence of *Eschrichtius* in the North Atlantic (True, 1904) and the fact that the term "scrag" or "scragg" was applied to different kinds of whales, particularly small, lean, right whales (Allen, 1916; Eschricht and Reinhardt, 1866). As the identity of Dudley's scrag whale can never be unequivocally determined, we agree with Cederlund (1939) and Schevill (1952) that Lilljeborg's specific name should be used for the Atlantic gray whales.

The question of the taxonomic relationship of the Pacific and Atlantic gray whale stocks has been investigated by van Deinse and Junge (1937) and Cederlund (1939), who compared the sub-fossil skeletal material from the Atlantic with skeletons and published data and photographs of Pacific gray whales. These authors found no consistent differences between the Atlantic and Pacific specimens and concluded that these populations were conspecific.

FIELD AND LABORATORY PROCEDURES

Collection of Specimens

A total of 316 gray whales was examined. These were collected by the whale catcher boats of the Del Monte and the Golden Gate Fishing Companies, Richmond, California, under special scientific permits issued to the Marine Mammal Biological Laboratory. The whales were taken along the coast of central California between Half Moon Bay ($37^{\circ}30'$ N lat.) and Point Reyes ($38^{\circ}00'$ N lat.).

The collections were scheduled to provide representative samples for the periods of the southward (December to January) and northward (February to April) migrations. The total sample included 180 southbound migrants (85 males, 95 females) and 136 northbound migrants (81 males, 55 females). Dates of collection, numbers of specimens (in parentheses), and persons who made the examinations and measurements are as follows: 23 to 26 February 1959 (two) Rice; 27 to 30 March 1962 (four) Rice; 14 to 25 March 1964 (20) Rice; 22 to 29 March 1966 (26) Rice, Wolman, Balcomb; 14 December 1966 to 19 January 1967 (95) Rice, Wolman, Ekberg, Kasuya; 21 February to 9 March 1967 (30) Wolman, Ekberg; 14 to 25 January 1968 (35) Rice, Wolman; 26 February to 11 March 1968 (24) Wolman, Lenheim; 2 to 11 April 1968 (seven) Rice, Wolman; 20 December 1968 to 9 January 1969 (50) Rice, Lenheim; 2 to 16 March 1969 (23) Wolman, Lenheim.

Whales were delivered to the shore stations of the Del Monte and Golden Gate Fishing Companies at Point San Pablo, Richmond, California, where the following data were recorded.

MEASUREMENTS AND COUNTS.—Twenty-two standard external body measurements of the first 177 whales collected were made with a steel tape graduated in centimeters. A preliminary analysis revealed that many of these measurements were redundant, imprecise, or useless. Consequently, only nine measurements were made on the last 139 specimens. These were: total length (straight line from tip of snout to notch of flukes); head length (from tip of snout to occipital condyles); tail length (from notch of flukes to anus); maximum girth of body

(determined by measuring from the mid-dorsal line to the mid-ventral line on the side of the whale that was uppermost as the animal lay on the flensing deck and multiplying by two); span of flukes; breadth of flukes (from notch to nearest point on leading edge); anterior length of flipper; posterior length of flipper; and maximum width of flipper. Sixteen skulls and one complete skeleton were collected for cranial measurements. Throat grooves, baleen plates, and knobs on the dorsal ridge of the caudal peduncle were counted on most specimens.

BODY WEIGHTS.—Weights of six whales were determined by summing the weight of the meat produced after it had been packaged in 50-pound (22.7 kilogram) bags and the weights of the blubber, viscera, and bones, which were determined by weighing each truckload of raw material on commercial truck scales. One near-term fetus was weighed in pieces.

ECTOPARASITES AND EPIZOITES.—Abundance, position, and sizes of ectoparasites and epizotes on the body surface and baleen plates were recorded, and a series of each species was collected for identification.

SCARS.—The nature and position of any scars and wounds were noted.

BLUBBER THICKNESS.—Thickness of the blubber was measured (to the nearest half centimeter) at a mid-lateral point on the body opposite the dorsal hump.

MAMMARY GLANDS.—Development of the mammary glands and presence or absence of secretory activity was noted. Maximum thickness of the glands, as determined by inspection, was measured to the nearest half centimeter. A small portion of mammary gland tissue was fixed in 10 per cent formalin or FAA (10 parts formalin, 30 parts isopropanol, 5 parts acetic acid, 55 parts water), sectioned at 10 microns, and stained with hematoxylin and eosin. The development of glandular tissue subsequently was determined by projecting a randomly selected section about one-quarter of a square centimeter onto a sheet of paper on which 100 dots were arranged in a regular 10 by 10 grid; the number of dots falling within glandular areas was used as an index of the proportion of glandular tissue.

OVARIES.—The ovaries of each female were collected and fixed in 10 per cent formalin. The preserved ovaries were weighed to the nearest hundredth of a kilogram and serially sectioned at half a centimeter on a mechanical meat slicer. Each corpus luteum and corpus albicans revealed through sectioning was measured, to the nearest millimeter, across its greatest diameter and across its maximum diameter at right angles to the greatest diameter; and the two measurements were averaged. The maximum diameter of the largest Graafian follicle also was measured to the nearest millimeter.

UTERUS.—The diameter of each uterine horn at approximately the middle was measured to the nearest half a centimeter. A sample of the uterine wall was fixed in 10 per cent formalin or FAA, sectioned at 10 microns, and stained with hematoxylin and eosin for histological study. In specimens in which a corpus luteum or recently ovulated follicle was present in either ovary, but there was no obvious indication of pregnancy, the entire uterus was removed from the carcass, each uterine horn slit open along its entire length, and the

surface of the endometrium carefully searched. Embryos and small fetuses were preserved in 10 per cent formalin and their length (crown to tip of tail, with body straightened) and sex recorded. Standard body measurements were made on near-term fetuses and the sex was noted.

TESTES.—Each testis was weighed to the nearest tenth of a kilogram at the whaling station. A small sample (1 to 2 cubic centimeters) of the largest testis of each whale was taken for microscopic examination from the middle of the gonad about halfway between the surface and center and fixed in FAA, 10 per cent formalin, or Bouin's solution. Specimens were sectioned at seven microns and stained with hematoxylin and eosin. Mean diameter of the seminiferous tubules was calculated from measurements with an ocular micrometer of the greatest diameter and maximum diameter at right angles to the greatest diameter of 20 tubules cut in cross section. The presence or absence of fluid in the epididymides and deferent ducts was noted.

PENIS.—The length of the extruded penis from the base on the ventral surface to the tip and the circumference at the base were measured to the nearest centimeter. These measurements could not be made on some males, especially immature individuals, because the penis was not completely extruded.

STOMACH CONTENTS.—The quantity of any food remains in the stomach was estimated and a sample preserved for identification.

ENDOPARASITES.—The stomach, intestine, liver, kidneys, lungs, peribullary sinuses, and blubber were examined for endoparasites. The intestine was slit open at three or more randomly selected points, and in the years 1967, 1968, and 1969 the rectum also was opened for inspection. The tips of the liver lobes were examined for evidence of cirrhosis and were sliced to reveal the bile ducts. The kidneys were slit to expose the main urinary duct.

VERTEBRAL EPIPHYSES.—The degree of fusion of the epiphyses of the anterior thoracic vertebrae to their centra was determined by chopping into the ends of the vertebrae with a hatchet to a depth of several centimeters.

EAR PLUGS.—An attempt was made to collect at least one ear plug from each whale. In a few animals, however, the plug was so soft that it could not be successfully removed. Ear plugs were preserved in 10 per cent formalin. They were bisected longitudinally and gently polished on a whetstone, so that the growth layers could be counted.

BALEEN PLATES.—Several of the longest baleen plates were collected from each whale. Variations in thickness of the plates were recorded graphically by means of an apparatus similar to that used by Ruud (1940).

Field Observations

Observations on living gray whales were made from coastal look-out points, chartered whale catcher boats, and light aircraft.

COASTAL STATIONS.—During the southward migration in 1967–68, 1968–69, and 1969–70, coastal lookout stations were established to count migrating whales. One was on Point Loma at San Diego, California ($32^{\circ}40'$ N lat.), 130 meters above sea level (Rice, 1961) and is the site where previous counts were made (Gilmore, 1960a, 1960b; Rice, 1961). This station was manned for 52 days (27 December to 16 February) in 1967–68 and for 57 days (20 December to 14 February) in 1968–69. The second station was 2 km. S Yankee Point, Monterey Co., California ($36^{\circ}29'$ N lat.), 23 meters above sea level and about 100 meters back from the shoreline. This was near the site where a partial count of migrating gray whales was made in 1966–67 (Adams, 1968). We manned this station for 49 days (18 December to 4 February) in 1967–68, 60 days (10 December to 7 February) in 1968–69, and 64 days (8 December to 9 February) in 1969–70.

Observations were made continuously from 0700 to 1700 hours (essentially sunrise to sunset) each day. At each station, two observers each worked a 5-hour shift; morning and afternoon shifts were alternated between the two observers. The number of whales, time of passage, estimated distance from shore, and direction of travel were recorded for each group sighted. Wind direction and force, cloud cover, precipitation, and fog were logged throughout the day.

VESSELS.—Between 25 January and 9 February 1968, we ran a series of transect cruises between Point Loma and a position west of Tanner and Cortez Banks. A similar transect was run off Yankee Point on 18 January 1968. While the vessel was underway, a constant watch for gray whales and other marine mammals was maintained on the bridge. All whales sighted were approached closely enough to ensure positive identification and the number of whales in each pod, the direction of travel, and the position and time of sighting recorded.

Observations on gray whales also were made during many cruises conducted for marking rorquals (*Balaenopteridae*) and sperm whales (*Physeter catodon*). The area covered included the waters along the coast from Point Reyes, California (38° N lat.), south to Isla Clarion off Colima, Mexico (18° N lat.). The cruises, totaling 15 months, were made mostly between December and April from 1962 to 1969. The calving grounds in Laguna Ojo de Liebre, Laguna Guerrero Negro, Laguna San Ignacio, and Bahía Magdalena, Baja California, were briefly visited. Gray whales were sighted on 304 occasions, and a total of 1045 individuals was recorded.

AIRCRAFT.—On 25 and 26 March 1969, an aerial survey was made in both directions along the entire coast between San Francisco, California (38° N lat.), and Cape Flattery, Washington (48° N lat.). Two aircraft (a Cessna 177 and a Cessna 185) were used, each with two observers in addition to the pilot. The flight path was 0.3 to 2.0 kilometers offshore at an average altitude of 230 meters and air speed of 200 kilometers per hour. When pods of whales were sighted they were often circled at a lower altitude. Data were recorded on a tape recorder. Sighting conditions were optimum, with calm seas and clear skies, throughout the period of the survey.

SEASONAL MIGRATORY CYCLE

GRAY whales now occur only in the North Pacific Ocean and adjacent waters of the Arctic Ocean. The species also existed in the North Atlantic until a few centuries ago. There are presently two geographically isolated stocks (Fig. 1): an eastern Pacific stock, which migrates between Baja California and the Bering and Chukchi seas, and a western Pacific stock, which migrates between South Korea and the Okhotsk Sea. These may be designated the California stock and the Korean stock, respectively, on the basis of their breeding grounds.

California Stock

SUMMER GROUNDS.—From late May through October, gray whales occupy the shallow waters of the northern and western Bering Sea, the Chukchi Sea, and the western Beaufort Sea. They are common along the Koryak coast of Siberia from Cape Navarin to Glubokoi Inlet (Berzin and Rovnin, 1966). Farther to the southwest they are rare; a few have been seen as far as Kronotskiy Bay on the Kamchatka Peninsula (Tomilin, 1957) and the Kommandorskiye Islands (Barabash-Nikiforov, 1938; Grebnitskii, 1902). In the Gulf of Anadyr, these whales are abundant along the southwest shore from Cape Navarin to Tymna Lagoon; they have not been seen in the northwestern part of the gulf from the Anadyr Estuary to Cape Kresta (Berzin and Rovnin, 1966). Gray whales are also common along the northeastern shore of the Gulf of Anadyr, from Cape Retkon to Cape Chaplino (Berzin and Rovnin, 1966), around St. Lawrence Island (Ichihara, 1958), around the shores of the Chukotskiy Peninsula as far northwest as Cape Serdtse Kamen' (Nikulin, 1946), in Kotzebue Sound (Wilke and Fiscus, 1961), and in the Chukchi Sea (north as far as 69° N lat.—Nasu, 1960). A few go westward along the coast as far as Tynkurginpil'gyn Lagoon (Berzin and Rovnin, 1966), and northwestward through the pack ice as far as Wrangel Island (Sleptsov, 1955).

Along the Arctic coast of Alaska they are found regularly from Cape Thompson (Pike, 1962a) east to Point Barrow, and a few have

been reported by Eskimos along the shores of the Beaufort Sea as far east as Barter Island (Maher, 1960). To the southeast, there are few records of gray whales. One was found stranded at Scammon Bay, south of the Yukon Delta, in September (Fay, *in* Pike, 1962a). There is only one published record of gray whales from the Pribilof Islands (Gilmore, 1960b), but several were seen around St. George Island in the summers of 1965 and 1968 by C. H. Fiscus, A. M. Johnson, and V. B. Scheffer (personal communication). Gray whale remains have been found on St. Matthew Island (Pike, 1962a), and C. H. Fiscus (personal communication) saw four gray whales in Sarichef Strait between St. Matthew Island and Hall Island on 3 August 1960.

Not all gray whales migrate to the Arctic in the summer. A few remain scattered along the west coast of North America. Pike and MacAskie (1969) reported several near Langara, Queen Charlotte Islands, British Columbia, in late August and early September of 1959 and 1960, and a young male stranded near Ucluelet, Vancouver Island, on 16 August 1966. Some were seen near Lapush, Washington, in June and July 1961 by C. Munsen (personal communication) and in July 1967 by the junior author. A few were seen near Kalaloch, Washington, in July 1968, by A. M. Johnson (personal communication). Fiscus (personal communication) saw one near Cannon Beach, Oregon, in July 1969. Gilmore (1960a) reported that a few regularly spend the summer in the vicinity of St. George Reef and Pelican Bay in northern California and southern Oregon. Whalers working off San Francisco occasionally see gray whales during the summer. L. Newton (personal communication), captain of the catcher boat "Lynnann," saw a few near the Farallon Islands, California, throughout the summer of 1964; they remained until late September or early October. K. C. Balcomb saw a small gray whale in Bahia Magdalena, Baja California, on 11 June 1965, during one of our whale marking cruises aboard the catcher boat "Sioux City."

The northern boundary of the known summer range of the gray whale corresponds closely with the southern edge of the zone of close pack ice during the period 1 to 15 September (U. S. Navy Hydrographic Office, 1958). Close pack ice may limit their movements. Scammon (1874) and Sleptsov (1955) have reported seeing

gray whales in broken pack ice. Gray whales do not arrive at Point Hope or at Barrow, Alaska, until most of the ice has gone out, long after the bowhead whales have arrived. As few observers experienced in identifying whales enter the close pack ice in ships or fly over it in the summer, the extent to which gray whales penetrate the pack ice is unknown. In the western Bering Sea, gray whales are confined to coastal waters, their seaward range being delimited by the edge of the Continental Shelf. They have never been found in the deep waters of the southwestern Bering Sea. Their feeding habits (see section on food and feeding) apparently restrict them to shallow water. Although most of the eastern Bering Sea is shallow, the scarcity of gray whales there is believed to be the result of a low biomass of benthos, 55 grams per square meter, compared with 200 to 900 grams per square meter in the northwestern region (Berzin and Rovnin, 1966; Neiman, 1963). ✓

MIGRATIONS.—Pike (1962a) summarized all published information on the migration route of the California population and presented significant new data. There are few observations on southward-migrating whales in the northern part of their range. From October through January, they probably move down the eastern side of the Bering Sea, go through Unimak Pass, and then follow the coast to Baja California. A few go around Cabo San Lucas and cross to the eastern side of the Gulf of California. From late February to June, the northward migration of males and females without calves, which is much better documented, follows the reverse route.

Our observations during whale marking cruises off California and Baja California show that the majority of gray whales migrate within a few kilometers of shore when passing points, headlands, and sectors of coastline where the Continental Shelf is narrow and there are no off-lying islands. Many tend to take the most direct route, however, when crossing bights and indentations of the coastline. For example, many southbound whales, after passing Point Conception ($34^{\circ}27'$ N lat.), head southeast through the Channel Islands, passing as much as 200 kilometers offshore from the mainland of southern California (Rice, 1965). Some gray whales make a similar offshore passage from about Punta Baja ($29^{\circ}57'$ N lat.). ✓

to Isla Cedros ($28^{\circ}22'$ N lat.), Baja California, thus avoiding the long journey around the shores of Bahía Sebastian Vizcaino. Quantitative data on offshore migration are presented in the chapter on populations.

The route taken by females with calves during the spring migration is unknown. During this study, the catcher-boat crews saw only one female with a calf—near Point Reyes on 15 March 1969. From 1959 through 1967, we collected no gray whales later than 30 March, and during that time we thought females with calves moved north later in the season. Therefore, in 1968 we hunted gray whales until 25 April, 14 days after the last whale was taken, and had one boat searching exclusively for females with calves from 2 to 25 April. Each year from 1956 through 1968, the regular sperm whaling season opened on 1 April and the baleen whaling season opened on 1 May (1956–59) or 16 April (1960–68). During these years, the whalers never saw a gray whale accompanied by a calf. Shore-based whalers working from San Simeon, California, in the 1880's likewise told Townsend (1887) that they never encountered females with calves.

✓ On whale marking cruises in 1965, 1966, 1967, and 1969, we traveled north during late February, March, and early April, by which time most females with calves had already left the calving lagoons. We put in at many points along the coast between Cabo San Lucas (23° N lat.), Baja California, and San Francisco (38° N lat.), California, but never encountered a female accompanied by a calf, although we saw many northward-migrating gray whales. During the transect cruises, we saw two females with calves on 10 February 1968 (at $32^{\circ}48'$ N and $118^{\circ}08'$ W, heading west-northwest near San Clemente Island). During the aerial surveys between San Francisco, California, and Cape Flattery, Washington, on 25 and 26 March 1969, no females with calves were identified among 816 gray whales sighted. Morejohn (1968) reported a female with a calf at Moss Landing, northeast of Monterey, California, on 2 May 1967.

✓ Gray whales observed on migration are usually swimming steadily and continuously in a constant direction on a course parallel to the shore. They surface regularly about every 3 to 5 minutes to blow three to five times. When out of sight of land,

they usually travel in a straight line. General observations indicate that the usual swimming speed is about 7 to 9 kilometers per hour (4 to 5 knots). Wyrick (1954) followed four separate gray whales migrating south past San Diego, California, for a total of more than 5 hours; their average speed was 8.5 kilometers per hour (4.6 knots). Cummings *et al.* (1968) tracked nine lone whales (some in daytime, others at night), over distances less than 1.7 kilometers and found the average speed to be 10.2 kilometers per hour (5.5 knots).

There was no consistent hourly variation in the number of gray whales migrating south past the counting stations, contrary to the opinion of Ramsey (1968). This lack of variation indicates that gray whales, on the average, maintain a constant speed throughout daylight hours.

There are few observations to show how fast gray whales travel at night. Unlike sperm whales, baleen whales are rarely, if ever, seen resting at the surface. Since they must rise to the surface regularly every few minutes to breathe, they must continue to swim at least slowly during hours of darkness. In polar regions during the summer when daylight is continuous, baleen whales appear to remain active continuously. ✓

Cummings *et al.* (1968) used an array of hydrophones mounted on the sea bottom off San Diego to track migrating gray whales. They reported the following: "Gray whales were soniferous day and night. One hundred twenty-four signals were recorded from at least 61 whales between 1800 and 0600 h, compared with 107 signals recorded from at least 157 whales between 0600 and 1800 h. All whales seen or heard at night apparently were migrating southward, and there was no evidence of the popular notion that gray whales characteristically stopped migrating at night to rest or to sleep." ✓

The average speed of gray whales along their entire migration route, calculated from dates of peak passage at various points along the coast, is about 185 kilometers per day, or 7.7 kilometers per hour, on the southward migration and half as fast on the northward migration (Pike, 1962a). If their average speed during the 10 hours of daylight is 8.5 kilometers per hour, they cover 85 kilometers; to travel the remaining 100 kilometers during the 14

FIG. 2. Collection dates of gray whales, according to sex, age, and reproductive status. Each square represents one animal.

hours of darkness, they must average 7.1 kilometers per hour, or 92 per cent of their speed during daylight.

During migration, there is a partial temporal segregation of gray whales according to sex, age, and reproductive status. This is evident from Fig. 2 in which the collection date of each whale is plotted according to sex, maturity, and reproductive status. These data cannot be regarded as strictly representative, however, because the collecting effort was not the same throughout the season. It must be kept in mind also that the gunners doubtless tended to select the larger animals, even though we imposed no size limitations. This tends to bias the sample in favor of mature animals and females, especially those in late pregnancy. The mean and extreme dates of passage for each class (Table 1), however, should be fairly reliable.

In general, in both the southward and the northward migration, females migrate earlier than males and adults migrate earlier than sexually immature animals. The vanguard of the southward migration from mid-December to the first of January is composed predominantly of females carrying near-term fetuses. The late-pregnant females are followed by adult females that have recently

TABLE 1

MEAN PASSAGE DATES OF MIGRATING GRAY WHALES OFF CENTRAL CALIFORNIA
(38° N LAT.) CLASSIFIED ACCORDING TO SEX, AGE, AND REPRODUCTIVE STATUS.

Category	Mean passage date		Days elapsed
	Southbound	Northbound	
Late pregnant (southbound); postpartum females (northbound)	31 December	26 March	85
Recently ovulated (southbound); early pregnant females (northbound)	5 January	28 February	54
Recently ovulated (southbound); metestrous and anestrus females (northbound)	5 January	14 March	68
Immature females	11 January	21 March	69
Adult males	9 January	12 March	62
Immature males	15 January	23 March	67

ovulated but have no macroscopically visible conceptus in the uterus; most of these females presumably weaned a calf a few months previously. The number of females in this class that were collected was fewer than expected. This probably resulted from gunner selection, although there also is a possibility that such females travel farther offshore. Next to pass are the immature females and, at about the same time, the adult males. Last to pass are the immature males.

During the northward migration, the first to pass are the newly pregnant females, which comprised the recently ovulated class of the preceding southward migration. Most of them pass within a limited period of about 15 days. We took them only between 21 February and 7 March in 1967, and between 26 February and 10 March in 1968. None was taken in 1969, when collecting did not commence until 2 March. The peak passage of adult males occurs more than 2 weeks later than that of the pregnant females. Adult males are followed by a few anestrus females that have failed to conceive. Immature whales of both sexes are the last to pass. Only two postpartum females were collected, both in late March. Neither was lactating; obviously their calves were stillborn or were lost shortly after birth.

Migrating gray whales travel singly or in pods of up to 16 individuals. In the course of the southward migration past Cali-

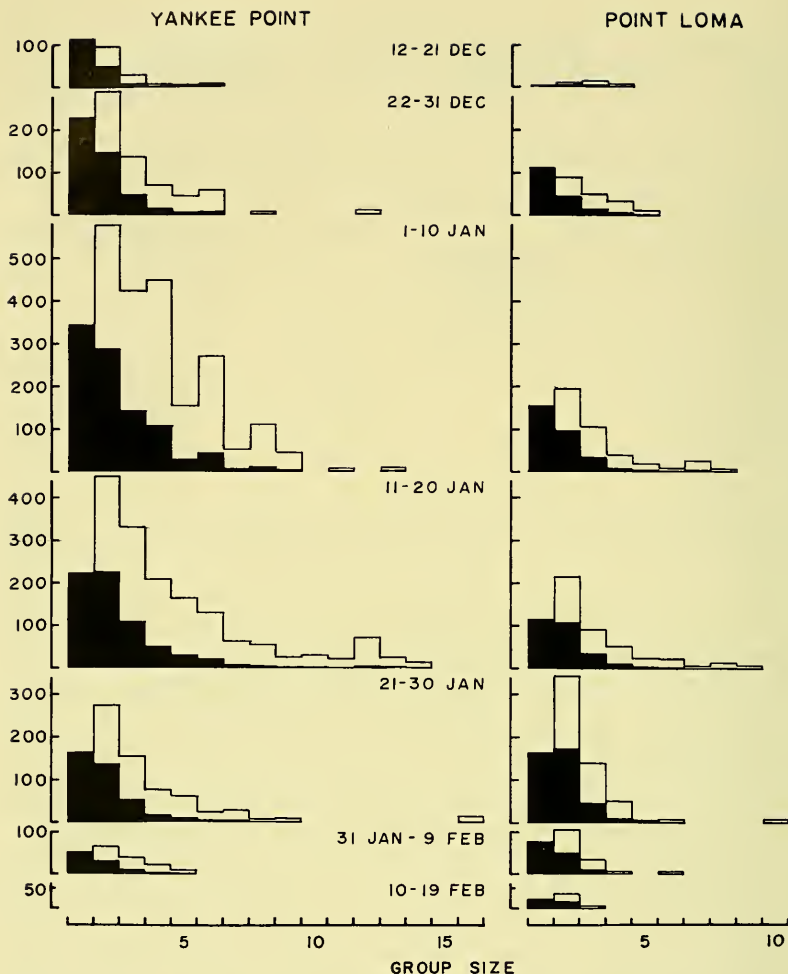

FIG. 3. Frequency distribution of group size of gray whales passing Yankee Point and Point Loma, by 10-day periods, during the southward migrations of 1967-68 and 1968-69. Solid bars indicate the number of groups, open bars the number of whales.

fornia, there are marked changes in the sizes of the groups (Fig. 3). During the early part of the migration, single whales (presumably mostly females carrying near-term fetuses) predominate, and almost no whales are in groups of more than six. During the

remainder of the migration, groups of two predominate. Most of the larger groups pass in the middle of the season, and towards the end of the season no groups contain more than five whales.

WINTER GROUNDS.—In January and February most gray whales of the eastern Pacific population are in warm temperate or tropical waters on the west coast of Baja California and the southern Gulf of California. Our southernmost sighting was at Punta Mita, Bahia de Banderas, Jalisco ($20^{\circ}45' \text{ N}$, $105^{\circ}34' \text{ W}$) on 17 February 1965. Gilmore (1960a) reported alleged sightings of gray whales at Isla Guadalupe and at Isla Clarion; we have seen none there nor anywhere else far off the coast of Mexico.

Most calves, as far as is known, are born in certain shallow lagoons. The six known calving areas, charted in detail by Gilmore (1960a), are as follows: *California and west coast of Baja California*—San Diego Bay (no longer occupied), Laguna Ojo de Liebre ("Scammon's Lagoon") and the adjacent Laguna Guerrero Negro, Laguna San Ignacio, and Bahia Magdalena and adjacent waters (including Bahia Almejas, Canal San Carlos, Estero Soledad, Estero Santo Domingo, Estero Las Animas); *eastern shore of Gulf of California*—open coast south of Yavaros, Sonora (see Gilmore *et al.*, 1967), and Bahia Reforma, Sinaloa.

Korean Stock

There is little information on the distribution of the Korean stock. No gray whales have been reported in recent years in either the Okhotsk Sea or the Sea of Japan, according to (personal communications) V. A. Arseniev and M. V. Ivashin of the All-Union Research Institute for Marine Fisheries and Oceanography, Moscow; H. Omura of the Whales Research Institute, Tokyo; and M. Nishiwaki of the Ocean Research Institute, Tokyo.

SUMMER GROUNDS.—Gray whales occupy, or at least formerly occupied, the northern Okhotsk Sea. They penetrated as far north as Penzhinskaya Bay (Krasheninnikov, 1755), and ranged southward as far as Akademii and Sakhalinskiy gulfs on the west (Sleptsov, 1955), and the mouth of the Kikhchik River on the east (Ditmar, 1890).

MIGRATIONS.—The migration route of the Korean stock of gray whales lay along the mainland coast of eastern Asia from Tatarskiy Strait to South Korea. Southbound whales passed Ulsan, South Korea, from late November to late January, and northbound whales passed there from the middle of March to the middle of May (Andrews, 1914). All the whales apparently passed through Tatarskiy Strait, as none was ever seen in La Perouse Strait between northern Hokkaido and southern Sakhalin (Mizue, 1951).

WINTER GROUNDS.—The channels, inlets, and bays along the southern coast of South Korea are believed to have been the winter calving grounds of the western Pacific gray whales. According to Andrews (1914): "In November and December, when the females are taken, almost every individual will be found to be carrying young nearly ready for birth. As these would necessarily be delivered within two or three weeks after passing Ulsan, the birth must occur in the bays among the numerous islands at the extreme southern end of the peninsula. Indeed Captain H. G. Melsom, who has hunted gray whales for 15 years along the Korea coast, has often observed them in this vicinity, but because of the abundance of other and more valuable species, they are not killed at this time by the Japanese."

Atlantic Stocks

Subfossil gray whale bones have been found at five localities along the coast of northwestern Europe: Pentuan, Cornwall, and Torquay, Devonshire, England, on the English Channel; IJmuiden and Wieringermeer Polder in the Netherlands; and on the Island of Gräsö, Sweden, in the northern Baltic (van Deinse and Junge, 1937). The most recent bones are those from IJmuiden, which date from about A.D. 500. There are no historical records of gray whales in the eastern North Atlantic. The summer grounds of the eastern Atlantic gray whales probably were in the Baltic Sea, where *Ampelisca macrocephala* (the predominant food of the California stock in the Bering Sea) is abundant (Kannevorff, 1965). Their winter grounds were perhaps along the Atlantic or Mediterranean coasts of southwestern Europe or northwestern Africa.

Discussion and Conclusions

In their annual migrations between summer feeding grounds in Arctic waters and winter breeding grounds in subtropical waters, gray whales may travel more than 18,000 kilometers each year, a distance exceeding that traveled by any other baleen whale. This extensive migration, spanning 50 degrees of latitude, exposes them to a broad range of environmental conditions. Sea surface temperatures on the summer grounds range from about 8° centigrade down to 0° or slightly less in the pack ice. On the winter grounds, temperatures range from about 18° centigrade at the latitude of Laguna Ojo de Liebre to 22° off Cabo San Lucas. In mid-summer most gray whales experience more than 22 hours of light each day, and those north of the Arctic Circle experience continuous daylight for several weeks. As the whales migrate southward, they are subjected to a rapidly decreasing photoperiod, which reaches a minimum of less than 8 hours in early December. Day length increases slowly during the remainder of the southward migration and while the whales are on the winter grounds, and then increases rapidly as the animals move north in the spring. The variable photoperiods to which the species is exposed may be an important proximate factor in regulating gonadal development.

There is no evidence to suggest that gray whales slow down at night while migrating southward. The length of their migration route, and their relatively slow swimming speed, makes it necessary for them to travel almost continuously at night as well as day.

The reasons for this long migration become apparent when the food habits of the gray whale are considered. In summer, the species requires areas of shallow water with an abundant benthos. In the North Pacific, large areas with such conditions are found only in parts of the Bering Sea and adjacent waters of the Arctic Ocean, and in the northern Okhotsk Sea. For almost half the year, the ice cover on these summer grounds cuts off the whales' major food supply and forces them to migrate.

Because they cannot feed much during the winter, it is necessary that they seek warmer waters to minimize energy requirements, particularly for the newborn calves. During the winter, the eastern North Pacific from California north is cold (less than 15° centigrade) and is subject to frequent storms with northwest winds that cause

heavy surf along the coast. The lagoons of Baja California are the nearest areas of warm, shallow, protected waters suitable for calving.

Females ready to bear a calf arrive on the winter grounds earlier and spend more time there than females that have recently mated. Apparently, calves must remain in warm protected waters until they have grown sufficiently to face the rigors of the long northward migration. The movements of females with calves after they leave the breeding lagoons are unknown. Unlike the other members of the population, they must travel farther offshore.

Pregnant females apparently are the first to arrive on the summer feeding grounds and spend more time there than lactating females. This is also true of fin whales, *Balaenoptera physalus* (Mackintosh, 1965), and humpback whales, *Megaptera novaeangliae* (Dawbin, 1966), and is no doubt related to the need of pregnant females to acquire more fat reserves (see discussion beyond of seasonal changes in nutritive condition).

FOOD AND FEEDING

Stomach Contents

SUMMER.—Few data are available on the stomach contents of gray whales killed on the summer grounds. Zenkovich (1934a, 1934b, 1937c) and Tomilin (1937) examined 104 and 54 stomachs, respectively, of whales taken in the Bering and Chukchi Seas from August to October. They did not publish quantitative data, but reported finding mostly gammaridean amphipods, of which were listed the following forms: Family Ampeliscidae—*Ampelisca macrocephala*; family Aoridae—*Lembos arcticus*; family Lysianassidae—*Anonyx nugax* and an unidentified species; family Haustoriidae—*Pontoporeia femorata*; family Eusiridae—*Eusirus* sp.; family Atylidae—*Atylus* sp.; family Gammaridae—unidentified species.

Ampelisca macrocephala predominated in the stomachs of whales killed in the Chukchi Sea and northern Bering Sea, whereas a species of Atylidae, apparently *Atylus carinatus*, predominated in those from along the coast between Natal'inskiy Bay and Cape Navarin. In addition to amphipods, several stomachs contained a few bottom-dwelling isopods, mysids (*Mysis oculata*), mollusks (*Buccinum* sp.), polychaetes (*Travisia forbesi*), and hydroids (Sertulariidae).

Pike (1962a) examined samples of the stomach contents of two gray whales killed by Eskimos off St. Lawrence Island in May and June. He found mostly the amphipods *Ampelisca macrocephala* and *A. eschrichti*, and a few *Anonyx nugax*; other items recorded were decapod crustaceans (including *Chionoecetes bairdi*, *Hyas coarcticus*, and *Liocyma fluctuosa*), cumaceans, polychaete (*Pectinaria* sp.) tubes, gastropods, and ascidians.

We examined a sample (collected by F. H. Fay) of the stomach contents of an immature female gray whale killed by Eskimos about 9 kilometers southwest of the village of Gambell, St. Lawrence Island, Alaska, in water about 30 meters deep. The sample of about 1 liter was a composite of random samples from several parts of the total contents of the stomach. More than 95 per cent of the sample consisted of gammaridean amphipods, ranging from less

than 6 to more than 25 millimeters in length. A few other invertebrates were present. Following is a complete list of the species identified. Classification of amphipods at the level of family and genus follows Barnard (1969). The numbers of each species of amphipod identified are given in parentheses, but they do not necessarily represent the proportion of each species in the total sample.

All of the organisms found in the stomachs of gray whales killed on the Arctic summer grounds are typically infaunal benthic species, that is, they burrow or live buried in the bottom sediments. *Ampelisca macrocephala*, the species most commonly eaten, is a large amphipod about 25 millimeters long. A study of its life history has been published by Kanneworff (1965). In the Bering and Chukchi Seas, *A. macrocephala* occurs mainly on sandy bottoms at depths of 5 to 300 meters (Gur'yanova, 1955).

Most of the amphipods in our sample were adult females, which are rarely found above the substratum during the day, although they form an appreciable part of the planktonic population at night; males alone tend to be pelagic during the day (E. L. Bousfield, personal communication).

In addition to food items, there was a considerable amount of fine gray sand or silt mixed with the stomach contents of the whale from St. Lawrence Island that we examined. Such extraneous material has also been recorded by other authors. Pike (1962a) found sand, silt, and bits of wood in the two samples he examined, and Zenkovich (1937a) found quantities of pebbles, as much as "2-3 pails," in many stomachs. Tomilin (1937) also reported finding silt, pebbles, and a large cobblestone, in addition to kelp leaves.

In northern California, Howell and Huey (1930) found a quantity of *Euphausia pacifica* in the baleen of a gray whale killed on 21 July 1926; they did not examine the stomach. This euphausiid is the chief food of rorquals in the waters off California.

The occasional infestation of gray whales with parasites that probably require fishes as intermediate hosts (see discussion of parasites in a later chapter) suggests that they sometimes eat fish.

DURING MIGRATION.—Our data confirm the reports by other authors (Andrews, 1914; Pike, 1962a; Scammon, 1874) that the stomachs of migrating gray whales are almost invariably empty. Stomachs of all 180 southbound migrants and those of 134 of the 136 northbound migrants examined contained no traces of food, and the intestines contained only small amounts of a thick greenish fluid, apparently bile and mucosal secretions. One of the two specimens containing food was an anestrous female taken on 20 March 1964. Its stomach contained about 20 liters of the zoea stage larvae of the littoral crab *Pachycheles rudis* (Anomura,

Porcellanidae) and a few brachyuran zoeae, probably of the genus *Fabia* (Brachyura, Pinnotheridae). The other animal was an immature female taken on 11 April 1968. Its stomach contained about 50 liters of the zoea stage larvae of a pinnotherid crab, probably the same species found in the preceding specimen, and a few scattered porcellanid zoeae, which were in too poor condition to identify further.

Migrating whales sometimes have gravel and other miscellaneous items in their stomachs. We found almost a kilogram of gravel in the stomach of one southbound, recently-ovulated female; mixed with the gravel were numerous ascidian tunics, fragments of hydroid stems and polychaete worm tubes, a few gastropod opercula, one pelecypod shell, and two tiny fragments of waterlogged wood. A late pregnant female had several liters of hydroid stems and a few polychaete tubes in her stomach, but no gravel or sand. The stomachs of two immature males collected during the northward migration each contained about 10 kilograms of gravel. The stomach of an early pregnant female contained about 100 kilograms of gravel in which were a few polychaete tubes, hydroid stems, and a small bit of waterlogged wood. A northbound immature female contained about 50 kilograms of sand and silt. The stomachs of several other animals contained traces of sand and gravel. Andrews (1914) found pebbles in the stomachs of two southbound migrants taken off Korea. Gravel and sand are probably ingested accidentally while the whale is feeding.

WINTER.—Scammon (1874) appears to have been the only person to examine the stomachs of animals taken in the calving lagoons. He examined "several" and found no food—only a small quantity of vegetable matter that was no doubt accidentally ingested.

According to Matthews (1932), Norwegian whalers found gray whales feeding on the "red crab," *Pleuroncodes planipes* (Anomura, Galatheididae), at Bahia Magdalena, Baja California, in 1926. He did not indicate whether this was ascertained by actual examination of stomachs. The red crab exists in both a benthic and pelagic phase (Boyd, 1967) and at times is extremely abundant off the western coast of central and southern Baja California. We found red crabs so abundant in Bahia Magdalena on the night of 6 February 1965 that they formed a continuous, tightly packed layer

on the surface, evidently attracted by the lights of our anchored vessel. On 1 March 1967, we passed through many dense shoals of these crabs, each a few meters wide and up to half a kilometer long or longer, just inside the 180-meter isobath about 45 km. SW Punta Abreojos. However, we never saw gray whales that appeared to be feeding on red crabs. *Pleuroncodes* apparently does not occur in Laguna Ojo de Liebre. According to Matthews (1932), Norwegian whalers noticed that the blubber oil obtained from "sei" whales (*Balaenoptera borealis* or *B. edeni*) on the Mexican coast was yellowish; he suggested that this was due to their feeding on *Pleuroncodes*. We have found that the blubber of gray whales is often yellow or orange during both the southward and northward migrations. A similar variation in blubber color was noted by Andrews (1914) in northbound Korean whales and by Zenkovich (1934a) in summer-taken specimens from the Bering Sea.

There is only one report on the stomach contents of gray whales on or near the wintering grounds in the western Pacific (Mizue, 1951). Two individuals killed in the northern waters of the Yellow Sea in May 1922 contained *Nephrops thomsoni*, a small benthic anomuran decapod similar to *Pleuroncodes*. These whales were taken unusually late in the spring and probably somewhat outside the normal range.

Seasonal Changes in Nutritive Condition

During southward migration, gray whales are fat, whereas during northward migration they are much thinner. Quantitative information on nutritive condition is provided by body weight, blubber thickness, and oil yield.

BODY WEIGHT.—We calculated and compared body weights of gray whales on southward and northward migrations, and attempted to estimate metabolic rate to determine if the difference between the two periods is sufficient to account for energy requirements in winter.

Weights and lengths of nine gray whales are given in Table 2. To calculate weights of other whales that could not be weighed, we used the formula $W = aLG^2$, where W = weight in kilograms, L = length in meters, and G = maximum girth in meters. The

FIG. 4. Comparison of calculated weights of immature male gray whales during the southward and northward migrations. Solid circles and unbroken line indicate southbound migrants; open circles and broken line indicate northbound migrants.

value of a was derived from the seven gray whales of known weight, length, and girth (Table 2); this ranged from 32 to 44. The limited data suggest that a and body length are not correlated. This lack of correlation is not unexpected, as there is virtually no change

FIG. 5. Comparison of calculated weights of adult male gray whales during the southward and northward migrations. Solid circles and unbroken line represent southbound migrants; open circles and broken line represent northbound migrants.

TABLE 2
WEIGHTS AND MEASUREMENTS OF NINE GRAY WHALES, UNLESS OTHERWISE NOTED SPECIMENS WERE COLLECTED IN PRESENT STUDY.

Sex	Age	Date	Body length (meters)	Girth (meters)	Weight ¹		Value of σ^2

FIG. 7. Comparison of calculated weights of recently ovulated female gray whales during the southward migration and early pregnant and anestrous females during the northward migration. Symbols are as follows: solid circles and unbroken line, southbound migrants; open circles and long-dashed line, early pregnant northbound migrants; triangles and short-dashed line, anestrous northbound migrants.

FIG. 8. Comparison of calculated weights of late pregnant female gray whales during the southward migration and postpartum females during the northward migration. Solid circles and unbroken line indicate southbound migrants; open circles and broken line indicate northbound migrants.

in body proportions with increasing length. We have used the mean value of 38. Estimates of percentage weight loss are independent of the value of a used.

The calculated weights of all whales (except for seven for which there were no comparable girth measurements) classified according to sex, age, and reproductive status, are plotted against body length in Figs. 4 to 8. Each class of southbound migrants is compared with the corresponding class of northbound migrants. Within each class, weight was closely correlated with length to the third power (in other words, there was no change in relative girth with increase in length), so we calculated mean weight-length curves for each

class with the equation $W = bL^3$. The value of b was calculated from the formula

$$b = \frac{\sum(G/L)^2}{N} a.$$

The mean absolute weights of whales of any given length during their southward and northward migrations may thus be compared. Their relative weights are simply a function of G^2 .

The total weight loss of gray whales between the southward and northward migrations varied from 11 to 29 per cent and was correlated with elapsed time (Table 3). Weight loss per day varied from 0.21 to 0.37 per cent. Weight lost by postpartum females is, of course, not entirely attributable to metabolism. The fetus and fetal membranes and fluids probably account for about 2000 kilograms. The nutritive condition and energy requirements of pregnant and postpartum females are discussed beyond.

To determine if the observed weight loss is sufficient to account for energy requirements during the 54 to 85 days elapsing between the southward and northward migrations past San Francisco, it was necessary to estimate the metabolic rate. For simplicity, we have estimated the metabolic rate of a near-average gray whale weighing 20 metric tons on the basis of oxygen consumption and have assumed that the number of kilocalories per day per kilogram of body weight expended is the same for all whales regardless of body length. This assumption is open to question, but more data are required before more refined estimates of metabolic rate can be made.

No data are available on the lung volume of gray whales. As the relative size and shape of the lungs are similar to those of fin whales, we have used Scholander's (1940) measurements of 800, 1500, and 2000 liters for the lung capacity of three fin whales 15.2, 20.7, and 22.0 meters long, respectively, as a basis for estimating a value for the gray whale. His estimates of the body weights of these whales were too high, so we used Ash's (1952) formula to recalculate the weights as 20, 49, and 58 metric tons, respectively. The mean lung capacity in liters is thus equal to 3.5 per cent of the body weight in kilograms. A 20-ton whale would, therefore, have a lung capacity of 20,000 by 0.035, or 700 liters. The volume

TABLE 3
WEIGHT LOSS OF GRAY WHALES BETWEEN SOUTHWARD MIGRATION (SM) AND NORTHWARD MIGRATION (NM).

Age, sex, and reproductive status	Number		Value of b^1 (mean \pm SE)		Total weight loss (per cent)	Mean number of days elapsed	Mean weight loss per day (per cent)

¹ See text for explanation.

of tidal air may be estimated at 80 per cent, as Irving *et al.* (1941) found in *Tursiops truncatus*, giving an estimate of 560 liters per breath. Oxygen utilization may be estimated at 10 per cent of tidal volume, based on *Tursiops* (Irving *et al.*, 1941), giving an estimate of 56 liters of oxygen per breath. As a gray whale breathes about once a minute, it uses an estimated 80,640 liters of oxygen per day, or 0.17 cubic centimeters per gram per hour. Since 1.99 liters of oxygen are required to oxidize 1 gram of fat (Bishop, 1950), 80,640 liters is sufficient to oxidize 41 kilograms or 0.20 per cent of the animal's body weight per day.

Oxidation of 1 gram of fat produces 9.54 kilocalories (Bishop, 1950), so the whale will produce about 3.8 by 10^5 kilocalories per day or 19 kilocalories per kilogram per day. This estimate of the metabolic rate is lower, on the basis of kilocalories per kilogram of body weight, than that of smaller mammals, but lies above Benedict's (1938) "mouse-to-elephant" curve. His curve gives a value of 70 times $20,000^{0.75}$, or about 1.2 times 10^5 kilocalories per day for a 20-ton animal. It should be noted, however, that our estimate cannot be considered a basal rate, because it is based on the respiration rate of an actively swimming animal. In some other mammals, the energy expended over a 24-hour period ranges between 1.3 and 4.0 times the basal rate, and for animals performing a moderate amount of work the average is approximately three times the basal rate (Brody, 1945). On this basis, the metabolic rates of large whales do not appear to be far above the "mouse-to-elephant" curve (see Kanwisher and Sundnes, 1966).

BLUBBER THICKNESS.—The thickness of the blubber has long been about the only measurement that has been used as an indicator of the nutritive condition of large whales (Slijper, 1954). Blubber thickness of gray whales was not correlated with body length, so we have used absolute measurements in our analysis. All sex and age classes of gray whales showed a slight decrease in blubber thickness between the southward and northward migration (Table 4), but this decrease was not statistically significant ($P > .05$) for any class.

Blubber thickness is less sensitive than girth as an indicator of the nutritive condition of gray whales. The reduction of girth reduces body surface area, and thus tends to make the blubber

TABLE 4

COMPARISONS OF BLUBBER THICKNESS OF GRAY WHALES DURING MIGRATION PERIODS.

Age, sex, and reproductive status	Number	Blubber thickness (cm)	
		Mean \pm SE	Range
Immature males			
Southward	17	12.8 \pm 0.3	10.5–15.0
Northward	25	12.6 \pm 0.3	9.5–16.0
Adult males			
Southward	66	13.5 \pm 0.2	9.5–17.5
Northward	44	12.8 \pm 0.2	10.5–16.0
Immature females			
Southward	11	14.4 \pm 0.4	12.5–16.5
Northward	23	12.8 \pm 0.4	8.0–17.0
Adult females			
Southward (recently ovulated)	27	15.7 \pm 0.4	10.5–20.0
Northward (early pregnant)	22	15.2 \pm 0.4	10.0–18.5
Northward (anestrous)	8	13.3 \pm 1.1	9.5–19.0
Southward (late pregnant)	53	15.7 \pm 0.2	12.5–19.0
Northward (postpartum)	2	14.5	10.0–19.0

thicker. It was apparent to us while examining the viscera of southbound and northbound migrants that weight loss is due more to utilization of body fat than to utilization of blubber.

OIL YIELD.—The oil yield of the carcass is probably the most reliable indicator of nutritive condition, but such data are not available for individual gray whales. The mean estimated body weight and mean yields of oil, meal, and meat from southbound whales were two and one-half to three times those of northbound animals (Table 5). The southbound sample consisted mostly of adult females carrying near-term fetuses; the northbound sample consisted mostly of males, and included many immature animals. The cubic mean length of the southbound whales was 12.62 meters, whereas that of the northbound animals was 11.23 meters. Quantities of each product were also affected by the relative amount of meat salvaged from each carcass. The remainder of each carcass was rendered for oil and meal. The difference between calculated body weight and total weight of oil, meal, and meat may be attributed to water loss during rendering of the oil and drying of the meal. Inasmuch as the samples are heterogeneous as regards

TABLE 5

MEAN WEIGHTS OF OIL, MEAL, AND MEAT PRODUCED FROM GRAY WHALES TAKEN IN SOUTHWARD AND NORTHWARD MIGRATIONS. MEAN CALCULATED BODY WEIGHT OF 26 SOUTHBOUND WHALES WAS 31,662 KILOGRAMS AND THAT OF THE 26 NORTHBOUND WHALES WAS 12,861 KILOGRAMS.

Products	Southward migration		Northward migration	
	Kilograms	Per cent	Kilograms	Per cent
Oil	7,559	39.6	2,496	38.1
Meal	6,834	35.8	2,520	38.5
Meat	4,689	24.6	1,533	23.4
Total	19,082	100.0	6,549	100.0

sex, age, and reproductive status, they are not directly comparable, but they do show the great difference in body weight between southbound and northbound migrants. The ratio of oil to meal also indicates a moderate decrease in relative oil yield between the southward and northward migrations.

Discussion and Conclusions

The predominance of gammaridean amphipods, especially *Ampelisca macrocephala*, among stomach contents indicates that gray whales, unlike other baleen whales, are primarily, if not exclusively, bottom feeders. The poor representation of polychaete worms and mollusks, which are usually dominant in the infauna, suggests that gray whales are selective feeders. Perhaps they stir up the bottom sediments with their snouts, then filter the turbid water immediately above the bottom from which the heavier mollusks have settled out. The worms presumably retreat deep into their tubes and burrows, whereas the amphipods, freely swimming, are trapped in the baleen plates. The occurrence of sand, silt, and gravel in the stomachs provides further evidence that gray whales feed on the bottom. In the Chukchi Sea, several observers (Pike, 1962a; Scammon, 1874; Wilke and Fiscus, 1961) have reported seeing gray whales, presumably feeding, surfacing with muddy snouts. Greater wear of the baleen on the right side suggests that gray whales swim on their right side while feeding (Kasuya and Rice, 1970). Fin whales (Gunther, 1949), Bryde's whales, *Balaenoptera edeni* (Rice, field notes), and humpback whales (Andrews, 1909)

swim on their sides when feeding near the surface. Swimming on their side permits whales to turn more easily in the horizontal plane.

While migrating, gray whales apparently rarely attempt to feed, at least along the southern sector of their migration route. What little evidence is available also indicates that gray whales seldom, if ever, feed while on the winter grounds. A calculated weight loss of 0.21 to 0.37 per cent of body weight per day between the southward and northward migration past San Francisco exceeds the hypothetical value of 0.20 per cent per day based upon their estimated metabolic requirements. Thus, there is no reason to assume that gray whales must feed while on the winter grounds. This conclusion may not apply to females with calves, however, as we have no data for them.

AGE AND GROWTH

Age Determination

No gray whales of known age have been studied. Age must be deduced from indirect evidence and by analogy with other species of baleen whales. Jonsgård (1969) reviewed methods of determining the ages of cetaceans. Three criteria appeared promising for determination of age in gray whales. These are the number of growth layers in the ear plugs, corpora albicantia in the ovaries, and growth zones in the baleen plates.

EAR PLUGS.—In balaenopterid whales, the number of growth layers in the ear plug is generally considered to be the most useful indicator of age (Purves, 1955; Laws and Purves, 1956). Each layer consists of one light and one dark lamina. There has been controversy, however, over the correlation between number of growth layers and absolute age. Data on ear plugs collected from fin whales marked more than 25 years previously, and several independent lines of indirect evidence, support the hypothesis that only about one growth layer is formed each year, at least in sexually mature fin whales (Ohsumi, 1964a). Ichihara (1966) provided evidence suggesting that in immature fin whales the rate of accumulation of ear plug laminae is irregular, varying from one to two annually, with a mean of one and one-half. Roe (1967a, 1967b), however, on the basis of histological examination of the ear plugs of fin whales collected in all months of the year, concluded that one growth layer is produced each year in both immature and adult whales of both sexes. He found that the light laminae are formed in summer and the dark laminae in winter. He also noted that the ear plugs of immature whales usually have minor laminae similar to but much thinner than the normal laminae; their significance is obscure, but he concluded that they should not be included in lamina counts for age determination.

Ear plugs of gray whales (Figs. 9–11) are soft, especially in the smaller animals, and difficult to remove without distortion or breakage. Some of the plugs have a fibrous, columnar, or amorphous

FIG. 9. Ear plugs of immature gray whales bisected longitudinally. A, 9.8-meter male, estimated age one year (attached to the "glove finger" of the tympanic membrane); B, 8.6-meter female, estimated age one year (attached to "glove finger"); C, 10.1-meter male with three growth layers; D, 11.3-meter female with six growth layers. All plugs are to same scale.

structure in which no laminae can be discerned. In the remaining plugs, laminae are vaguely to moderately well defined. Readable ear plugs were obtained from only 100 (60 per cent) of 166 males and 68 (45 per cent) of 150 females. On the better plugs, repeated counts of the laminae were consistent to within plus or minus 10 per cent of the total count. Males more often show regular laminae than do females, presumably because the annual physiological rhythm of females is modified by their longer and more irregular reproductive cycle.

The ear plug laminae are broad and poorly defined in immature whales but narrow and more sharply defined in adults. In many plugs from mature gray whales, the laminae are clear in the basal portion but indistinct or absent in the distal portion. This dif-

FIG. 10. Ear plugs of adult gray whales bisected longitudinally. A, 11.7-meter male with 11 growth layers; B, 11.4-meter female with 14 growth layers; C, 12.8-meter female with 18 growth layers; D, 12.3-meter male with 21 growth layers. All plugs are to same scale.

ference in the two regions suggests that the laminae laid down during immaturity may disappear as the plug grows. Another possible explanation—that some animals do not begin to produce clear laminae until they attain sexual maturity—appears unlikely, because the proportion of readable plugs was higher in immature than in mature whales (65 compared to 59 per cent in males and 56 compared to 42 per cent in females).

We found no ear plugs in several near-term fetuses that we dissected, and found no individuals with only one growth layer in the ear plugs. The smallest animals collected, 8.63 to 10.34 meters long, had two growth layers. We assumed that most of these animals were yearlings, and that the first layer forms during the nursing period and the second in late summer after weaning. As a working hypothesis, we assumed that each subsequent growth layer represented one year of growth in both immature and mature whales

FIG. 11. Ear plugs of adult gray whales. A, 11.7-meter male with 23 growth layers; B, 12.5-meter female with 24 growth layers; C, 12.5-meter male with 40 growth layers; D, 11.7-meter male with amorphous plug showing no growth layers. All plugs are to same scale.

This interpretation is consistent with our estimate of the rate of accumulation of corpora albicantia in the ovaries (see discussion of reproductive cycle beyond). As it appears that two layers are formed the first year, the age of a whale in years should be one less than the number of growth layers in its ear plug. If, as suggested above, the earlier layers disappear in older animals, the count of growth layers provides only a minimum estimate of age.

OVARIES.—As the ovulation rate appears to be regular at about 0.50 per year, and the corpora albicantia remain permanently visible in the ovaries, the number of corpora in the ovaries provides a reliable estimate of the number of years elapsed since a female attained puberty. The mean age at puberty appears to be about 8 years (see below). Therefore, the age of a recently ovulated or early pregnant female is about twice the number of corpora (including

FIG. 12. Body length in relation to number of growth layers in ear plugs of female gray whales (open circles, immature females; solid circles, adult females; line, von Bertalanffy growth curve).

the corpus luteum) in her ovaries plus 6 years, and that of a late pregnant or postpartum female twice the number of corpora plus 7 years.

BALEEN PLATES.—Ruud (1940, 1945) found that the growth of baleen plates of blue (*Balaenoptera musculus*), sei (*B. borealis*), and fin whales is characterized by seasonal changes in thickness and that the pattern of variation in thickness can be used to estimate the age of the whales (see van Utrecht-Cock, 1965). Because of constant wear, there is rarely more than 5 or 6 years of growth present in a baleen plate. Thus this method is useful only for young whales.

Baleen plates of most gray whales show moderately well-defined "steps," or growth zones, each of which presumably represents one year of growth. None of the baleen plates we examined showed more than four growth zones, regardless of the age of the whale as estimated from the ear plugs. The number of growth zones in the baleen plates of most whales was less than the number of growth layers in the ear plug, and in no specimen was it greater. It thus appears that wear on the baleen plates of the gray whale is more rapid than in other baleen whales, probably because of greater abrasion resulting from bottom-feeding habits.

FIG. 13. Body length in relation to number of growth layers in ear plugs of male gray whales (open circles, immature males; solid circles, adult males; line, von Bertalanffy growth curve).

Growth

The external morphology and osteology of the gray whale have been described in detail by Andrews (1914), Zenkovich (1934a), and Tomilin (1957). Further data on growth in length, ontogenetic changes in body proportions, and sexual dimorphism were obtained in this study.

LENGTH.—Body lengths of males and females one year old and older have been plotted against the number of growth layers in the ear plugs in Figs. 12 and 13. Growth curves for each sex were calculated by using the von Bertalanffy equation (von Bertalanffy, 1938; Beverton and Holt, 1957) as follows: $l_t = L_\infty [1 - e^{-K(t-t_0)}]$, where l = body length in meters, L_∞ = asymptotic body length, K = rate at which length approaches the asymptote, and t = time in years. The results are given below (mean and standard deviation).

Females	Males
$L_\infty = 12.97 \pm 0.11$	$L_\infty = 12.43 \pm 0.12$
$K = 0.246 \pm 0.035$	$K = 0.141 \pm 0.021$
$t_0 = -2.842 \pm 0.772$	$t_0 = -8.346 \pm 1.721$

It should be emphasized that because of the small sample sizes and the difficulty of reading ear plugs these curves are not com-

FIG. 14. Body length in relation to number of corpora albicantia and corpora lutea in ovaries of adult female gray whales. Crosses are running means of two; growth curve fitted by eye to mean values.

pletely reliable. The samples of the younger age groups are biased in favor of the larger individuals. Furthermore, possible disappearance of some ear plug laminae in older animals may have resulted in the estimated mean length at any given age being greater than the true mean.

In Fig. 14, the body length of adult females has been plotted against the number of corpora in the ovaries and a curve fitted by eye to the running means of two. This curve is probably a more accurate representation of the growth characteristics of adult females than the von Bertalanffy curve.

From a mean length at birth in January of about 4.9 meters, calves grow to a mean length of about 8.5 meters at weaning in August and to 9.3 meters by the following winter. With this first annual increment of 90 per cent of neonatal size, the females attain 66 per cent of their ultimate body length and the males 72 per cent. The growth rate drops to 7 per cent during the second year and continues to decline in subsequent years, but growth continues until at least about 30 years of age.

TABLE 6

BODY PROPORTIONS (EXPRESSED AS PERCENTAGE OF TOTAL BODY LENGTH) OF NEAR-TERM FETUSES AND POSTNATAL GRAY WHALES. SEE TEXT FOR DESCRIPTION OF MEASUREMENTS.

Measurement	Females				Males			
	Fetuses		Postnatals		Fetuses		Postnatals	
	N	Mean \pm SD	N	Mean \pm SD	N	Mean \pm SD	N	Mean \pm SD
Head length	17	22.4 \pm 1.1	136	23.2 \pm 1.0	25	22.5 \pm 1.3	155	23.3 \pm 0.9
Tail length	25	28.4 \pm 2.4	147	30.3 \pm 1.6	30	28.2 \pm 2.6	167	29.7 \pm 1.3
Fluke span	25	22.8 \pm 1.8	120	24.3 \pm 1.8	30	22.6 \pm 1.8	138	24.9 \pm 1.6
Fluke breadth	25	7.6 \pm 0.6	141	7.3 \pm 0.5	30	7.3 \pm 0.6	152	7.3 \pm 0.6
Flipper length	25	19.6 \pm 1.0	147	17.3 \pm 1.1	29	19.9 \pm 0.8	166	17.8 \pm 1.2
Flipper width	25	6.8 \pm 0.5	144	6.5 \pm 0.5	29	7.0 \pm 0.4	166	6.7 \pm 0.6

PROPORTIONS.—We have analyzed the following six body measurements to determine if body proportions change with age: (1) head length, (2) tail length, (3) span of flukes, (4) breadth of flukes, (5) length of flippers, and (6) width of flippers.

A comparison of these measurements (expressed as a percentage of body length) of near-term fetuses with those of postnatal whales (Table 6) shows that mean tail length increases from 28.2 to 29.7 per cent in males ($P < .05$) and from 28.4 to 30.3 per cent in females ($P < .001$). Relative flipper length decreases from 19.9 to 17.8 per cent ($P < .001$) in males and from 19.6 to 17.3 per cent ($P < .001$) in females. Fluke span increases from 22.6 to 24.9 per cent ($P < .005$) in males and from 22.8 to 24.3 per cent ($P < .01$) in females. Examination of near-term fetuses suggests that the apparent increase in relative fluke span does not represent differential growth, but instead is simply the result of postnatal abduction of the flukes in the horizontal plane from the adducted and folded position *in utero*. There are no significant age differences in relative head length, fluke breadth, or flipper width.

The magnitude of changes in body proportions of gray whales from one year of age to physical maturity also was examined. All postnatal animals of each sex were grouped into one-meter length classes. The mean and standard deviation of each measurement for each length class were calculated and the mean expressed as a percentage of total body length (Table 7). Only specimens for which

all six measurements were available were included. For each series of measurements, we calculated the allometric equation $Y = bX^d$, where X = body length and Y = measurement being compared with X . The constant of allometry, d , does not differ significantly ($P > .05$) from unity for any of the series of measurements for either sex, indicating that body proportions change little after one year of age.

SEXUAL DIMORPHISM.—There was no significant difference between the sexes in body length of near-term fetuses. As noted above, females grow more rapidly after birth and average larger than males at any given age, as is true for all other species of baleen whales.

The data in Tables 6 and 7 reveal small but statistically significant postnatal differences between the sexes in some body proportions. Thus, males have longer flippers ($P < .01$) and shorter tails ($P < .01$) than females. There is no sexual dimorphism in number of throat grooves, baleen plates, or crenulations on the dorsal ridge of the caudal peduncle.

Puberty and Sexual Maturity

As ordinarily used by cetologists, puberty refers to the age at which gametes are first produced, and sexual maturity is the age at which the animal reaches its full reproductive power. For purposes of this study, any animal that had attained puberty is referred to as an adult.

Puberty in the female is indicated by the presence of a corpus luteum or at least one corpus albicans in the ovaries. Females are considered to be sexually mature at the onset of the first pregnancy. Evidence of sexual maturity thus is pregnancy, lactation, or the presence of mature but involuted mammary glands and a parous type uterus. In the female gray whale, attainment of puberty and sexual maturity usually coincide, but in five of 15 nulliparous and primiparous females, the presence of a corpus albicans (in one case, three corpora), in addition to a corpus luteum or recently ovulated follicle, indicated that they had attained puberty but had not conceived at least a year before their most recent estrous cycle.

Males are considered to be sexually mature when first capable of successfully impregnating females. It is impossible to make a distinction between puberty and sexual maturity in the male on

FIG. 15. Percentage of adult gray whales according to body length (grouped by 0.3-meter length classes). Open circles and broken lines represent males; solid circles and unbroken lines represent females.

the basis of our data. We determined the attainment of puberty by histological examination of the testes and regarded as adult all males whose testes showed evidence of spermatogenesis.

Fig. 15 shows that 50 per cent of the females have attained puberty by the time they reach a length of about 11.7 meters. The two smallest females that had reached puberty were 10.92 meters and 11.20 meters long; both were nulliparous and had recently ovulated for the first time. The smallest parous female was 11.24 meters long, whereas the largest immature female was 12.92 meters in length.

Fifty per cent of the males had attained puberty at a length of 11.1 meters (Fig. 15). The smallest male showing spermatogenic activity was 10.56 meters long, and the largest immature male was 11.75 meters long.

The age at puberty was estimated by plotting the percentage of animals that had attained puberty against the number of growth layers in the ear plug (Fig. 16). The mean number of growth layers at puberty was nine, giving an estimated age of 8 years. In both males and females, the fewest growth layers found in the ear plug

FIG. 16. Percentage of adult gray whales in relation to number of growth layers in ear plugs. Open circles represent males and solid circles represent females; line connects running means of three for both sexes combined.

of an adult animal was six, whereas the highest number in an immature animal was 11 (excepting one female with 13). On this basis, age at puberty is estimated to range from 5 to at least 11 years. Because of the difficulty of counting growth layers in ear plugs of immature animals, these figures may not be entirely reliable.

Physical Maturity

We collected few physically mature animals, as determined by the complete fusion of the vertebral epiphyses with the centra. Only two of the females examined fell in this class. They were 13.98 and 14.20 meters long. The smaller had 35 corpora in the ovaries and about 41 growth layers in the ear plugs, whereas the larger had 22 corpora and 43 laminae in the ear plugs. Physically immature females had 20 or fewer corpora and as many as 40 growth layers. Except for one individual with unreadable ear plugs that was 14.05 meters long, physically immature females were 13.75 meters or less in length.

Five males were regarded as physically mature. They ranged from 12.75 to 13.30 meters in length. The smallest had only 21 growth layers in the ear plug, whereas the others had 38 to 70 (the plugs of one were unreadable). Physically immature males did not exceed a length of 12.80 meters, except for one with 23 growth layers that was 13.23 meters long.

The largest reliably measured gray whales on record are males 14.3 meters long and a female 15.0 meters in length (Zenkovich, 1937a).

Discussion and Conclusions

Growth layers in the ear plugs have limited use for age determination in the gray whale because of uncertainty in counting them and because not all individuals have readable plugs. They provide a minimum estimate of age because laminae produced early in life may disappear in older whales. The number of corpora in the ovaries appears to be a more reliable method for age determination in adult females. Growth zones in the baleen plates are of little use for age determination because of the rapid wear of the plates.

Gray whales grow rapidly during their first year. Rapid initial growth is essential in large aquatic mammals that depend primarily on size for thermoregulation and protection from predators.

Between late fetal life and one year of age, relative length of the flipper decreases slightly and relative length of the tail increases slightly. There are no appreciable changes in body proportions from one year to physical maturity. The latter conclusion is contrary to the findings for blue whales and fin whales (Mackintosh and Wheeler, 1929; Ohsumi, 1960), sei whales (Matthews, 1938), humpback whales (Matthews, 1937), right whales, *Balaena glacialis* (Omura *et al.*, 1969), and bowhead whales, *Balaena mysticetus* (Eschricht and Reinhardt, 1866). In most of these species, as body length increases the head becomes relatively longer, the tail relatively shorter, and the flippers and flukes relatively shorter and narrower.

Sexual maturity is attained in both sexes at a mean age of 8 years (range, 5 to 11), at a mean length of 11.1 meters in males and 11.7 meters in females. This estimate of age at sexual maturity is

in general agreement with estimates for fin whales (Nishiwaki *et al.*, 1958) and humpback whales (Chittleborough, 1959) that were based on counts of growth layers in the ear plugs. Physical maturity is attained at a mean length of about 13.0 meters in males and 14.1 meters in females, at a mean age of about 40 years. As in other baleen whales, females are larger than males. Sexual dimorphism in body proportions is slight, but males have slightly larger flippers and shorter tails than females.

FEMALE REPRODUCTIVE CYCLE

REPRODUCTION in cetaceans has been reviewed by Harrison (1969), Rice (1967), and Slijper (1956, 1963). Our collection of 116 adult females included animals in four stages of the reproductive cycle (sample sizes in parentheses): southbound females that had recently ovulated (28); northbound females in early pregnancy (22); southbound females in late pregnancy (56, including one recently aborted individual); and northbound postpartum females (two, neither of which was lactating, apparently having lost their calves). In addition, eight northbound metestrous and anestrous females, which had failed to conceive, were included in the sample. Some anestrous females would also be expected on the southward migration, but none was collected in this study.

Where appropriate, the data on the 15 females undergoing their first reproductive cycle were analyzed separately from the data on the 101 females that had previously experienced one or more cycles. We defined a female as *nulliparous* if she has never given birth (or aborted) and was not visibly pregnant (although she may contain a macroscopically undetectable conceptus), as *primiparous* if she was in her first pregnancy or had given birth (or aborted) only once, and as *multiparous* if she had given birth (or aborted) at least twice or had given birth (or aborted) only once and was currently pregnant; *parous* refers to any female that had conceived at least once (North Pacific Fur Seal Commission, 1963). Nulliparous females and primiparous females in early pregnancy were recognized by the condition of the mammary glands and uterus as described below. Females in late pregnancy and postpartum females with a single corpus luteum and no corpora albicantia were obviously primiparous, and those with at least one corpus albicans in addition to the corpus luteum were regarded as multiparous.

Ovarian Cycle

The ovaries of the gray whale are morphologically similar to those of the fin whale (Laws, 1961; Mackintosh and Wheeler, 1929; Ommanney, 1932), and the humpback whale (Dempsey and Wislocki,

FIG. 17. Ovaries of gray whales showing various stages of ovarian cycle. A, 8.6-meter immature female with no large Graafian follicles; B, 11.2-meter immature female with enlarged Graafian follicles; C, southbound female with recently ruptured Graafian follicle in right ovary and corpus luteum of ovulation in left ovary; D, southbound, recently ovulated female with developing corpus luteum in left ovary. All ovaries are to same scale.

1941). They are elongate, flattened, and oval, with the anterior end slightly larger than the posterior end. Some are exceptionally long and narrow, being almost strap-shaped. The larger Graafian follicles and corpora albicantia protrude from the surface. Ovaries

FIG. 18. Transverse sections of ovaries shown in Fig. 17. Sections shown in C and D transect the most recent corpora. All sections are to same scale.

representative of various stages of the reproductive cycle are shown in Figs. 17 to 20.

OVARY WEIGHTS.—There is no marked or consistent difference in weight between left and right ovaries. The mean weight of both ovaries of sexually immature females is plotted against body length in Fig. 21. In the smaller individuals, ovary weights range from 70 to 250 grams, with a mean of 136. At a body length of 11.2 to 11.4 meters, corresponding to an estimated age of about 5 years,

FIG. 19. Ovaries of gray whales showing various stages of the ovarian cycle. A, northbound, early pregnant female (90-millimeter fetus) with corpus luteum in left ovary; B, southbound late pregnant female (4.86-meter fetus) with corpus luteum in right ovary; C, northbound postpartum female (that had lost her calf) with regressing corpus luteum in left ovary; D, northbound anestrous female with large corpus albicans derived from the most recent corpus luteum in right ovary. All ovaries are to same scale.

ovarian weight increases abruptly to 250 to 550 grams (mean, 312), approximating that of younger sexually mature females.

The weight of the ovaries of sexually mature females is greatly increased when a corpus luteum is present. As most mature females

FIG. 20. Transverse sections through the most recent corpus in each pair of ovaries shown in Fig. 19. All sections are to same scale.

FIG. 21. Ovary weights of immature female gray whales plotted against body length. Line connects mean weights at one-meter length intervals.

FIG. 22. Ovary weights of adult female gray whales plotted against number of corpora in ovaries.

FIG. 23. Diameter of largest Graafian follicle versus body length of immature female gray whales. Solid circles indicate southbound migrants; open circles indicate northbound migrants.

had a corpus luteum in one ovary, we have used only the weight of the other ovary in making comparisons. For females without a corpus luteum, we have used the mean weight of the two ovaries. In Fig. 22, these weights are plotted against the number of corpora in both ovaries.

The weights of mature ovaries without a corpus luteum vary from 170 to 1270 grams. The regression of ovary weight on number of corpora is $Y = 316 + 15X$, where Y = ovary weight in grams and X = number of corpora. As the slope of this line differs significantly from zero ($P < .001$), ovarian weight apparently increases with age from a mean of 331 grams at puberty to 646 grams at an age of 50 years.

FOLLICLES.—None of the follicles in the ovaries of immature females up to 9.6 meters long exceeded 7 millimeters in diameter; in all immature females longer than 10.2 meters, the largest follicle

FIG. 24. Frequency distribution of diameter of largest Graafian follicle in ovaries of adult female gray whales in different phases of the reproductive cycle (N, northbound migrants; S, southbound migrants).

in either ovary exceeded 14 millimeters (Fig. 23). In the latter animals the largest follicles ranged from 18 to 34 millimeters (mean, 27) in southbound animals and from 14 to 28 millimeters (mean, 21) in northbound animals. These data suggest that females first begin to undergo a seasonal cycle of follicle-stimulating hormone secretion when they reach a length of between 9.6 and 10.2 meters at an estimated age of 2 or 3 years. Laws (1961) found a seasonal follicular cycle in immature fin whales. It should be noted that the follicles in these older immature females are significantly larger than those of late pregnant or postpartum females and slightly larger than those of northbound anestrus females. It is probable that the southbound immature females with follicles about 30 millimeters in diameter or larger (see below) are destined to ovulate for the first time later in the same season.

The size of the largest follicle in either ovary of adult females differs markedly in various phases of the reproductive cycle (Fig. 24). All southbound females not carrying near-term fetuses had recently ovulated. The largest follicle in these specimens ranged

from 18 to 40 millimeters (mean, 28) in diameter (except for one nulliparous animal in which maximum follicle diameter was only 6 millimeters). Assuming that the largest follicle had ovulated, the biggest remaining follicle in these females would have been the second largest follicle just before ovulation. It thus appears that in gray whales the follicle exceeds 30 millimeters and may reach 40 before rupturing. Chittleborough (1954) found that the follicles of humpback whales exceed 30 millimeters before ovulation.

In the northbound early-pregnant females, the diameter of the largest follicles average less than two months earlier, ranging from 16 to 33 millimeters, with a mean of 22.

In strong contrast to females that had recently ovulated, southbound pregnant females carrying near-term fetuses had no greatly enlarged follicles. The largest follicle varied from 3 to 16 millimeters, with a mean of only 6. A female taken on 8 January that had apparently aborted recently likewise had no follicles larger than 6 millimeters. Such follicles are significantly smaller than those of anestrus females. The small size of follicles in late-pregnant females suggests that the progesterone secreted by the corpus luteum suppresses follicular maturation. Chittleborough (1954) found that the follicles of humpback whales in late pregnancy were smaller than those in anestrus animals. No such marked reduction has been found in blue whales and fin whales examined mostly during midpregnancy (Laws, 1961; Mackintosh and Wheeler, 1929; Nishiwaki and Oye, 1951).

In the two northbound females examined that were nonlactating and postpartum, the largest follicles were 24 and 29 millimeters in diameter. Their size suggests a resumption of follicular maturation after regression of the corpus luteum.

Northbound females that were neither pregnant nor postpartum had follicles ranging from 1 to 37 millimeters (mean, 18) in diameter. In three of these females that had recently ovulated, the largest follicles ranged from 14 to 37 millimeters, with a mean of 24. These approximate maximum follicle sizes of southbound females that had recently ovulated and were presumably pregnant. These three females probably should be regarded as being in metestrus. Five anestrus females that had not ovulated recently had follicles with maximum diameters of 1 to 25 millimeters, with a mean of 14.

This size range is probably closest to that of follicles of fully anestrus females.

Nine pairs of ovaries contained one to several thin-walled, fluid-filled cysts up to about 8 centimeters in diameter. Presumably, these are cystic follicles.

FREQUENCY OF OVULATION.—Nonpregnant adult females regularly ovulate in late November and early December (see discussion of gestation period and fetal growth beyond), while still north of central California on the southward migration. All of the adult females collected in southward migration that were not carrying near-term fetuses had recently ovulated, as revealed by the presence of recently ruptured follicles or developing corpora lutea. The mean number of recent ovulations in these females was 1.14 for nulliparous animals and 1.10 for parous animals (Table 8). It is possible that some of these whales would have ovulated again later if their most recent ovulation did not result in conception.

The mean number of recent ovulations in northbound females (excluding postpartum animals) was 1.33 in the nulliparous and the primiparous pregnant females and 0.85 in the parous non-pregnant and the multiparous pregnant females. The diameter of the largest corpus albicans in the ovaries of each metestrous and anestrus female suggests, however, that some of these may have been fairly recently formed corpora whose recent origin was no longer apparent. These corpora ranged from 24 to 39 millimeters in diameter, with a mean and standard error of 32.3 ± 3.0 , whereas the largest corpus albicans in each early pregnant female ranged from 18 to 42 millimeters, with a mean and standard error of 27.4 ± 1.6 . The latter presumably were the corpora lutea of the previous pregnancy that had regressed after the end of lactation several months earlier.

The mean ovulation rate estimated for females during their regular biennial breeding season was 1.20 for nulliparous females, 0.96 for parous females, and 1.00 for all females (Table 8). For reasons stated above, these estimates may be slightly low.

Each of two females taken on 16 and 18 January had both recently ruptured follicles and a corpus luteum of ovulation. This observation suggests that about 40 days intervene between successive ovulations during one breeding season.

¹ Figures in body of table indicate the number of whales that had the number of recent ovulations shown at the top of each column.

The only evidence for multiple (simultaneous) ovulation was one female with two recently ruptured follicles of the same size.

The nature of the estrous cycle in baleen whales has been the subject of controversy, because few specimens taken during the breeding season have been available for study, and conclusions have had to be drawn mostly from indirect evidence. Harvey (1963) reviewed the relevant literature and concluded that balaenopterid whales are monestrous. Chittleborough (1965), however, presented direct evidence that female humpback whales, although they usually conceive after ovulating only once, may undergo two or three estrous

cycles if pregnancy does not intervene. Gambell's (1968) data strongly suggest a similar condition in sei whales. Potential polyestry would be of considerable selective advantage in a species that can produce no more than one offspring every 2 years, that does not form permanent pair bonds, and that may be so widely dispersed that a male might not be available when the female first comes into estrus.

As southbound female gray whales carrying near-term fetuses had no enlarged follicles, it may be concluded that there is usually no postpartum estrus in this species. However, postpartum estrus sometimes occurs in other whale species. A postpartum estrus resulting in pregnancy almost invariably occurs in the minke whale, *Balaenoptera acutorostrata* (Jonsgård, 1951; Omura and Sakiura, 1956). Postpartum estrus in a high proportion of Southern Hemisphere humpback whales also is indicated by the fact that eight (44 per cent) of 19 lactating animals examined in one study were simultaneously pregnant (Chittleborough, 1958). Likewise, 15 (12 per cent) of 129 lactating Southern Hemisphere fin whales also were pregnant (Laws, 1961). According to Gambell (1968) an estimated 11 per cent of female Southern Hemisphere sei whales experienced postpartum estrus.

The two nonlactating postpartum females examined had not recently ovulated, but the fact that they had follicles (24 and 29 millimeters) much larger than any late pregnant female and larger than the average for anestrus females indicates a resumption of follicular maturation after the corpus luteum starts to regress and progesterone secretion is reduced. It is possible that such follicles may develop sufficiently to undergo ovulation. Chittleborough (1958) has shown that humpback whales usually recommence estrous cycles immediately after stillbirth or early loss of the calf. Ovulation following stillbirth or loss of a calf would be so infrequent that it would not significantly affect the mean ovulation rate.

The possibility of postlactation ovulation, or ovulation by any nonpregnant females during the summer, remains to be considered. The southbound females that had recently ovulated, most of which presumably had ceased lactating about 5 months previously, gave no evidence of having ovulated more than once since that time.

In each, the largest corpus albicans was 22 to 38 millimeters in diameter (mean, 29); this was no doubt the regressing corpus luteum of lactation. Only data from females collected on the summer grounds can provide direct evidence on this point. There is evidence that a considerable proportion of Southern Hemisphere fin whales experience a postlactation ovulation (Laws, 1961), and about 12.5 per cent of the female Southern Hemisphere sei whales ovulate in the summer (Gambell, 1968). These summer ovulations almost never result in pregnancy. In humpback whales, which lactate for approximately 10½ months, an estrous cycle usually commences immediately following the end of lactation; this cycle corresponds with the normal winter breeding season and usually results in pregnancy (Chittleborough, 1958).

The two oldest females studied, with 19 and 34 corpora albicantia, were pregnant, so there is no indication of cessation of breeding in old females.

In summary, female gray whales normally experience one estrous cycle every 2 years, although rarely they may ovulate twice or perhaps three times during one breeding season. The mean ovulation rate for parous females is 0.96 per breeding season. A female that fails to conceive during one breeding season probably undergoes an estrous cycle again the following year. As the pregnancy rate is 0.46 (see below), the mean ovulation rate per year of parous females is 0.52 ($[1.00 - 0.46] \times 0.96$).

CORPORA LUTEA.—Our material included three ovaries with recently ruptured Graafian follicles that provided data on early development of the corpus luteum. In one case the rupture site was still open (Figs. 17 and 18), and in the other two the rupture sites were still obvious as dark spots, although no actual openings were visible. These follicles, 24, 25, and 25 millimeters in diameter, were smaller than mature unruptured follicles. Loss of fluid presumably causes the follicle to collapse immediately after rupture. There is a marked infolding of the walls and a proliferation of luteal tissue from the membrana granulosa. The luteal tissue fills almost the entire antrum. One corpus contained a small amount of liquor folliculi in the central cavity. Subsequent development of the corpus luteum depends upon whether or not pregnancy ensues.

It is difficult to distinguish corpora lutea of ovulation from corpora lutea of pregnancy, because failure to find a visible conceptus in the uterus is not proof that an animal has not conceived. Only in the four females that had recently undergone more than one estrous cycle was it certain that corpora lutea of ovulation were present (Figs. 17 and 18). In these animals the penultimate corpora were 13, 15, 21, and 25 millimeters in diameter. Because of their small size, they did not greatly protrude from the surface of the ovaries. In cross section, the corpora were somewhat irregular or stellate in outline. The layer of luteal tissue was thin and greatly plicated, and no cavity remained. The luteal tissue was pale yellow, as in corpora lutea of pregnancy, in the larger two of the four corpora and more orange-yellow in the two smaller corpora.

Three northbound females had corpora lutea 22, 81, and 102 millimeters in diameter but showed no macroscopic evidence of pregnancy. The two larger corpora in this series were indistinguishable from corpora lutea of pregnancy.

The above data indicate that corpora lutea of ovulation do not attain a size greater than about 25 millimeters and rapidly regress if the female comes into estrus again after a brief diestrous period. The fate of the corpus luteum when the female does not become pregnant or undergo another estrous cycle requires further study.

Corpora lutea of pregnancy in the gray whale (Figs. 17 and 20) are similar to those of the fin whale (Laws, 1961) and humpback whale (Chittleborough, 1954). They protrude from the body of the ovary, from which they are separated by a constricted neck.

In most of the southbound females that had recently ovulated but were not yet visibly pregnant, the corpora lutea ranged from 37 to 87 millimeters (mean, 56; standard deviation, 16). Females with small fetuses collected two months later during northward migration had corpora lutea ranging from 61 to 100 millimeters in diameter (mean, 82; standard deviation, 11). In these animals, the size of the corpus luteum was correlated with the length of the fetus. The female carrying the smallest fetus (25 millimeters long) had a corpus luteum only 63 millimeters in diameter. In females with fetuses 120 to 140 millimeters in length (estimated age 87 to 89 days), the average diameter of the corpus luteum was 84 millimeters, which is not significantly different from that in late pregnant females.

Chittleborough (1954) has shown that it takes nearly three months for the corpus luteum of the humpback whale to reach maximum size. In southbound female gray whales with near-term fetuses, the corpora lutea varied from 61 to 115 millimeters in diameter (mean, 87; standard deviation, 12). No data were obtained on the condition of the corpora lutea in lactating females.

Twenty-one per cent of the corpora lutea of pregnancy contained central vesicles filled with liquor folliculi. Thus, in this species the presence or absence of a central vesicle is of no use in distinguishing corpora lutea of ovulation from those of pregnancy. Laws (1961) has refuted the contention of some authors (for example, Robins, 1954) that the absence of a central vesicle is diagnostic of corpora lutea of ovulation in balaenopterid whales. The largest vesicle in our animals was 54 millimeters in diameter. A few were irregularly shaped or eccentrically located. Some corpora lutea had gel-filled cavities up to 24 millimeters in diameter located around their periphery or at the base (Fig. 20). Although these structures resemble large, flattened follicles, their close association with the corpus luteum suggests that they are part of it.

Only one whale, a primiparous late pregnant female, had an accessory corpus luteum (in the opposite ovary from the primary corpus luteum). It was 14 millimeters in diameter and lacked a stigma, suggesting that it must have developed from an unruptured follicle.

CORPORA ALBICANTIA.—The corpora albicantia (Fig. 20F) of gray whales are morphologically similar to those of balaenopterid whales, and the sequence of changes during regression is essentially the same as described by Laws (1961) and van Lennep (1950) for the fin whale.

The earliest stages of regression were seen in the two postpartum females that had recently lost their calves (Figs. 19, 20). The corpora lutea in these individuals were 53 and 60 millimeters in diameter. The connective tissue septa characteristic of corpora albicantia were already obvious, and the color of the luteal tissue was more orange than is typical of the corpus luteum of pregnancy.

As the corpus albicans continues to shrink, it recedes below the surface of the ovary. The color changes to brown as collagen

TABLE 9
DIAMETER (mm) OF CORPORA ALBICANTIA IN OVARIES OF GRAY WHALES AT DIFFERENT STAGES OF THE REPRODUCTIVE CYCLE.

replaces the luteal cells, and the proportion of connective tissue increases. Some of the smaller corpora albicantia consist almost entirely of unpigmented connective tissue.

The corpora albicantia persist throughout life in the ovaries of fin whales (Laws, 1961) and this probably applies to all large balaenopterids. This also occurs in sperm whales (Best, 1967), but not in at least some of the smaller odontocetes, such as the pilot whale, *Globicephala melaena* (Harrison, 1949; Sergeant, 1962).

The corpora persist as permanently recognizable structures in the ovaries of gray whales. The corpora albicantia of each female (excluding nulliparous and primiparous ones) were classified according to relative size in the following manner: class 1, the largest corpus in each whale; class 2, the second largest, and so on. The mean, standard error, and range for each of these classes in females in each phase of the reproductive cycle are presented in Table 9. It is apparent from the size distribution that after an initial phase of rapid regression, there is little further decrease in size of the corpora albicantia. Few were less than 12 millimeters in diameter.

In the discussion of time and frequency of ovulation, it was concluded that females usually ovulate only once every 2 years. If this is true, and the corpora albicantia persist for life, the rate of accumulation of corpora albicantia would be close to 0.5 per year. We examined two other lines of evidence bearing on this question: the size frequency distribution of the corpora albicantia and the correlation between number of corpora albicantia and number of growth layers in the ear plug.

The means, standard errors, and ranges of the diameters of the corpora lutea and two largest corpora albicantia of females in each stage of the reproductive cycle are shown in Fig. 25. We assumed that each female ovulates only once every 2 years, and adjusted the horizontal time scale accordingly. The smooth line shows the presumed rate of regression in size of the corpus albicans during the first 4 years. If the smaller corpora albicantia (Table 9) were similarly plotted, the line would gradually approach the horizontal at about 14 millimeters beyond 20 years. It is apparent from Fig. 25 that a presumed accumulation rate of one corpus albicans every 2 years is consistent with the observed size-frequency distribution of

FIG. 25. Diameter of corpus luteum and two largest corpora albicantia in ovaries of gray whales in different stages of the reproductive cycle. The horizontal scale represents the age of each corpus, assuming one ovulation every two years. RO, recently ovulated females; EP, early pregnant females; LP, late pregnant females; PP, postpartum females. The two postpartum females had lost their calves, thus their corpora lutea were smaller than in lactating animals. Horizontal dashes, mean; vertical bars, two standard errors on either side of mean; vertical lines, range. Curve fitted by eye to mean diameters of corpora.

corpora. If the ovulation rate were significantly greater, the size-frequency data would not show such a regular decline. The data on ovulation further indicate that the rate cannot be less than about 0.5 per year.

The relationship between number of corpora albicantia and the number of growth layers in the ear plug is presented in Fig. 26. The solid line ($Y = 0.5X - 3.5$) represents the expected correlation between number of corpora and number of growth layers under the assumptions that two growth layers are formed the first year

FIG. 26. Number of corpora in the ovaries versus the number of growth layers in the ear plugs of adult female gray whales. The hypothetical correlation is represented by the unbroken line (mean) and the broken lines (range).

and one each year thereafter, and that one corpus is formed every 2 years beginning at 8 years of age (mean age at sexual maturity). The two broken lines ($Y = 0.5X - 2.0$ and $Y = 0.5X - 5.0$) represent the lower and upper limits, respectively, of variation expected because of the variation in the age at sexual maturity of from 5 to 11 years. Deviations from the hypothetical mean number of growth layers are markedly skewed. The mode falls on the lower limit (-3); 41 per cent of the specimens fall within the expected limits (-3 to $+3$). Only one whale falls above the expected limits ($+7$); 57 per cent fall below the lower limit (-3 to -37), with 33 per cent falling between -3 and -7 . These data are thus consistent with the conclusions that corpora accumulate at a rate of 0.5 per year and growth layers in the ear plug accumulate at a rate of one per year, although the earlier layers may not be discernible.

The only corpora albicantia that are unquestionably derived from corpora lutea of ovulation are those in nulliparous and

primiparous females. These corpora do not differ in size or other respects from those representing corpora lutea of pregnancy. In three recently ovulated nulliparous females, the largest corpora albicantia were 23, 30, and 34 millimeters in diameter, and in two primiparous females in early pregnancy they were 13 and 29 millimeters in diameter. All except the smallest of these were within the size range of the largest corpora albicantia in multiparous females in corresponding phases of the reproductive cycle (Table 9).

In addition to normal corpora albicantia, the ovaries of 13 females each contained one to three small orange bodies 4 to 9 millimeters in diameter and which were either compressed and elongate, or stellate, in cross section. The total number of these structures in the 13 animals was 17, which was 2 per cent of the corpora albicantia present in all the females. They are similar to the corpora atretica described by Laws (1961) for the fin whale and presumably originate by atresia of follicles that have not ovulated. This assumption is supported by the finding of a few unruptured follicles with a partial lining of yellow-orange colored tissue. These corpora apparently do not represent ovulations and they were not included in counts of corpora albicantia.

FUNCTIONAL SYMMETRY AND POLARITY OF OVARIES.—Of the total of 756 corpora, 418 (55.3 per cent) were in the left ovary and 338 (44.7 per cent) in the right ovary. The probability of this ratio occurring in a random distribution is less than .05, suggesting that the observed dominance of the left ovary may be real. Laws (1961) found a slight but statistically insignificant dominance of the right ovary in fin and blue whales. In many odontocetes, most ovulations occur in the left ovary (Ohsumi, 1964b).

The position of each of 179 corpora in the anterior, second, third, or posterior quarter (measured linearly) of 52 mature ovaries was recorded. There was a significant ($P < .005$) preponderance of corpora toward the anterior pole. The numbers of corpora in each quarter, from anterior to posterior, were: 61 (34 per cent), 48 (27 per cent), 45 (25 per cent), and 25 (14 per cent). A preponderance of ovulations from the anterior pole of the ovary was also found in fin and sei whales (Laws, 1957) and in the sperm whale (Best, 1968), but not in the pilot whale (Harrison, 1949; Sergeant, 1962) or false killer whale, *Pseudorca crassidens* (Comrie and Adam, 1938).

Pregnancy

PREGNANCY RATE.—The pregnancy rate is difficult to determine directly because of bias introduced into the sample by the temporal and spatial differences in migration patterns between females in different phases of the reproductive cycle and by gunner selection for the larger animals. In the series of 84 southbound migrants examined, the ratio of late pregnant females to other mature females was two to one, whereas the actual ratio in the population must be less than one to one. The sample of northbound adult females consisted of 22 early pregnant females and eight anestrus females, but only two postpartum females. As it is logical to assume that the number of postpartum females in the spring population should be nearly equal to the number of pregnant females, the sample was obviously biased.

Because the proportion of late pregnant and postpartum females in the samples was biased, these animals were excluded from calculations of the pregnancy rate and appropriate corrections made to determine the overall pregnancy rate in the adult female segment of the population.

The pregnancy rate of females that had already undergone at least one pregnancy will be considered first. During the southward migration, all females that were not carrying near-term fetuses had a developing corpus luteum. If we assume that all of them had conceived, their pregnancy rate would be 1.00. As a few may not have conceived, this figure may be a slight overestimate. During northward migration, 20 of 27 females (exclusive of postpartum females) were pregnant, giving a pregnancy rate of 0.74. Two of the females that were not visibly pregnant each had a corpus luteum that we assumed to be a corpus luteum of ovulation. Although it is possible that they had recently conceived and were carrying a conceptus too small to detect, we think this is unlikely so late in the season. Considering both the northbound and southbound migrants, 41 of the 48 were pregnant or could reasonably be assumed to have already conceived. This gives a pregnancy rate of 0.85 per breeding season.

Considering females that had not undergone a previous pregnancy, all seven taken on the southward migration had recently

ovulated. Each of five animals had a single corpus luteum 19 to 62 millimeters in diameter and were assumed to have already conceived. One with a recently ruptured follicle and a corpus luteum of ovulation (25 millimeters in diameter) possibly had done so. The last had what appeared to be a corpus luteum of ovulation (27 millimeters in diameter) and Graafian follicles up to 35 millimeters in diameter, so it might have ovulated again later and then conceived. Of the three northbound animals examined, two were pregnant. The third had two fairly recent corpora lutea (22 and 13 millimeters in diameter) and was probably not pregnant. Thus, of 10 females that had not previously been pregnant, seven were pregnant, two were not pregnant but probably would have conceived later, and one probably would not have conceived that season. These data indicate a probable pregnancy rate of 0.90 per breeding season, but further data are needed to determine whether newly mature females are as fertile as older individuals.

The combined pregnancy rate for nulliparous and parous females, exclusive of late pregnant and postpartum animals, is 0.86. To determine the overall pregnancy rate for all adult females in the population, we made a correction for the biased representation of late pregnant and postpartum females in the sample. If the pregnancy rate remains constant from year to year, or if the sample was taken over a period of several years, the overall pregnancy rate may be calculated as $0.86/1.86$, or 0.46 per year.

Zenkovich (1937a) examined a large series of gray whales taken in the Bering Sea between August and October from 1933 to 1936. Assuming that all females 12.0 meters or more in length were sexually mature, there were 57 mature females in his sample. Of these, only 16 were pregnant, giving a calculated pregnancy rate of only 0.28. G. C. Pike (unpublished data) reported that only one of three adult females he examined off British Columbia in April was pregnant.

Of the seven northbound adult females (exclusive of postpartum individuals) that were not pregnant, only three had recently ovulated, indicating that missed pregnancies may result from either failure to ovulate or failure to conceive following ovulation.

BREEDING SEASON.—Almost all of the adult females (except those carrying near-term fetuses) taken during southward migration

probably had already conceived, although none was visibly pregnant. The mean conception date calculated from the fetal growth curve (see below) is 5 December. We calculated the duration of the breeding season by estimating the ages of the 22 embryos and early fetuses collected. The estimated ages were based on certain assumptions about early fetal growth discussed below. The calculated conception dates fall between 27 November and 13 December, except for one on 22 December and one on 5 January. The female that conceived about 22 December was multiparous and showed evidence of two recent ovulations, indicating that she had failed to conceive following her first ovulation that season. The female that conceived about 5 January was primiparous; Laws (1961) found that newly mature female fin whales conceive, on the average, later than multiparous females.

The duration of the breeding season also was estimated on the basis of length measurements for 16 fetuses collected in late summer by Zenkovich (1937*a*). The estimated conception dates of 12 (75 per cent) of these fetuses fall between 23 November and 14 December, and all fall between 13 November and 10 January. Individual variations in growth rate will give a spurious spread to the calculated range, so that the actual breeding season is doubtless even shorter than these data indicate. For the same reason, the

FIG. 27. Embryos and early fetuses of gray whales. A, 25-millimeter (10 millimeters crown-rump) female embryo, estimated age 55 days; B, 39-millimeter (16 millimeters crown-rump) male embryo, estimated age 70 days (note hind limb buds); C, 120-millimeter male fetus, estimated age 87 days (note size and position of penis); D, 110-millimeter female fetus, estimated age 86 days (note size and position of clitoris).

data from near-term fetuses are even less useful for calculating conception dates.

GESTATION PERIOD AND FETAL GROWTH.—Available measurements of fetuses are limited to the periods of early and late pregnancy.

A total of 22 embryos and early fetuses was collected between 21 February and 10 March (Table 10, Fig. 27). Body length, measured from the crown to the tip of the straightened tail varied between 25 and 140 millimeters (mean, 96; standard error, 6).

Additional data on fetal sizes in the gray whale are contained in a number of reports. Scammon (1874) examined five embryos taken on the California coast, but gave no measurements or dates. Andrews (1914) reported fetuses 180 and 250 millimeters long taken on 13 and 14 March 1912, on the coast of Korea. Pike (unpublished data) found a 250-millimeter fetus the first week of April from the coast of Vancouver Island, British Columbia. Zenkovich (1937a) published data for 16 fetuses collected in the Bering Sea between 8 August and 24 September. Their lengths ranged from 1.70 to 2.64 meters, with a mean and standard error of 2.05 ± 0.06 . Townsend (1887) examined four fetuses taken in December 1885 at San Simeon, California, and stated: "Their average length was about 12 feet [3.66 meters]; the longest . . . 17 feet [5.18 meters] long." Andrews (1914) inconsistently reported one fetus taken at Ulsan, Korea, on 8 January 1912, as 4.35 and 4.76 meters long.

We measured 55 near-term fetuses (30 males, 25 females) collected during a 38-day period from 14 December to 20 January. The length varied between 3.60 and 5.31 meters, with a mean and standard error of 4.62 ± 0.05 (Table 11, Fig. 28). The average length of females (4.65 ± 0.06 meters) was slightly greater than that of males (4.60 ± 0.08), but the difference was not statistically significant ($P > .10$). If these measurements are grouped by shorter time periods, they show no change in mean length from mid-December until late January. This suggests that the timing of migration of a pregnant female depends upon how advanced her pregnancy is.

The statistics for Norwegian factory ship operations near the calving grounds on the west coast of Baja California from 1924 to 1927 (published in part by Risting, 1928) list 20 fetuses taken from 29 December to 16 February with estimated (not actually

measured) lengths ranging from 6 to 18 Norwegian feet (1.90 to 4.71 meters).

Measurements of six recently born calves found dead at Laguna Ojo de Liebre, Baja California, in late January and early February, are given by Eberhardt and Norris (1964). These ranged from 3.95 to 5.40 meters (mean, 4.68; standard error, 0.245). Gilmore (1960a) also listed measurements of seven recently born calves found in the same lagoon. The total lengths given for these calves (3.54 to 4.51 meters, mean, 4.05) are well below those presented by Eberhardt and Norris and even average less than our December fetuses. Therefore, we can only conclude that Gilmore made his measurements differently or that the published figures are in error.

FIG. 28. Near-term gray whale fetus 4.54 meters long. Note color pattern of whitish rings and blotches (the other marks are postmortem abrasions).

Only three of the series of measurements presently available are large enough to provide statistically reliable data for use in constructing a fetal growth curve for the gray whale. These include our series of early embryos and fetuses, Zenkovich's series taken in late summer, and our series of near-term fetuses. The means for these three sets of measurements have been plotted in Fig. 29. It is apparent that the points do not fall on a straight line. Laws (1959) found that in balaenopterid whales, excepting the earliest

FIG. 29. Estimated prenatal growth curve based on measurements of 22 embryos and early fetuses collected in February and March, Zenkovich's (1937a) 16 mid-term fetuses collected in August and September, and 55 near-term fetuses collected in December and January. Horizontal dashes indicate means; vertical bars represent two standard errors on either side of mean, and vertical lines represent the range. For estimation of t_0 see text.

part of pregnancy, the length of the fetus increases linearly during the first half of pregnancy and logarithmically during the last half. A similar curve fits the present data (Fig. 29). From the slope of the lower portion of this curve, we estimated the "specific fetal growth velocity," or a of Huggett and Widdas (1951), as 0.95.

To determine the total gestation period, it is necessary to estimate the length of the gestation period before the beginning of the linear growth phase, termed t_0 by Huggett and Widdas (1951). J. G. Sinclair, who is studying the anatomy of two early fetuses (25 and 39 millimeters long from crown to tip of tail, and 10 and 16 millimeters in crown-rump length), has, on the basis of their stage of development, estimated their ages at about 55 and 70 days. According to Sinclair, the rapid linear growth phase starts when ossification begins, at a crown-rump length of about 35 millimeters; this is equivalent to a length of about 55 from crown to tip of tail. Judging from the estimated ages of the two early embryos, this length would be reached at an age of at least 80 days, or perhaps slightly more. An estimate of t_0 will therefore be $80 - (5.5 \times 0.95)$, or about 75 days. The growth curve, extrapolated backwards, intercepts the abscissa on 18 February (Fig. 29). Adding to this the estimate of t_0 , the calculated mean conception date falls on 5 December.

If the growth curve is projected forward, it intercepts the mean length of the six newborn calves observed by Eberhardt and Norris (1964) on 2 January, only 2 days later than the mean date of passage of pregnant females past San Francisco. Considering the speed of migration, it would take the whales at least 9 to 12 days to travel from San Francisco to the major calving grounds at Laguna Ojo de Liebre, Laguna San Ignacio, and Bahia Magdalena. Therefore, the mean birth date would be about 10 January, when the projected growth curve reaches 4.90 meters. This estimate of length at birth falls within one standard error of the mean of newly born calves, so the agreement is close.

Based upon the calculated mean dates of conception and parturition, the mean length of the gestation period is estimated to be slightly more than 13 months, or about 400 days.

Applying Laws (1959) method of estimating t_0 for baleen whales to the data of this study yields values of only 31 days for t_0 and

FIG. 30. Diameter of the uterine cornua of gray whales in different stages of the reproductive cycle. For pregnant and postpartum females, measurements of the horn in which implantation occurred are plotted above the base line and those for the other horn below. Symbols are as follows: horizontal dashes, mean; vertical bars, one standard deviation on either side of the mean; vertical lines, range; S, southbound migrants; N, northbound migrants.

no more than one year for total gestation period, which are not consistent with the actual data. The discrepancy results from the way in which Laws interpreted data for several species of terrestrial mammals given by Huggett and Widdas (1951) in estimating the length of t_0 for three species of odontocetes in which fetal growth is linear until the end of pregnancy. His estimates showed an *inverse* relationship between t_0 and length of gestation period (and also a). Huggett and Widdas' data show, however, that " t_0 *increases as gestation times lengthen* but forms a decreasing fraction of total gestation time" (*italics added*). There are no data to justify Laws' conclusions; his error appears to be the result of using imprecise, arbitrary percentage values for t_0 . Laws then estimated the length of t_0 in the humpback whale as 38 days on the basis of published fetal length data and Chittleborough's (1954, 1958) data on the mating and calving seasons. Chittleborough's data suggest, however, a peak conception date in late July, not early August as stated by Laws, so Laws' estimate of t_0 is doubtless too short. Since his four estimates of t_0 , for three species of odontocetes and one

mysticete, showed an apparently consistent inverse relationship between t_0 and a , he extrapolated these results to other species of baleen whales. This resulted in his inexplicable and anomalous conclusion that the larger species of balaenopterid whales have shorter gestation periods than the smaller ones. Any logical extrapolation of the data presented by Huggett and Widdas would result in an estimate of at least 50 or 60 days for the duration of t_0 in larger cetaceans. In any event, it is dangerous to extrapolate from small terrestrial mammals to large cetaceans.

We suspect that when more direct evidence is available on early embryonic growth, most large mysticetes will be found to have a gestation period of about a year or somewhat longer. It is certainly approximately 13 months in the gray whale, and probably more than a year in the humpback whale. A gestation period longer than one year would not preclude an occasional pregnancy resulting from a postpartum ovulation, as has been reported in fin whales (Laws, 1961) and humpback whales (Chittleborough, 1958), but it does indicate that such pregnancies cannot occur regularly if a marked seasonality of breeding is to be maintained.

CALVING SEASON.—The mean calving date, as indicated above, is estimated to be about 10 January. The duration of the calving season should be generally similar to that of the breeding season, but slightly more prolonged because of individual variation in the length of the gestation period. As noted above, the timing of the southward migration of pregnant females depends on the stage of gestation. Because late pregnant females pass San Francisco for at least 38 days, we may assume that the calving season lasts about that many days. Therefore, we estimate that calving occupies a period of 5 or 6 weeks from late December to early February. This is corroborated by field observations of recently born calves (Eberhardt and Norris, 1964; Gilmore, 1960*a*, 1960*b*; Gilmore and Ewing, 1954; Hubbs and Hubbs, 1967).

CYCLIC CHANGES IN THE UTERUS.—Gray whales have a bipartite uterus similar to that of other baleen whales (Mackintosh and Wheeler, 1929; Matthews, 1948). The placenta is of the diffuse, nondeciduate, epitheliochorial type. Measurements of the diameter of the uterine cornua of specimens examined in this study are presented in Fig. 30. Histological characteristics of the endometrium

FIG. 31. Photomicrographs of sections of the endometrium of gray whales in different stages of the reproductive cycle. ³ N = 45 for stratum compactum thickness.

are illustrated in Fig. 31 and endometrial measurements are presented in Table 12. There was no endometrial epithelium in any of our specimens, probably because of postmortem changes.

In immature whales (Fig. 31A), the diameter of the uterine cornua ranges from 3.5 to 12.0 centimeters. The average thickness of the wall is 9 millimeters and the mean height of cornual folds is 10 millimeters. The average thickness of the endometrium is 2.9 millimeters in southbound animals and 1.6 in northbound animals. The surface of the endometrium is fairly smooth, with only a few small furrows, and it has few glandular ducts that have a mean diameter of 44 microns. The lumina of the glands are either small or not visible. Capillaries are scattered but fairly numerous.

At any stage of the reproductive cycle the uterine cornua of primiparous females average smaller than the cornua of females that have undergone a previous pregnancy, but they cannot be distinguished on the basis of histological criteria.

The cornua of northbound, sexually mature, anestrus females (Fig. 31B) are in the fully involuted condition. They range from 11 to 26 centimeters in diameter and 19 millimeters in thickness, and the folds are high, averaging 15 millimeters. The mean thickness of the endometrium is 1.8 millimeters, of which the stratum compactum comprises 96 microns. The area of division between the stratum compactum and the stratum spongiosum is poorly defined. The glands are small, with a mean diameter of 39 microns, and are more closely spaced than in immature females.

The cornua of southbound whales that have recently ovulated (Fig. 31C) are slightly larger than those of anestrus females. They range from 15 to 28 centimeters in diameter. Mean fold height has decreased to 10 millimeters, and the mean thickness of the endometrium and stratum compactum have increased to 3.3 millimeters and 135 microns, respectively. The inner surface of the uterus is more uneven than in immature individuals, with deeper furrows and a greater number of glandular openings. The average diameter of the glands has increased to 61 microns, and the lumina are mostly open. These data on gray whales differ from Matthew's (1948) observation (based on one specimen) that in fin whales there is a marked temporary increase in endometrial thickness and gland diameter at the time of ovulation.

In early pregnancy (Fig. 31D), the cornua range from 12 to 34 centimeters in diameter, the difference between gravid and non-gravid cornua not being statistically significant. Mean fold height is 10 millimeters. The endometrium (mean, 3.4 millimeters) and the stratum compactum (mean, 153 microns) are slightly thicker than in recently ovulated animals, and there are many large vessels visible in the stratum spongiosum. The glands have a mean diameter of 57 microns, slightly less than in females that have recently ovulated. No dendritic structures are visible yet, though the surface is quite uneven and numerous crypts are visible in the stratum compactum.

Whales in advanced pregnancy (Fig. 31E) have wide cornua, ranging from 76 to 120 centimeters in diameter in the horn carrying the fetus and from 40 to 105 in the other horn. The nongravid horn contains part of the placental membranes of the fetus and is filled with fluid. The uterine wall is greatly thickened, mostly as a result of an increase in the thickness of the inner layer of circular muscles. The folds have almost disappeared, contrary to the condition reported in blue and fin whales by Slijper (1956). Their disappearance seems to be a direct result of the distension of the uterine wall, and they tend to reappear when samples of the wall contract in fixatives. The endometrium is relatively thick (mean, 3.9 millimeters) because of highly developed dendritic structures, which average 724 microns in height. One female with a length of 12.98 meters had a maximum stratum compactum thickness of 3600 microns. This is markedly thicker than that of the fin and blue whales in late pregnancy which Matthews (1948) examined, the thickest of which was 200 to 1000 microns. Vessels in the stratum spongiosum are large and many are filled with blood cells. The mean diameter of the glands has increased to 128 microns.

In the two postpartum whales examined (Fig. 31F), the cornua that had contained the fetus were 34 and 70 centimeters wide, whereas the others were 16 and 34. The uterine folds were 14 and 25 millimeters high. The thickness of the endometrium had decreased to 1.0 to 2.1 millimeters and the stratum compactum to 70 to 80 microns. Dendritic structures were absent, and blood vessels were fewer and smaller. Gland diameters also had decreased to 30 to 50 microns.

POSITION OF THE FETUS.—All near-term fetuses were positioned in the uterus with the tail towards the cervix; this would ensure caudal presentation at birth, as is usual in cetaceans (Slijper, 1956). Inasmuch as the uterine horns are curved during advanced pregnancy, the head of the fetus is actually oriented towards the tail of the mother.

There was no evidence of differential tendency for implantation to occur in the right or left uterine horns. In 76 pregnant females, the fetus was in the left cornu in 37 and in the right in 39. In three cases, the fetus was in the cornu on the side opposite the ovary containing the corpus luteum, indicating transuterine migration of the ovum.

WEIGHT GAIN DURING PREGNANCY.—During the southward migration, females carrying near-term fetuses averaged 35 per cent heavier than those that had recently ovulated and most of which had presumably weaned a calf a few months previously (Table 3; Figs. 7–8). About 1000 to 2000 kilograms of this difference can be attributed to the fetus and fetal membranes and fluids, so that the gain in body weight attributable to fat stores is about 25 to 30 per cent. As there is no difference in blubber thickness between these two classes of females, most of the weight increase may be attributed to increased body fat stores.

Extra energy stores are necessary in late pregnant females to sustain rapid fetal growth and maintain the newborn calf, as well as provide for their own needs during the southward migration, the winter, and the northward migration. Acquisition of extra fat stores during pregnancy is characteristic of some other marine mammals that fast throughout the entire lactation period (Kenyon and Rice, 1959; Rice, 1960).

Lactation

LACTATION PERIOD.—According to Tomilin (1957), juvenile gray whales taken during August, September, and October in the Bering and Chukchi seas had already been weaned. He assumed that animals 8.5 to 9.5 meters long were calves of the year, an assumption supported by our data (see section on growth). None had milk in its stomach and even the smallest had been feeding on crustaceans,

although many still accompanied their mothers (Zenkovich, 1937a). These Russian workers examined 57 sexually mature females (we are assuming that females 12.0 meters or more in length were sexually mature); of these, 16 were pregnant. Of the remaining 41, only three were still lactating, including one collected on 21 August and another on 1 September. The collection date for the third is not given.

Maher (1960) reported the capture of two lactating females accompanied by calves at Barrow, Alaska, on 19 July and 13 September. The calf of the specimen taken in July had an estimated length of 25 to 28 feet (7.6 to 8.5 meters) and the young of the other was also about 25 feet. On 10 August a 25-foot calf associating with an adult was killed in the same area.

Tomilin and Zenkovich estimated 6 months as the mean length of the lactation period. They believed that most calves were born in February. As the present data indicate mid-January as the peak of the calving season, 7 months seems a more reasonable estimate of the mean duration of lactation. However, more data are needed. As with other cetaceans, weaning is probably gradual and prolonged.

CYCLIC CHANGES IN THE MAMMARY GLANDS.—In gross anatomy, position, and relative size, the mammary glands of gray whales are similar to those of other baleen whales. Changes in thickness of the gland at different phases of the reproductive cycle are shown in Fig. 32. The histological specimens were not fresh enough at time of fixation to allow study of cellular details.

The mammary glands of one 11.8-meter, sexually immature female were 77 centimeters long and 17 wide. The maximum thickness of the glands of immature females was 1.0 to 6.5 centimeters. The fresh tissue of mammary glands of virgin females is pinkish in color. The glands consist mostly of stroma. The lacteal ducts are small, widely spaced, and surrounded by only a thin layer of glandular tissue.

The mammary glands of nulliparous females at puberty and females early in their first pregnancy resemble those of virgin females in their histology, but they may be slightly thicker (up to 9.0 centimeters). The mammary glands of primiparous females in late pregnancy consist of 66 to 91 per cent (mean, 81) glandular

FIG. 32. Thickness of mammary glands of gray whales in different stages of the reproductive cycle. Symbols are as follows: horizontal dashes, mean; vertical bars, one standard deviation on either side of mean; vertical lines, range; S, southbound migrants; N, northbound migrants. Values plotted for post-partum females were from nonlactating individuals.

tissue and are grossly and histologically indistinguishable from those of multiparous females.

The involuted glands of parous animals in anestrus taken during the spring migration are larger than those of virgin individuals. One female 13.3-meters long had mammary glands 145 centimeters long and 32 wide. The mammary tissue varies from 3.5 to 10.0 centimeters (mean, 7.8) in thickness and is pale yellowish-brown in color. Histologically, the glands consist of 37 to 66 per cent (mean, 56) glandular tissue separated by a moderate amount of stroma. They show an extensive system of secretory lobules, which in section are somewhat polygonal and flattened. No secretory activity is apparent.

All females collected during southward migration that had recently ovulated, the majority of which had presumably ceased lactating about the previous July, had nearly or completely involuted glands 5.0 to 9.5 centimeters in thickness. They consisted of 41 to 65 per cent (mean, 53) glandular tissue, and were not distinguishable histologically from the glands of the anestrous females taken in spring. No secretory activity was noted.

The mammary glands of northbound females in early pregnancy also were grossly and histologically indistinguishable from the involuted glands of anestrous females. They consisted of 24 to 63 per cent (mean, 43) glandular tissue.

The mean depth of the lacteal tissue of females in advanced pregnancy was 13.0 centimeters. The mammary tissue is pink and softer than that of involuted glands, and histologically it shows extensive proliferation of the lobule-alveolar system. In section the lobules are large and round, comprising 67 to 91 per cent (mean, 80) of the gland, with relatively little stroma. In a few of the glands examined at this stage, no secretory activity was noticeable, but most already showed a considerable amount of secretory activity. Some had only a small amount of translucent, yellowish fluid in the ducts, others contained so much fluid (colostrum?) that it spurted from the teats when the animals were hauled onto the flensing deck. One female that apparently had recently aborted (or was immediately postpartum), killed on 8 January, had the thickest glands (21.0 centimeters) of any examined and was secreting colostrum copiously.

Unfortunately, we collected no actively lactating animals. The glands of the two nonlactating, postpartum females were grossly and histologically indistinguishable from those of females in late pregnancy. Their thickness was slightly reduced; they consisted of 56 to 72 per cent (mean, 64) glandular tissue and were secreting yellowish, translucent fluid.

Zenkovich (1938) reported that the milk of gray whales taken in August near the end of the lactation period consisted of 53.04 per cent fat, 6.38 per cent dry residue, and 40.58 per cent water. The fat content is greater than has been reported for any other species of cetacean.

Anestrus

Females are probably in anestrus for 3 to 4 months from the end of lactation about August until the onset of the next estrous period in late November or December. As noted earlier, a few females fail to come into estrus at this time and presumably would not do so again until at least a year later; they would thus undergo an anestrus period of 16 months or longer. Other females come into estrus but fail to conceive and return to the anestrus state, probably nearly a year in duration.

Discussion and Conclusions

The complete reproductive cycle of the female gray whale occupies 2 years. Females come into estrus during about a 3-week period in late November and early December. They usually conceive following their first ovulation, but if they fail to do so, they may undergo another estrous cycle about 40 days later. Pregnancy lasts for about 13 months (400 days). Parturition occurs within a period of 5 to 6 weeks from late December to early February. The calf is nursed for about 7 months. After weaning their calf about August, females are in anestrus for 3 or 4 months until November or December, when most of them go into estrus and commence a new pregnancy. A few either fail to ovulate, or ovulate but fail to conceive, and are in anestrus for another year. There is no evidence for postpartum or postlactation ovulation. Evidence for the possible occurrence of ovulation following stillbirth or early loss of the calf is suggestive but inconclusive.

The reproductive cycle of the female gray whale is basically similar to that of the larger rorquals. One important difference is that the extremely long migration route and restricted calving grounds of the gray whale impose a much stricter annual schedule. For example, the majority of gray whale calves are born during a period of 5 to 6 weeks, as contrasted with about 5 months in the rorquals.

The gray whale's ovulation rate of about 0.50 per year is less than that reported by some authors for rorquals. The ovulation rate of the fin whale was estimated as 1.40 per year by Laws (1961) and 1.25 per year by van Utrecht-Cock (1965). Laws, however, admitted

that the rate may be only half his estimate. Nishiwaki *et al.* (1958) estimated the ovulation rate of southern fin whales as 0.90 per year and that of North Pacific fin whales as 0.80 per year. Chittleborough (1959) estimated the ovulation rate of humpback whales at 1.10 per year. Nishiwaki *et al.* and Chittleborough assumed that two growth layers were formed in the ear plug each year, so the true ovulation rates are probably nearer 0.40 to 0.45 per year for fin whales and 0.55 per year for humpback whales. The annual ovulation rate of Southern Hemisphere sei whales is 0.69 (Gambell, 1968). Rorquals, apparently unlike gray whales, sometimes experience postpartum and postlactation or summer ovulations.

When comparing ovulation and pregnancy rates of different species and stocks of whales, it must be borne in mind that the reproductive performances of mammals—even large, late maturing and slow breeding species—are quite labile in response to population density in relation to carrying capacity of the range. Laws (1962) and S. Ohsumi and Y. Shimadzu (personal communication) have shown a reduction in age at sexual maturity and an increase in the pregnancy rate of Southern Hemisphere fin whales in response to excessive exploitation. Among large terrestrial mammals, Buss and Smith (1966) have shown a marked decrease in pregnancy rate in a population of African elephants, *Loxodonta africana*, brought about by an increase in population density and resultant deterioration of the habitat.

Presumably population density influences reproduction through nutrition or through ethological factors. In the gray whale, nutrition could be of critical importance, because the pregnant female must accumulate enough energy stores during the summer to support herself and her fetus through a long migration, to support herself and the newborn calf for a month or more on the wintering grounds, and to sustain both herself and the rapidly growing calf during the long return migration to the summer feeding grounds. Under such conditions, selective pressure for suppression of ovulation at times when the female is not physiologically capable of carrying a new pregnancy to term might be expected. Thus it may be that in the gray whale the potentiality for a postpartum estrous cycle is being or has been genetically eliminated from the population.

MALE REPRODUCTIVE CYCLE

DATA on the reproductive biology of the male gray whale were obtained from a sample of 166 animals. Of this number, 123 had attained puberty, including 67 southbound and 56 northbound migrants.

Testes

The testes of gray whales are cylindrical, moderately elongate, and generally similar to those of rorquals.

WEIGHTS.—No significant or consistent difference in weight between left and right testes was found.

In all sexually immature males examined, both testes weighed less than 8.2 kilograms and, in all individuals except three, the combined weight of the testes was less than 5.0 kilograms (Fig. 33). With one exception, the testes of mature males weighed more than 5.7 kilograms and few had testes lighter than 17.0 kilograms. The exception was a mature northbound animal with unusually small testes that weighed only 0.8 kilogram. Following the abrupt increase in testis weight immediately after puberty, the rate of increase rapidly declines with increasing body length.

The paired testes of the southward migrating adult males taken in December and January ranged from 7.9 to 67.5 kilograms, with a mean and standard error of 38.4 ± 1.4 . Mean testis weights for 10-day intervals throughout the southward migration period show no significant changes (Table 13). In northbound adults, the testes were much lighter, ranging from 5.7 to 44.8 kilograms with a mean and standard error of 22.5 ± 0.9 . Mean testis weights decreased from 24.8 kilograms in late February to 18.0 kilograms by the end of March. Zimushko (1969b) found that the testes of 25 adults taken from July through October ranged from 14 to 27 kilograms (mean, 23).

HISTOLOGY.—Because of the rapidity of postmortem degeneration of testis tissue, detailed cytological study of our material was not possible. Representative histological sections are shown in Fig. 34.

FIG. 33. Testes weights of gray whales in relation to body length. Symbols are as follows: solid triangles, southbound immature males; solid circles, southbound adult males; open triangles, northbound immature males; open circles, northbound adult males. Unbroken line connects means of 0.3-meter length groups of southbound males; broken line connects means of 0.3-meter length groups of northbound males.

In immature testes, the seminiferous tubules were closed and small, their average diameters ranging from 45 to 102 microns (mean, 75). In mature testes, the tubules had open lumina and average diameters ranging from 104 to 214 microns. In males that have reached puberty, there is a significant ($P < .001$) positive correlation between tubule diameter and testis weight (Fig. 35). This correlation is expressed by the formula $Y = 120 + 1.3X$, where Y = tubule diameter in microns and X = testis weight in kilograms.

Mean tubule diameters of the testes of southbound migrants ranged from 114 to 214 microns (mean, 177; standard error, 2). Mean tubule diameter of northbound migrants was significantly smaller, ranging from 104 to 186 microns, with a mean of 148 and a standard error of 3). Mean tubule diameters for each 10-day

12-21 March	15	21.8 \pm 1.6	5.7-31.5	14	143 \pm 6	107-186
22-31 March	9	18.0 \pm 1.4	11.7-23.3	9	156 \pm 4	142-186

¹ One male with abnormally small testes weighing 0.8 kg omitted.

interval do not reveal any significant increase or decrease within either migration period (Table 13).

The seminiferous tubules of almost all adult males appeared to be undergoing spermatogenesis, but it was difficult or impossible to ascertain the precise stages. The vasa deferentia and epididymides of all postpubertal males that were examined contained abundant fluid. Because of the long postmortem time, we did not attempt to collect vas deferens fluid for counts of sperm density.

Penis

The penis of the gray whale is an elongate, evenly tapering, conical, flesh-colored organ similar to that of the rorquals, and unlike the slender cylindrical black organ of right whales.

The length of the penis ranged from 55 to 145 centimeters in immature males and from 100 to 170 in adults. There is a significant ($P < .001$) positive correlation between penis length and body length (Fig. 36). This correlation is expressed by the formula $Y = 0.21X - 1.14$, where Y = penis length in meters and X = body length in meters. On the basis of this formula, at a body length of 11.1 meters, which is the average length at puberty, mean penis length is 1.08 meters. A penis length of 114 centimeters correctly separates 79 per cent of our specimens into immature and adult categories.

FIG. 34. Photomicrographs of sections of testes of gray whales in different stages of the reproductive cycle. A, immature male; B, pubertal male with both closed and open seminiferous tubules; C, adult southbound male; D, adult northbound male. All sections are to same scale.

Discussion and Conclusions

Testes weighing more than 5.0 kilograms are a reliable indication of maturity in male gray whales. A penis length greater than 1.1 meters also separates most mature animals from those that are sexually immature.

The much heavier testes and larger seminiferous tubules of males taken during southward migration compared with those of males collected during northward migration and on the summer grounds indicate that male gray whales have a marked seasonal sexual

FIG. 35. Relation between size of seminiferous tubules and weight of testes of gray whales. FIG. 36. Relation between penis length and body length of gray whales. Open circles represent immature males and closed circles represent adult males.

cycle, with a peak of spermatogenetic activity in late autumn or early winter. This period correlates closely with the time females come into estrus. Although there are no reported field observations of copulation at this time, biologists have not studied the behavior of gray whales in southward migration north of San Francisco. Courting and copulating gray whales often are seen on and near the calving grounds in Baja California in January (Gilmore, 1960a); this period coincides with the second estrous cycle of those few females that are not impregnated during their first cycle. Apparent courtship behavior, including males with an erect penis, has been observed during northward migration on the coast of California in March (Houck, 1962) and on the coast of Washington as late as April (C. E. Munsen, personal communication). Courtship behavior and apparent copulation also have been observed in the Bering Sea in June, July, August, and September (Sauer, 1963; Fay, 1963; Tomilin, 1937). Its significance at these times is unknown; certainly it never results in successful conception. In the bottlenose dolphin (*Tursiops truncatus*), copulation behavior does not necessarily indicate sexual fertility in males, as males born in captivity may begin to copulate frequently when only a few days old (Caldwell and Caldwell, 1968).

The existence of a male reproductive cycle in other mysticetes appears to be variable. Male humpback whales show a marked seasonal variation in weight of the testes and spermatogenetic activity (Chittleborough, 1955; Nishiwaki, 1959; Omura, 1953; Symons and Weston, 1958). In blue and fin whales there is a less well-marked seasonal cycle in spermatogenetic activity, although available data do not clearly demonstrate an associated cycle in testis weight (Laws, 1961; Mackintosh and Wheeler, 1929). In sei whales there is no seasonal variation in either weight or histology of the testes (Gambell, 1968).

PREDATORS

KILLER whales, *Orcinus orca*, are the only known predators of baleen whales (Nishiwaki and Handa, 1958). Killer whales rarely have been observed attacking gray whales. However, Scammon (1874) saw three killer whales attack and kill a gray whale calf accompanied by its mother in a lagoon in Baja California. Gilmore (1961) reported an unsuccessful attack by six killer whales on two gray whales at La Jolla, California. Morejohn (1968) observed an unsuccessful attack by seven killer whales on three gray whales, including a female with a calf, at Moss Landing, California. V. B. Scheffer (personal communication) saw six killer whales unsuccessfully attack a gray whale in Monterey Bay, California, on 9 March 1952. Burrage (1964) observed avoidance behavior of a pod of six gray whales on the approach of five killer whales at La Jolla. Pike and MacAskie (1969) reported killer whales attacking a pair of gray whales off the Queen Charlotte Islands. Andrews (1914) recounted descriptions by whalers of the reaction of gray whales to the approach of killer whales in Korean waters and reported killers feeding on the carcasses of gray whales being towed by catcher boats.

We found healed parallel scars that were obviously the tooth marks of killer whales on 57 (18 per cent) of the gray whales that we examined. Other whales doubtless bore unrecognizable killer whale tooth scars. Fifty-two of the whales had scars on the flukes, and 15 animals had scars on one or both flippers. Eight other whales had scars elsewhere on the body, as follows (number of individuals in parentheses): flanks (four), caudal peduncle (one), anal region (one), dorsal hump (one), throat (one), and snout (one). The predominance of scars on the flukes and flippers suggests that killer whales usually attempt to kill gray whales by seizing their flukes and flippers so as to immobilize and drown them. The number of scarred animals indicates a fairly high frequency of unsuccessful attacks on gray whales by killer whales. The proportion of successful attacks is unknown. Like other predators such as the wolf, *Canis lupus*, killer whales probably succeed

in killing only a small proportion of the large prey that they attack (Mech, 1966). Jonsgård (1968) has pointed out that there is no incontrovertible proof that killer whales are capable of killing baleen whales that are not incapacitated or otherwise at a disadvantage.

We found no gray whale remains in the stomachs of 10 killer whales taken in the eastern North Pacific, although five of the killer whales were collected at a time when gray whales were present in the vicinity (Rice, 1968).

PARASITES AND EPIZOITES

Ectoparasites and Epizootes

ALL gray whales examined were heavily infested with ectoparasites and epizootes, including three species of cyamids and one species of barnacle. Zenkovich (1937a) reported that a few gray whales, which had presumably just emerged from brackish lagoons bordering the Bering Sea, carried no cyamids and no live barnacles. He experimentally showed that brief immersion in fresh or brackish waters kills these parasites. We found small patches of an olive-colored skin film on a few whales, but were unable to find any diatoms in scrapings from such areas. Hubbs' (1959) report of kelp growing on gray whales probably was based on observation of whales that had temporarily picked up strands of kelp while swimming through kelp beds. The baleen plates of the whales examined in this study were generally clean and carried no film of microorganisms.

BARNACLES.—*Cryptolepas rhachianecti* Dall, 1872 (Fig. 37), is the only barnacle found on gray whales, to which it is host-specific. This sessile species is closely related to the genus *Coronula*, which occurs regularly on humpback whales but rarely on other species. Its mode of attachment to the skin appears to be similar to that of *Coronula* (Darwin, 1854).

These barnacles were present on every whale examined, which has been the experience of other workers who have studied gray whales. They may occur in small clusters almost anywhere on the trunk or on the surfaces of the flukes and flippers, but are most abundant on areas that are exposed to the air when the whale surfaces. They often form a continuous mass on the dorsal aspect of the rostrum and the most anterior part of the back. These areas also are those most directly exposed to food-carrying water currents as the whale stirs up the bottom sediments. The barnacles are oriented with their cirri generally directed towards the anterior end of the whale (Kasuya and Rice, 1970).

Virtually all barnacles on whales taken during the southbound migration are large (20 to 40 millimeters in diameter). Only one

FIG. 37. Barnacles *Cryptolepas rhachianecti* on skin of gray whales. A, southbound whale with large barnacles only; B, northbound whale with many small as well as large barnacles. The anterior end of each whale is to the left. Note the many *Cyamus scammoni* on the barnacle clusters and a few *C. ceti* mostly around the periphery of the clusters.

southbound whale, a pregnant female taken on 27 December 1968, bore small barnacles (3 to 5 millimeters in diameter). Northbound whales carry two discrete size groups of barnacles. Besides the large individuals that are 20 to 40 millimeters in diameter, there are usually large numbers of small individuals that range from 2 to 5 millimeters in diameter. Thus it is apparent that barnacles spawn while the whales are concentrated on their winter grounds and when the cypris larvae of the barnacles have the greatest opportunity for finding a new host. The small barnacles often are located close together, so there must be much mortality due to crowding as they grow.

CYAMIDS.—Gray whales are host to three species of cyamids (Fig. 37). Most previous workers have reported only one species, the unique and easily recognized *Cyamus scammoni*, but they doubtless overlooked the other species. Hurley and Mohr (1957) were the first to report the other two, *Cyamus ceti* and *C. kessleri*. Few cetaceans are host to more than one species of cyamid. The only other cetaceans on which three species have been found are the right whale and the sperm whale (Leung, 1967), but it is not known how frequently three species of cyamids may occur on a single individual of these host species. All except one of our gray whales were lightly to heavily infested with cyamids, and the three species occurred together on 310 (98.1 per cent) of the 316 examined. However, they tended to segregate on different parts of the body as described below.

Cyamus scammoni Dall, 1872, is invariably the most abundant cyamid on the gray whale and is restricted to this host. We found it on 315 (99.7 per cent) of the 316 whales examined. It is found mostly around clusters of barnacles. A few individuals may be scattered elsewhere on the body, most often in the fold at the axilla of the flippers, in the notch of the flukes, in the umbilicus, and sometimes in the genital groove. We found no trace of the cornified area on the dorsal surface of the rostrum reported by Andrews (1914) and supposed by him to be produced by the action of cyamids. On several whales, we found large numbers of *C. scammoni* in fairly fresh wounds. The two most notable cases were a large adult male taken on 25 March 1964 with a deep wound 1.40 meters long and 0.35 of a meter wide in the blubber of the back slightly to the right

of the middorsal line opposite the flipper; and a female taken on 20 December 1968 with a wound 0.85 by 0.85 meters and 14 centimeters deep on the back about 2 meters anterior to the dorsal hump. In both specimens, the wounds were completely filled with tightly packed masses of cyamids, mostly, if not entirely, *C. scammoni*. More than 100,000 were collected from the male (Leung, 1965). Many of the individuals were exceptionally large.

Cyamus ceti Linnaeus, 1758, was originally described from the bowhead whale from the Atlantic sector of the Arctic Ocean. Hurley and Mohr (1957) first found it on the gray whale at Barrow, Alaska. They reported that their specimens agreed closely with descriptions of this species and with specimens taken from bowhead whales captured at Barrow. L. Margolis (letter, July 1959), however, is somewhat doubtful about the identification of specimens from gray whales as *C. ceti*, because he has found minor differences between specimens from gray whales and those from Atlantic-Arctic bowheads. As most cyamids are host-specific, it would be most unusual for one species to infest hosts belonging to different families. This specificity is, no doubt, primarily a result of cyamids spending their entire life upon the host, so that transference can rarely occur except between members of a pair during copulation or between mother and calf during birth or suckling. This species is much less numerous than *C. scammoni*, but usually more frequent than *C. kessleri*. We recorded it on 314 (99.4 per cent) of 316 whales. It most commonly lives in grooves and skin folds on the body as follows: around the blowholes; in the angle of the gape; in the throat grooves; around the eyes; at the bases of the flippers; on the umbilicus; in the mammary slits; and, rarely, in the genital and anal grooves. Small patches of them are sometimes found elsewhere on bare skin. A few may be found adjacent to *C. scammoni* around the edges of clusters of barnacles, but competition with the larger species appears largely to exclude *C. ceti* from barnacle clusters.

Cyamus kessleri Brandt, 1872, was first described from an unidentified species of whale from the Bering Sea. Hurley and Mohr (1957) rediscovered it on a gray whale killed at Barrow, Alaska. It has subsequently been found only on gray whales. This is usually the least abundant species of cyamid on the gray whale. We found it on 310 (98.1 per cent) of 316 whales. It occurred almost exclusively

around the anus and in the genital grooves. A few were occasionally located in the mammary slits and elsewhere on the body.

Endoparasites

Before these studies, no endoparasites had been identified from the gray whale, although an unidentified cestode was reported by Tomilin (1937) from individuals of this species in the Chukchi Sea. We found eight species of endoparasites in the digestive system, including three trematodes, two cestodes, one nematode, and two acanthocephalans. Some of these seem to represent undescribed species. The taxonomy of the cestodes is being studied by R. Rausch and that of the acanthocephalans by K. Neiland. We found no parasites in the kidneys, lungs, peribullary air sinuses, or blubber. Treshchev *et al.* (1969) have published an abstract of recent studies on the helminthofauna of gray whales in the Bering and Chukchi seas.

TREMATODES.—*Lecithodesmus goliath* van Beneden, 1959, was found in only two gray whales. These large flukes live in the bile ducts of the liver. Specimens from gray whales range from 35 to 54 millimeters (mean, 45) in length and 10 to 14 millimeters (mean, 12) in width. This species differs from *L. spinosus* Margolis, 1955, in its incompletely spined cuticle. *L. goliath* has been reported from many species of baleen whales (Delyamure, 1955). Two flukes were found in an immature female whale taken on 16 March 1969; no pathological conditions were grossly visible in the liver. Forty-seven flukes were recovered from a mature male whale taken on 13 March 1969, and many others were doubtless present. The bile ducts of this whale had distorted, inflamed biliary epithelium and were rimmed with thick walls of dense scar tissue. We have never observed such marked pathogenic effects associated with heavy infestations of *Lecithodesmus* in sei whales, which suggests that the gray whale is not a normal host for these flukes.

Orthosplanchnus pygmaeus was described by Yurakhno (1967) from the intestine of a gray whale taken off the Chukotskiy Peninsula. Other members of this genus infest the bile ducts and gall bladder of Arctic pinnipeds.

Ogmogaster pentalineatus Rausch and Fay, 1966, was described as a new species on the basis of our specimens and the type series

collected by Fay from a gray whale at St. Lawrence Island, Alaska. The name *Ogmogaster delamurei* Treshchev (1966a), based upon specimens found in gray whales taken in the Chukchi Sea near Enurmino on the Chukotskiy Peninsula, is a junior synonym of *O. pentalineatus* (Skriabin, 1969). *O. pentalineatus* has been found only in gray whales. Entire specimens are easily recognized by the smoothly rounded or weakly undulate edge of the body and by the five ridges on the ventral surface. The species usually does not attain a length greater than about 3.5 millimeters, although one specimen measured 5.6 millimeters.

Field inspection of the surface of the mucosa of the small intestine at several randomly selected points revealed *O. pentalineatus* in only eight (2.5 per cent) whales. A more careful search of a section of the small intestine in a tray of water sometimes showed these flukes to be present in whales in which our spot-check had revealed none. The type series of more than 200 individuals was found in the small intestine (Rausch and Fay, 1966). In 1967, large numbers of this species were discovered in the rectum of one whale, so in 1968 and 1969 that portion of the rectum exposed on the inner side of the blubber after the blubber had been flensed from the whale was routinely examined. *O. pentalineatus* was recorded from 31 (22 per cent) of 139 whales examined in this manner. In all except seven cases, this species was living alongside *O. antarcticus*, although usually in lesser numbers. Of 1280 *Ogmogaster* collected from the rectum of 53 whales, only 227 (18 per cent) were *O. pentalineatus*. Usually fewer than 20 individuals of the latter species were present, but one whale contained well over 100.

Ogmogaster antarcticus Johnston, 1931, occurred in 46 (33 per cent) of 139 whales examined in 1968 and 1969. This species is distinguished from *O. pentalineatus* by the greater number of ridges (12 to 15) on the ventral surface, the 15 to 20 conspicuous marginal crenulations on each side of the body, and the four or five lateral loops in each intestinal caecum. It also typically attains larger size, reaching 6.0 millimeters in length. In rorquals (*Balaenoptera* species), this species has a maximum length of 10 millimeters (Rausch and Fay, 1966). Our specimens agree well with the descriptions of *O. antarcticus* as diagnosed by Delyamure (1955) and Rausch and Fay (1966). *O. antarcticus* has been reported previously from the intestines of Antarctic seals (tribe Lobodontini) and from

the intestines of rorquals in the North Pacific and North Atlantic as well as the Southern Hemisphere. In this study *O. antarcticus* was found only in the rectum. The maximum number recovered from one whale was 199. In 24 of the 139 whales examined it was associated with lesser numbers of *O. pentalineatus*. Treshchev *et al.* (1969), strangely enough, did not find this species in gray whales collected on the summer grounds.

Ogmogaster plicatus Creplin, 1829, was reported in a gray whale obtained off the Chukotskiy Peninsula (Treshchev *et al.*, 1969). Otherwise the species has been found only in the intestines of rorquals in the North Pacific and North Atlantic; we have found it in fin whales collected off San Francisco. This species differs from *O. antarcticus* in having more ventral ridges (19 to 28), more than 20 marginal crenulations on each side of the body, and larger size (maximum length 14 millimeters).

The life histories of the species of *Ogmogaster* are unknown. The food habits of their definitive hosts suggest that their second intermediate hosts are crustaceans.

CESTODES.—The genus *Priapocephalus* includes cestodes characterized by a bulbous scolex that lacks suckers and has a basal collar. *P. eschrichtii* recently has been described by Murav'eva and Treshchev (1970) from gray whales in the Chukchi Sea. The other two described species are *P. grandis* Nybelin, 1922, from rorquals (*Balaenoptera* species) and right whales in the Southern Hemisphere, and *P. minor* Nybelin, 1928, from rorquals in the North Atlantic and North Pacific (Baer, 1954; Delyamure, 1955; Markowski, 1955). The larval host of *Priapocephalus* is unknown. We collected two kinds, apparently different species, from the gray whale.

The commonest species has a narrow (less than 1 millimeter wide) strobila that is of uniform width throughout. It is difficult to collect complete strobilae, but they attain a length of at least 25 centimeters. The proglottids are about 0.3 to 0.4 of a millimeter long, and the scolex is about 3 millimeters in diameter. This species was found in the small intestine of 94 (30 per cent) of the 316 whales. Usually infestations were light and rather local, although a few whales were heavily infested.

The second species differs from the previous species in that its strobila is much wider—2 to 4 millimeters. Although the proglottids

adjacent to the scolex are as narrow as those of the previous species, they rapidly become wider distally. The proglottids are about 0.5 to 0.8 of a millimeter long. The scolex is similar to that of the previous species. This cestode was found in the large intestine of an immature female whale taken on 11 April 1968. The whale was heavily infested with this parasite, and no other species of cestode was present.

Tomilin (1937) reported an unidentified cestode from the gray whale. He stated (translation): "In 1934, internal parasites (tapeworms) Cestoda Ord. Pseudophaliidae [sic] (species not determined) 40 meters in length (deposited in parasitological laboratory of the Institute of Zoology, MGU) were found in the intestines of two gray whales. Their segments attained a width of 2 centimeters. The worms equaled about 48 liters in volume, in each animal." From their size, we would guess that these must be *Diplogonoporus balaenopterae* Lönnberg, 1891, a species frequently found in rorquals (*Balaenoptera* and *Megaptera*). The life cycle of *Diplogonoporus* is unknown, but the plerocercoids can be expected to occur in fishes (Rausch, 1964).

NEMATODES.—*Anisakis simplex* Rudolphi, 1809, was found in only one gray whale. There were many immature individuals, 20 to 35 millimeters long, of this species in the first and second chambers of the stomach of an immature male killed on 3 April 1968. They were not attached to the mucosa. In a recent revision of this genus, J. T. Davey (personal communication) recognized only three species. Our specimens differ from *A. physeteris* Baylis, 1923, in the possession of a sigmoid esophagus. Only mature males of *A. simplex* can be distinguished from *A. typica* Diesing, 1860. *A. simplex* occurs in all species of balaenopterid whales as well as many other species of marine mammals from all over the world, especially from colder seas, whereas *A. typica* is known only from delphinids from warmer seas. Therefore Davey (personal communication) had little hesitation in assigning our specimens to *A. simplex*. The life cycle of *Anisakis* is unknown, but it is probable that two intermediate hosts are needed (Berland, 1961). Fishes are the usual source of infestations in marine mammals (van Thiel, 1966), in which these worms reach maturity.

ACANTHOCEPHALANS.—*Corynosoma* sp. was found in 18 (5.7 per cent) of the 316 gray whales studied. They were rather loosely attached to the mucosa of the small intestine. Most infestations were light, the heaviest being a whale that had 60 individuals within a 0.3-meter section of intestine. Specimens from gray whales are 4 to 5 millimeters long; the anterior half of the trunk is bulbous, the posterior half elongate and tapering. Treshchev (1966*b*) described a new species, *C. septentrionalis*, and reported (Treshchev *et al.*, 1969) *C. semerme* Forssell, 1904, *C. strumosum* Rudolphi, 1802, and *C. validum* Van Cleave, 1953, from gray whales collected off the Chukotskiy Peninsula. The life cycles of a few species of *Corynosoma* are known. All these involve crustaceans as first intermediate hosts, and fishes as second intermediate hosts (Golvan, 1959). Seals and aquatic birds are the definitive hosts of most species of this genus; a few species parasitize toothed whales (Delyamure, 1955; Golvan, 1959). The discovery of species of this genus in gray whales is the first known occurrence in a baleen whale, although we recently have found *Corynosoma* in fin whales.

Bolbosoma sp. was present in the small intestine of an immature male whale captured on 3 April 1968. The two specimens found were white and about 30 millimeters long. The trunk (when turgid after being placed in fresh water) was slightly more than a millimeter in diameter. One was loosely attached to the mucosa; the head of the other was imbedded in a small, thick-walled, pus-filled cyst in the mucosa. The life cycles of species of *Bolbosoma* are unknown.

Discussion and Conclusions

The gray whale is more heavily infested with a greater variety of ectoparasites and epizotes than any other species of cetacean. This may be at least partly due to the fact that they swim slowly and live throughout the year in shallow coastal waters rich in nutrients. In contrast, they are infrequently infested with endoparasites. Their long period of fasting each year may inhibit the survival of parasites in the digestive tract. Except for liver flukes, none of the ectoparasites or endoparasites appears to have any significant pathogenic effects.

POPULATION

ALTHOUGH a reasonably complete understanding of the population dynamics of the California stock of gray whales will require further investigation, data obtained in the present study provide a basis for some tentative conclusions.

Present Numbers

Because gray whales migrate close to the coast, a large proportion of the population may be counted from vantage points on shore, providing an index of population size. Between the migration seasons of 1952-53 and 1960-61, four essentially full-time counts were made at the Point Loma coastal station (Gilmore, 1960a, 1960b; Rice, 1961). In the course of offshore cruises for marking whales of other species, beginning in 1964, we found unexpectedly large numbers of southbound gray whales passing the coast of southern California far offshore (Rice, 1965; unpublished data). However, in the area of the counting station south of Yankee Point, observations during whale marking cruises indicated that few gray whales pass so far offshore that they cannot be seen from land.

Daily counts of southbound whales migrating past these two points are shown in Fig. 38. In 1967-68, 3120 whales were counted at Yankee Point and 1324 at Point Loma. In 1968-69, 3280 were counted at Yankee Point and 1154 at Point Loma. Thus, of the number of whales that passed Yankee Point only 35 to 42 per cent were seen passing Point Loma. In 1969-70, 3345 were counted at Yankee Point, and no count was made at Point Loma.

To calculate total population size from these counts, we must estimate the number of whales that were missed because of poor visibility, the whales that passed too far offshore to be seen, and the whales that passed at night. We estimated the number of whales missed because of poor visibility by considering only the counts made during days when visibility was good. As visibility is limited most by fog, drizzle, or rain, and by winds strong enough to create whitecaps, we considered only the days when there was no precipitation or fog and winds were below 19 kilometers per

FIG. 38. Daily counts of gray whales passing Yankee Point and Point Loma, California, during the southward migrations of 1967-68 and 1968-69.

hour (10 knots). Days with good visibility and days with poor visibility were interspersed at random throughout each census period, so we extrapolated the counts made during the days with good visibility to include the entire period of each census. Some whales were doubtless missed even during days with good visibility, and, of course, a few passed early in the season before the counts began and late in the season after the counts ended.

To determine the number of whales passing too far offshore to be seen, we ran transect cruises from Yankee Point and Point Loma across the migration path of the whales. In a transect from Yankee Point on 18 January 1968, extending 37 kilometers offshore, no gray whales were seen farther from shore than 6 kilometers, and only nine of the 33 whales sighted were beyond 4.5 kilometers from shore. The remaining 24 were within 1.5 kilometers of land. Under conditions of good visibility, observers on shore could detect whales at an estimated distance of 7.4 kilometers, but 95 per cent of the whales were estimated to be within 1.9 kilometers of shore. Therefore, we conclude that the number of whales passing too far off-

shore from Yankee Point to be seen by the observers during periods of good visibility was insignificant.

Between 25 January and 9 February 1968, we ran seven transects totaling 1572 kilometers between Point Loma and longitude $119^{\circ}20' W$, just beyond Tanner and Cortez Banks. During 100 kilometers of cruising within 9.3 kilometers of shore, 37 gray whales were seen, an average of 0.37 per kilometer cruised. During 1472 kilometers of cruising beyond 9.3 kilometers from shore, 40 gray whales were sighted, an average of 0.027 per kilometer. The width of the migration path at this latitude is at least 194.5 kilometers, of which 9.3 kilometers is within sight from Point Loma. The ratio of whales passing offshore to those passing within sight of land is thus $(185.2 \times 0.027) : (9.30 \times 0.37) = 5.00 : 3.44$. This ratio indicates that only 41 per cent of the whales migrating south past southern California passed within sight of Point Loma. This agrees with our estimates of 35 to 42 per cent based upon a comparison of the Point Loma and Yankee Point counts. Therefore, we have multiplied the Point Loma counts by 2.44 ($100/41$), to estimate the total number of whales moving past the latitude of Point Loma during daylight hours.

Because there is no evidence that migrating gray whales slow down at night, we have multiplied the estimated number of whales passing during the 10 hours of daylight during which counts were made by 2.4 to estimate the total number of whales passing each counting station during each of the two seasons.

Estimates of total population size, based on the foregoing corrections, are shown in Table 14. The Yankee Point estimates are probably more accurate than the Point Loma estimates, because of the greater possibility of error in adjusting for offshore migration at Point Loma. The 1968-69 and 1969-70 estimates are probably more accurate than those for 1967-68 because the counts started earlier in the season. The best estimate of the present population size of the California gray whale stock is approximately 11,000.

The reliability of this estimate is difficult to assess. A probable lower limit may be estimated by multiplying the actual counts at Yankee Point by 2.4 to allow for the whales passing at night, which gives figures of about 7500 for all three seasons. An upper

COUNTS OF SOUTHWARD MIGRATING GRAY WHALES AND ADJUSTED ESTIMATES OF
TOTAL GRAY WHALE POPULATION SIZE, 1967-68 TO 1969-70.

Season	Locality	Entire period		Days with good visibility		Whales per day	Estimate of whales passing during daylight	Adjusted for offshore migration	Adjusted for night migration
		No. of days	No. of whales	No. of days	No. of whales				
1967-68	Yankee Point	49 ¹	3,120	32	2,430	76	3,724		8,938
	Point Loma	52	1,324	29	879	30	1,560	3,806	9,134
1968-69	Yankee Point	60	3,280	29	2,174	75	4,500		10,800
	Point Loma	57	1,154	26	758	29	1,653	4,033	9,679
1969-70	Yankee Point	64	3,345	32	2,257	71	4,544		10,906

¹ No count made on two of these days.

limit was estimated by drawing a line connecting the highest daily counts at Yankee Point and measuring the area under the line to estimate the number of whales passing during daylight. The total was then calculated by multiplying this value by 2.4 to compensate for night migration. The resulting estimates of the upper limit were about 13,000 in 1967-68, and 12,000 in 1968-69 and 1969-70.

Population Trends

In the decades prior to 1947, before legal protection was afforded by the International Convention for the Regulation of Whaling, the gray whale population is believed to have been considerably lower than it is now, but there are no quantitative data available upon which to base an estimate of its size during this period.

The estimated population size based upon four complete counts made at Point Loma from 1952-53 to 1959-60 (Gilmore, 1960a; Rice, 1961) showed a rather consistent increase of about 11 per cent per year. A regression analysis of the logarithms of these counts gives an estimate of the rate of population change as +12.2 per cent per year, with a 95 per cent confidence interval of -4.0 to +31.2 per cent. This study, however, has thrown doubt on the reliability of estimates of absolute population size based upon these counts.

The most questionable factor is the estimate of the extent of offshore movement, which Gilmore arbitrarily estimated at 5 per cent of the inshore movement. In contrast, present evidence indicates that offshore movement is about 144 per cent of the inshore movement along this stretch of coast.

The 1967-68 and 1968-69 counts at Point Loma were 44 and 51 per cent, respectively, below the 1959-60 count of 2344. Either some factor such as increase in small boat traffic has caused a larger proportion of the population to pass farther offshore at Point Loma, or the population in 1959-60 actually was much higher than estimated and has since decreased.

Hubbs and Hubbs (1967) made aerial surveys of the gray whale wintering grounds in Baja California between late January and early March in most years from 1952 to 1964. They suggested that the population increased from 1952 to 1954 and thereafter remained constant at about 3000. A regression analysis of the logarithms of their five complete counts from 1954 to 1964 gives an estimated rate of population change of +0.8 per cent per year, with a 95 per cent confidence interval of -4.5 to +6.4 per cent. Their estimate of absolute population size was based on an "admittedly rather intuitive estimate that about half of the population was observed on the flights." Between soundings, gray whales are at the surface or sufficiently near it to be visible for only about 1 out of every 5 minutes. Therefore, applying this correction to the data of Hubbs and Hubbs would give an estimate of about 7500 animals. Gilmore (1960a), who participated in some of these aerial counts, came to a similar conclusion.

In 1966-67, Adams (1968) made a partial count during the southward migration at Yankee Point. His counts were conducted only during periods of optimum visibility and included only 9.16 per cent of the daylight hours during the migration period. The number of whales actually counted was 1084. This count was adjusted to cover all daylight hours, increased by 5 per cent to account for offshore migration and 70 per cent for night migration, to yield a total estimate of 18,300. This estimate is probably too high because the counts were made only during limited periods when the most whales could be seen. Adams reported an average of up to 55 whales passing per hour, which extrapolates to a rate

of 550 per 10-hour day; we never counted more than 46 whales in one hour nor more than 197 per day during our full-time counts from 1967-68 to 1969-70.

Our counts at Yankee Point suggest that the population remained essentially stable from 1967-68 to the 1969-70 season.

Density and Biomass

Population density is ecologically most significant in relation to the feeding grounds. The summer range of the gray whale in the Bering and Chukchi seas occupies about 1,000,000 square kilometers. With a population of about 10,000, the average density is approximately one whale per 100 square kilometers. Density, of course, may vary markedly between different portions of the summer grounds (Berzin and Rovnin, 1966).

The total biomass of the gray whale population based on estimated numbers, sex and age structure, and mean body weights of each sex, age, and reproductive category is estimated at approximately 1.4×10^5 metric tons. The weight of an average gray whale is thus about 14 metric tons. The mean biomass on the summer grounds would thus be about 14 metric tons per 100 square kilometers, or 140 kilograms per square kilometer.

As a gray whale requires an estimated 19 kilocalories per kilogram per day, a 14-ton individual will require about 2.7×10^5 kilocalories per day, or 9.7×10^7 kilocalories per year. Inasmuch as gray whales must consume enough food during about half the year to sustain them the entire year, their daily energy requirements on the summer grounds would be about 5.3×10^5 kilocalories. Thus, if one kilogram of amphipods supplies 500 kilocalories, a gray whale weighing 14 tons must consume about a ton, or approximately 7 per cent of its weight, of amphipods per day.

The gray whale population consumes about 10 kilograms of food per day, or nearly 2 tons a year, per square kilometer. This quantity represents about 0.2 to 1.0 per cent of the standing crop of benthos (Neiman, 1963). Energy exchange amounts to 5.3×10^3 kilocalories per day. Although these figures are rough approximations, they provide some indication of the magnitude of the ecological role of the gray whale in the shallow waters of the Bering and Chukchi seas.

TABLE 15
SEX RATIOS OF GRAY WHALE AGE GROUPS.

Age group	No. males	No. females	Per cent males

Near-term fetuses	30	25	55
Immatures	43	34	56
Adults	123	116	51
Combined total	205	188	52

Population Structure

SEX RATIO.—The combined sex ratio of fetal, immature, and adult gray whales was 52 per cent males to 48 per cent females (Table 15). In none of the age classes does the ratio differ significantly from one to one. The observed slight preponderance of males is probably not real, especially in view of the fact that lactating females were not represented in the sample.

AGE COMPOSITION.—Age composition of our sample, based on counts of corpora in the ovaries of adult females and counts of growth layers in the ear plugs of both sexes, is given in Tables 16 and 17. Although corpora counts are believed to be more

reliable than the data from ear plugs, the latter are useful because they are the only known means of determining the ages of males and of immature whales, and they permit a comparison between the sexes.

Immature whales comprised 24 per cent of the sample (26 per cent males, 23 per cent females). The data for this age class are biased because gunners select against smaller animals and because a larger proportion of immature whales have "readable" ear plugs. The proportion of immature whales in the population is certainly higher than indicated by our sample. If the apparent annual survival rate (S) of immature whales were the same as that of adults (0.92—see below) and sexual maturity were attained at 8 years of age, the proportion of immature whales 1 to 7 years old in the population would equal $1-S^7$, or 44 per cent. This is probably an underestimate, as the mortality of immatures is more likely to be greater than that of adults.

Another method of estimating the proportion of immature whales in the population based on the birth rate is applicable only if the population is stable. The birth rate is about 0.23 of the adult stock (see below). Since births must balance deaths in a stable population, the birth rate would be $(1-S)/S$, or 0.09 of the total stock alive at the beginning of the calving season. With a birth rate of 0.23 of the adult stock, the proportion of immature whales in the population would be $(0.23 - 0.09)/0.23$, or 61 per cent.

Population Dynamics

NATALITY.—On the basis of our estimate of a pregnancy rate in adult females of 0.46 per year and an assumption of an equal sex ratio, the birth rate in the California gray whale population is about 0.23 of the adult stock. As the present data indicate that adults constitute no more than 56 per cent of the population, the overall birth rate would not exceed 0.13. The approximate potential maximum rate of increase would approach this value.

MORTALITY.—The mean annual mortality rate of the adult female component of the sample, based on ages estimated from corpora counts, was calculated using Chapman and Robson's (1960) formula $M = 1 - (T/[N + T - 1])$, where M = annual mortality

rate and $T = \Sigma(\text{age}-8)$ (frequency). The resulting estimate of the mortality rate is 0.082.

The mortality rate for each sex was also calculated from the ear-plug data. As the proportion of immature whales in the sample is apparently biased, only whales of estimated ages of 8 years or older were used in the analysis, thus making the estimates directly comparable with those based on ovarian data. The resultant mortality values are 0.081 for males and 0.095 for females, which agree well with the estimates based on ovary analysis. They also indicate that there is probably little sex difference in mortality rate, a conclusion further supported by the essentially equal sex ratio at all ages.

Discussion and Conclusions

The California gray whale population was probably at least 8000 but less than 13,000 during the southward migration in 1969-70, with 11,000 being the most reasonable estimate.

Estimates of population size in earlier years based on shore counts at Point Loma (Gilmore, 1960a, 1960b; Rice, 1961) and aerial censuses in Baja California (Hubbs and Hubbs, 1967) are probably too low. However, they suggest that the population increased moderately from the early 1950's to 1960. The evidence for population trends from 1960 to 1967 is equivocal. The counts at Yankee Point suggest that the population has remained essentially stable from 1967-68 to 1969-70.

The sex ratio is about one to one at all ages. Probably at least 44 per cent of the population is sexually immature. The birth rate is 0.13 or slightly less. The age structure of the population suggests that the mortality rate has been 0.08. The size of any age class at a given time depends on its initial size and on its mortality rate. Therefore, the mortality rate calculated from the age composition represents the true mortality rate only if the initial size of each age class was the same, a situation likely to exist only in a stable population with a constant birth rate. In an increasing population with a constant birth rate, the initial size of each succeeding age class is greater. If the gray whale population was increasing at a rate of about 0.12 per year between 1952-53 and 1959-60, as the

counts from Point Loma suggest, mortality would have to have been almost zero to produce the observed age structure. A low mortality rate would be expected in an initially small, rapidly increasing population comprised predominantly of younger animals. Inasmuch as the population has been stable since 1967, the mortality rate must have increased to equal the birth rate, but this change would have been too recent to have had a noticeable effect on the age structure of the population. However, additional data are needed, particularly on the actual age structure of the immature segment of the population and on population trends, before recruitment and mortality can be more accurately estimated.

EXPLOITATION

Aboriginal Whaling

The Nootka, Makah, Quillayute, and Quinault Indians, the renowned aboriginal whalers living on the west coast of Vancouver Island and the State of Washington, regularly hunted gray whales since prehistoric times. Gray whale bones have been found in ancient middens near Lapush, Washington (Reagan, 1917). Indians chased whales in dugout canoes and struck them with harpoons attached to a line and float (Swan, 1870; Swanson, 1956; Waterman, 1920). Aboriginal whaling survived until 1928 on the coast of Washington (Anonymous, 1949).

Indians of the Kodiak Island and eastern Aleutian area killed whales with aconite-poisoned lances, a method also used by the Kamchadal in Kamchatka (Heizer, 1943). It is not known to what extent these people captured gray whales; their usual quarry was probably the right whale or the humpback whale.

The Koryaks who lived on the shores of Olyutorskiy Gulf north of the Kamchatka Peninsula in the 18th century regularly caught gray whales in large nets made of strips of walrus skin, which they set at the mouths of inlets (Krasheninnikov, 1755; Steller, 1774). Gray whales still are occasionally caught in this manner (Tomilin, 1957).

The Eskimos of Arctic Alaska and the Chukchi of eastern Siberia have for thousands of years hunted the bowhead whale and the gray whale from skin-covered "umiaks." In aboriginal times they used hand harpoons. After contact with American whalers in the late 19th century, they adopted the darting-gun and bomb-lance (Rainey, 1947). Whaling is still regularly practiced by the Eskimos of the villages of Barrow, Wainwright, and Point Hope on the Arctic coast of Alaska. In this area the catch is mostly bowhead whales. From 1954 through 1959, only nine gray whales were killed at Barrow and one at Wainwright (Maher, 1960). The natives of the village of Gambell on St. Lawrence Island (Francis H. Fay, personal communication) and the villages of Sireniki, Imtuk, Chaplino, Naukan, Uelen, and Enurmino on the Chukotskiy Peninsula

(Tomilin, 1957; Treshchev, 1966a) also still hunt whales. The catch in these areas is almost entirely gray whales. One hundred fourteen were killed in 1965 and 53 in 1966 off the Chukotskiy Peninsula (Zimushko, 1969a).

Commercial Whaling

Whaling in Japan dates back more than a thousand years, but it was not until about 1606 that commercial whaling was established. From the town of Taiji, the industry spread rapidly throughout the islands. At first, hand harpoons were used, but in 1674 the use of nets was introduced and widely adopted. Early 19th century Japanese illustrations show that gray whales were hunted in addition to the commonly taken right and humpback whales (Fraser, 1937; Japanese Fisheries Agency, 1954; Omura *et al.*, 1953).

The possibility that gray whales survived in the North Atlantic until the early 18th century and were pursued by New England whalers is suggested by Dudley's (1725) account of the enigmatic "scrag whale" mentioned earlier.

During the late 18th and 19th centuries the American high-seas, open-boat whale fishery developed and gradually spread to all oceans. In 1846, the whalers discovered the winter grounds of the Pacific gray whale along the west coast of Baja California. Scammon (1874) estimated the gray whale population as "probably not over 30,000" between 1853 and 1856. The annual congregations of gray whales in the lagoons attracted the American whalers, and by the winter of 1860-61 about 60 whaling vessels were engaged in lagoon whaling in Baja California (Starks, 1922). The first shore whaling station was established in 1854 (Starks, 1922), and by 1874, 11 shore stations were operating along the coast of California and Baja California (Scammon, 1874; Jordan, *in* Clark, 1887). Scammon estimated that about 10,800 gray whales were killed there between 1846 and 1874. Others were killed in the Bering Sea and Arctic Ocean. Scammon estimated the population of gray whales as 8000 to 10,000 in 1874. By 1886 only five shore whaling stations remained; they took 58 gray whales in 1883-84, 68 in 1884-85, and 41 in 1885-86 (Townsend, 1887). During the latter season, Townsend estimated that only 160 southbound gray whales passed

San Simeon, California, in December and January. Regular shore whaling ceased about 1900 (Starks, 1922).

During the early 20th century there was little exploitation of gray whales, although American whaling ships doubtless took a few; 31 were taken in waters off Mexico and California, and one off Alaska, by the whaling schooner "Carolyn Frances" as late as 1921 (Starks, 1922; Bower, 1923). During this period the stock probably increased.

The perfection of the modern harpoon gun in 1864 by the Norwegian whaler Svend Foyn ushered in the era of modern whaling. Captain H. G. Melsom of the Toyo Hogeï Kabushiki Kaisha [Oriental Whaling Co., Ltd.] of Osaka, Japan, inaugurated a winter fishery for the gray whale at a shore station at Ulsan on the east coast of Korea, about 1899 (Andrews, 1914). A total of 1474 gray whales was killed off Korea from 1910 to 1933. Catches were declining by the 1920's, and whaling ceased after 1933, when only two gray whales were taken. This rapid decline suggests that the Korean stock numbered only some 1000 to 1500 whales in 1910, and was virtually extinct by 1933.

Exploitation of the California stock of gray whales by modern methods began with the establishment of several shore whaling stations along the west coast of North America, the first in 1905. Few gray whales were killed, however, because they were rare and could be taken only during the winter and early spring when the weather was bad. The few taken were brought into the stations at Port Hobron on Sitkalidak Island and Port Armstrong on Baranof Island, Alaska, Bay City, Washington, and Trinidad and Moss Landing, California.

The introduction of floating factory ships gave modern whalers a mobility that greatly increased their efficiency. Because whales were flensed while floating alongside the ship, these early floating factories could operate only in sheltered anchorages. A Norwegian factory ship, "Capella I," took 19 gray whales off Baja California in the spring of 1914. From 1924-25 until 1928-29, Norwegian whaling interests operated factory ships each winter and spring at Bahía Magdalena and other points along the coast of Baja California. Catches of gray whales steadily declined from 100 in 1924-25 to two in 1928-29 as the whalers turned their attention

¹ Catch by shore stations, almost all in Korea; for particulars see Mizue (1951). The whale taken in 1942 was killed in the Kuril Islands.

to the abundant and more profitable blue and humpback whales. A total of 181 gray whales was killed during these five seasons. One of these Norwegian factory ships, the "Kommandören I," took 33 gray whales in Natal'inskiy Bay, northeastern Kamchatka, in the summer of 1925. An American floating factory, the "Lansing," began operating in California in 1927. In 1932 she was replaced by the "California," which operated until 1937.

The invention of the stern slipway in 1925 made it possible to haul whales aboard the factory ship, thus permitting whalers to operate on the high seas and freeing them from regulation by national governments. The Soviet floating factory "Aleut" began operating in the western Bering Sea in 1933. Gray whales were an important part of her catch. The Japanese floating factory "Tonan Maru" took 58 gray whales in the Chukchi Sea in 1940, and the "Aleut" continued to take gray whales until 1946. From 1933 to 1946, a total of 681 gray whales was killed in the Bering and Chukchi seas. Annual catches provide no clear evidence of any changes in population size during this period.

The 1937 International Agreement for the Regulation of Whaling, which forbade the killing of gray whales, was adhered to by the governments of many whaling nations, including the United States, Canada, and Mexico, but not Japan or the Soviet Union. The 1946 International Convention for the Regulation of Whaling was ratified by the Governments of 17 nations, including Canada, Japan, Mexico, the Soviet Union, and the United States. This convention forbids the killing of gray whales, except by aborigines or a contracting government on behalf of aborigines and only when the meat and products are to be used exclusively for local consumption by the aborigines. Contracting governments may also grant special permits authorizing the collecting of gray whales for scientific research.

Statistics on catches of gray whales by modern style whaling as published in the International Whaling Statistics (IWS) are incomplete and in some instances erroneous; many data from prior to 1937 are combined under the category "North Pacific." We have attempted to compile a complete record of all gray whales killed from 1910 to 1946 (Table 18). No data are available on Korean catches before 1910. Although modern style whaling began on the

west coast of North America in 1905, no gray whales were killed until 1913. No gray whales have been taken commercially since the International Convention for the Regulation of Whaling went into effect in 1947, except for one taken in error by the shore station at Coal Harbour, British Columbia, in 1951. In 1953, 10 specimens were taken under a special scientific permit at Coal Harbour. As far as we can ascertain, these statistics are complete except for possible catches off California during the years 1930 and 1932-36, as noted below, and for any that might be included under a few unspecified whales taken in California, British Columbia, and Alaska. The sources of our data for each area in which modern whaling has been conducted are given below.

Baja California.—Data on the 1914 catch of the floating factory “Capella I” are from Tønnessen (1967). Catch figures for 1924-25 through 1929 and for 1935 are from original daily catch records submitted by whaling companies to the Bureau of International Whaling Statistics and kindly made available by Einar Vangstein.

California.—Data from 1918 through 1929 are from Starks (1922), Radcliffe (1933), and Kellogg (1931). Catch statistics by species are not available for the floating factory “Lansing” in 1930 or the floating factory “California” from 1932 through 1936 (total catches for all species are listed in the annual statistical issues of “Pacific Fisherman”). No whaling was conducted in 1931. Catch statistics subsequent to 1936 are from files of the U. S. Bureau of Commercial Fisheries.

Washington.—Catch statistics of the shore station at Bay City, Washington, from 1911 to 1925, as compiled by Scheffer and Slipp (1948).

British Columbia.—Catch statistics for 1905 through 1946, compiled by Gordon Pike (1962*b*) from Annual Reports of the Canadian Department of Fisheries, list no gray whales.

Alaska.—Catch statistics are on file with the U. S. Bureau of Commercial Fisheries.

Bering and Chukchi seas.—Catch statistics for the Norwegian floating factory “Kommandören I” are from IWS, those for the Soviet floating factory “Aleut” are from Sleptsov (1955), and those

for the Japanese floating factory "Tonan Maru" are from Sakiura *et al.* (1953).

Korea.—Catches by Korean shore stations are from Mizue (1951) and IWS. Their figures for the period 1920 to 1930 are erroneous; correct figures were published by Tønnessen (1967) and in Norsk Hvalfangst-Tidende, 16:13 (1927), 19:161 (1930), and 20:142 (1931).

Kuril Islands.—Mizue (1951) recorded one gray whale taken by a shore station at Otomae (on Shiashkotan Island), in the northern Kuril Islands, in 1942; this locality is outside the normal range of the species.

SUMMARY

1. This study is based on data obtained from 316 gray whales collected off the coast of central California between 1959 and 1969 and on field observations. The latter included counts of southward migrating whales from shore stations during the winters of 1967-68 to 1969-70, observations made during cruises off California and Mexico from 1962 to 1969, and aerial observations along the coast of Washington, Oregon, and California in 1969. In addition, the stomach contents of a gray whale killed by Eskimos at St. Lawrence Island, Alaska, were analyzed.

2. Gray whales usually travel within a few kilometers of shore while migrating from their summer grounds in the Bering and Chukchi seas to their winter grounds along the coast of Baja California, but off southern California the majority take a more direct offshore route from Point Conception to northern Baja California. The northward migration follows the same route, except that females with calves apparently travel offshore. Migrating gray whales swim at about 8.5 kilometers per hour; on the southward migration they travel about 185 kilometers per day. There is no evidence that the whales travel slower at night than during daylight. Migrating gray whales are temporally segregated according to sex, age, and reproductive status. During southward migration, the sequence of passage is as follows: females in late pregnancy, females that have recently ovulated, adult males, immature females, and immature males. During northward migration, the sequence is as follows: newly pregnant females, anestrus females, adult males, immature females, immature males, and postpartum females. The earliest southbound migrants (mostly late pregnant females) usually travel singly, whereas later migrants usually are in pods of two or more.

3. Food of gray whales on their summer grounds in the northern Bering and Chukchi seas includes at least 17 species of benthic gammaridean amphipods, among which *Ampelisca macrocephala* predominates. The nature of the food indicates that gray whales are bottom feeders. Virtually no food is consumed during migration,

although rarely small quantities of decapod nauplii (*Pachycheles rudis* and ?*Fabia* sp.) are eaten. There is little evidence that gray whales feed on their winter grounds off Baja California. In the interval between their southward and northward migration past San Francisco, the whales lose from 0.21 to 0.37 per cent of their body weight per day. This weight reduction is sufficient to account for the estimated energy expenditure during the winter. Blubber thickness and oil yield also decrease during winter.

4. Age may be estimated from the number of growth layers in the ear plug, indirect evidence suggesting that two layers are formed the first year and one each year thereafter. However, the value of ear plugs for age determination is limited because many plugs do not have clear laminations, and earlier laminations may disappear in older animals. The number of corpora albicantia in the ovaries provides a more reliable estimate of the age of adult females. Growth zones in the baleen plates are of little use for age determination because of rapid wear.

5. Mean body length at birth is about 4.9 meters. Mean length at weaning at an age of 7 months is about 8.5 meters. Puberty is attained at an estimated mean age of 8 years (range, 5 to 11 years) and a mean body length of about 11.1 meters in males and 11.7 meters in females. Physical maturity is attained at about 40 years at a mean body length of about 13.0 meters in males and 14.1 meters in females.

6. Ontogenetic changes in body proportions are slight. From late fetal life to a year of age, relative length of the flippers decreases and relative length of the tail increases. There are no significant changes in body proportions between the end of the first year and physical maturity. Females have slightly shorter flippers and longer tails than do males.

7. In immature females, seasonal enlargement of the follicles begins at a body length of about 9.9 meters and an age of 2 or 3 years. Mean weight of individual ovaries increases rapidly from about 140 to 300 grams when body length reaches about 11.3 meters at about 5 years of age. The ovaries weigh about 340 grams at sexual maturity and continue to increase slowly throughout life,

reaching about 646 grams at 50 years of age. The uterine cornua are 3.5 to 12.0 centimeters in diameter in immature females and more than 11.0 centimeters in adult females. The mammary glands do not develop until the female is well into her first pregnancy.

8. Female gray whales normally come into estrus biennially in late November and early December. Most individuals ovulate only once each season, although whales failing to conceive after their first ovulation may experience a second estrous cycle the same season. Multiple ovulations are extremely rare. Mean ovulation rates are 1.20 per breeding season for nulliparous females and 0.96 per breeding season (0.52 per year) for parous females. There is no evidence for postpartum ovulation or for ovulation at any other time of year. However, increase in follicle size following stillbirth or early loss of the calf suggests that females might ovulate following such an event. Females continue to breed at an advanced age. Corpora lutea of pregnancy average 8.7 centimeters in diameter, whereas corpora lutea of ovulation do not exceed 2.5 centimeters (at least if another estrous cycle soon follows). Corpora albicantia derived from corpora lutea of ovulation are indistinguishable from those derived from corpora lutea of pregnancy. Corpora albicantia persist in the ovaries throughout life. About 55 per cent of ovulations occur in the left ovary and 61 per cent occur in the anterior half of the ovaries.

9. Most conceptions occur within a 3-week period during southward migration, with a peak about 5 December. The pregnancy rate is 0.86 per breeding season (0.46 per year). The gestation period is about 13 months, and fetal growth is accelerated during the last half of pregnancy. During southward migration, late pregnant females (exclusive of their conceptus) average 25 to 30 per cent heavier than the other adult females. Births occur within a period of 5 to 6 weeks, with a peak occurring about 10 January. Caudal presentation at birth is normal.

10. Lactation lasts an average of about 7 months, ending in August.

11. Females are usually in anestrus from August to November or December. However, females that fail to ovulate or conceive

during the winter are probably in anestrus for the following 12 months.

12. In immature males, the weight of both testes is usually less than 5 kilograms, and the seminiferous tubules average 45 to 102 microns in diameter. Testis weight of sexually mature males is more than 5 kilograms, and the average diameter of the seminiferous tubules exceeds 104 microns. Penis length is correlated with body length and is usually less than 1.1 meters in immature males.

13. The average weight of the testes of adult males during southward migration in December and January is 38 kilograms, and the mean diameter of the seminiferous tubules is 177 microns. During northward migration in February and March, mean testes weight and tubule diameter are 22 kilograms and 148 microns, respectively. From July through October, the testes average 23 kilograms. These differences suggest a marked seasonal sexual cycle in the male, with a peak of spermatogenetic activity in autumn or early winter.

14. The killer whale, *Orcinus orca*, appears to be the only predator on gray whales. The mortality rate from killer whale attacks is unknown. However, frequency of tooth scars indicate that killer whale attacks on gray whales are often unsuccessful.

15. Epizoots of gray whales include the following (percentage of occurrence in parentheses): the barnacle *Cryptolepas rhachianecti* (100) and the cyamids *Cyamus scammoni* (99.7), *C. ceti* (99.4), and *C. kessleri* (98.1). Endoparasites collected include the trematodes *Lecithodesmus goliath* (0.6), *Ogmogaster pentalineatus* (more than 22), and *O. antarcticus* (33); two apparently undescribed species of the cestode *Priapocephalus*, one in the small intestine (30) and the other in the large intestine (0.3); the nematode *Anisakis simplex* (0.3); and two acanthocephalans, *Corynosoma* sp. (5.7) and *Bolbosoma* sp. (0.3). Obvious pathogenic effects were noted only for the liver fluke, *Lecithodesmus goliath*.

16. Population size of the California stock during the southward migration of 1969-70 was estimated to be about 11,000. Although previously published estimates of numbers of the California stock are questionable, the population appears to have increased from

1947 to 1960. Trends from 1960 to 1967 are uncertain. Since 1967, population size has remained essentially stable.

17. The sex ratio is essentially equal in all age groups. The birth rate does not exceed 0.13. The calculated annual death rate of adults is 0.08. This is probably an overestimate, although, if the population is now stable, the death rate must have recently increased to near the birth rate.

18. The California gray whale stock was severely overexploited between 1846 and 1900. During the present century this population has been only lightly exploited. Factory ships took an average of 36 gray whales per year in Mexico from 1924-25 to 1928-29 and an average of 48 per year in the Bering Sea from 1933 to 1946. Since then the species has been protected from commercial whaling by the International Convention for the Regulation of Whaling. The Korean stock was virtually exterminated between 1899 and 1933.

Gray whale (*Eschrichtius robustus*) in the Mediterranean Sea: anomalous event or early sign of climate-driven distribution change?

On 8 May 2010, a gray whale was sighted off the Israeli Mediterranean shore and twenty-two days later, the same individual was sighted in Spanish Mediterranean waters. Since gray whales were last recorded in the North Atlantic in the 1700s, these sightings prompted much speculation about this whale's population origin. Here, we consider three hypotheses for the origin of this individual: (1) it represents a vagrant individual from the larger extant population of gray whales found in the eastern North Pacific; (2) it represents a vagrant individual from the smaller extant population found in the western North Pacific; or (3) it represents an individual from the previously thought extinct North Atlantic population. We believe that the first is the most likely, based on current population sizes, on known summer distributions, on the extent of cetacean monitoring in the North Atlantic and on the results of a performed route analysis. While it is difficult to draw conclusions from such singular events, the occurrence of this individual in the Mediterranean coincides with a shrinking of Arctic Sea ice due to climate change and suggests that climate change may allow gray whales to re-colonize the North Atlantic as ice and temperature barriers to mixing between northern North Atlantic and North Pacific biomes are reduced. Such mixing, if it were to become widespread, would have implications for many aspects of the marine conservation and ecology of these two regions.

Keywords: global warming, climate change, migration, vagrancy, sea ice, ecosystem sentinels

Submitted 29 July 2010; accepted 5 December 2010

INTRODUCTION

Gray whales (*Eschrichtius robustus*) (Lilljeborg 1861) were once found in the coastal waters of both the North Pacific and the North Atlantic. However, while historical sources indicate that gray whales were recorded on both sides of the North Atlantic until 1700, the North Atlantic population(s) seems to have been eradicated a few decades later (Lindquist, 2000). The southernmost specimen of gray whale in the eastern North Atlantic was found on the southern coast of England (Mead & Mitchell, 1984), while the southernmost western record is from Florida, USA (27°04.6'N 080°07.7'W) (Odell, 1983). While the latter record implies that a part of the North Atlantic population may have bred and calved in the lagoons of the central and south-eastern Florida coasts, the breeding and migratory habits of the gray whales that once inhabited the North Atlantic are not known.

In the North Pacific, two populations currently exist. These are a large (18,000) eastern North Pacific stock and a small (125), remnant western North Pacific stock (Swartz *et al.*, 2006). Both populations migrate northward through coastal

waters in spring and summer to high latitude feeding grounds. The eastern population summers in feeding grounds in the northern Bering and southern Chukchi Seas (Moore *et al.*, 2002), yet some whales of this population have been reported to reach longitude 174°E off the northern Chukotka coast, Russia (Berzin, 1984) and east to longitude 130°W in the Beaufort Sea, Canada (Rugh & Fraker, 1981). In autumn, this population migrates south along the eastern Pacific coast primarily to the west coast of Peninsula de Baja California, but also into the Gulf of California (Mead & Mitchell, 1984). The western population summers on feeding grounds primarily on the shallow-water shelf of north-eastern Sakhalin Island, Sea of Okhotsk (Weller *et al.*, 2002), but also off the south-eastern coast of the Kamchatka Peninsula (Vertyanin *et al.*, 2007). The wintering grounds of the western population are currently unknown, but may be in Asian coastal waters at latitudes as low as 20°N (Zhu, 2002).

The gray whale is the only baleen whale known to regularly consume benthic resources (Mead & Mitchell, 1984). They bottom-feed by using suction to take in food, water, and sediment, then expelling the water and sediment, while trapping the prey on the inside of their coarse baleen plates. However, gray whales are flexible foragers and respond to a variety of feeding opportunities throughout their coastal range

Corresponding author:
A.P. Scheinin
Email: scheinin@research.haifa.ac.il

(Moore *et al.*, 2007). For example, while most gray whales forage primarily upon the shallow benthic communities of the northern seas (Nerini, 1984), whales spending the summer in lower latitudes (e.g. off Vancouver Island, Canada) can rely heavily on planktonic prey (Dunham & Duffus, 2001).

In this paper, we report on a record of an individual gray whale from two locations in the Mediterranean Sea in May 2010. Three possibilities are suggested for the population of origin of this whale:

- (1) it represents a vagrant individual from the larger extant population of gray whales found in the eastern North Pacific;
- (2) it represents a vagrant individual from the smaller extant population found in the western North Pacific; or
- (3) it represents a surviving individual from an extant (rather than extinct) North Atlantic population.

Of the three, the first was deemed to be the most plausible, and a route analysis was done to suggest how the whale travelled to the Mediterranean and to account for its movements therein. The implications of this record for both our understanding of gray whale behaviour and the potential impacts of climate change on marine ecosystems in the North Atlantic and the North Pacific are also considered.

MATERIALS AND METHODS

Sighting records from the Mediterranean Sea

Sightings of a gray whale were recorded first off Israel and later Spain during routine cetacean surveys conducted in May 2010 in the Mediterranean Sea. During each sighting, information was gathered on the size of the individual, its body condition, behaviour such as speed and direction of travel, and photographs were taken to confirm species and individual identification, as gray whales are characterized by unique pigmentation patterns (Darling, 1984).

Investigating potential routes from the North Pacific to the North Atlantic and within the Mediterranean

In order to assess how a gray whale could have reached the Mediterranean, a geographical information system (GIS) was created in Arcview 9.3. Information entered into this database included water depth (ETOPO2, 2006), land forms and the minimum Arctic ice extent in September 2009 (from the National Snow and Ice Data Center, http://nsidc.org/data/seaice_index/), as it was assumed the odyssey began at this time. This information was then used to estimate the position and length of a number of likely migration routes from a starting point in the Bering Sea to Israel, and within the Mediterranean, for two separate scenarios. The lengths of time taken to traverse these possible routes were assessed using typical gray whale migration swimming speeds recorded in the eastern North Pacific (Mate & Harvey, 1984).

Individual identification attempts

Several eastern and western gray whale biologists were contacted and asked to review their photographic catalogues of

individual gray whales in an attempt to find a match to the gray whale sighted in the Mediterranean Sea. Western population: the Russia–US western gray whale research program catalogue, 1994–2009 (181 individuals), and in two catalogues of the A.V. Zhirmunsky Institute of Marine Biology, Russian Academy of Sciences (Vladivostok, Russia): (1) The Western Pacific Gray Whales of Sakhalin Island, 2002–2009 (177 individuals); and (2) The Pacific Gray Whales of Kamchatka Peninsula, 2004 & 2006–2009 (116 individuals). Eastern population: Cascadia Research Collective's catalogue of 'seasonal resident' gray whales that feed in the summer and autumn off California, Oregon, Washington and British Columbia (approximately 1000 individuals); the catalogue of Cape Caution in northern British Columbia (approximately 100 individuals); the catalogue of Vancouver Island (approximately 200 individuals); and the catalogue of Laguna San Ignacio Ecosystem Science Program (LSIESP) and Programa de Investigacion de Mamiferos Marinos (PRIMMA–UABCS) representing the Mexican breeding lagoons (approximately 6500 individuals).

RESULTS

Description of the sightings

Israel: a ~13 m long gray whale (estimated visually relative to the length of a boat) was spotted on 8 May 2010 2 km off Herzliya Marina (32°11.5'N 034°47.4'E) at 9:00 hours and followed for an hour and 10 minutes, southward along the coast. It maintained a distance of 2 km offshore, travelling at a constant speed of 5–7 km/h and performing a continuous series of short (3–5 minutes) dives occasionally displaying its flukes. A few reports of a whale near the shore had been received by the IMMRAC (Israel Marine Mammal Research and Assistance Center) stranding network two weeks before the documented sighting, suggesting that the whale was not simply transiting the area. Assessing the whale's body condition following the scale of Bradford *et al.* (2008), scapular condition scored 1, post-cranial condition scored 1 and lateral flank condition scored 1, for an overall inclusion in the 'poor condition' category; however, the whale did not appear to be in critical condition (i.e. near starvation) (J. Calambokidis, personal communication).

Spain: a gray whale was spotted by a sailing vessel at 16:30 hours on 30 May 2010 0.9 km away from the coast of Barcelona (41°21.32'N 002°12.2'E; north-east Spain). The whale was swimming in shallow waters of about 40 m deep, at an average speed of 7.2 km/h. The sighting lasted 20 minutes. During this period, the whale was diving constantly and displayed its flukes 4–5 times. The whale was moving southwards during the sighting period. Photographs of the tail fluke confirmed that this was the same individual previously sighted in Israel (Figure 1).

Investigating potential routes from the North Pacific to the North Atlantic

While we cannot entirely rule out the possibilities of a wintering east Pacific gray whale passing through the lock systems of the Panama Canal or around Cape Horn in order to reach the North Atlantic, nor that of a wintering west Pacific gray whale

Fig. 1. The pigmentation patterns of the flukes photographed in (A) Israel and (B) Spain, confirm that the two sightings are of the same individual. Photographs: (A) ©A. Scheinin/IMMRAC; (B) © R.Barahona/SUBMON.

traversing the South Pacific, Indian Ocean and Red Sea to enter the Mediterranean through the Suez Canal, these highly unlikely possibilities were not considered. Consequently, we considered the two most likely routes of summer-feeding whales from the Bering Sea to the North Atlantic and from there to the Mediterranean: one along the northern coast of Eurasia and the other along the northern coast of North America. Passage along either route would require that it is not blocked by sea ice. In summer 2009, of these two possible routes, the one across the northern coast of Eurasia was the most open and ice free (Figure 2), potentially making it more likely. In addition, if gray whale movements during migration are restricted to shallow shelf waters, with minimal deep-water crossings, the route via the Northwest Passage has a number of large barriers in the form of the Faroe–Iceland Rise and the Faroe–Shetland channels, while the Eurasian route does not require any deep-water crossings. On average, an eastern gray whale migrating south travels 127 km per day or 5.3 km/h (Mate & Harvey, 1984). At this speed, these two coastal routes would take a whale more than 100 days to travel between the Bering Strait and Israel. In contrast, if substantial deep-water crossings are not a barrier to migration, both routes shorten to around 85 days.

Investigating routes of movements within the Mediterranean

We considered two possible routes between the locations in Israel and Spain where this gray whale was recorded. One is a direct route over deep water, while the other is a coastal route passing only through shallow shelf waters. The former route is around 3000 km in length, while the latter is almost twice as long (Figure 2). As a result, while it would take an average swim speed of around 5.7 km/h to complete the direct route within 22 days, it would take an average swim speed of around 11 km/h to complete the coastal route. This is twice the typical migration speed for gray whales, making this route unlikely. As a result, the length of time between these two sightings suggests that this gray whale made substantial deep-water crossings during its movements.

Individual identification

The attempts to find a photographic match of the Mediterranean individual to catalogued eastern and western gray whales were unsuccessful. This might partly be due to

the fact that we have good quality images of the fluke and of the left dorsal ridge while many photo-identification catalogues are based on the right dorsal ridge and reflect surveys in shallow water areas where individuals do not regularly show their flukes.

DISCUSSION

Of the three considered points of origin, it is least likely that the gray whale observed in the Mediterranean is a remnant of a previously thought extinct North Atlantic population. In particular, given the extensive whaling and cetacean research conducted in the North Atlantic in the last 100 years, it seems unlikely that a population of shelf-foraging, large baleen whales could have survived almost 300 years without being detected.

Of the two possible North Pacific origins, the most likely origin is that of the eastern North Pacific. This population is much larger than the western Pacific population and eastern gray whale summering grounds penetrate higher into the Arctic waters to both the east and the west of the Bering Strait (Figure 2). As a result, vagrant individuals which moved further east or west than usual during the summer feeding period could end up in the North Atlantic. In contrast, the known summering grounds of the western population are at lower latitudes in the Okhotsk Sea and the eastern side of the Kamchatka Peninsula (Figure 2). This hypothesis is supported by the results of the photo-identification catalogue comparison. Given the high photographic coverage of the small western gray whale population and the more limited coverage of the larger eastern population, the fact that a match was not made suggests that the Mediterranean vagrant was not a western gray whale.

For a gray whale from the eastern population to migrate to the Mediterranean, it requires that there is an ample ice-free passage between the North Pacific and the North Atlantic, either across the top of Eurasia or North America. Therefore, the occurrence of a gray whale within the Mediterranean suggests that ice barriers to the movements of species between these two oceans have weakened to the point where passage between them is possible (MacLeod, 2010). While it is not yet clear whether such passage will become a regular event as sea ice continues to decline in response to climate change, this event suggests that such exchanges are becoming more feasible.

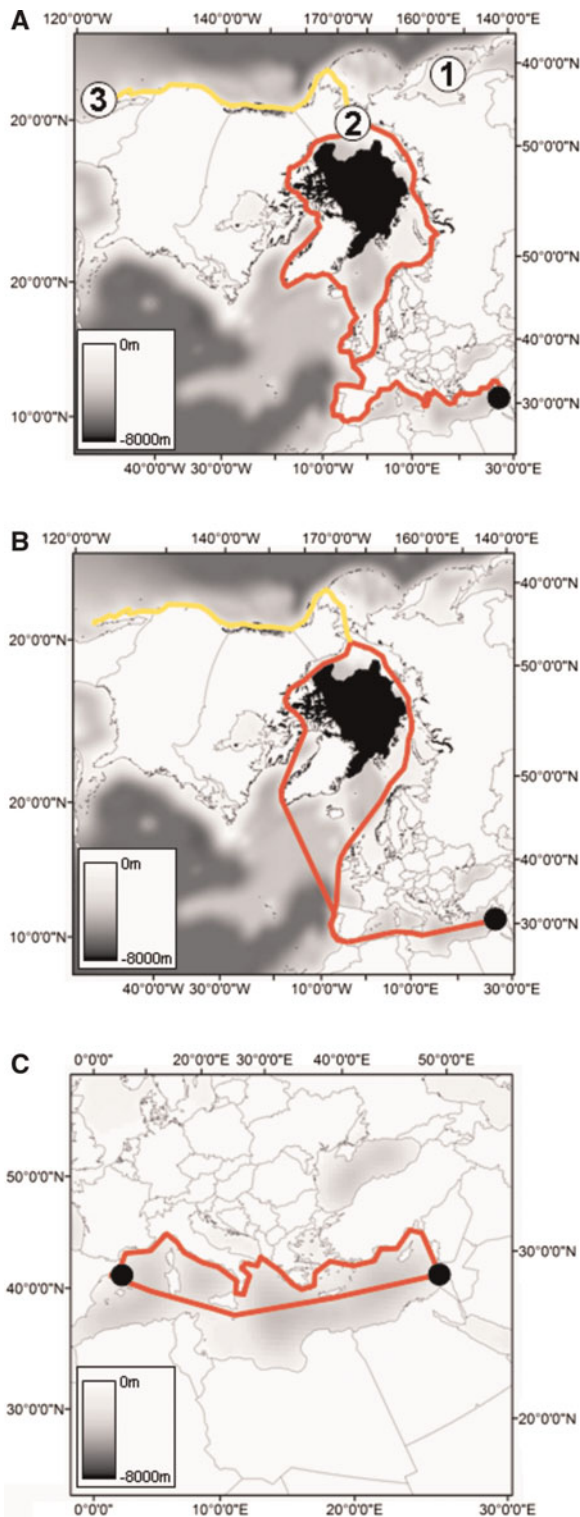

Fig. 2. (A) Possible routes from the typical summering ground of eastern gray whales in the Bering Sea if the whale remained in shelf waters as much as possible and restricted travel over deep water to a minimum; (B) possible routes allowing for extensive crossing of deep-water areas to minimize the distance travelled; (C) comparison of coastal versus shortest route between the sighting in Israel and the sighting near Barcelona 22 days later. Yellow lines: usual migration route for eastern Pacific gray whales; red lines: possible routes to reach the Mediterranean and to move between sighting locations; black circles: sightings locations in the Mediterranean; (1) summer feeding area for western Pacific population; (2) summer feeding area for eastern Pacific population; (3) winter breeding area for eastern Pacific population. Background shading represents depth. The solid black is the ice extent in September 2009.

Thus, as this species and others (such as fin, humpback, and minke whales and harp, hooded, ribbon, and spotted seals) are already predisposed to disperse and become established further northward if the current overall trend toward a warmer Arctic climate continues (Moore & Huntington, 2008), the Arctic could soon become a dispersion corridor between ocean ecosystems. Therefore, the presence of a gray whale in the Mediterranean Sea concurrently with an ice-free summer Arctic passage could potentially be considered the first manifestation of such biome mixing between the North Pacific and the North Atlantic due to global climate change.

The occurrence of new species in non-native regions is thought to negatively impact marine ecosystems in many parts of the world (Ruiz *et al.*, 1997; Hayes & Sliwa, 2003) and the spread of such species may be facilitated by changes in climate (Stachowicz *et al.*, 2002). Specifically, the breakdown of barriers between previously isolated oceans as a result of climate change, such as that which allowed a gray whale to move into the Atlantic, could result in species moving between ocean basins with implications for the well-being of native marine ecosystems (Stachowicz *et al.*, 2002). The record of this gray whale suggests that this species could potentially provide an easy-to-detect indicator of such potential exchange between the North Pacific and the North Atlantic as the Arctic ice-cap continues to shrink in response to climate change. In particular, since gray whales are a seasonally migrant species for which sea ice can act as a barrier, climate change impacts on sea ice might result in noticeable effects in their migratory behaviour, which is a conspicuous sign of ecosystem change (Laidre *et al.*, 2008). As such, gray whales are already considered ideal sentinels of the effects of climate change on Arctic ecosystems (Moore & Huntington, 2008) and this capacity could be extended to include their use as an indicator of the ease of movement of marine mammal and other species between the Pacific and Atlantic Oceans through the currently warming Arctic corridor.

The presence of this whale within the Mediterranean also provides us with novel information about gray whales. In particular, in order to make the passage between Israel and Spain in 22 days, it is likely that this individual whale made substantial directional movements over deep-water areas where it could not forage benthically. We fully acknowledge the fact that this whale was in extraordinary circumstances, likely unfamiliar with its surroundings, such that its behaviour cannot be presumed as normal. Yet, its performance suggests that gray whales, when faced with such circumstances, can utilize and potentially forage in deep water. These observations support the concept of gray whales as the most adaptable and versatile of the mysticete species (Moore & Huntington, 2008).

Finally, the arrival of this individual to the Mediterranean also suggests that gray whales may be capable of much longer movements than are exercised during their routine migrations. If we take the breeding grounds of the eastern population as a starting point and Israel as being the southeastern extent of this individual's migration route, the whale covered a minimum distance of between ~22,000 km and ~23,500 km, depending on the exact starting point in the eastern Pacific wintering grounds. Stevick *et al.* (2010) report on a humpback whale that travelled more than 9800 km from breeding areas in Brazil to those in Madagascar, setting a record for the largest geographical displacement ever documented in a mammal. Our results suggest

that the Mediterranean gray whale travelled more than twice that distance, resulting in what is by far the most extreme vagrancy known to have been exercised by a mammal.

ACKNOWLEDGEMENTS

The authors wish to thank Sea-Gal Sailing Club, Herzliya, and IMMRAC volunteers. Thanks are also due to Rodrigo Barahona and to the crew of ONAS sailboat for documenting the sighting off Barcelona. Special thanks are due to Phillip J. Clapham for valuable comments on the manuscript. We are grateful to all the catalogue-searching colleagues: Amanda Bradford, John Calambokidis, Dave Duffus, Alejandro Gómez-Gallardo U., Sergio Martinez, William Megill, Jorge Urbán-Ramírez, Steve Swartz, Olga Yu. Tyurneva, Yuri M. Yakovlev and Dave Weller and to two anonymous referees whose comments greatly helped to improve the manuscript.

INTERNATIONAL
WHALING COMMISSION

Plausibility of stock structure hypothesis 6b

Jonathan Scordino – Makah Fisheries Management

John Bickham – Professor Emeritus Texas A&M University

A workgroup of the IWC has conducted annual meetings on a range-wide review of gray whale stock structure and status since 2014 (IWC 2014). One of the primary objectives of the range-wide review was to develop one or more plausible stock structure hypotheses for use in population modeling (IWC 2014). The workgroup proposed seven hypotheses, with 12 sub-hypotheses, at the 2014 meeting based on review of Bickham et al. (2013) and discussions of the workgroup (IWC 2014a). These hypotheses were presented in table 7 of the 2017 workgroup report (IWC 2017) and are included in this paper as table 1. The workgroup decided that two of the hypotheses had low plausibility and these were excluded from further evaluation. The workgroup decided to assign low priority for modeling any of the remaining hypotheses that would use the same modeling framework as other hypotheses. In addition, low priority was assigned to hypotheses that have little to no data to test plausibility.

Table 1: List of stock structure hypotheses considered by the workgroup

A summary of the stock structure hypotheses initially under consideration (2015, 2016) and their status

Description	Status	Comment
(1) Panmixia with no matrilineal fidelity to feeding grounds - persistent A single breeding stock; no matrilineal fidelity to feeding grounds	No	not consistent with available data (IWC 2015)
(2) Panmixia with no matrilineal fidelity to feeding grounds - post-exploitation A single breeding stock exists, although multiple stocks may have existed in the past. No matrilineal fidelity to feeding grounds.	No	not consistent with available data (IWC 2015)
(3) Maternal feeding ground fidelity, one migratory route/wintering region used by Sakhalin whales, random mating (a) A single breeding stock (EBS) exists. The EBS includes three feeding groups: NFG, PCFG, WFG. SKNK is used by some whales that belong to the WFG and some whales that belong to the NFG.	High	
(b) The EBS is as described in 3a, except that NFG whales do not feed off SKNK. In addition, a WBS exists that overwinters in VSC and feeds in the OS (but not SI) and SKNK. Thus SKNK is used by both the WFG whales and the whales of the WBS.	Low	few or no data to assess plausibility (IWC 2015), but may be reconsidered during SC67a
(c) Same as 3a except that WFG whales migrating from SI to M occasionally travel through BSCS.	Medium	Sensitivity test
(d) Same as 3a except the EBS contains the original three feeding groups and a fourth feeding group that uses SEA.	Low	few or no data to assess plausibility (IWC 2015)
(e) Same as 3a except that a WBS exists that feeds in the OS (but not SI), EJPI, and KWJ and overwinters in VSC.	High	
(4) Maternal feeding ground fidelity, one migratory route/wintering region used by Sakhalin whales, non-random mating (a) Two breeding stocks exist and overwinter in M. One breeding stock includes NFG and PCFG, and the second breeding stock includes WFG whales. Separation between breeding stocks is maintained by WFG whales mating largely with each other while migrating to M.	Low	represented in the same way as other hypotheses in modelling (IWC 2015)
(b) Same as 3b except that a WBS exists and is made up of WFG whales that largely breed with each other while on migration to M.	Low	represented in the same way as other hypotheses in modelling (IWC 2015)
(5) Maternal feeding ground fidelity, two migratory routes/wintering grounds used by Sakhalin whales, random mating. (a) Two breeding stocks exist: EBS and WBS. The EBS includes three feeding groups: PCFG, North, and the WFG that feeds off SI. The WBS whales feed in SI, OS, and SKNK and then migrate to VSC to overwinter. SKNK is used by the WFG, the NFG, and the feeding whales that are part of the WBS.	High	
(b) Three breeding stocks exist. The EBS is as described in 5a. Two breeding stocks exist in the WNP. Both W breeding stocks feed in SI, OS, and SKNK but whales show fidelity to two different migratory routes (Pacific coast of Japan and eastern Sea of Japan) and use two separate wintering grounds.	Low	few or no data to assess plausibility (IWC 2015)
(6) Maternal feeding ground fidelity, Sakhalin whales use two migratory routes/wintering grounds without fidelity, random mating (a) A single breeding stock exists that uses wintering grounds off M as well as of VSC. Whales do not exhibit fidelity to a wintering ground. Three feeding groups exist: WFG, NFG, and PCFG. SKNK is used by both WFG and NFG.	Low	few or no data to assess plausibility (IWC 2015)
(b) Same as 6a, except the WFG whales largely breed with each other during migration, creating a second breeding stock. Whales from both breeding stocks overwinter in M and in VSC, and show no fidelity to a wintering ground.	High ¹	
(c) Same as 6a except that females' part of the WFG show fidelity to one of the two wintering areas (M and VSC), while males of the WFG do not show fidelity to a wintering ground.	Low	few or no data to assess plausibility (IWC 2015); modelling framework represented in the same way as other hypotheses (IWC 2015)
(7) Maternal feeding ground fidelity, Sakhalin whales use two migratory routes/wintering grounds with fidelity, non-random mating Three breeding stocks exist - a breeding stock comprised of WFG whales that migrate to M, a breeding stock (EBS) comprised of PCFG and NFG whales, and a WBS that includes whales that feed off SI and in the OS.	Low	modelling framework represented in the same way as other hypotheses (IWC 2015)

¹ Initially considered to be of low priority because modelling framework represented in the same way as other hypotheses (IWC 2015); when revisited, the Workshop determined that this hypothesis does differ from 5a, in that: (1) all catches off Japan are assumed to be Western stock animals; and (2) the abundance estimates off Sakhalin are assumed to relate only to the Western stock. Thus the Workshop agreed to change the status of this hypothesis to high priority (IWC 2017).

In 2014, the workgroup rated three hypotheses as high priority for modeling: hypotheses 3a, 3e, and 5a (IWC 2014a). Hypothesis 3a considers there to be a single breeding stock that winters in Mexico (EBS), with matrilineal fidelity to feeding grounds, and the EBS includes three feeding groups: Pacific Coast Feeding Group (PCFG), Northern (NFG), and Sakhalin (WFG). Hypothesis 3e is identical to 3a except that the Asian breeding stock is extant and feeds in the Okhotsk Sea but not at Sakhalin Island, whales that feed at Sakhalin Island overwinter in Mexico. Hypothesis 5a considers Sakhalin Island a mixed stock feeding ground with both whales that have fidelity to either Asian or North American wintering grounds.

The workgroup decided that hypothesis 3c should be included as a sensitivity test (IWC 2014a). Hypothesis 3c is structurally the same as 3a except that Sakhalin whales who migrate to North American wintering grounds occasionally use northern feeding grounds in the Chukchi Sea and are available to the Chukotkan harvest.

In 2016, the working group decided to add hypothesis 6b to the high priority list of hypotheses to model (IWC 2016). Under hypothesis 6b, there are two breeding populations of gray whales. The whales of the ENP breeding population migrate to feeding grounds in the PCFG (BCNC), Southeast Alaska (SEA), Bering Sea and Chukchi Sea (BSCS), and Kamchatka (SKNK). Whales of the WNP breeding population migrate to feeding grounds in the Okhotsk Sea (OS), Sakhalin Island (SI), and Kamchatka (SKNK). The text in table 1 from IWC (2017) states erroneously that both breeding stocks utilize wintering grounds at Mexico (M) and at Vietnam and South China Sea (VSC). As can be seen clearly in figures 1 and 2, taken from Annex D of IWC (2017), the correct wording for the hypothesis should be as follows: *ENP gray whales have fidelity to their wintering ground but the WNP breeding population has no fidelity to a wintering ground and uses both M and VCS.*

Figure 1: Hypothesized range, migratory routes, feeding grounds, and wintering grounds of the ENP population.

Clapham and Zerbini (2015) showed that it is mathematically possible that the high rate of increase observed in the Eastern Australia humpback whales was due to the SAH. They postulated that it is unrealistic for humpback whales to continue to return to largely empty wintering grounds when there is an alternative, more attractive destination available. Their suggested mechanism for whales finding the new wintering ground is through hearing the singing of the humpback whales at the more populated wintering ground, thus drawing migrating whales of the source population to the new wintering ground outside their normal migratory path.

However, the authors also note that there are reasons to be skeptical of the application of SAH to humpback whales. The simulations required an increasingly larger proportion of the source stock temporarily immigrating into the base population each year. Eventually the demand for new immigrants would exceed the supply and exhaust the source population (Clapham and Zerbini 2015). The scenario in the paper that produced a rate of growth most similar to the observed rate of increase in Australia was scenario 12. In this scenario the source population was modeled to have a negative population trend by 2015. However, recent surveys have shown that the hypothetical source population in Fiji is increasing. An issue that the authors did not discuss is the fact that, if SAH were occurring, you would expect to observe more genetic, photographic, and acoustic matches of humpback whales between the wintering grounds. For scenarios that had a rate of change of 10% or greater, between 8 and 33% of the population making up the count at the base wintering ground would be from the source population. Humpback studies have documented some mixing of individuals on the wintering grounds, but not to the scale suggested by the modeling of Clapham and Zerbini (2015). In summary, although mathematically possible, it does not seem very plausible that the SAH is occurring among humpback whales. It appears even less plausible that SAH has led to a change in the migratory behavior of WNP gray whales.

The SAH was proposed for humpback whales due to their tendency to aggregate for mating. In contrast, gray whales are thought to primarily mate during the fall southbound migration (Rice and Wolman 1971), although mating behaviors are observed on the wintering grounds and to a lesser extent on the northbound migration and on the feeding grounds (Youngson and Darling 2016). There are no reports of gray whales aggregating during migration for mating. Migrating to North America rather than Asia from Sakhalin would cost whales ~4,000 km more migratory distance and greater energetic demands than migrating to Asia (Villegas-Amtmann et al. 2017). Biologically there does not appear to be any benefit to WNP whales to change their wintering ground from Asia to North America, especially given the expectation in hypothesis 6b that they primarily mate within their own group.

Clapham and Zerbini (2015) hypothesized that the singing behavior of male humpback whales during migration and on their 'modified leks' could provide other migrants auditory clues to adjust their migratory path to a base population. In contrast to humpback whales, gray whales appear to only produce sounds when there is a need to be acoustically active (Dahlheim et al. 1984). Dahlheim et al. (1984) reported that gray whales produce sound when grouped together, when on collision course with other whales or boats, when interacting with dolphins, and when single whales are chasing a cow/calf pair. They also noted that no signals were detected in presence of courting whales (Dahlheim et al. 1984), although Youngson and Darling (2016) did record sound in the presence of gray whales they thought were mating during the feeding season off Vancouver Island, Canada. Given that generally gray whales are quiet (Cummings et al. 1968, Dahlheim et al. 1984), there is no obvious acoustic mechanism for gray whales to learn of

a new wintering ground. This is particularly true under hypothesis 6b where ENP and WNP whales are found together only at Kamchatka, whereas the majority of the ENP population is found over the vast area of the Bering and Chukchi Seas and isolated from WNP whales.

Clapham and Zerbini (2015) explored the SAH to determine if the rapid increase of the East Australia humpback population could be due to temporary immigration from neighboring source populations. There is no similar basis for exploring the SAH with respect to gray whales. The gray whale population has been monitored thoroughly since the 1970s and during that time the rate of increase of the population has been well within the biological expectation for the population (Laake et al. 2012; Punt and Wade 2012). Efforts to model the ENP population of gray whales back through the mid-1800s likewise do not show a rapid rate of increase consistent with the rate of increase observed in the East Australia humpback whale population, suggesting that immigration from the WNP did not affect population dynamics (Punt and Butterworth 2002).

It is possible under hypothesis 6b that the WNP had a long-established behavior pattern of using both wintering grounds of both Asia and North America instead of a change in behavior through the SAH. However, if that were the case, the whaling efforts that pushed the ENP close to extinction in the 1800s should have severely depressed the WNP population, making it unlikely that the whale hunting observed by Andrews in the early 1900s would have been possible. As such, it is not plausible that the WNP whales had a long-established tradition of migrating to both Asian and North American wintering grounds.

Genetic arguments on why hypothesis 6b has lower plausibility than other stock structure hypotheses are supplied in Bickham et al. (2013) for their hypothesis 5, which is essentially the same as our hypothesis 6b. They gave four reasons that their hypothesis 5 is unlikely. These include: 1) the population does not show a significant signature of a bottleneck. This is not particularly important because as they point out bottleneck tests are not very sensitive. Nonetheless, the observation of a significant genetic bottleneck would be consistent with the Sakhalin whales being the surviving remnant of the western gray whales; 2) paternity analysis revealed a high percentage of “missing fathers” within this population (Lang et al., 2010a), these likely are part of the eastern gray whale population; 3) the population possesses a number of nuclear microsatellite loci that are out of Hardy-Weinberg equilibrium which could be evidence of a Wahlund effect (mixing of populations). Thus, both points 2 and 3 are more consistent with the Sakhalin population being a mixed stock assemblage rather than a pure breeding stock.

There is likely a continuum of plausibility for the hypotheses considered (Table 1). We have already concluded that hypothesis 1 and 2, which have panmixia and no fidelity to feeding grounds, have low plausibility based on genetic and behavioral data. Based on the arguments presented in this paper hypothesis 6, and 6b in particular, should rank as low plausibility. Of the other priority hypotheses, hypothesis 3a and 5a are the most consistent with the available data and should be considered the most plausible. The plausibility of hypothesis 3e is questionable. It is doubtful that western breeding stock whales would feed in the Okhotsk Sea in all areas except near Sakhalin Island where there is abundant prey that has supported a large aggregation of feeding whales since at least the mid-1990s (Cooke et al. 2017).

Ranking the plausibility of hypotheses based on the biology of gray whales should help us improve our ability to interpret the final results of the range-wide review. We suggest focusing future discussions on hypotheses 3a and 5a since they are the most biologically defensible hypotheses. There may be value in modeling hypothesis 6b as a sensitivity test to understand what the impact would be if all of the whales caught in Asia were from the western

feeding group. Likewise, there could be value in modeling 3e for sensitivity to not having an abundance estimate of the western breeding stock. When presenting our results we should be clear that hypotheses 3c, 3e, and 6b were run as a sensitivity tests and not because they represent biologically plausible models of gray whale stock structure.

The gray whale (*Eschrichtius robustus*, Lilljeborg, 1861) as an Arctic species with seasonal migration may serve an indicator for climate changes in the Arctic (Moore and Huntington, 2008). The gray whale earlier inhabited the Pacific and Atlantic oceans and the adjacent northern seas; however, by the beginning of the 18th century, this species had been extirpated in the Atlantic (Mead and Mitchell, 1984). In the Pacific Ocean, two gray whale populations are recognized (LeDuc et al., 2002): Okhotsk–Korean and Chukotka–Californian. The Okhotsk–Korean population spends summer in the Sea of Okhotsk, while the Chukotka–Californian population summer feeding grounds lie mainly in the Arctic between 174° E and 130° W in the Bering, Chukchi, and Beaufort seas; there are records of the gray whales visiting the East Siberian Sea (Rice, 1998). In the summer months of the years with poor ice conditions, individual gray whales were sighted near the mouth of the Kolyma River (Bogoslovskaya, 2002) and even more westward, “on the approach to the New Siberian Islands” (Matishov et al., 2000), namely, according to the map scheme in the publication, between 153° E and 158° E. In the fall, the Chukotka–Californian population migrates southward, crosses the Pacific Ocean, and descends along the North American coast to California and Mexico to their reproduction area; and in the spring these whales again cross the ocean to return to the north, to the coasts of Kamchatka and Chukotka (Swartz et al., 2006).

Recently, the gray whale was again recorded in the Atlantic basin. On May 8, 2010, an individual of this species was observed in the Mediterranean Sea off the Israeli coast and, three weeks later, near the coast of Spain. The proposed explanation, supported by many specialists, was that this gray whale had entered the Mediterranean Sea by the Northern Sea Route (Scheinin et al., 2011). No matter what brought this gray whale to the Mediterranean, its migration along the northern Eurasian coast became possible due to a

considerable reduction in the ice-covered area in the Arctic.

In September–October, 2011, a series of observations on marine mammal distribution was conducted under the White Whale Program onboard the RV *Mikhail Somov* in the White, Barents, Kara, and Laptev seas.

The observations were conducted from a platform located at 18 m a.s.l. At the beginning of each shift, as well as additionally in the case of changing conditions, the meteorological parameters (cloud cover, presence/absence of precipitation, wind direction and force) and quality of visibility (sea state according to the Beaufort scale, presence and position of the sun glare, and general estimate of visibility according to five-point scale) were recorded. When marine mammals were sighted, the species, number, vessel GPS coordinates (using a Garmin 60csx) at the moment of detecting animals, distance to the animals, and bearing angle relative to the vessel course were recorded, as well as their behavior when possible. The animals were photographed with a Nikon D300S camera equipped with Nikkor 80–200 mm f2.8, 70–200 mm f2.8, 18–200 mm f3.5–5.6 lenses; a Kahles 10 × 42 binoculars was used for species identification.

On September 23, 2011, observer O. Shpak sighted two whales at 2:40 a.m. UTC (13:40 local time). At that moment, the vessel was 90 km to the west of the northern part of Kotel’nyi Island (New Siberian Islands) and kept westward. The GPS coordinates for the vessel position at the moment the whales were detected were 76°06.8' N and 134°47.5' E. The animals were sighted right ahead at a distance of 1.5 km from the vessel and were approaching (moving eastward) being close to one another. The precise distance between the individuals was not possible to detect, but their mutual position was assessed as “next to each other.” The weather was good for observation: air temperature, 7°C; pressure, 1008 hPa; 50% cloud cover; sea surface state at Beaufort scale, 2; sea

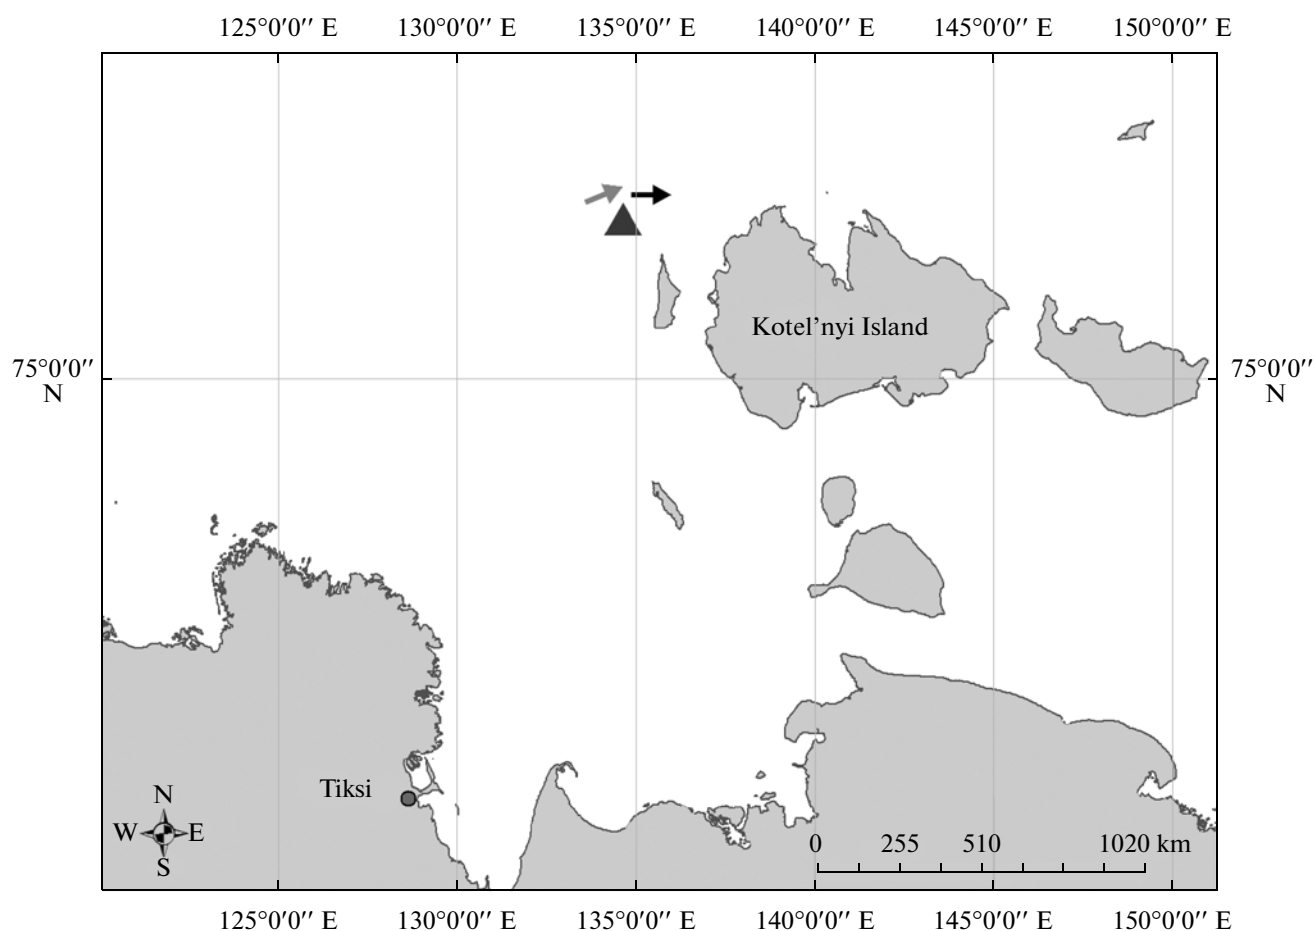

Fig. 1. The site where gray whales were encountered in the Laptev Sea (denoted with triangle). Arrows show the directions of their athwartships movement (signs are not scaled).

swell, 1–1.5 m; the sun glare at 8:00–8:30 o'clock relative to the vessel course; and total visibility according to five-point scale, 5–. When approaching the vessel, the whales separated, one of them passed by the portside retaining its previous direction, while the other individual turned by 20°–30° and passed by the starboard at approximately half a kilometer from the vessel (Fig. 1).

Athwartships, the former whale was at a distance of approximately 100 m from the observer and was photographed several times. Although the whale's position during hyperventilation coincided with the sun glare, and correspondingly, its images were taken against a back light, these photos nonetheless allow for confirmation of its species (Fig. 2). The second whale was too far from the observation platform for sufficient quality photography; and only the cloud of its blow was photographed. In its external appearance (observation with binoculars) and the shape of the blows in photos, the second whale appeared similar to the first individual.

As compared to the other gray whales sighted by the observer in the Sea of Okhotsk, the one that passed near the vessel was darker and had no pronounced light spots (dark uniform coloration is, possibly, an observation artifact due to the back light). A poorly noticeable neck depression, a blow in a shape of a woolpack, and, most importantly, the dorsal ridge knuckles, later detected in the photos, prove that the whale photographed in the Laptev Sea belonged to the species *Eschrichtius robustus*. All observations allow us to attribute the second individual to this species as well.

The whales reacted to the vessel (hull length, 133 m; the speed at the moment of encounter, 16 km/h) in the following way: the first whale displayed no anxiety, advanced to the vessel, and then passed by its side, surfacing several times and spouting water while exhaling. The whale's body condition looked normal (Fig. 2). The second whale, although it deviated from its initial course upon the vessel approach and passed by at a considerable distance, also surfaced several times

Fig. 2. A gray whale in the Laptev Sea. The inset shows the dorsal ridge knuckles characteristic of the gray whale.

while athwartships. Thus, the whales' reaction to the vessel may be regarded as neutral.

This observation is the first documented encounter of the gray whale in the Laptev Sea, which is over 500 km farther from the earlier recorded western boundary of the species penetration, the East Siberian Sea (Matishov et al., 2000). It is also interesting that this encounter took place at the end of September rather than at the beginning of the Arctic summer when several weeks or even months of open water are ahead, and the whales may move westward along the continent with a low risk. Presumably, in recent years, the trend of an expansion in the summer distribution range of this species is observed, and the visits of the gray whale to the East Siberian and Laptev seas is no longer an extraordinary event, while the small number of encounters may be explained by a very low intensity of the studies in the Arctic.

The described observation conforms well to the hypothesis on the migratory route of the "Mediterranean" gray whale along the Eurasian coast via the Northern Sea Route, and favors an interhemispheric dispersal of marine organisms through the Arctic corridor.

Taking into account the current changes in the distribution of Arctic and Subarctic species (ACIA, 2005), monitoring of marine animals in the Arctic

seas has acquired paramount importance. This implies the presence of qualified observers onboard the ships cruising along the Northern Sea Route and in the Arctic as well as establishment of a network of observers from the staff of polar meteorological and hydrographic stations, supplying of ship crews with descriptive material for species identification, and stimulation of their interest in studying Arctic fauna.

ACKNOWLEDGMENTS

This work was performed under the White Whale Program for studying the beluga whale distribution and migration by the Permanent Expedition of the Russian Academy of Sciences for Studying Animals of the Red Book of the Russian Federation and Other Key Species of Russian Fauna with financial support by the Russian Geographic Society.

ABSTRACT

Since 2002, annual photo-identification (photo-ID) research of gray whales offshore Sakhalin Island has been conducted by the Institute of Marine Biology, Far East Branch, Russian Academy of Sciences (IBM FEB RAS). Two main feeding areas were studied offshore Sakhalin Island (Piltun and Offshore) and one area along the Kamchatka coast (Olga and Vestnik Bay). This paper reports the data collected in the summer and fall of 2011 and compares results to data collected since 2002.

In 2011, the data of the IBM FEB RAS photo-ID team were supplemented with the data obtained within the joint research program of A.N. Severtsov Institute of Ecology and Evolution, Russian Academy of Sciences (IPEE RAS) and Oregon State University (OSU) of the Okhotsk-Korean Gray Whale (*Eschrichtius robustus*) population habitat using satellite telemetry, which is coordinated by International Whaling Commission and funded by Exxon Neftegas Limited and Sakhalin Energy Investment Company (hereinafter referred to as the satellite tagging program). The latter team photographed 192 whales, including repeat sightings, of which 94 individuals were identified. Of these, 13 individuals were not recorded by the IBM team in 2011; 30 individuals were identified only by the IBM team and not seen by the satellite tagging program team.

In 2011, a total of 124 whales, including 15 calves (including 13 calves and 2 possible calves) were documented in the Sakhalin area and 30 individuals (including 2 calves) were recorded in Olga Bay (Kamchatka). A total of 12 whales from the Sakhalin GW catalogue were identified in Olga Bay (Kamchatka) and one whale was registered in both regions during the same season of 2011. Five whales from Sakhalin catalogue were registered in Vestnik Bay (Kamchatka) by another research team, three of these were found on Sakhalin shelf in the same season of 2011. Thus, during the 2011 field season, a total of 137 whales were documented off Sakhalin and Kamchatka. Currently, there are a total of 205 identified whales in the Sakhalin GW Catalogue maintained by the IBM team, and 150 whales in the Kamchatka GW Catalogue.

KEY WORDS: WESTERN GRAY WHALE, PHOTO-ID, DISTRIBUTION, COW-CALF, SAKHALIN, PILTUN, KAMCHATKA, OIL AND GAS.

Introduction

From 2002 to 2011, photo-ID studies of the endangered population of western gray whales (*Eschrichtius robustus*) have been conducted annually offshore northeast Sakhalin Island as part of an industry-sponsored monitoring program jointly funded by the Sakhalin-1 and Sakhalin-2 oil and gas development projects, operated by Exxon Neftegas Limited (ENL) and Sakhalin Energy, respectively. Two main feeding areas utilized by whales during the ice-free season have been identified along the northeast Sakhalin coast: the nearshore Piltun feeding area

adjacent to Piltun Bay (52°40' N to 53°30' N), where whales predominantly feed in shallow waters <20 m depth, and the Offshore feeding area approximately 30-40 km east of Chayvo Bay (51°50' N. to 52°25' N), where whales feed in greater water depths of 35-60 m (Fig. 1).

The discovery of the Offshore feeding area in 2001 gave the IBM research team an opportunity to gather evidence on whale movements between the two (Piltun and Offshore) feeding areas off Sakhalin Island (Maminov and Yakovlev, 2002). Observations of solitary gray whales within the range of the Offshore area were reported before 2001 (Sobolevsky 2000; Miyashita *et al.* 2001) and it is possible that the Offshore area was used as a feeding ground by gray whales before 2001. However, whale sightings in the Offshore area prior to 2001 were sporadic. Photo-ID of gray whales in the Offshore area was initiated in 2002 (Yakovlev and Tyurneva 2003) and demonstrated that some of the individuals observed in this area were also observed in the Piltun feeding area during the same year. Photo-ID research in subsequent years confirmed the existence of intra- and interannual exchange of whales between the Piltun and Offshore feeding areas (Yakovlev and Tyurneva 2005, 2011; Tyurneva *et al.*, 2009, 2011a,b; Yakovlev *et al.*, 2009, 2011).

Since 2006, gray whales have also been identified feeding along the southeast coast of the Kamchatka Peninsula. Gray whales were observed in Nalycheva Bay (2004) in water depths of about 30 m, in Vestnik Bay (2006, 2007, 2009) in water depths of about 15-24 m, and in Olga Bay (2006-2011) in water depths of about 5-17 m (Tyurneva *et al.* 2009, 2010a; Yakovlev *et al.* 2012). Since 2005, a number of individuals from the IBM Sakhalin catalogue have been recorded near the coast of the eastern Kamchatka Peninsula (Yakovlev *et al.* 2009, Tyurneva *et al.* 2010a,b). To reach Sakhalin from Olga Bay, tagging studies have shown that whales swim along a direct (i.e., straight line across the Sea of Okhotsk) route of ~ 1500 (Fig. 1) (<http://mmi.oregonstate.edu/sakhalin2010Map>).

In 2005 and 2007, individual whales were observed by the IBM team over an extended period of time, i.e. over most of the feeding season. The physical condition in some underweight whales was observed to improve over the course of the feeding season (Yakovlev and Tyurneva 2006; Yakovlev *et al.* 2007). Improvement in the whales' physical condition was also recorded throughout the field seasons of 2008 -2011 (Yakovlev *et al.* 2009b; Tyurneva *et al.* 2010b).

Visual assessment of (presumed) indicators of health such as skin anomalies, body conditions, etc. have been used to monitor the overall health of individuals, which is used as an indicator of the health of the entire population. Photo-ID research is instrumental in monitoring skin condition, including skin sloughing and white patches (blotches), and barnacle load on the skin. For example, white patches or blotches on skin surface have been observed in Gray Whales

although these are poorly understood and their origins are still unknown (Tombach Wright *et al.* 2007).

When multi-annual photo ID data sets are available individuals expressing changes in skin condition over time (e.g. intra and inter seasonal) can be visually monitored through multiple resightings. Repeat encounters allowed the researchers to track the dynamics of the condition throughout the season and between seasons

Methods

During the 2011 feeding season, photo-identification of gray whales took place on the northeastern shelf of Sakhalin and in Olga Bay in southeastern Kamchatka. In the Offshore feeding area off Sakhalin whales were not photographed from "Zodiac" due to technical limitations. Photographs were obtained opportunistically from the deck of the vessel. During marine mammal surveys in the Offshore area MMOs reported the presence of a significant number of gray whales by the end of field work.

In 2011, in addition to the IBM team, the satellite tagging program team photographed whales opportunistically while carrying out their primary task of placing tags on candidate whales. Hence two teams performed photo-ID surveys. Photographs of the satellite tagging program team were included in this report as well.

In 2011, no work was planned in Vestnik Bay as part of the annual Gray Whale Study Program, but as a result of pilot studies associated with another project, gray whale photographs taken in Vestnik Bay in 2011 were obtained. These materials were given to the IMB photo-ID laboratory for identification and permission was obtained to use them in this report.

Field photo-ID procedures used by the IBM team offshore Sakhalin Island since 2002 are based on IWC recommendations for photo-ID work of marine mammals (Hammond *et al.* 1990). The research vessel *Akademik Oparin* was the base vessel for the photo-ID research, with the actual work conducted from a 3.8 m long Zodiac launched from the vessel. On scheduled photo-ID days, weather and sea conditions permitted, the Zodiac was deployed from the mother vessel whenever gray whales were sighted. The whales' position (computed from the GPS position of the Zodiac), the time, behavior, number of whales in the group, direction of their movement, the presence of other groups of gray whales, killer whales and passing vessels, airplanes, or helicopters, and presence of mud plumes in the observation area were documented.

A Nikon D2X digital camera with a fixed 300 mm f/4 telephoto lens or a Nikkor 80-400 mm zoom lens with image stabilizer (IS) was used for photography. The photographs were

recorded at a high resolution in large JPEG and RAW format. An attempt was made to photograph all aspects (head, flanks and flukes) of each whale. A whale was photographed in sequence, from head to fluke on both the right and left sides, and the dorsal and ventral fluke surfaces. Priority was given to photographing the right and left sides of each whale, as fluking frequency varies with individual behavior and foraging depth. Preference was given to photographing the right sides (flanks) of whales as right sides have been arbitrarily chosen among gray whale researchers as a baseline identifier. Matchable right side photographs are required for an individual whale to be included in the photographic identification catalogues. A matchable quality photograph for photo-identification of gray whales is any photograph of the appropriate region of the body (aspect) that can be reliably identified as belonging to a particular individual whale when compared to other photographs of the same target region of that same whale.

Annual photo-ID research conducted in Olga Bay, Kamchatka Peninsula, by the Kronotsky State Biosphere Reserve, (Fig. 1), used vessel-based field procedures similar to those used in the Piltun and Offshore feeding areas along Sakhalin Island. A Canon 40D digital camera equipped with Canon 75-300 mm zoom lens with IS was used. All photographs were taken at the highest resolution and saved in JPEG format. To recognize whales by their distinguishing marks on their sides and flukes, standard IWC-recommended methods were applied (Hammond *et al.* 1990). Confident left-to-right side matches were established based on the following criteria: (1) the whale was photographed as a solitary individual; (2) sequences of the left and right sides were compared with flukes in common for a single sighting; and (3) as a final check to compare matches and assist with right to left matches, whale knuckle height, spacing and ratios were considered (Calambokidis *et al.* 1999; Weller *et al.* 2002). Whale body coloration and pattern of spots served as the basic feature for whale identification; scars and barnacle spots were used as additional features for comparison. Whales identified offshore Kamchatka Peninsula were assigned catalogue numbers KamGW# in the Kamchatka catalogue, and whales identified offshore Sakhalin Island were assigned catalogue numbers KOGW# in the Sakhalin catalogue. Whales identified in both regions carry two (KamGW# and KOGW#) catalogue numbers and appear in both the Kamchatka and Sakhalin catalogues.

Cow/calf pairs were recorded in accordance with methods outlined in the 2010 annual report (Yakovlev and Tyurneva, 2011). Analysis of photo-ID data also incorporated the identification of whales with deviations from the “physiological norm”. Such deviations included: (1) emaciation (“skinny” whales); and (2) obvious sloughing of skin or other anomalous skin conditions.

Results

The main results of the photo identification studies in 2011, combined with results from previous years, are as follows:

Catalogue Overview

The Sakhalin WGW Catalogue now contains 205 individual gray whales. Some of these whales were registered repeatedly over several years, whereas others (18 whales) are new to the catalogue.

The Kamchatka catalogue consists of photographs of animals observed in three areas - Khalaktyrskiy Beach, Vestnik Bay and Olga Bay - during 2004 and 2006-2011. At present, this catalogue contains 150 fully gray whales. A total of 84 whales were also observed on Sakhalin shelf during various years. It is yet unclear where the other 66 animals photographed near Kamchatka Peninsula reside during the feeding season, since they are not identified in the Sakhalin catalogue.

Whales Identified in 2011 on Both Sakhalin and Kamchatka Shelves

In 2011, between August 19 and October 19, 124 whales were observed off the shore of Sakhalin by the two research teams. This number is higher than in 2008 (98 whales), 2009 (117 whales), and 2010 (105 whales), but comparable with 2007 (125 whales), and the high number might have been a result of a long observation season and the efforts of two combined photo-ID teams (2011) as there is a correlation between the length of the studies and the number of whales sighted. The IBM team recorded 233 whales, including repeat sightings, with 111 individuals identified. The satellite tagging program team photographed 192 whales, including repeat sightings, of which 94 individuals were recognized. Thirty individuals were identified only by the IBM team and not seen by the satellite tagging program team, while 13 individual whales were not recorded by the IBM team during the 2011 expedition.

In 2011, 18 new gray whales, including 15 calves, were identified off Sakhalin. Two of the adult animals were first sighted in Olga Bay (Kamchatka), and had only been recorded there until 2010 when they were first seen near Sakhalin. One of the new whales was recorded for the first time in the northern part of the Sea of Okhotsk and in subsequent years was recorded only in Olga Bay (Kamchatka).

Between July 22 and August 8, 2011, 30 whales including 2 calves were sighted in Olga Bay, Kamchatka. This number is lower than in 2010 (82 whales), 2009 (75 whales) and 2008 (50

whales) (Table 1). This might have been due to a later start to the field season and briefer study period compared to previous years (Table 1, fig. 2).

Twenty-one of these 30 whales were already known, having been observed previously in Olga Bay. The other 9 were new to Olga Bay; 2 of them had previously been seen off NE Sakhalin. Twelve of these 30 whales were registered in the Sakhalin WGW catalogue. Of the 30 whales identified in Olga Bay (Kamchatka) in 2011, only two whales were registered near Sakhalin later in the season. Ten whales had been seen in Sakhalin in previous years but were not sighted in 2011.

Every year since the start of the surveys in Olga Bay in 2006, researchers have identified some whales that had been registered as calves in Piltun area in the previous years. Three of the five calves registered in the Sakhalin shelf in 2008 were identified in Olga Bay in 2009. In 2009, out of eight calves observed in Olga Bay (of which only one was sighted in Olga Bay in 2010), five were recorded off Sakhalin. Not a single calf encountered in Piltun in 2010 was encountered in 2011 in Olga Bay, but five yearlings were identified on the Sakhalin shelf that had first been sighted in 2010.

In 2011, no work was planned in Vestnik Bay as part of the annual Western Gray Whale Monitoring Program, but as a result of pilot studies associated with another project, gray whale photographs taken in Vestnik Bay in 2011 were obtained. These materials were given to the IBM photo-ID laboratory for identification and permission was obtained to use them in this report.

In 2011, two days, May 8 and May 16, were spent in Vestnik Bay. As a result 847 images were shot of six individual whales, five of which had already been identified in the Sakhalin catalogue, of which two whales had not been encountered on the Sakhalin shelf in 2011. Three of the five were observed in the Piltun and Offshore areas in 2011. Two whales were new to the Kamchatka catalogue. One of these two had previously been observed in Sakhalin and was assigned a dual identification number and one whale was new to both catalogues. None of the 6 whales seen in Vestnik Bay was also seen in Olga Bay in 2011.

In 2011, a total of 137 individual whales (out of 205 whales contained in the IBM Sakhalin catalogue of gray whales) were recorded off both Sakhalin and Kamchatka. The total number of identified gray whales included in the Kamchatka and/or Sakhalin catalogues in 2011 alone was 156 whales, 120 of which were registered only on Sakhalin shelf, 32 only off the shore of Kamchatka (13 of which have been registered in the Sakhalin catalogue in the previous years), and 4 were seen in both locations.

Migration of Gray Whales between Feeding Areas in 2011

For this section on migration between different feeding areas only data obtained by the IBM team was used, since the satellite tagging program team did not record the location of whales. The 13 whales photographed only by the satellite tagging program team were encountered in coastal areas (Piltun and Chayvo areas).

In 2011, of the 111 animals identified by the IBM team, a total of 89 whales were identified in the Piltun feeding area, of which 74 were observed only in this area. A total of 14 individuals were identified in the Offshore feeding area off Sakhalin Island, of which nine whales were observed in that area only.

In the Offshore area, a smaller number of whales was identified in 2011 compared to most of earlier years (Table 2), which can be attributed to a reduction of survey effort designated for photo-ID in the Offshore area due to (a) a shorter field season and (b) a new increased satellite tagging program effort in the Piltun area. For this last reason, the vessel could not leave the coastal areas to conduct work in the Offshore area from August 23 to September 21. After the satellite tagging program team completed their work, worsening weather conditions and a tight work schedule for executing other expedition tasks did not allow the IBM team to perform Zodiac-based surveys in the Offshore area. In contrast to 2010, whales were registered in the Chayvo area in 2011; 35 whales were photographed off Chayvo, including repeat sightings. Of the 23 identified individuals, 14 were photographed only in this area, based on the data collected by the IBM team (Table 2).

During the 10 years of the study (2002-2011), out of a total of 205 whales currently included in the IBM catalogue, 99 whales were identified in both the Piltun and Offshore feeding areas over the years. In addition, 102 individual whales were sighted only in the Piltun area and 3 individual whales were sighted only in the Offshore area. One whale was photographed near Cape Elizabeth in 2005 and was never seen since. In all the years of the study, 12 individuals have been encountered near Okha, all of these have been sighted in other areas as well.

In 2011, the number of whales, which used both Kamchatka and Sakhalin regions within the same season, was substantially lower than before. Of the 82 whales identified in Olga Bay (Kamchatka) in 2010, 25 whales were spotted near Sakhalin later in the season, while in 2011 out of 30 whales, only 4 whales were registered in both regions (Fig. 2). This can be explained partly by a later start of the field season in Kamchatka in 2011 compared to the three previous years.

During all these years, cow/calf pairs were registered only in the Piltun area and not in the Offshore area. Cow/calf pairs have recently been observed in Olga Bay as well.

The dynamic nature of the utilization of available feeding grounds offshore Sakhalin by gray whales appears to be a normal behavior aimed at exploiting ever-changing forage habitat.

Body Condition

Since 2005, data have been collected to monitor gray whales' body condition (BC) within and between feeding seasons. If the BC of a particular whale improved upon subsequent observation, then the data used in calculations of the number of visually malnourished animals was based on the latest observation. In 2011, 33 whales with poor body condition (BC) were identified, including 7 nursing females. This constitutes 20.7% of the total number of identified animals (111 individuals – data of the IBM group). All calves observed during these years were physically normal (BC 0). According to our observations, 9 whales improved their BC during the 2011 study period.

In Olga Bay, 20 of the 30 whales (66.6%) showed poor BC. Two of these were nursing females in 2011. Yearly we recorded high percentage of gray whales with poor body conditions near Kamchatka versus Sakhalin (Yakovlev *et al.* 2012), which may be explained by the early photo-identification survey period, as whales have just arrived to the feeding grounds from their winter-long fast and have not had time to accumulate body fat.

Cow/Calf Pairs

In 2011, 7 cow/calf pairs and 8 calves without mothers (15 calves in all) were recorded off Sakhalin, which is the highest number of calves ever recorded over a season. Cow/calf pairs were first sighted on August 21, 2011. One of the photo-identified mothers was sighted with a calf for the first time; the other six had been recorded with calves in prior years. Eight calves unaccompanied by cows were encountered either near females who were not their mothers or in calf groups.

Two cow/calf pairs were recorded in Olga Bay (Kamchatka) in 2011. Both cows were sighted only in Olga Bay (Kamchatka). One of them had been there with a calf in 2009. These data show that the Piltun area of the Sakhalin shelf is not the only feeding area for cow/calf pairs and that another foraging, and potential “nursery”, ground is located in Olga Bay.

CONCLUSIONS

Based on the reproductive success, the number of animals observed, and the ability to recover after malnourishment or skin abnormalities, it can be concluded the population is in satisfactory state of health.

In 2009-2011 a total of 182 KOGW individuals, including calves, were observed by IBM teams (Sakhalin and Kamchatka regions).

ACKNOWLEDGMENTS

These studies were supported and funded by the Sakhalin-1 and Sakhalin II projects operated by Exxon Neftegas Limited and Sakhalin Energy Investment Company, respectively. We would especially like to thank Jennifer Dupont and Mike Jenkerson (ExxonMobil Upstream Research), Mike Swindoll, and Ervin Kalinin (Exxon Neftegas Limited), and Koen Broker (Shell Global Solutions International) for providing support in organizing and conducting the expedition. Jennifer Dupont, Aleksei Vladimirov (Sakhalin Energy), Koen Broker, Yuri Bychkov and Sergey Yazvenko (LGL Limited) for providing valuable comments and editing revisions; and Ye. P. Shvetsov, K. A. Drozdov, A. Yu. Yakovlev, and O. A. Miroshnikova for assistance with data processing. We would also like to thank A.N. Severtsov Institute of Ecology and Evolution Russian Academy of Sciences and Oregon State University for providing photographs obtained in the course of the satellite tagging program.

ABSTRACT

Photographs of 217 identified gray whales obtained from the Sakhalin Island, Russia feeding grounds were compared with 6,546 photo-identified individuals from the Baja California Peninsula, Mexico breeding lagoons to identify matches between these two populations. A total of 13 matches of individuals were found, including six males, five females and two of unknown sex. Twelve whales had sightings prior to and after to their respective sighting in Mexico. Twelve whales were observed in Laguna San Ignacio and one in Laguna Ojo de Liebre. Ten of the 13 whales were photographed in Mexico only in one year and the other 3 in two years. Twelve whales were sighted in Sakhalin in the summer of 2011. Eleven whales were sighted in consecutive seasons, eight of them in three consecutive seasons (summer-winter-summer), three in two seasons (summer-winter), and four in two seasons (winter-summer). Three whales were sighted the same day in Laguna San Ignacio suggesting that these animals were traveling in association with each other. Four females with calves were sighted in the winter in Mexican waters and in the next summer off Sakhalin, three of them without calves suggesting that these females had either separated from their calves or that their calves did not survive. The time between the last sighting in one season and the first one in the next season was $\bar{x}=195.4$ days ($n=11$, 141-255) during the summer-winter migration, and $\bar{x}=150.9$ days ($n=12$, 131-213) during the winter-summer migration. The matches made between whales sighted off Sakhalin and the Mexican Pacific are the first results of the multinational collaboration "PACIFIC WIDE STUDY ON POPULATION STRUCTURE AND MOVEMENT PATTERNS OF NORTH PACIFIC GRAY WHALES" initiated under the coordination and support of the International Whaling Commission last year.

INTRODUCTION

Recent results of genetic and photographic identification comparisons between western and eastern North Pacific gray whales (see IWC, 2011) suggest a mixing of these populations during the winter reproductive season, and illustrate the great conservation and management importance of a more comprehensive examination of gray whale movement patterns and population structure in the North Pacific. The Scientific Committee recommended that a collaborative Pacific-wide study be developed

under the auspices of the IWC, recognising that *inter alia* this will contribute to the Committee-endorsed Conservation Plan for western North Pacific gray whales and incorporate previous recommendations made by the Committee. Such a study will involve collaborative analysis and sharing of existing data as well as the collection of new data. This report summarizes the results of the “(Phase 1) photo-identification project”. The purpose of this project was to undertake a comparison of two western gray whale catalogues from Sakhalin Island, Russia with the Mexican gray whale catalogue.

METHODS

The comparison was done based on two catalogues of photo-identified gray whales from Sakhalin Island and one catalogue of gray whales from Laguna San Ignacio and Laguna Ojo de Liebre on the west coast of the Baja California Peninsula, México.

The Sakhalin catalogues

The first step was to compare the two catalogues available at that moment:

1) The Russia-US catalogue (2012).

Burdin, A. M., Weller, D., Sychenko, O., and Bradford, A. 2012. “*WESTERN GRAY WHALES OFF SAKHALIN ISLAND, RUSSIA: A CATALOG OF PHOTO-IDENTIFIED INDIVIDUALS*”.

205 individuals. Period 1994-2011

2) The IBM catalogue.

Tyurneva, O. Yu. and Yakovlev, Yu. M. 2010. “*THE WESTERN PACIFIC GRAY WHALES OF SAKHALIN ISLAND 2002-2008, LEARNING ABOUT A POPULATION OF WHALES THROUGH PHOTOGRAPHS*”.

165 individuals. Period: 2002-2008

As result of these comparisons 217 photo-identified gray whales from Sakhalin were used in the comparison with the Mexican catalogue. All are represented by the right-side dorsal flank and 215 are associated with the left-side dorsal flank

The Mexican catalogue

This catalogue includes 6,546 gray whales. 5366 photo-identified in Laguna San Ignacio between 1993 and 2011, and 1180 in Laguna Ojo de Liebre (Scammon’s Lagoon) between 2001 and 2003. Of the 6,546 whales in the catalogue 5,890 are represented by a right-side of the dorsal flank image and 1,837 were associated with a left-side dorsal flank image (Table 1).

Total	6546	1181	4709	656	

RESULTS.

The Sakhalin to Mexico catalog comparison resulted in a total of 13 confirmed matches of individuals, including six males, five females and two of unknown sex. Twelve whales had sightings prior and after to their respective sighting in Mexico. Twelve whales were observed in Laguna San Ignacio and one (#3) in Laguna Ojo de Liebre. Ten of the 13 whales were photographed in Mexico only in one year and the other 3 in two years. Twelve whales were sighted in Sakhalin in the summer of 2011 (Table 2).

All 13 whales were sighted in consecutive seasons, eight of them in three consecutive seasons (summer-winter-summer), three in two seasons (summer-winter), and five in two seasons (winter-summer). Whale #2, male, was sighted in summer-winter (2006-2007), and summer-winter-summer (2009-2010); the whale #9, female, was sighted in summer-winter-summer (2006-2007), and in the winter-summer (2011); and the whale #11, was sighted in summer-winter-summer (2007-2008), and in the summer-winter (2009-2010) (Table 3).

The whales #5, #6 and #12 were sighted the same day, February 24 2006, and whale # 20 was sighted two days later in Laguna San Ignacio. The whales #5 and #12 were in the same group and #6 in a different group, suggesting that these animals were traveling in association with each other (Table 3).

The five known females were sighted with calves in the winter in Mexican waters and in the next summer in their feeding grounds, three of them without calves (Table 3), suggesting that these females had either separated from their calves (e.g. weaned) or that their calves did not survive (e.g., due to predation).

The female #7 was observed with calf in March 11, 2009 in Laguna San Ignacio and 122 days later, on July 11, off the Kamchatka Peninsula where she stayed with her calf at least until September 2.

The time between the last sighting in one season and the first one in the next season was $\bar{X}=195.4$ days ($n=11$, 141-255) during the summer-winter migration, and $\bar{X}=164.3$ days ($n=13$, 122-213) during the winter-summer migration. The shorter time between Laguna San Ignacio and Sakhalin was of the whale #13, of unknown sex, with 131 days followed by the whale #4, a male, with 139 days, and the whales #8 and #11, mothers with calves, with 144 and 143 days respectively (Table 3).

Table 2. Sighting summary information for 13 gray whales matched between Sakhalin and Mexico. * = With calf.

DISCUSSION

The 13 individuals sighted in Mexican waters represent about 10% of the western gray whale population based on the population assessment of an estimate of 130 individuals (90% Bayesian CI = 120-142) (Cooke *et al.* 2008). If we combine these matches with the six matches found off the coast of Vancouver Island reported by Weller *et al.*, (2011), presumably during their migration from the breeding lagoons along the Mexican coast, and the two genetic matches noted by Lang *et al.*, (2011) with whales sampled in southern California, a total of 21 whales identified as part of the western gray whale population have migrated, at least in some years, to the eastern North Pacific during the winter breeding season.

The presence of three of these whales the same day in Laguna San Ignacio, two in the same group, indicate that these whales may travel in association or in groups, as Weller *et al.*, (2011) observed

based on six matches off Vancouver Island, British Columbia, Canada. This also suggests that these whales may stay together in groups while on the breeding grounds.

The sex of the whales (six males, five females and two of unknown sex) indicates that both sexes, in approximately equal numbers, migrate to Mexican waters during the winter breeding season.

The sighting of females without their calves on the Russian feeding grounds suggests a high mortality of the calves, based on the small sample of four mothers with calf sighted in Laguna San Ignacio and the next summer off Sakhalin and one off Kamchatka (i.e., only a 40% survivorship). The long distance of their migratory destination compared to the Bering and Chukchi Seas could be an important factor in the survivorship of the calves. Alternatively, these females may have separated from their calves as the normal weaning process when the calves were of sufficient age to begin foraging for themselves.

The number of days between the last photograph of the season and the first one of the next season represents the maximum migration time and depends on the presence of the whale, the chance to find and photograph it, and the field work seasons of the different research teams. The shorter times observed between Laguna San Ignacio and Sakhalin, 131-143 days, could be close to the real migration times of these whales.

The matches made between whales sighted off Sakhalin and the Mexican Pacific are the first results of the multinational collaboration "PACIFIC WIDE STUDY ON POPULATION STRUCTURE AND MOVEMENT PATTERNS OF NORTH PACIFIC GRAY WHALES" initiated under the coordination and support of the International Whaling Commission last year. Additional comparisons and analyses of photographs from the Western and Eastern gray whales are ongoing and will include photographs from the IBM Sakhalin catalogue 2008-2011, IBM Kamchatka catalogue, and from Laguna San Ignacio and Bahia Magdalena winter aggregation and breeding areas, obtained during the winter 2012.

Acknowledgements

We wish to thank our field researchers and colleagues that assisted with the documentation of the gray whales in Laguna San Ignacio and Laguna Ojo de Liebre. We also thank The Ocean Foundation, and the World Wildlife Fund-Mexico for their support of the field work and analysis of our results. This research was conducted as part of the Laguna San Ignacio Ecosystem Science Program (LSIESP) under special scientific research permits No.SGPA/DGVS/11560/10 and SGPA/DGVS/00640/12 from the Subsecretaría de Gestión Para La Protección Ambiental, Dirección General de Vida Silvestre, de Mexico.

ABSTRACT

Photographs of 382 identified gray whales obtained from summer feeding grounds off Russia (232 from Sakhalin Island 1994-2012; and 150 from Kamchatka Peninsula 2004-2011), were compared with 4,352 photo-identified individuals from winter calving lagoons off the Baja California Peninsula, Mexico between 2006 and 2012. The Sakhalin, Kamchatka and Mexico catalogs comparison resulted in a total of 9 confirmed matches of individuals, including 1 males, three females and five of unknown sex. Two whales were observed in the three places, three in Sakhalin and Mexico and four in Kamchatka and Mexico. Eight of the 9 whales in Mexico were sighted in Laguna San Ignacio and one in Bahía Magdalena. Seven of the 9 whales were photographed in Mexico only in one year, one in two years and one in three years. Five whales were sighted in consecutive seasons. These results offer the first complete migratory information for some gray whales that summer off Russia and provide new information important to the evolving understanding of gray whale population structure in the North Pacific. The matches made between whales sighted off Sakhalin, Kamchatka and the Mexican Pacific are the results of the second year of the multinational collaboration “PACIFIC WIDE STUDY ON POPULATION STRUCTURE AND MOVEMENT PATTERNS OF NORTH PACIFIC GRAY WHALES” initiated under the coordination and support of the International Whaling Commission in 2011.

INTRODUCTION

Recent results of genetic and photographic identification comparisons between western and eastern North Pacific gray whales (Lang *et al.* 2011; Weller *et al.* 2012) suggest a mixing of these populations during the winter reproductive season, and illustrate the great conservation and management importance of a more comprehensive examination of gray whale movement patterns and population structure in the North Pacific. The Scientific Committee recommended that a collaborative Pacific-wide study be developed under the auspices of the IWC, recognising that *inter alia* this will contribute to the Committee-endorsed Conservation Plan for western North Pacific gray whales and incorporate previous recommendations made by the Committee. Such a study will involve collaborative analysis and sharing of existing data as well as the collection of new data. This report summarizes the results of

the comparison of the gray whales photo identified off Sakhalin Island and the Kamchatka Peninsula with the Mexican gray whale catalogue.

METHODS

The comparison was done based on:

1. The combination of two catalogues from Sakhalin Island. **217 individuals**

Burdin, A. M., Weller, D., Sychenko, O., and Bradford, A. 2012. *“WESTERN GRAY WHALES OFF SAKHALIN ISLAND, RUSSIA: A CATALOG OF PHOTO-IDENTIFIED INDIVIDUALS”*. 205 individuals. Period 1994-2011 (Russia-US)

Tyurneva, O. Yu. and Yakovlev, Yu. M. 2010. *“THE WESTERN PACIFIC GRAY WHALES OF SAKHALIN ISLAND 2002-2008, LEARNING ABOUT A POPULATION OF WHALES THROUGH PHOTOGRAPHS”*. (IBM) 165 individuals. Period: 2002-2008

2. A catalogue from Kamchatka. **150 individuals**

Tyurneva, O. and V.Vertyankin. 2012. *THE NORTH PACIFIC GRAY WHALES MASTER CATALOGUE 2004-2011*. Kamchatka. Institute of Marine Biology Russian Academy of Sciences

3. New photo-identified whales from Sakhalin from the Institute of Marine Biology Russian Academy of Sciences. **15 individuals**

4. The catalogue from Mexico 2006-2011. **3,405 individuals**

5. The catalogue from México 2012. **947 individuals** (including 670 from Laguna San Ignacio and 272 from Bahía Magdalena).

RESULTS.

The Sakhalin, Kamchatka and Mexico catalogs comparison resulted in a total of 9 confirmed matches of individuals, including 1 male, three females and five of unknown sex. Two whales were observed in the three places, three in Sakhalin and Mexico and four in Kamchatka and Mexico. Eight of the 9 whales in Mexico were sighted in Laguna San Ignacio and one in Bahía Magdalena. Seven of the 9 whales were photographed in Mexico only in one year, one in two years and one in three years. (Table 1).

Five whales were sighted in consecutive seasons. Whale #2, female, was observed in Kamchatka in 2008, in San Ignacio in 2009, with a calf, and again in Kamchatka in the summer 2009. The same whale was observed again in San Ignacio 2012 and Sakhalin 2012.

The whale #4 also a female, was observed in Sakhalin 2007, San Ignacio 2008 and Sakhalin 2008. The same whale was observed in Sakhalin 2009 and San Ignacio 2010 and again Sakhalin 2011 and San Ignacio 2012.

These two whales, #2 and #4 were reported last year (Urbán *et al.* 2012) and they were photographed again during the winter season of 2012 at Laguna san Ignacio.

In summary the results of this report together with the report from last year (Urban *et al.* 2012) are show in the figure 1:

Figure 1. Matches between the two feeding areas: Sakhalin and Kamchatka with Mexico. A total of 21 whales considering that two individuals were observed in the three places. 7 females, 7 males and 7 of unknown sex.

DISCUSSION

Recent results of genetic, telemetry and photographic identification comparisons between western and eastern North Pacific gray whales suggest a mixing of these populations during the winter reproductive season. These findings illustrate the great conservation and management importance of a more comprehensive examination of gray whale movement patterns and population structure in the North Pacific.

These results offer the first complete migratory information for some gray whales that summer off Russia and provide new information important to the evolving understanding of gray whale population structure in the North Pacific.

The matches made between whales sighted off Sakhalin, Kamchatka and the Mexican Pacific are the results of the second year of the multinational collaboration “PACIFIC WIDE STUDY ON POPULATION STRUCTURE AND MOVEMENT PATTERNS OF NORTH PACIFIC GRAY WHALES” initiated under the coordination and support of the International Whaling Commission in 2011 (IWC, 2011)

Acknowledgements

We wish to thank our field researchers and colleagues that assisted with the documentation of the gray whales in Laguna San Ignacio and Laguna Ojo de Liebre. We also thank The Ocean Foundation, and the World Wildlife Fund-Mexico for their support of the field work and analysis of our results. This research was conducted as part of the Laguna San Ignacio Ecosystem Science Program (LSIESP) under special scientific research permits No.SGPA/DGVS/11560/10 and SGPA/DGVS/00640/12 from the Subsecretaría de Gestión Para La Protección Ambiental, Dirección General de Vida Silvestre, de Mexico.

ABSTRACT

The annual return, seasonal occurrence, and site fidelity of Korean-Okhotsk or western gray whales on their feeding grounds off northeastern Sakhalin Island, Russia, were assessed by boat-based photo-identification studies in 1994–1998. A total of 262 pods were observed, ranging in size from 1 to 9 whales with an overall mean of 2.0. Sixty-nine whales were individually iden-

¹ We dedicate this paper to Ken Norris, a pioneer and leader of research on the behavioral ecology and conservation-related status of gray whales.

² Present address: Southwest Fisheries Science Center, National Marine Fisheries Service, P.O. Box 271, La Jolla, CA 92038, U.S.A.

tified, and a majority of all whales (71.0%) were observed in multiple years. Annual sighting frequencies ranged from 1 to 18 d, with a mean of 5.4 d. The percentage of whales reidentified from previous years showed a continuous annual increase, reaching 87.0% by the end of the study. Time between first and last sighting of identified individuals within a given year was 1–85 d, with an overall mean of 40.6 d. Annual calf proportions ranged from 4.3% (1997) to 13.2% (1998), and mother-calf separations generally occurred between July and September. The seasonal site fidelity and annual return of whales to this part of the Okhotsk Sea emphasize its importance as a primary feeding ground for this endangered population.

Key words: western gray whale, *Eschrichtius robustus*, Okhotsk Sea, Russia, photo-identification, occurrence patterns, site fidelity.

Gray whales are known to occur as two separate populations along the eastern and western margins of the North Pacific (Rice and Wolman 1971). While both populations were hunted to near extinction, only the eastern North Pacific or California-Chukchi gray whale has returned to pre-exploitation population levels (Reilly 1992, Clapham *et al.* 1999). The western North Pacific or Korean-Okhotsk gray whale was thought to be extinct as recently as the early 1970s (Bowen 1974) but is known to survive today as a remnant population (Brownell and Chun 1977, Blokhin *et al.* 1985, Berzin *et al.* 1990). This western population is presently considered one of the most endangered and little-known large-whale populations in the world (Berzin *et al.* 1995, Brownell *et al.* 1997, Brownell 1999, Clapham *et al.* 1999). The current population size has been reported as 100–250 whales (Vladimirov 1994; Blokhin 1996; Berzin, in press); however, no reliable quantitative data have existed to confirm these assessments.

Basic information regarding the life history and biology of western gray whales is sparse, and only recently has this population come under concerted study (Brownell *et al.* 1997, Würsig *et al.* 1999). Historic sighting data and whaling records suggest that summer feeding grounds are in the Okhotsk Sea and that the whales migrate to presently unknown breeding grounds suspected to be along the coast of southern China (Henderson 1972, 1984, 1990; Yablokov and Bogoslovskaya 1984; Kato and Kasuya, in press). Sighting records from aerial and vessel surveys in the Okhotsk Sea between 1979 and 1989 indicated that feeding gray whales aggregated predominately along the shallow-water shelf of northeastern Sakhalin Island, Russia, and were particularly abundant off the southern portion of a coastal lagoon called Zaliv Pil'tun (Blokhin *et al.* 1985; Berzin *et al.* 1988, 1990, 1991, in press; Blokhin 1996).

Concerns regarding the status of western gray whales have intensified as a result of continued low-level human-related mortality south of the Okhotsk Sea (Brownell 1999) and the onset of large-scale U.S.-Russian oil and gas development programs near the only known gray whale feeding ground within Okhotsk waters (Brownell *et al.* 1997, Würsig *et al.* 1999). In response to these concerns, a joint research project under the U.S.-Russian Environmental Agreement (Marine Mammal Project) was initiated in 1995 to examine the conservation status, occurrence, distribution, behavior, and potential human-

related disturbance of gray whales off the northeastern coast of Sakhalin Island. Principal research components of this project included aerial surveys, shore-based behavioral observations, theodolite tracking, acoustic monitoring, biopsy sampling, and photo-identification (Würsig *et al.* 1998, 1999). Findings presented here represent information from photo-identification studies between 1994 and 1998, and summarize patterns of seasonal and annual occurrence of western gray whales on their feeding grounds in the Okhotsk Sea.

METHODS

Study Area

Zaliv Pil'tun (referred to here as Piltun Lagoon) is located on the northeastern shore of Sakhalin Island, Russia (Fig. 1). The lagoon is approximately 80 km long and 15 km across at its widest point. A single entrance connecting the inner lagoon with waters of the Okhotsk Sea occurs at 52°50'N, 143°20'E. This channel, approximately 18 km north of the lagoon's southern boundary, served as the base from which studies reported here were conducted. The nearshore marine environment of the study site is predominately sand substrate, characterized by a gradually sloping and broad continental shelf. Water depths within 5 km of shore are almost uniformly less than 20 m (Fig. 1). Sea-surface temperature and salinity, as measured from our research vessel during 1997–1998, were 4°–15°C and 28‰–34‰, respectively. Periods free of sea ice occur mainly between May and December; however, significant interannual variability exists.

Datasets

Data presented here were collected during four years: 1994, 1995, 1997, and 1998. Gray whale photographs from 1994 were taken 7–12 September during the filming of a wildlife documentary by one of the authors (HM). No information other than sighting locations is available for the 1994 sampling period. In 1995 a pilot study to determine the feasibility of conducting systematic research in the Piltun area was completed 14–20 August (Brownell *et al.* 1997). Intensive follow-up work in July–September 1997 and 1998 contributed substantially to the findings presented here. Because of the opportunistic nature of the 1994 season and the brevity of the 1995 season, many analyses detailed here were restricted to only the more comprehensive 1997 and 1998 datasets. However, the 1994 and 1995 samples provided particularly valuable information regarding interannual sightings and general site fidelity patterns for known individuals. The sampling periods used for each respective analysis are defined. For example, the term “1995–1998” is used to define analyses that incorporated data from 1995, 1997, and 1998.

Photo-Identification Surveys

Boat-based photo-identification surveys following nearly identical research protocols were conducted during each of the 1995–1998 field seasons. These

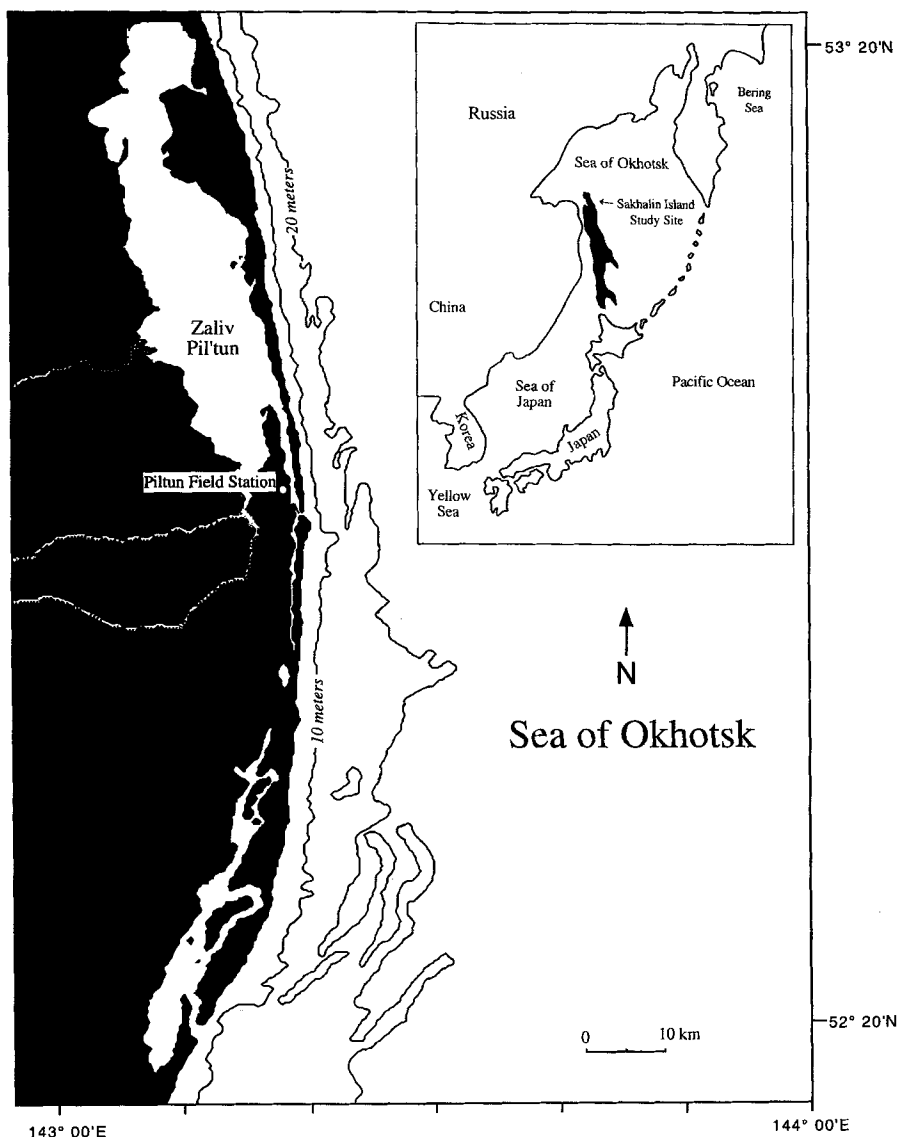

Figure 1. Map of Piltun study area. Inset shows relative location of Sakhalin Island in Sea of Okhotsk.

surveys followed no predetermined systematic vessel track and were conducted in such a manner as to maximize encountering and photographically identifying as many whales as possible. Photographic data from 1994–1995 targeted right-side dorsal flank markings as the primary body aspect for identification purposes (Brownell *et al.* 1997). For the sake of intra- and interannual reliability, this methodological approach was continued in 1997–1998. Photographs from 1997–1998 were taken with a Nikon F5 35-mm camera equipped

with a 100–300-mm zoom telephoto lens, 8 frames per sec motordrive, and databack. Video footage was recorded with a Sony DCR-VX1000 digital camera. Two 35-mm film types were used: Kodachrome 200 ISO color and T-Max 400 ISO black and white.

Photographic surveys involved slow travel in a 4.5-m outboard-powered inflatable boat. The research team consisted of a boat driver, data recorder, digital video camera operator, and 35-mm camera photographer. Systematic search from the survey vessel was maintained until a whale sighting was made. Upon initial sighting of a pod, the survey vessel slowed to idle speed and maneuvered to a vantage point approximately 50 m from the whale(s). From this position observations on pod location (as determined by Global Positioning System), time, behavior, and number of whales were recorded.

The research vessel was then maneuvered within 5–15 m of the pod and individual whales were photographed. During the 1997–1998 photographic efforts, running commentaries regarding film-frame and video-counter number as related to particular whales were recorded on data sheets. Measures of water depth, location, and environmental conditions were documented on average every 3–5 min throughout the entire photographic session. In all cases attempts were made to simultaneously photograph and videotape the right dorsal flank of each whale, followed by the left dorsal flank, and dorsal and ventral aspects of the flukes. Written observations and video footage collected at the time of each photographic session were used to link inter- and intraindividual body aspects whenever possible.

Contact with whale pods was maintained until all individuals encountered had been photographed. The boat then motored away from the pod, where initial estimates of pod size and composition were revised if necessary and all film and written records reviewed for completeness. These procedures were repeated as the research vessel resumed travel and additional whale pods were encountered.

A pod was defined as either a solitary individual, or two or more whales observed in close spatial proximity (within several body lengths of each other) and swimming in close association and generally coordinating their diving or direction of movement (see Clapham 1993). Pod size estimates were based on field observations and represented the product of a consensus among observers on the survey vessel. The term “calf” is used here to refer to young of the year. In all cases calves were initially identified by their small body size (about one-third that of a mature adult) and constant association with a particular adult whale. Calves documented to disaffiliate from their mothers at some point during the field season were termed “newly independent calves.”

Photo-Identification Analysis

Photographic identification has proved to be a valuable research tool for gray whale studies (Darling 1984, Swartz 1986, Jones 1990) and served as the primary method for collecting the data presented here. As is true for the eastern population, western gray whales are easily identified by pigmentation

Figure 2. Examples of coloration patterns used for individual recognition of gray whales.

patterns and scars (Fig. 2). Patches of barnacles (*Cryptolepas rhachianceti*) and cyamids (*Cyamus scammoni* and/or *Cyamus ceti*) and occasionally-apparent killer whale (*Orcinus orca*) tooth rakes were not used for long-term recognition.

Images of individual gray whales consisted of various aspects of the body, including the head, back, dorsal flanks, and flukes. To prevent cataloging different aspects of the same whale as more than one individual, the right flank was always used as the basis for initial identification. A whale was not given a subject identification number unless its right dorsal flank was photographed at some point during the field season. Additional aspects of the body were used as identification aids, only if they were first matched with the respective right flank.

Photographic matching was done by comparing new photographs to a catalog of previously identified whales. Once a prospective resighting was located, the current photograph was repeatedly compared to previous images and was required to match before being confirmed as a re-identification of a known individual. If a new photograph could not be matched after comparison to all other cataloged individuals, the whale was considered new and given the next available subject identification number. All images were processed and cata-

^b Number of whales identified annually includes resightings of individuals from previous years, resulting in total of 69 known individuals.

logged by a single expert operator, with confirmation of both re-identifications and new whales by additional personnel.

Digital video footage was collected simultaneously with still photography during a majority of the photo-identification surveys conducted in 1997 and 1998. Each video session was reviewed frame by frame to verify and enhance the already established 35-mm photographic catalog. If the videographer recorded a previously unphotographed whale or an additional aspect of an identified whale, then a still print was made. Video images of whales not accounted for by 35-mm photographs were systematically matched following the protocol described above. The use of digital video proved especially valuable in increasing sighting frequencies and providing additional aspects of already identified whales.

RESULTS

Observation Effort

Sixty-two photo-identification surveys totaling 94 h spent in direct observation of whale pods were completed in 1995–1998 (Table 1). The greatest amount of observation occurred during 1998 (50.5 h), and the lowest during the pilot study in 1995 (10.1 h). A total of 511 whales in 262 pods were encountered, and 178 rolls of film and nine hours of digital videotape were used for individual identification.

Rate of Discovery

The number of whales identified increased during each of the four annual sampling periods (Fig. 3). Nine whales were identified in 1994 and 21 additional whales (including two calves) in 1995. The number of known individuals increased to 56 (including two calves) in 1997, representing an increase of 26 new whales. With the addition of 13 new whales (including seven calves)

Figure 3. Rate of discovery curve for whales identified 1994–1998. Each solid circle represents one photo-identification survey.

in 1998, a total of 69 individual whales (including 11 calves) were identified during the study. The continuous increase in the number of new identifications through 1997 and into 1998 indicated that at least some previously unidentified whales were present in the study area on a yearly basis. However, the rate at which previously unidentified whales were sighted reached an apparent asymptote by 24 July 1998, with only two new individuals identified in the final 26 surveys of the study.

Occurrence and Resighting Patterns

Sighting frequencies for the 66 whales identified in 1997–1998 are plotted in Figure 4. As some whales were sighted more than once per day, the following analyses were constrained to include only one sighting per day. The number of sightings per individual ranged from 1 to 8 in 1997 and 1 to 18 in 1998, with an overall mean of 5.4 sightings per yr (Fig. 4). The period between the first and last sighting of an individual whale in either 1997 or 1998 ranged from 1 to 85 d. This measure was calculated only for whales photographed on two or more days in a year and does not assume that the individual was absent from or present in the study area for the period between sightings (see Seipt *et al.* 1990, Clapham *et al.* 1993). The mean period between first and last sighting for whales observed in 1997 and 1998 was $35.9 \text{ d} \pm \text{SD } 17.74$ ($n = 34$) and $45.2 \text{ d} \pm \text{SD } 24.38$ ($n = 35$), respectively, with an overall combined mean of $40.6 \text{ d} \pm \text{SD } 21.73$ ($n = 69$).

Monthly occurrence patterns, a partial indicator of site fidelity, were ex-

Figure 5. Cumulative percentage and number of individuals sighted in each possible monthly combination of 1997 and 1998.

Table 2. Annual return rates of identified whales. Numbers in year columns represent percentage and number of whales identified in given year that were resighted in additional years. For example, 44.4% of whales first identified in 1994 were sighted in all four years of study.

Year first identified	Number of whales identified	1 year	2 years	3 years	4 years
1994	9	—	44.4% (<i>n</i> = 4)	11.1% (<i>n</i> = 1)	44.4% (<i>n</i> = 4)
1995	21	14.3% (<i>n</i> = 3)	33.3% (<i>n</i> = 7)	52.4% (<i>n</i> = 11)	—
1997	26	34.6% (<i>n</i> = 9)	65.4% (<i>n</i> = 17)	—	—

amined for the 1997 and 1998 datasets. The number of individuals occurring in each of seven possible monthly combinations is shown in Figure 5. In 1997, 67.4% (*n* = 31) of the individuals identified were seen in two or three months. In 1998, 54.7% (*n* = 29) of the whales identified were sighted in two or three months (Fig. 5). It is likely, however, that the limited number of surveys (*n* = 4) conducted in the third month of 1997 may have contributed to an underestimate of actual monthly occurrence patterns for that year.

Seasonal sighting patterns were also investigated for intra- and inter-annual consistency (Fig. 5). A majority of the whales sighted in two months during either 1997 or 1998 were sighted in consecutive months (*i.e.*, July–August or August–September) as opposed to an interrupted (*i.e.*, July–September) monthly sighting pattern. Interannual repetition of individual monthly sighting patterns was not apparent. Of 15 whales sighted in only a single month of 1997, 26.7% (*n* = 4) showed a similar pattern in 1998. None of the whales sighted in 1997 and 1998 had the same two-month occurrence pattern, and of the 13 whales sighted in all three months of 1997, 53.8% (*n* = 7) were also sighted in all three months of 1998.

Annual sighting frequencies for the 56 whales identified between 1994 and 1997 ranged from one to four years (Table 2 and Fig. 6). Seventy-one percent of all whales identified (excluding seven 1998 calves) were sighted in multiple years. The longest interval between sightings was documented for whales 050 and 068, which were first identified in 1994 and not seen again until 1998 (Fig. 6). Interannual resighting patterns are detailed in Table 3. In 1995, 26 individuals (including two calves) were identified; of the 24 non-calves, 20.8% (*n* = 5) were first identified in 1994. This resighting trend, albeit greatly amplified, was also apparent for the 1997 sample. During this effort, 46 individuals (including two calves) were identified; of the 44 non-calves, 45.5% (*n* = 20) were previously identified in either 1994 or 1995. These interannual sighting patterns, based on 1994 and 1995 data, are likely to underrepresent actual return rates due to the limited number of sampling days in those years (see Table 1). In 1998, 53 individuals (including seven calves) were identified; of the 46 non-calves, 87.0% (*n* = 40) were already known from previous years,

Table 3. Annual sighting trends and resighting percentages of photo-identified whales.

Year	Number of whales identified	Number of calves	Number of new whales identified	Percentage of non-calves identified from previous years	Number of whales seen only in that year
1994	9	—	9	N/A	0
1995	26	2	21	20.8% ($n = 5$)	3
1997	46	2	26	45.5% ($n = 20$)	9
1998	53	7	13	87.0% ($n = 40$)	13 ^a

^a Seven of these 13 whales were "young of the year" calves, and therefore could not have been sighted in any other sampling period.

including one whale recorded as a calf in 1997. Therefore, during the 1998 field effort only six new non-calf individuals were identified, and all but two of the 13 new whales for this year were photographed in the first month of the three-month field effort.

Based on 1998 data alone, the minimum number of gray whales utilizing the study area was 53, consisting of 46 non-calves and seven calves. However, if each whale identified between 1994 and 1998 is assumed to be living, this number can be increased to 69 whales, including a minimum of 11 calves born between 1995 and 1998.

Pod Sizes

A total of 262 whale pods were observed between 1995 and 1998. Pod sizes ranged from 1 to 9 whales, with an overall mean of $2.0 \pm \text{SD } 1.18$ ($n = 262$), a median of 2, and a mode of 1 (Table 4, Fig. 7). Pods containing a single whale were the most frequently encountered, and accounted for 43.1% ($n = 113$) of all sightings. Overall, pods of 4 or fewer accounted for 97.7% ($n = 256$) of all sightings.

The largest pod sizes were documented in 1995 ($\bar{x} = 2.3 \pm \text{SD } 1.18$, $n = 23$) and the smallest in 1997 ($\bar{x} = 1.8 \pm \text{SD } 1.33$, $n = 114$) (Table 4). Between 1997 and 1998 overall pod sizes were larger in July ($\bar{x} = 2.1 \pm \text{SD } 1.29$, $n = 89$) and smaller in August ($\bar{x} = 1.8 \pm \text{SD } 0.92$, $n = 77$) and September ($\bar{x} = 1.8 \pm \text{SD } 1.26$, $n = 73$). Analysis of variance revealed no significant difference in mean pod size by month ($F(2,236) = 2.52$, $P = 0.08$) or between years ($F(1,237) = 0.86$, $P = 0.35$).

Figure 6. Occurrence patterns for whales photographically identified 1994–1998. Shaded cells represent presence in study area, M = mother with calf, and C = calf of that year.

Table 4. Pod size summary statistics.

Year	Number of pods	Mean pod size	Median pod size	Mode pod size	± SD pod size	Range in pod size
1995	23	2.3	2	2	±1.18	1–6
1997	114	1.8	1	1	±1.33	1–9
1998	125	2.0	2	2	±1.02	1–6
Overall	262	2.0	2	1	±1.18	1–9

Pods With and Without Calves

Eleven calves and nine mothers were identified in 1995 and 1998 and ranked among the most frequently sighted whales. The observed crude birth rate, as calculated by dividing the total number of all whales identified (including calves) in a given year by the number of calves observed (see Clapham and Mayo 1990), ranged from 4.3% (1997) to 13.2% (1998). Of the two mothers identified in 1995, one was sighted in four years and one in three years (Fig. 6). The two mothers identified in 1997 were sighted in one and

Figure 7. Frequency distribution of pod sizes between 1995 and 1998.

three years, respectively. Finally, of the seven mothers identified in 1998, one was first sighted in that year, while 57.1% ($n = 4$) were observed in two years and 28.6% ($n = 2$) were sighted in each of the four years. When accompanying a calf in either 1997 or 1998, 55.6% ($n = 5$) of these mothers were sighted in all three months of that respective year, 33.3% ($n = 3$) were observed in two months, and 11.1% ($n = 1$) in one month (Fig. 6).

Pods containing one or more calves in 1997–1998 ranged in size from 1 to 8 whales, with a mean of $2.6 \pm \text{SD } 1.19$ ($n = 63$), a median of 2, and a mode of 2. Pods without calves ranged in size from 1–9 whales, with a mean of $1.7 \pm \text{SD } 1.09$ ($n = 176$), a median of 1, and a mode of 1. The number of calves identified in each field season between 1995 and 1998 was two, two, and seven, respectively (Table 3). Only one of the four calves identified prior to the 1998 season was subsequently resighted. Seven (77.8%) of the nine mothers identified were sighted in at least one year with a calf and one year without a calf. Five (71.4%) of these seven mothers had a higher number of total sightings when accompanying a calf than in years in which they had no calf. None of these mothers were sighted with a calf in sequential years. Of the two mothers identified with calves in 1995, one was subsequently sighted in 1997 with a calf and in 1998 without a calf, and one was sighted in 1997 without a calf and in 1998 with a calf. While no data were collected in 1996, these calving patterns suggest a one to two-year interbirth interval for at least some reproductive females.

Mothers and calves were closely bonded at the onset of each sampling period. However, photographic sighting records indicated that in 1997 one of the two mother-calf pairs had separated sometime between 27 August and 5 September. In 1998 mother-calf disaffiliations were observed for five of the seven pairs. Apparent calf separations occurred between the following dates in 1998: 8 July–13 August, 29 July–13 August, 29 July–18 August, 23 August–28 August, and 3 September–17 September. These dates extend from one day after the last sighting of the mother-calf pair together until the next sighting of either the mother or calf independent from one another. The earliest mother-calf separation may have occurred by 8 July–13 August, while the latest apparent separation occurred sometime between 3 and 17 September. Newly independent calves were occasionally sighted together or in the company of other still affiliated mother-calf pairs.

DISCUSSION

During the study most whales demonstrated high levels of seasonal site fidelity and annual return to the area off the northeastern coast of Sakhalin Island, Russia. These inter- and intra-annual resighting patterns, combined with the continuous occurrence of feeding behavior, suggest that this coastal habitat plays an important role in the feeding ecology of this endangered population.

Pod sizes observed during the present study were primarily small, with most groups composed of 4 or fewer whales. These observed pod sizes closely

correspond with those reported for eastern gray whales feeding in the Bering and Chukchi Seas (Zimushko and Ivashin 1980, Votrogov and Bogoslovskaya 1980, Bogoslovskaya *et al.* 1981, Würsig *et al.* 1986). Variables thought to influence group size include social factors, predation pressure, and prey availability (Krebs and Davies 1993). As social factors related to breeding are presumably relaxed on the feeding grounds (Würsig *et al.* 1986), and predation pressure does not appear to be excessive (as measured by the low number of killer whale sightings during the study), the major determinate of group size during summer feeding is probably related to foraging efficiency.

During the study period a limited number of whales ($n = 69$) were identified. The rate at which previously unidentified whales were photographed reached a pronounced asymptote early into the final year of the study. Only six previously unidentified whales (excluding seven calves) were photographed in 1998, resulting in an overall 87.0% resighting rate. It is intriguing that the reported asymptote was reached in such a short period of time, especially given the limited number of surveys in 1994 and 1995. These findings represent a clear departure from the typical patterns reported from other large-whale studies, and suggest that the western gray whale population is perhaps smaller than previously estimated (Vladimirov 1994; Blokhin 1996; Berzin, *in press*), or it may be only a discrete subpopulation consistently using the northeastern Sakhalin Island feeding ground.

Gray whales in other parts of the North Pacific are suspected to sometimes segregate by age while on their feeding grounds (Zenkovich 1937, Votrogov and Bogoslovskaya 1980, Bogoslovskaya *et al.* 1981, Darling 1984, Darling *et al.* 1998). One possible explanation for the low number of individuals identified during the present study could be that only an age-specific portion of the population uses the northeastern Sakhalin coast. Age-class segregation was not, however, apparent in our observations. During the course of study we regularly documented the presence of adult reproductive females, their young of the year calves, numerous whales of apparent adult body size, and at least one known two-year-old individual.

An additional alternative explanation for the low number of whales identified during the study is that only a small portion of a larger population migrates to the northeastern Sakhalin Island coast. Small numbers of eastern gray whales have been reported to summer along the North American coast from Alaska to California, never fully migrating to more northern feeding areas (Rice and Wolman 1971). While a similar pattern may occur for the western population, aerial and ship-based surveys in the northern Okhotsk Sea reported finding concentrations of gray whales only in a small area off Piltun Lagoon (including some area outside the boundary typically covered by our research vessel during this study) (Blokhin *et al.* 1985; Berzin *et al.* 1988, 1990, 1991; Blokhin 1996; Berzin, *in press*). Our lack of photographic effort in other regions along the Sakhalin Island coast, and the virtual absence of data from this population's southern range off China, Korea, and Japan prohibit further speculation regarding potential subpopulation structuring. We are hopeful that a third sampling period equal in effort to 1997–1998 and

covering a broader geographic area will be completed in 1999, allowing the first quantitative mark-recapture population estimate to be calculated (Hammond 1986, Hammond *et al.* 1990).

A majority of the whales identified between 1994 and 1998 displayed high rates of annual return to the study area. The annual return of whales to this region is similar to that reported for eastern gray whales off Vancouver Island (Darling 1984) and may be suggestive of foraging area philopatry as has been hypothesized for humpback whales (*Megaptera novaeangliae*) in the southern Gulf of Maine (Clapham *et al.* 1993). Annual return to the same geographic feeding area has been observed for a variety of other baleen whales (Aglar *et al.* 1990, Dorsey *et al.* 1990, Sears *et al.* 1990, Clapham *et al.* 1993), and in the present case emphasizes the significance of the Piltun region as an important feeding ground for at least some portion of the western gray whale population.

Occurrence patterns of the 66 whales identified between 1997 and 1998 suggested a reasonably strong intraseasonal fidelity to the area. The mean period between first and last sighting of whales in the Piltun region was 40.6 d, and over one-half of the whales identified on a yearly basis were sighted in either two or three months. However, even whales demonstrating seemingly strong site fidelity were on occasion apparently absent from the region. It is difficult to determine if breaks in individual resighting patterns represent occasions when whales were in the study area but were missed photographically, or if they were indicative of movements to other regions between sightings. We suggest that whales take short excursions away from the study site, presumably related to foraging, but eventually return. Support for this idea comes from several survey days on which we sampled 20–25 km north and up to 10 km offshore of our typical search area. In each case whales found at the periphery of the study site were feeding, and all identified individuals (including one mother-calf pair) had previous and subsequent sightings within the more typical survey area.

Darling *et al.* (1998) characterized gray whales off Vancouver Island as having “foraging ranges” that in some cases extend over hundreds of kilometers. While existing data are insufficient to allow us to reliably assess movement patterns outside the current study area, we suggest that the unique habitat structure and infaunal prey ecology characteristic of our study site favors seasonal site fidelity as opposed to the coastal ranging behavior described by Darling *et al.* (1998). Our photographic resighting data showing seasonal and annual fidelity appear to support this hypothesis, as do findings from over 200 shore-based whale counts conducted between 1997 and 1998 from a 35-m lighthouse near the mouth of Piltun Lagoon (Würsig *et al.* 1999). Theodolite-determined pod locations during these counts indicated that the highest concentrations of feeding gray whales were usually within 10 km of the lagoon mouth and less than 5 km offshore (Würsig *et al.* 1999). Similarly, aerial and ship-based surveys of the Okhotsk Sea found only limited numbers of gray whales away from the northeastern Sakhalin Island coast (Blokhin *et al.* 1985; Berzin *et al.* 1988, 1990, 1991; Blokhin 1996; Würsig *et al.* 1998;

Berzin, in press). This apparent distributional fidelity to the coastal waters near the channel opening of Piltun Lagoon may reflect a particular biological richness of the region, perhaps related to enrichment of nearshore marine waters by tidal effluent from the lagoon. While further information regarding the benthic ecology of the region is needed, this explanation may at least partially account for the high annual return and intraseasonal site fidelity observed.

Eleven mother-calf pairs and nine mothers were identified during the study. Calves separated from their mothers between July and mid-September. Using a mean birth date of 10 January as calculated for eastern gray whales (Rice and Wolman 1971), it appears that calves off Sakhalin Island separate from their mothers at 6–8 mo. This age at separation closely corresponds with the 7-mo lactation period estimated for the species (Rice and Wolman 1971). Thus, if August is used to estimate the typical period of separation for western gray whale mother-calf pairs, January may represent the peak calving period, as is true for the eastern population (Rice and Wolman 1971).

Mother-calf pairs ranked among the most commonly sighted individuals on an intraseasonal basis, and 77.8% of these known mothers were sighted in multiple years of the study. Of the seven mothers identified in 1998, six were sighted in 1997 when they were newly pregnant. Both lactating and pregnant females are under especially high energy demands (Rice and Wolman 1971, Lockyer 1984). Therefore, it is imperative that they feed in regions capable of meeting their elevated energy requirements. The seasonal site fidelity and annual return of reproductive females reported here, combined with their need for high-quality habitat, suggests that the northeastern Sakhalin Island coast is of particular biological importance to this endangered whale population.

ACKNOWLEDGMENTS

Our sincere gratitude goes to S. Reeve for her participation in all aspects of this study. In the field we were fortunate to work with G. Carlash, B. Ferriss, R. LeDuc, D. Golovenkova, Y. Ivashenko, T. Kasuya, R. Pitman, I. Seryodkin, Y. Shvetsov, G. Tsidulko, E. Vorobieva, V. Vladimirov, B. Ward, and K. Zharikov. Preparations for the study were provided by A. Acevedo, S. Arms, J. Blum, S. Bräger, S. Lynn, K. Maze, M. Metro, A. Roberts, B. Walker, K. Willis, and S. Yin. Data reduction was patiently pursued by D. Allen, K. Bertalan, G. Gailey, A. Hamilton, C. Littnan, J. Oswald, G. Parra, and L. Torres. M. DeAngelis cataloged the first Piltun gray whales from 1994 and 1995. P. Clapham, one anonymous reviewer, and S. Reeve provided valuable comments on an earlier draft of this manuscript. Thanks to P. Clapham, J. Darling, D. DeMaster, T. Kasuya, S. Reilly, S. Swartz, and A. Yablokov for their excellent advice and willingness to serve as scientific advisors, and to W. Perryman for his valuable insight regarding eastern gray whales. Funding for the work in 1995 was provided by the Bureau of Oceans and International Environmental and Scientific Affairs, U.S. Department of State, International Whaling Commission, National Marine Fisheries Service, and the Humane Society of the United States. The 1997–1998 studies were funded by Sakhalin Energy Investment Company and Exxon Neftegas, and we acknowledge the assistance of N. Kralik, J. Ralston, L. Reitsema, P. Benefiel, and G. Kolesnikov. This project (1995–1998) was conducted as part of the Marine Mammal Project under Area V: Protection of Nature and the Organization of Reserves within

the U.S.-Russia Agreement on Cooperation in the Field of Environmental Protection. This represents contribution #65 of the Marine Mammal Research Program, Texas A&M University.

ABSTRACT

Gray whales (*Eschrichtius robustus*) occur along the eastern and western coastlines of the North Pacific as two geographically isolated populations and have traditionally been divided into the eastern (California-Chukchi) and western (Korean-Okhotsk) populations. Recent molecular comparisons confirm, based on differences in haplotypic frequencies, that these populations are genetically separated at the population-level. Both populations were commercially hunted, but only the eastern gray whale has returned to near pre-exploitation numbers. In contrast, the western population remains highly depleted, shows no apparent signs of recovery and its future survival remains uncertain. Research off Sakhalin Island, Russia between 1995 and 1999 has produced important new information on the present day conservation status of western gray whales and provided the basis for the World Conservation Union (IUCN) to list the population as 'Critically Endangered' in 2000. The information presented here, in combination with potential impacts from anthropogenic threats throughout the range of this population, raises strong concerns about the recovery and continued survival of the western gray whale.

KEYWORDS: GRAY WHALE; PACIFIC OCEAN; NORTHERN HEMISPHERE; CONSERVATION; OKHOTSK SEA; EXPLOITATION; POPULATION STATUS

INTRODUCTION

Gray whales (*Eschrichtius robustus*) are known to occur along the eastern and western margins of the North Pacific (Andrews, 1914; Rice and Wolman, 1971); they have been extinct in the North Atlantic for several hundred years (Mead and Mitchell, 1984). Recent genetic studies show that animals from the eastern (California-Chukchi) and the western (Korean-Okhotsk) Pacific should be recognised as geographically and genetically separated at the population level (LeDuc *et al.*, 2002). Although both populations were greatly reduced by commercial whaling, only the eastern gray whale has returned to numbers approaching the suspected pre-exploitation population size (IWC, 1998). In contrast, the western gray whale was thought to be extinct as recently as the early 1970s (Bowen, 1974), but later published reports confirmed that the population was extant (Berzin, 1974; Brownell and Chun, 1977). Today, the western gray whale population remains highly depleted and shows no apparent signs of recovery (e.g. Weller *et al.*, 1999; IWC, 2002b). Information regarding the life history and biology of the western population is sparse (Andrews, 1914; Rice and Wolman, 1971) and only recently has it come under concerted study (e.g. Brownell *et al.*, 1997; Weller *et al.*, 1999).

Historic records and recent data suggest that summer feeding grounds for the western population are in the Okhotsk Sea, but the location(s) of the winter breeding grounds, suspected to be along the coast of southern China, remain unknown (Wang, 1984; Henderson, 1990). Contemporary findings from an ongoing US-Russia mark-recapture photo-identification project between 1995 and 2001 suggest that the total population size is <100 individuals (e.g. Weller *et al.*, 1999; IWC, 2002b). Low-level human-related mortality south of the Okhotsk Sea (Brownell and Kasuya, 1999; Baker *et al.*, 2002), and the onset of large-scale multinational oil and gas development programmes within Okhotsk waters, pose potential new threats to the continued survival of this population.

Serious concern over the status of this population has been expressed by the World Conservation Union (by assigning it 'Critically Endangered' - Hilton-Taylor, 2000) and by the International Whaling Commission (IWC, 2002b).

RANGE AND DISTRIBUTION

Western gray whales occur off Russia, Japan, the Democratic People's Republic of Korea (North Korea), Republic of Korea (South Korea) and People's Republic of China (China). Although historic sighting and whaling records indicate that gray whales occurred in areas north of the presently described Okhotsk Sea feeding ground, the present day population range appears to be largely confined to the region between the west central Okhotsk Sea off the northeastern coast of Sakhalin Island (summer-autumn) and the South China Sea (winter). Individuals remain in shallow, mainly nearshore waters, year-round; except when crossing the La Perouse and Tartarskiy Straits off the southern end of Sakhalin Island or during north-south migrations in the Sea of Japan, and the Yellow and East China Seas. Although few records of gray whales are available south of Hong Kong (Wang, 1984; Zhu, 1998), it is presumed that they maintain a nearshore affinity throughout the southern portion of their range.

Main habitat

Gray whales are known for their long-distance migrations between sub-tropical calving and mating grounds near continental coasts and high-latitude feeding grounds in the Arctic and sub-Arctic (e.g. Rice and Wolman, 1971; Swartz, 1986). As bottom-feeding specialists, gray whales aggregate during summer and autumn in shallow shelf waters and offshore banks where benthic and epibenthic invertebrate communities are concentrated (Nerini, 1984; Oliver *et al.*, 1984; Kim and Oliver, 1989). Traditional nearshore migratory routes connect high-latitude feeding areas with warm-water coastal and inshore wintering grounds. Today, the primary summer-autumn feeding habitat for western

gray whales is located off the northeastern coast of Sakhalin Island (Weller *et al.*, 1999; 2002). The calving and mating grounds for this population are unknown, but records from sightings, strandings and whaling catches from 1933-1996 indicate that at least some western gray whales occur in coastal waters off China in the South China Sea (Wang, 1984; Zhu, 1998).

Distribution

Key areas of distribution include the summer feeding grounds off northeastern Sakhalin Island ($\sim 52^{\circ}50'N$ $143^{\circ}20'E$). Known portions of the north-south migratory route include regions off the eastern shore of Sakhalin Island in the Okhotsk Sea and along the eastern shores of mainland Russia near Peter the Great Bay and along the Korean peninsula in the Sea of Japan (Andrews, 1914; Brownell and Chun, 1977; Berzin, 1990). It is thought that prior to the 20th century, two groups of gray whales may have migrated to coastal waters off Japan (Omura, 1984). One of these groups was thought to travel along the eastern (Pacific) shore of Honshu during their southbound migration while en route for a supposed calving ground in the Seto Inland Sea (Omura, 1984). The other group was suspected to migrate along the eastern shore of Korea, cross the Korean Strait near Ulsan, and ultimately arrive at southwest Honshu and northwest Kyushu (Omura, 1984). Although gray whales were once hunted by net fishermen off the eastern shore of Honshu (Omura, 1984), present-day sightings of the species off Japan are very rare (Kato and Tokuhiro, 1997).

The winter distribution of this population is unknown. Whaling records indicate that peak gray whale numbers off southern Korea occurred in two seasonal pulses, one during the southward migration between December and January, and the other between March and April during the northward migration (Andrews, 1914; Kato and Kasuya, 2002). Whalers working off Ulsan, South Korea found that a majority of adult females taken between December-January were carrying near-term foetuses and were thought to be within two to three weeks of parturition (Andrews, 1914). Based on these observations, and his own measurement of one 4.76m foetus, Andrews suggested that calves were probably born somewhere off the southern end of the Korean Peninsula, and that this region represented the probable southern terminus of the winter migration (Andrews, 1914).

The idea that western gray whales overwinter off the southern coast of Korea, as suggested by Andrews (1914), was largely speculative (Rice, 1998). Several lines of evidence suggest that Andrews miscalculated the true position of the wintering grounds. Rice and Wolman (1971) reported an average near-term foetus size of 4.62m for eastern gray whales taken off central California between December and January. Thus, the observed foetus size, seasonal timing and latitudinal position (about $34^{\circ}N$) reported for Korea and central California closely corresponded. However, eastern gray whales migrate to breeding areas as far south as 20° - $27^{\circ}N$ off Baja California (Rice and Wolman, 1971; Swartz, 1986). Although Andrews suspected that western gray whales terminated their southern migration off southern Korea, a location approximately 7° - 14° north of the eastern gray whale wintering grounds, historical records indicate that they occur as far south as the Yellow Sea, East China Sea and South China Sea (Henderson, 1972; 1984; 1990; Wang, 1978; 1984; Omura, 1988; Zhu, 1998; Kato and Kasuya, In press). Some evidence is available that western gray whales range at least as far south as $20^{\circ}N$ off Hainan Island in southeastern China

(Wang, 1984; Zhu, 1998). In addition, several unverified sighting reports led Omura (1974) to suggest that an alternative or additional calving and mating area was in the Seto Inland Sea (34° - $35^{\circ}N$) off southern Japan, but little direct evidence is available to support this idea.

EXPLOITATION

Groups of Koryak natives (Kamentsy, Parentsy and Itkantsy) living along the northeastern shores of the Okhotsk Sea hunted whales, although the particular species killed by these aboriginal whalers were not well documented (Krupnik, 1984); the author, however, believed that gray whales were hunted until the early 20th century. Whaling by Japanese hand-harpoon whalers was underway by at least the 16th century and Japanese net-whalers continued to take whales during the 17th-19th centuries (Omura, 1984). European and American whalers operating in the western North Pacific (mainly in the Okhotsk Sea) took gray whales from the late 1840s to perhaps the start of the 20th century (Henderson, 1984; 1990). Russian steam whalers took gray whales in the coastal waters of the Far East at the end of the 19th century (Andrews, 1914; Brownell, unpublished data). Japanese and Korean whalers continued to hunt gray whales until as recently as 1966 (Kasahara, 1950; Mizue, 1951; Brownell and Chun, 1977; Omura, 1984).

The reduction in the western Pacific gray whale population can be attributed largely to modern commercial whaling off Korea and Japan between the 1890s and 1960s. The population has been protected from commercial whaling since 1946, under the International Convention for the Regulation of Whaling. The Soviet Union and Japan joined the International Whaling Commission (IWC) in 1948 and 1951, respectively. The Republic of Korea and China, however, did not join until 1978 and 1980, respectively. Prior to their IWC membership, at least 67 gray whales were killed in the period 1948-1966 off the Republic of Korea (Brownell and Chun, 1977). Although no capture records are available from 1967 to the time that either the Republic of Korea or China joined the IWC, it cannot be assumed that gray whale catches did not occur during this period. Kasahara (1950) summarised whaling operations off northern Korea prior to 1945. Today, the Democratic People's Republic of Korea is not a member of the IWC and nothing is known about whaling in its waters since the end of World War II.

Western gray whales were probably never as numerous as their eastern counterparts. While pre-exploitation numbers for the western population are unknown, it has been speculated that they once may have numbered between 1,500-10,000 individuals (Yablokov and Bogoslovskaya, 1984). Berzin and Vladimirov (1981) estimated that only 1,000-1,500 gray whales remained in the population by 1910, after some commercial exploitation had already occurred. However, details of how these pre-exploitation and 1910 estimates were derived are not provided.

Kato and Kasuya (In press) estimated that some 1,800-2,000 whales (including 44 individuals killed by net whaling in the 1890s) were taken in the period 1891-1966, mostly off Korea and Japan. Peak annual catches of 100-200 whales began as early as 1907, but occurred primarily between 1911 and 1919 (no data were available for 1910) during which time at least 1,034 whales were killed, with a mean annual take of 115 whales. In the period 1920-1929, 289 whales were killed, with a mean annual take of 29 whales. By the 1930s, gray whale captures had greatly declined, with only 48 whales killed between 1930 and 1934

for a mean annual take of 10. No known additional catches occurred until 1942. Based on these catch data, it is apparent that by the early 1930s gray whales were far less abundant off the coasts of Korea and Japan and had likely reached commercial extinction. Continued low-level hunting between the 1940s and 1966, including the 67 whales captured in waters off South Korea, resulted in at least 71 whales killed. Kato and Kasuya (In press) hypothesise that the continued, albeit low-level, whaling pressure during this time is responsible for hindering the recovery of the western population. If the projected population size in 1910 was between 1,000-1,500, as estimated by Berzin and Vladimirov (1981), the removal of at least 1,442 whales recorded in the period 1911-1966 lends support to the above hypothesis offered by Kato and Kasuya (In press).

By the 1930s, the western gray whale was considered by many to be extinct (Mizue, 1951; Bowen, 1974). Nishiwaki and Kasuya (1970), believing the western population to be extinct and unaware of the Korean catches and sightings in the 1960s, suggested that sightings of two gray whales, one in about 1959 and one in 1968 off the coast of Japan, represented strays from the eastern population. However, Brownell and Chun (1977) described the probable existence of the western population based on catch records from the Korean coast during a nearly 20-year period between 1948 and 1966. These catch records, combined with the observation of four gray whales in the western Okhotsk Sea in 1967 (Berzin, 1974) and the sighting of a female gray whale and her calf in Korean waters in May 1968 (Brownell and Chun, 1977) indicated that western gray whales continued to survive in small numbers and that the observations reported by Nishiwaki and Kasuya (1970) were likely to be of western rather than eastern gray whales.

CURRENT POPULATION STATUS

The western gray whale population survives as a small remnant population (Blokhin *et al.*, 1985; Weller *et al.*, 1999). Aerial and ship-based sighting records in the Okhotsk

Sea between 1979 and 1989 indicated that gray whales aggregated predominantly along the shallow-water shelf of northeastern Sakhalin Island and were most common offshore of the southern portion of Piltun Lagoon (Blokhin *et al.*, 1985; Berzin *et al.*, 1988; 1990; 1991; Berzin, 1990; Blokhin, 1996). Two non-quantitative population estimates have been reported in the Russian literature (Vladimirov, 1994; Blokhin, 1996). An estimate of 250 by Vladimirov (1994) was derived from cetacean sighting records collected between 1979 and 1992 in the Okhotsk Sea; these records were collected from a variety of observation platforms, during different seasons, and employed mostly non-systematic sampling strategies. Although counts may be inflated by repeated observations of the same individuals, the highest number reported by Vladimirov (1994) during any sampling period was 34 gray whales observed in 1989 off northeastern Sakhalin Island. The author does not explain the origin of the estimate 250. An estimate of 100 by Blokhin (1996) was based on eight shore counts and one helicopter survey conducted between July and August of 1995 along the northeastern Sakhalin Island coast. The highest number of whales counted on any one day during that period was 42 but again, the author did not explain the origin of the estimate of 100. Therefore, both of these estimates must be considered unreliable.

Recent photo-identification studies conducted between 1994 and 1999 on the primary feeding ground off northeastern Sakhalin Island (Weller *et al.*, 1999; 2000; Würsig *et al.*, 1999; 2000) have identified a total of 88 individual whales (Table 1). These photo-identification data indicate high levels of annual return and pronounced seasonal site fidelity for most whales (Table 2). While new individuals continue to be identified annually, the rate at which this is occurring is low. Only 18 previously unidentified whales (excluding calves) were photographed during 91 days of effort between 1998 and 1999. This finding suggests that a majority of the population had been identified in the period 1994-1997 (Weller *et al.*, 2000). Between 1995 and 1999, 11 reproductive females and their

Year	Whales identified	Calves/non-calves identified (crude birth rate)	New non-calves	Non-calves identified from previous years
1994	10		10	
1995	27	2/25*	20	20.0% (<i>n</i> = 5)
1997	47	2/45 (4.3%)	25	44.4% (<i>n</i> = 20)
1998	54	8/46 (14.8%)	5	89.1% (<i>n</i> = 41)
1999	70	3/67 (4.3%)	13	80.6% (<i>n</i> = 54)

* Insufficient data available to calculate crude birth rate.

15 calves were observed (Weller *et al.*, 2000). Two calves were observed in each of 1995 and 1997, eight in 1998 and three in 1999. Crude birth rates ranged between a low of 4.3% in 1997 and 1999, to a high of 14.8% in 1998. Of the 12 calves identified between 1995–1998, seven (58.3%) have not been resighted on the Sakhalin feeding grounds subsequent to their birth year.

Mature population size¹

Estimating the number of whales inferred to be capable of reproduction or 'number mature' is problematic for western gray whales because there are limited direct data, and demographic estimates depend on the population growth rate, which is currently unknown. Two approaches are used here to estimate plausible, albeit conservative, numbers mature. The first uses information from Rice and Wolman (1971), who found that 24% of the eastern gray whales in their sample were sexually immature and from this suggested that the total proportion of immature animals in the population was more likely to be 44%–61%. Using the minimum estimate of 88 western gray whales (Weller *et al.*, 1999; 2000) and using the estimated proportion immature from Rice and Wolman (1971), the number of mature whales in the western population ranges between 34 and 49.

However, the eastern gray whale population was growing at the time Rice and Wolman conducted their study and would therefore be expected to consist primarily of immature animals; this would not be the case for a stable population. The second method used here is based on the premise that the proportion mature for a stable population can be estimated using age-specific birth and mortality rates. Rice and Wolman (1971) reported the mean age of sexual maturity for eastern gray whales to be eight years (range = 5–11 years). Reilly (1992) estimated adult survival to be 0.95. Although there are no data for first year survival in gray whales, it is assumed here that survival does not differ strongly from that for humpback whales (*Megaptera novaeangliae*), which is 0.875 (Barlow and Clapham, 1997). For a stable population, therefore, the estimated proportion mature is 63%, which for the estimate of 88 whales in the present case results in 55 mature animals.

In addition to the uncertainty surrounding the estimated values of the population parameters, this estimate assumes that all mature adults are capable of reproduction. If, as suspected, the western population is not growing, then it is plausible that reproduction has been compromised because the population is so small. Data from another small population that has failed to recover provide a pessimistic comparative scenario. Only 70% of North Atlantic right whale (*Eubalaena glacialis*) females known to be mature are reproductively active (IWC, 2001). If it is assumed that all males reproduce but only 70% of the females do, then 85% of the sexually mature animals are capable of reproduction. Thus, of the 55 mature western gray whales estimated using this approach, only 47 would meet the IUCN definition of mature (see below).

Clearly, both these approaches are somewhat crude and are based on assumptions that may not be valid. However, both suggest a mature population size of less than 50 mature individuals, including only 11 known calf-bearing females documented between 1995 and 1999.

¹ In terms of evaluating the western gray whale population under 'Criterion D' (population estimated to number less than 50 mature individuals) of the World Conservation Union (IUCN), the definition of 'mature individuals' in this context is defined as 'the number of individuals known, estimated or inferred to be capable of reproduction' – see section on 'International concern and conservation measures'.

Potential threats to the population

Although there is some evidence that an undetermined level of hunting may occur (e.g. Brownell and Kasuya, 1999; Baker *et al.*, 2002), it seems likely that the major threats for this population may stem from indirect mortality (e.g. bycatches and ship strikes) and habitat pollution and degradation.

Gray whales are known to be vulnerable to incidental catches in fisheries (e.g. IWC, 1994) and there are extensive coastal net fisheries off southern China, Korea and Japan (Zhou and Wang, 1994; Kato, 1998; Kim, 2000). The substantial nearshore industrialisation and shipping congestion throughout the migratory corridor(s) of this population also represent potential threats by increasing the likelihood of exposure to chemical pollution and ship strikes. Present and planned large-scale offshore gas and oil development in the South China Sea and in close proximity to the only known feeding ground for western gray whales off northeast Sakhalin Island in the Okhotsk Sea is of particular concern (e.g. see Brownell *et al.*, 1997; Brownell and Yablokov, 2001; IWC, 2002b). Activities related to oil and gas exploration, including high-intensity geophysical seismic surveying, drilling operations, increased ship and air traffic, and oil spills all pose potential threats to gray whales (e.g. Moore and Clarke, 2002). Disturbance from underwater industrial noise may displace whales from critical feeding, migratory and breeding habitat (e.g. Bryant *et al.*, 1984; Richardson *et al.*, 1995; Brownell and Yablokov, 2001). Physical habitat damage from drilling and dredging operations, combined with possible impacts of oil and chemical spills on benthic prey communities, also warrant concern.

A recent concern is the deterioration in physical condition of numerous individuals; during 1999, 2000 and 2001 whales have been observed that appeared to be unusually thin ('skinny') while on the summer feeding grounds (Weller *et al.*, 2000; authors' data). Morphological attributes correlated with this description varied among individuals, but consisted of at least one of the following: (1) an obvious sub-dermal protrusion of the top edge of the scapula from the body with associated thoracic depressions at the anterior and posterior insertion points of the flipper; (2) the presence of depressions near and posterior to the blowholes and head; and (3) a pronounced depression along the neural/dorsal spine of the lumbar and caudal vertebrae resulting in the appearance of a 'bulge' along the lateral flank.

While the causal mechanism(s) for the observed deterioration in physical condition and apparent health status of some whales is unknown, any of the following alone or in combination may be contributing factors: (1) natural or human produced changes in prey availability or habitat quality; (2) physiological changes related to stress; or (3) disease. Regardless of the cause, the loss of even a few whales (especially reproductive females) due to this deterioration in physical condition will greatly hinder population growth and ultimately prevent its recovery. Therefore, it is essential that this situation is carefully monitored and that all anthropogenic activities be reduced to an absolute minimum.

Although a natural occurrence, predation by killer whales (*Orcinus orca*) may also pose an additional threat to the recovery of this population at its currently reduced number. Killer whales are known to kill eastern gray whales, especially calves, off central and northern California (Rice and Wolman, 1971; Baldrige, 1972). Andrews (1914) found killer whale tooth raking on the flukes and flippers of a majority of the gray whales killed off Korea and

documented numerous accounts of killer whales attacking both living and already captured gray whales. Although killer whales are somewhat common off the Sakhalin Island gray whale feeding ground, no aggressive interactions between the two species have been observed (Weller *et al.*, 2000). However, of 69 gray whales photographically identified between 1997 and 1998 on the feeding ground off Sakhalin, over 33% had tooth rakes from killer whales on their flukes, flippers or bodies (authors' data). This finding suggests that killer whales are at least threatening, and perhaps killing, western gray whales somewhere within their range but any associated mortality related to these observations is currently unknown.

Other factors, for which the cause is unknown but which give rise to concern for this population include low calf survival estimates (<42%) between 1995 and 1998; a male bias (59.4% males, 40.6% females; $n=64$) in the [biopsy] sampled population and a more pronounced male bias (77.8% males, 22.2% females; $n=9$) in sampled calves.

INTERNATIONAL CONCERN AND CONSERVATION MEASURES

Largely on the basis of the recent information provided by the joint USA-Russia research programme (1995-2001) initiative and summarised here, the World Conservation Union (IUCN) listed the western gray whale population as 'Critically Endangered' in 2000 (Hilton-Taylor, 2000). In particular, this was due to the criterion that the population is estimated to have less than 50 mature individuals.

Serious concern over the status of the population has also been expressed by the Scientific Committee of the International Whaling Commission (IWC, 2002b). As a result of this, the Commission itself passed a Resolution in 2001 calling for concerted action by range states and others to pursue actions to eliminate anthropogenic mortality and disturbances on this population (IWC, 2002a). The IWC also strongly endorsed a continuation and expansion of the current research programme.

CONCLUSION

It is apparent that long-term research and monitoring efforts of the western gray whale population need to be continued and expanded. The extensive past exploitation of this population, in combination with potential new threats from anthropogenic activities throughout its range, raises questions about the potential recovery and continued survival of the western gray whale. Future measures to protect this population will require international research collaboration between all range state countries and development of effective conservation measures and dedicated cooperation between science, industry and government.

ACKNOWLEDGEMENTS

In the field we were fortunate to work with S. Blokhin, A. Bradford, Y. Ivashchenko, S. Reeve-Rickards, Y. Shvetsov, G. Tsidulko and Y. Zhalinsky. Thanks to P. Clapham, J. Darling, D. DeMaster, T. Kasuya, S. Reilly, S. Swartz, W. Perryman and A. Yablokov for their excellent advice and willingness to serve as scientific advisors. A. Dizon and R. LeDuc conducted genetic analyses of the tissue samples to determine the sex of individuals. R. Reeves and the Editor

provided quality advice and comments on earlier drafts of this manuscript. Financial support for studies conducted between 1997-1999 were provided by Sakhalin Energy Investment Company (1997-1999) and Exxon Neftegas Ltd. (1997-1998). This project was conducted as part of the Marine Mammal Project under Area V: Protection of Nature and the Organization of Reserves within the US-Russia Agreement on Cooperation in the Field of Environmental Protection. This represents contribution no.75 of the Marine Mammal Research Program, Texas A&M University.

ABSTRACT

Between 2005 and 2007, four female western gray whales were accidentally entrapped and died in Japanese set nets while migrating along the Pacific coast of Honshu, Japan. Photographs of these animals were compared to a photo-identification catalogue of western gray whales from their feeding ground off Sakhalin Island, Russia, to look for matches of individuals between the two areas. Although useable quality photographs were available for only one of the four whales from Japan, a confirmed match was made to a whale photographed off Sakhalin Island. This match represents the first link between the feeding ground and a migratory corridor and highlights the importance of multi-national research collaboration in the formation of range-wide conservation measures to protect this critically endangered population.

KEYWORDS: GRAY WHALE; PHOTO-IDENTIFICATION; ENTRAPMENT; BYCATCH; CONSERVATION; NORTHERN HEMISPHERE; INCIDENTAL CATCHES; FEEDING GROUNDS; MIGRATION; PACIFIC OCEAN

INTRODUCTION

The western North Pacific population of gray whales (*Eschrichtius robustus*) is critically endangered (Baillie *et al.*, 2004; Weller *et al.*, 2002). The population is estimated to contain about 130 individuals of age one or older, of which only 23 are known to be reproductive females (Cooke *et al.*, 2008; Weller *et al.*, 2008). The population faces a number of potential anthropogenic threats throughout its range, primarily as a result of oil and gas development on its feeding ground off Sakhalin Island (Reeves *et al.*, 2005) and fishing activities in much of its range. These threats include: collisions with ships, exposure to underwater noise (e.g. seismic surveys); modifications to physical habitat; and entrapment or entanglement in fishing gear (Brownell *et al.*, 2007; Reeves *et al.*, 2005; Weller *et al.*, 2002).

Western gray whales migrate to summer feeding grounds off the northeastern coast of Sakhalin Island, Russia, from winter breeding grounds suspected to be in the South China Sea. While the coastal waters of eastern Russia, the Korean Peninsula and Japan have all been recorded as migratory corridors historically, the current migration route(s) of the population is not well understood (e.g. see review in Weller *et al.*, 2002). Although western gray whales were hunted centuries ago by net fishermen off the eastern shores of Japan (Omura, 1984), present-day sightings in that country are uncommon (Kato *et al.*, 2007). Of the 17 records since 1955 that exist in Japan, 76% ($n=13$) were reported from the Pacific (east) coast while 24% ($n=4$) came from the Sea of Japan (west) coast. Eleven (65%) of these records are from the period 1990 to 2007, with none reported between 1970 and 1982, suggesting that occurrence patterns, sighting effort or both have recently increased. All occurrences took place between January and July with the highest number of records ($n=11$) reported between March and May. Six (35%)

of the 17 observations were reported as 'entanglements' by Kato *et al.* (2007). The importance of these records is two-fold in that they: (1) provide recent evidence for use of the eastern and western shores of Japan as migration corridors for at least some whales; and (2) identify and highlight the problem of interactions with coastal fishing gear during migration.

Between 2005 and 2007, four female western gray whales were unintentionally entrapped and died in Japanese set nets (i.e. trap nets) while migrating off the Pacific coast of Honshu, Japan (Kato *et al.*, 2006; Kato *et al.*, 2007; 2005). These four animals included: (1) a 7.8m female found in the southeastern part of Tokyo Bay on 11 May 2005; (2) a large 12.7m female and a smaller 7.7m female (considered a mother-calf pair) found about 340km northeast of Tokyo (near Enoshima, Onagawa Peninsula, Miyagi Prefecture) on 15 July 2005; and (3) a 9.1m female found approximately 430km northeast of Tokyo (in Yoshihama Bay, Ofunato City, Iwate Prefecture) on 18 January 2007 (Fig. 1). Photographs of these entrapped animals were compared to a photo-identification catalogue of western gray whales (Weller *et al.*, 2006; 1999) from their feeding ground in the Okhotsk Sea off Sakhalin Island, Russia, to look for matches of individuals between the two areas. The results of this comparison are presented herein.

METHODS AND RESULTS

Since 1995, a collaborative Russia-US photo-identification study of western gray whales on their summer feeding ground off the northeastern coast of Sakhalin Island, Russia, has been ongoing (Weller *et al.*, 2008; Weller *et al.*, 1999). Through 2006, 158 individually identified whales have been catalogued, including 59 whales first identified as calves

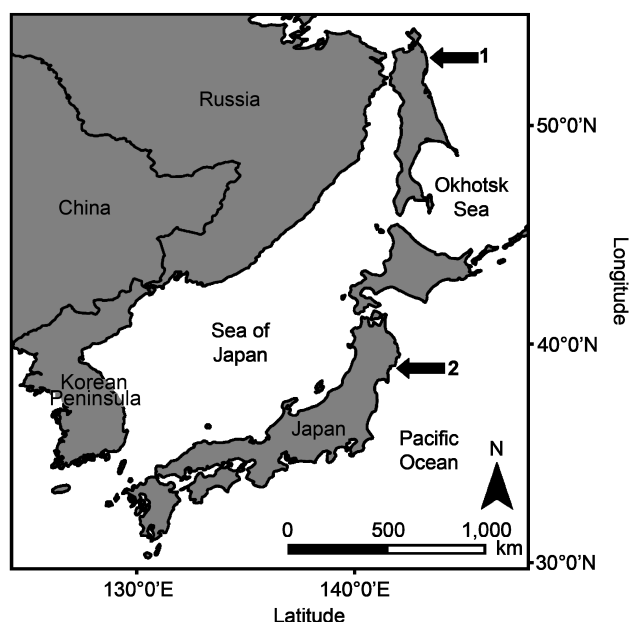

Fig. 1. Map of western North Pacific region showing where western gray whale no. 151 was sighted on the feeding ground off Sakhalin Island, Russia (52°50'N, 143°20'E) on 23 July 2006 (Arrow 1) and found in a trap net off Honshu, Japan (39°08'N, 141°54'E) on 18 January 2007 (Arrow 2).

(Weller *et al.*, 2008). This catalogue of known individuals served as the basis for comparison to images collected from the whales entrapped off Japan. Upon initial inspection of the available photographs of the four whales taken in set nets between 2005 and 2007, it was found that the only images of suitable quality for comparison to the Sakhalin Island catalogue were those of the Yoshihama Bay whale. Left and right dorsal flank images of this whale were examined and found to match whale no. 151 from the Russia-US catalogue.

Whale no. 151 was first sighted off northeastern Sakhalin Island on 23 July 2006. It was sighted again two days later, when a biopsy sample was taken. The final sighting of whale no. 151 occurred on 24 August 2006. During each encounter, this whale was observed in close association with a known reproductive female who was last observed to have a calf in 2002. Based on this relationship and the size difference of the two animals, these whales were recorded as a mother-calf pair, one of four such pairs observed during the 2006 field season (Weller *et al.*, 2008). This mother-calf designation was subsequently confirmed by genetic analysis (A.R. Lang, pers. comm.). Whale no. 151 would have been weaned on the Sakhalin feeding ground in the late summer or early autumn of 2006 before migrating southward along the eastern coast of Japan. Based on the mean birth date of mid-January (Rice, 1983; Rice and Wolman, 1971) and southbound migratory timing (Rugh *et al.*, 2001) reported for eastern gray whales, whale no. 151 was approximately one year old and migrating south when entrapped in a set net off Japan in January 2007.

DISCUSSION

The photographic match reported here is the first to link the feeding ground of western gray whales to a location more than 1,500km to the south within a migratory corridor. This finding, when combined with other data on gray whales off Japan (see Kato *et al.*, 2007), adds useful contemporary information on when and where gray whales might be found during their migration as well as the pathways being used.

Omura (1984) hypothesised that gray whales occurring off the Pacific coast of Japan could comprise a distinct stock or substock of the western population and Park (2001) went on to suggest that this supposed substock might summer off the coast of southern Kamchatka and migrate along the Kuril Islands. The evidence presented herein does not support the reasoning offered by Omura (1984) and Park (2001). In a broader context, this match highlights the importance of obtaining photographs (and genetic samples) from western gray whales outside of the Sakhalin Island feeding ground whenever possible and emphasises how multi-national research collaboration can benefit range-wide conservation measures designed to best protect this critically endangered population.

ACKNOWLEDGEMENTS

Our appreciation goes to Greg Donovan and two anonymous reviewers for helpful comments on an earlier draft of this manuscript. We would also like to thank the numerous people who have provided assistance to the Russia-US research team in the field, especially: S. Blokhin, Y. Ivashchenko, H.W. Kim, A. Lang, S. Reeve and G. Tsidulko. We gratefully acknowledge the 2006-2007 support granted to the joint Russia-US research programme from (in alphabetical order): Alaska Sea Life Center, International Fund for Animal Welfare, International Whaling Commission, Ocean Park Conservation Foundation, University of Washington, US Marine Mammal Commission and the US National Marine Fisheries Service. Fieldwork in Russia was conducted as part of the Marine Mammal Project under Area V: Protection of Nature and the Organisation of Reserves within the US-Russia Agreement on Cooperation in the Field of Environmental Protection.

ABSTRACT

The western North Pacific (WNP) population of gray whales (*Eschrichtius robustus*) is listed as critically endangered by the IUCN and its continued ability to survive is of concern. As part of a long-term study on WNP whales off Sakhalin Island, Russia, a photo-catalog comparison to eastern North Pacific (ENP) gray whales was undertaken to detect possible population mixing. The WNP/ENP catalog comparison involved 181 and 1,200 individuals, respectively, and resulted in six matches (three males, two females, and one whale of unknown sex). Three of the six whales were first identified as calves (with their mothers) off Sakhalin. All ENP sightings of Sakhalin whales occurred off southern Vancouver Island, BC, and were collected during only two days of effort. Three whales were identified on 02 May 2004 and 25 April 2008, respectively. The three whales in 2004 were together in a single group, while the three whales in 2008 were in two groups in close proximity. All six whales were sighted off Sakhalin prior to their ENP sightings and five were observed off Sakhalin subsequent to being sighted in the ENP. Four whales were sighted in both the ENP and WNP in the same year, three in 2004 and one in 2008. As the ENP catalog represents only a fraction of the total number of individuals in the ENP population (~19,000), it is likely that more WNP/ENP exchange has occurred than was detected during this comparison. Although these matches provide new records of WNP to ENP movements, winter/spring observations of gray whales off Japan, including a 2006/2007 photo-match from Honshu to Sakhalin, indicate that not all gray whales identified off Sakhalin share a common wintering ground. Thus, it is possible that the number of whales in the WNP population is smaller than previously estimated and therefore of increased conservation concern.

KEYWORDS: GRAY WHALE; PACIFIC OCEAN; MOVEMENT PATTERNS; CONSERVATION

INTRODUCTION

The western gray whale (*Eschrichtius robustus*) population is listed as critically endangered by the IUCN and its continued ability to survive is of concern. The most recent population assessment by Cooke *et al.* (2008), using a Bayesian individually-based stage structured model, reported a median 1+ (non-calf) estimate of 130 individuals (90% Bayesian CI = 120-142). Research on this population has been ongoing since 1995, primarily on the feeding ground off northeastern Sakhalin Island, Russia (Weller *et al.*, 1999; Bradford *et al.*, 2008; Lang *et al.*, 2010) but also, recently, off southeastern Kamchatka (Vertyanin *et al.*, 2004; Tyurneva *et al.*, 2010; Burdin *et al.*, 2011).

Our photo-identification studies on the Sakhalin feeding ground have documented (1) pronounced seasonal site fidelity and annual return of known individuals, (2) utilization of the area by reproductive females when pregnant, resting and accompanying their calves and (3) return to the area by many individuals first identified as calves (Weller *et al.*, 1999, 2002; Bradford *et al.*, 2008). Genetic studies utilizing both mitochondrial and nuclear markers have observed significant levels of differentiation between western North Pacific (WNP) and eastern North Pacific (ENP) gray whales, indicating that some degree of reproductive isolation occurs (Lang, 2010; Lang *et al.*, 2011).

Some of the whales identified feeding in the coastal waters off Sakhalin, including reproductive females and calves, have also been documented off the southern and eastern coast of Kamchatka (Tyurneva *et al.*, 2010; Burdin *et al.*, 2011). Further, sightings of whales observed off Sakhalin have been recorded off the northern Kuril Islands in the eastern Okhotsk Sea and Bering Island in the western Bering Sea (Weller *et al.*, 2003).

While information regarding the summer feeding areas of gray whales in the WNP has become increasingly available in the past decade, little is known about the current migratory routes and wintering areas of these animals. Historic evidence suggests that the coastal waters of eastern Russia, the Korean Peninsula and Japan were part of the migratory route at one point in time and that areas in the South China Sea may have been used as wintering grounds (see review in Weller *et al.*, 2002). Observations of gray whales off Japan have been made for hundreds of years (Omura, 1984), including 13 records since 1990 (Kato *et al.* 2010). Between 2005 and 2007, four female gray whales were fatally entrapped in set nets while migrating along the Pacific coast of Honshu. One of these females, entrapped in January 2007, was matched to an earlier photograph of it as a calf (with its mother) while on the Sakhalin feeding ground in 2006 (Weller *et al.*, 2008). This match provided the most contemporary link between the Sakhalin feeding ground and a winter migratory route in WNP.

In an effort to obtain more information about the southern migration route(s) and wintering area(s) of WNP gray whales, a collaborative satellite telemetry project was undertaken in 2010 by a team of Russian and American scientists¹. A 13-year old male gray whale named “Flex” was tagged on the Sakhalin feeding ground in October 2010 and tracked to the ENP off the west coast of the U.S.^{2,3} While the objective of this tagging study was to document gray whale movements in the WNP, the tracking of “Flex” to the ENP provided the impetus for the WNP/ENP photo-identification catalog comparison described herein.

METHODS

Photo-identification images of 181 individual western gray whales (called the WNP catalog herein⁴) collected off Sakhalin between 1994-2009 by a Russia-U.S. joint research program were compared to a catalog of nearly 1200 eastern gray whales (called the ENP catalog) identified by Cascadia Research Collective and its collaborators working in U.S. and Canadian waters from California to Alaska (Calambokidis *et al.*, 2002; 2010). The ENP catalog focuses on several hundred gray whales called the Pacific Coast Feeding Group (PCFG) that feed during summer and fall in coastal waters between northern California and the Gulf of Alaska but also includes a small number ($n=247$) of migrating gray whales identified in the spring (March to May) during their northward passage to the Bering, Beaufort and Chukchi Seas.

RESULTS

The WNP/ENP catalog comparison resulted in a total of six confirmed matches, including three males, two females, and one whale of unknown sex (Table 1). None of these six whales are known PCFG animals and, to date, have only ever been sighted a single time during either May or April.

⁴ The number of whales in this catalog ($n=181$) does not correspond to the estimated size of the population.

Remarkably, all six of the matches were from only two days of effort in the ENP, with three whales identified on 02 May 2004 and three on 25 April 2008. The three whales identified on 02 May 2004 were together in a single group while the three whales recorded on 25 April 2008 were in two separate groups but in close proximity. All of the sightings of WNP gray whales in the ENP occurred off the west coast of southern Vancouver Island, BC (near Barkley Sound).

Three of the six whales were first identified as calves (with their mothers) on the Sakhalin feeding ground during 1997 (no. 032/1045), 2003 (no. 119/1040) and 2004 (no. 135/1042), respectively. All six whales had sightings off Sakhalin prior to their respective sightings in the ENP and five (83%) had sightings off Sakhalin subsequent to their ENP sightings. Four whales were sighted in the ENP and WNP in the same year, three in 2004 and one in 2008. Of the three whales identified off Vancouver Island on 02 May 2004, two were sighted off Sakhalin on 31 July 2004 while the third was first sighted on 6 August 2004. "Flex" (no. 032/1045) was sighted off Sakhalin in 2007 during July (29th), August (4, 18, 25th) and September (7, 8, 9th), off southern Vancouver Island on 25 April 2008 and then back off Sakhalin on 19 July 2008. The movements of "Flex" detailed here were all prior to the telemetry derived track showing him moving from the WNP off Sakhalin in October 2010 to the ENP off the U.S. west coast in February 2011¹. Thus, "Flex" has made the trip from the WNP to the ENP more than once.

DISCUSSION

The six photographic matches reported here provide new information that is of broad significance to understanding the population structure and mixing of gray whales in the Pacific (see Lang *et al.*, 2011). Particularly intriguing is the high number of matches made given that the ENP catalog used for comparison focuses on PCFG whales and has only a small number ($n=247$) of the approximately 19,000 gray whales (Laake *et al.*, 2009) that pass the Pacific Northwest during the spring migration (March to May). Even smaller numbers of whales in the ENP catalog have been identified during the spring off the coast of Vancouver Island where the six whales matched were observed ($n=26$ for southern Vancouver Island; $n=48$ for all of western Vancouver Island). Given that the ENP catalog contains only a small fraction (1,200) of the total number of individuals (~19,000) in the ENP population, it is likely that more WNP/ENP exchange has occurred than was detected during this comparison.

The high match rate observed in this study suggests there is a spatio-temporal behavioral factor that makes WNP whales more likely to have been identified in the small ENP spring sample. That all the matches came from sightings on only two days, mostly in the same groups and in localized areas, indicates that whales from the Sakhalin feeding ground remain associated, at least to some degree, even when in the ENP. These six whales were sighted in an area where some whales tend to linger and feed during the northbound migration. Feeding whales are often found in more nearshore waters and over extended periods of time, potentially making them more likely to be photographed than animals rapidly migrating pass the area. The long distance and potential open water crossing required for transit from the ENP to the WNP may make it advantageous for whales to spend time feeding in the Pacific Northwest (e.g. Vancouver Island) prior to undertaking a westerly passage to Sakhalin.

Although the high number of matches reported here was somewhat surprising, WNP to ENP movements were not completely unexpected. Lang (2010) reported that two adult individuals from the WNP, sampled off Sakhalin in 1998 and 2004, matched the microsatellite genotypes, mtDNA haplotypes, and sexes (one male, one female) of two whales sampled off central California on 20 and 23 March 1995. When these two genetic matches are combined with the six photographic matches reported herein, a total of eight adult WNP gray whales have been matched to the ENP. These eight matches include four males and three females, providing evidence that both sexes, in approximately equal numbers, move between the WNP and the ENP. Interestingly, one of the males (no. 035/0809) matched in this study was determined to be the father of two and possibly four calves identified off Sakhalin (Lang, 2010). Despite this level of mixing, significant mtDNA and nuclear genetic differences between whales utilizing the Sakhalin feeding ground and those summering in the ENP support the continued recognition of Sakhalin animals as a distinct unit (Lang *et al.*, 2011).

Adding to the complexity of mixing between the WNP and ENP are contemporary records of gray whales off Japan. There have been 13 reports of gray whales in Japanese waters since 1990 (Kato *et al.*, 2010). One of these reports includes a whale first identified as a calf accompanied by her mother off Sakhalin Island in 2006 that was later fatally entrapped in a set net off the Pacific coast of Honshu in January 2007

Weller *et al.*, 2008). While observations of gray whales in Japan have been made between November and August, a majority of these records are concentrated between March and May. This March to May period coincides with when the six matched whales described here were sighted in the ENP. These findings indicate that not all gray whales identified off Sakhalin share a common wintering ground and suggest that the number of whales estimated to be in the WNP population may possibly be lower than previously thought.

The use of photo-identification methods, in combination with genetic and telemetry techniques, are essential to furthering our understanding of gray whale population structure. It is recommended that other existing photo collections and tissue samples of WNP and ENP gray whales (e.g. those from Sakhalin, Kamchatka, Chukotka, Mexico and Japan) be used to further examine gray whale movement patterns and population structure within the Pacific. Ideally, a collaborative Pacific wide study should be undertaken, similar in scope to what has been done for humpback whales in the Atlantic and Pacific.

ACKNOWLEDGEMENTS

We extend our deepest appreciation to all of those that have contributed photographs and data to the WNP and ENP catalogs. Ryan Wulff and Doug DeMaster were instrumental in securing funding for this comparison. Justin Cooke, Greg Donovan, Randy Reeves and Wayne Perryman provided valuable insight and encouragement throughout this project. The Protected Resources Division, Southwest Fisheries Science Center, National Marine Fisheries Service, National Oceanic and Atmospheric Administration provided support for the participation of RLB, ARL and DWW.

ABSTRACT: The western North Pacific (WNP) population of gray whales *Eschrichtius robustus* is redlisted by the IUCN as Critically Endangered. As part of a long-term study on whales off Sakhalin Island, Russia, photo-catalog comparisons of gray whales in the western and eastern North Pacific (ENP) were undertaken to assess population mixing. These comparisons involved 2 approaches: (1) a systematic comparison of the WNP 'Sakhalin Catalog' to an ENP 'Pacific Northwest Catalog' that consisted of images from the northwest coast of North America and (2) a non-systematic comparison of the WNP 'Sakhalin Catalog' to an ENP 'Laguna San Ignacio Catalog' that consisted of images from central Baja California, Mexico. The Sakhalin to Pacific Northwest comparison consisted of 181 and 1064 whales, respectively, and resulted in 6 matches (3 males, 2 females, and 1 whale of unknown sex). All sightings of 'Sakhalin whales' in the Pacific Northwest occurred off southern Vancouver Island, British Columbia, Canada. The Sakhalin to Laguna San Ignacio comparison consisted of 181 and 2514 whales, respectively, and resulted in 4 matches (2 males and 2 females). As the Pacific Northwest and Laguna San Ignacio catalogs represent only a small fraction of the total estimated number of individuals in the ENP population (~19 000), it is likely that more WNP/ENP exchange has occurred than was detected by these photo-catalog comparisons. Although these matches provide new records of movements between the WNP and ENP, recent observations of gray whales off Japan and China suggest that not all gray whales identified in the WNP share a common wintering ground.

Once thought to be extinct, an endangered western North Pacific gray whale breaches off Sakhalin Island, Russia.

INTRODUCTION

Gray whales *Eschrichtius robustus* are presently recognized as 2 populations in the North Pacific Ocean. Recent genetic studies using both mitochondrial and nuclear markers have demonstrated significant differentiation between the western North

*Email: dave.weller@noaa.gov

Pacific (WNP) and eastern North Pacific (ENP) populations (LeDuc et al. 2002, Lang 2010, Lang et al. 2011). The ENP population ranges from calving areas off Baja California, Mexico, to feeding areas in the Bering, Beaufort, and Chukchi Seas. The WNP population feeds in the Okhotsk Sea off Sakhalin Island, Russia, and in nearshore waters of the southeastern Kamchatka Peninsula (southwestern Bering Sea). Little is known about the current migratory routes and wintering areas of the WNP population, but historic evidence indicates that the coastal waters of eastern Russia, the Korean Peninsula, and Japan were part of the migratory route and that areas in the South China Sea were used as wintering grounds (see review by Weller et al. 2002).

Both populations were dramatically reduced by commercial whaling during the 19th and 20th centuries (Henderson 1984, Weller et al. 2002, Reeves et al. 2010). The ENP population was removed from the U.S. List of Endangered and Threatened Wildlife in 1994 and is currently estimated to number approximately 19 000 individuals (Laake et al. 2009). At the single species-level unit, gray whales are redlisted by the International Union for Conservation of Nature (IUCN) as being of Least Concern (Reilly et al. 2008). The WNP subpopulation, however, is redlisted by the IUCN as Critically Endangered (Reilly et al. 2008). The most recent assessment of the Sakhalin population, using a Bayesian individual-based stage-structured model, resulted in a median 1+ (non-calf) estimate of 130 individuals (90% Bayesian CI = 120–142) in 2008 (Cooke et al. 2008).

Research on gray whales in the WNP has been ongoing since 1995, predominantly on the primary feeding ground off northeastern Sakhalin Island (Weller et al. 1999, Bradford et al. 2008, Lang et al. 2011), and more recently off southeastern Kamchatka (Vertyanin et al. 2004, Tyurneva et al. 2010, Burdin et al. 2011). These studies monitor gray whales using photo-identification methods, as gray whales are individually identifiable based on unique, permanent pigmentation features (Darling 1984). Such monitoring on the Sakhalin feeding ground has documented (1) pronounced seasonal site fidelity and inter-annual return of known individuals, (2) consistent use of the area by adult females when pregnant, resting (i.e. when not pregnant or lactating), and accompanied by calves, and (3) annual return by many individuals that were first identified there as young-of-the-year (Weller et al. 1999, 2002, Bradford et al. 2008, Bradford 2011).

Whales associated with the Sakhalin feeding area can be absent for all or part of a given feeding season (Bradford et al. 2008), indicating that they probably use other areas during the summer and fall feeding period. Some of the whales identified feeding in the coastal waters off Sakhalin, including reproductive females and calves, have also been documented off the southern and eastern coast of Kamchatka (Tyurneva et al. 2010, Burdin et al. 2011). Further, whales observed off Sakhalin have been sighted off the northern Kuril Islands in the eastern Okhotsk Sea and Bering Island in the western Bering Sea (Weller et al. 2003). Finally, Lang (2010) reported that 2 adult individuals from the WNP, sampled off Sakhalin in 1998 and 2004, matched the microsatellite genotypes, mtDNA haplotypes, and sexes (1 male, 1 female) of 2 whales sampled off Santa Barbara, California, USA (Area 3 in Fig. 1) on 20 and 23 March 1995. The study by Lang (2010) was the first to suggest that some level of interchange might be occurring between the WNP and ENP.

While information regarding the summer feeding areas of gray whales in the WNP has become increasingly available in the past decade, current data from the historic migratory corridor(s) are limited and data from the presumed wintering area(s) are essentially unavailable. There have been only 13 known sightings or strandings in Japanese waters since 1990 (Nambu et al. 2010). Between 2005 and 2007, 4 female gray whales were fatally entrapped in set nets along the Pacific coast of Honshu, Japan. One of these females, entrapped in January 2007, was matched to earlier photographs of it as a calf (with its mother) while on the Sakhalin feeding ground in July and August 2006 (Weller et al. 2008). This match provided the most contemporary link between the summer feeding ground off Sakhalin and a winter location along the coast of Asia.

In an effort to obtain more information about the southern migration route(s) and wintering area(s) of gray whales in the WNP, a satellite telemetry project was undertaken in 2010 by a team of Russian and American scientists (Mate et al. 2011). While the objective of that study was to document gray whale movements in the WNP, the only whale tagged was tracked from the WNP to the ENP. The result of this telemetry study, together with the genetic matches reported by Lang (2010), provided the impetus for WNP/ENP photo-identification catalog comparisons, which we conducted to further assess population mixing.

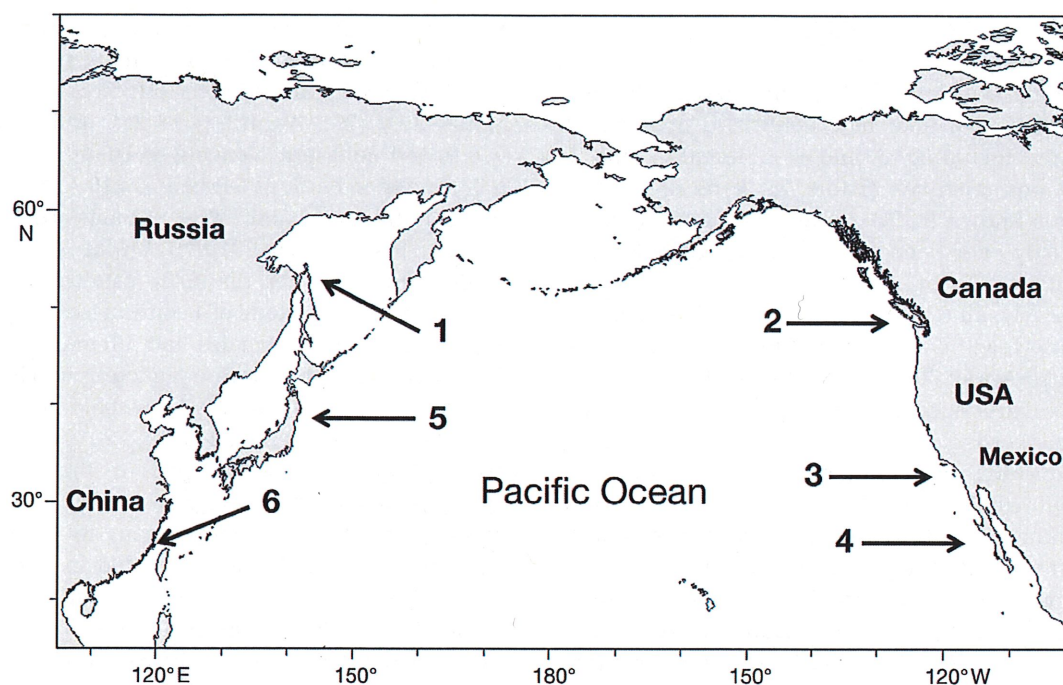

Fig. 1. *Eschrichtius robustus*. North Pacific Ocean, showing: (1) Western North Pacific (WNP) feeding ground off Sakhalin Island, (2) Eastern North Pacific (ENP) region off Vancouver Island where 6 photographic matches to Sakhalin individuals were found, (3) ENP region off California where 2 genetic matches were found (Lang 2010), (4) ENP region off Baja California where 4 photographic matches to Sakhalin individuals were found, (5) WNP region of Japan where a photographic match was found (Weller et al. 2008), and (6) WNP region of China where a gray whale stranded in November 2011 (Zhu 2012)

MATERIALS AND METHODS

Photo-identification images of 181 Sakhalin gray whales (the Sakhalin catalog, hereafter SAK catalog) collected off Sakhalin Island (Area 1 in Fig. 1) between 1994 and 2009 by a joint Russia-U.S. research program (Weller et al. 1999, 2002) were compared to a catalog of 1064 'Pacific Northwest gray whales' (hereafter, PNW catalog) identified by Cascadia Research Collective and collaborators working in U.S. and Canadian waters from California to Alaska (Area 2 in Fig. 1) primarily between 1998 and 2009 (Calambokidis et al. 2002, 2010). The PNW catalog focuses on gray whales that feed during summer and fall in coastal waters between northern California and the Gulf of Alaska, referred to as the Pacific Coast Feeding Group (PCFG), but also includes some migrating whales identified in the spring (March to May) during their northward passage to high-latitude feeding grounds.

Of the 181 whales in the SAK catalog, all were represented by a right-side dorsal flank image, and 179 were associated with a left-side dorsal flank image. Of the 1064 whales in the PNW catalog, 845 were represented by a right-side dorsal flank image, and 898 were associated with a left-side dorsal flank

image. Each individual in the SAK catalog was compared in numerical order to all individuals in the PNW catalog as follows. First, the left-side dorsal flank of each individual in the SAK catalog was compared to the left-side dorsal flank of all individuals in the PNW catalog. This process was then repeated using the right-side dorsal flank and ventral aspect of the tail flukes. Comparisons were made by a single analyst (A.K.), but resulting matches were confirmed by 3 independent researchers skilled in gray whale photo-identification (including A.L.B. and J.C.).

Similarly, photo-identification images of 181 whales in the SAK catalog were compared to an online catalog of 2514 'Laguna San Ignacio gray whales' (hereafter, the LSI catalog) identified between 2006 and 2010 in Baja California, Mexico (Area 4 in Fig. 1). This assessment was not comprehensive or systematic, as was the case for the PNW catalog, because the LSI catalog represented a collection of 'annual working catalogs' rather than a single multi-year catalog of known individuals. Thus, the comparison to the SAK catalog reported herein was undertaken opportunistically. A single analyst (A.L.B.) conducted the appraisal, with identified matches confirmed by 2 additional observers (including D.W.W.).

RESULTS

The comparison of the SAK catalog to the PNW catalog resulted in a total of 6 confirmed matches of individuals, including 3 males, 2 females, and 1 whale of unknown sex (Table 1). None of these 6 whales is a known PCFG animal, and, to date, each one has only ever been photographed a single time during either April or May.

Remarkably, all 6 of the matches were from only 2 days of effort, with 3 whales identified on 2 May 2004 and 3 on 25 April 2008. The 3 whales identified on 2 May 2004 were together in a single group, while the 3 whales recorded on 25 April 2008 were in 2 separate groups but in close proximity. All of the sightings of Sakhalin whales in the Pacific Northwest occurred near Barkley Sound off the west coast of southern Vancouver Island, British Columbia, Canada.

Three of the 6 whales were first identified as calves (with their mothers) on the Sakhalin feeding ground during 1997 (no. RUS-U.S. 032/CRC 1045), 2003 (no. RUS-U.S. 119/CRC 1040), and 2004 (no. RUS-U.S. 135/CRC 1042; Table 1). Interestingly, a genetic analysis of paternity classified one of the matched males (no. RUS-U.S. 035/CRC 0809) as the putative father of 2, or possibly 4, calves identified off Sakhalin (Lang 2010). All 6 whales had sightings off Sakhalin prior to their respective sightings off Vancouver Island, and 5 (83%) had sightings off Sakhalin subsequent to their Vancouver sightings. Four whales were sighted off Vancouver Island and Sakhalin in the same year: 3 in 2004 and 1 in 2008. Of the 3 whales identified off Vancouver Island on 2 May 2004, 2 were resighted off Sak-

halin on 31 July 2004, while the third was first resighted on 6 August 2004. Whale no. RUS-U.S. 032/CRC 1045 was sighted off Sakhalin in 2007 during July (29), August (4,18,25), and September (7,8,9), off southern Vancouver Island on 25 April 2008, and then back off Sakhalin on 19 July 2008. This whale is the same individual satellite-tracked from Sakhalin to the ENP in 2010/2011 (Mate et al. 2011).

The comparison of the SAK catalog to the LSI catalog resulted in a total of 4 confirmed matches of individuals, including 2 males and 2 females (Table 2). Three of these 4 whales were photographed in Laguna San Ignacio in only 1 year, while whale no. RUS-U.S. 052 was identified in both 2007 and 2010. All 4 whales had sightings off Sakhalin prior to their respective sightings in Laguna San Ignacio, and 3 (75%) had sightings off Sakhalin subsequent to their lagoon sightings. Two whales were sighted in Laguna San Ignacio and Sakhalin in the same year: one in 2008 (no. RUS-U.S. 063) and one in 2010 (no. RUS-U.S. 052).

One of the 4 whales (no. RUS-U.S. 020) was first identified as a calf on the Sakhalin feeding ground

^aSame whale satellite-tagged in 2010 (Mate et al. 2011). First identified off Sakhalin as a calf in 1997. ^bPutative father of 2 (strict criterion) or 4 (relaxed criterion) Sakhalin calves (for definitions see Lang 2010). Years that these calves were first identified are: 1998, 2001, 2002, and 2003. ^cFirst identified off Sakhalin in 2003 as a calf. ^dFirst identified off Sakhalin in 2004 as a calf

during 1997 (Table 2) and photographically matched to the Commander Islands in June 2000 (Weller et al. 2003). A genetic analysis of paternity classified 1 of the matched males (no. RUS-U.S. 052) as the putative father of a calf identified in 1998 off Sakhalin (Lang 2010). Both of the matched females were identified as mothers with calves while in Laguna San Ignacio. Whale no. RUS-U.S. 042 was identified as a mother with a calf in 2009 but has never been seen with a calf off Sakhalin. Whale no. RUS-U.S. 063 was identified as a mother with a calf in 2008 and was also observed with a calf off Sakhalin (in 1998).

DISCUSSION

The photographic matches reported here provide new information that is of broad significance to understanding the migration patterns and mixing of gray whales in the North Pacific. The high number of matches made between the SAK and PNW catalogs is particularly intriguing given that the PNW catalog used for comparison focuses on PCFG whales and thus greatly underrepresents individuals that pass off the Pacific Northwest during the spring migration. Limited numbers of whales in the PNW catalog have been photographed during the spring off the coast of Vancouver Island where the 6 matched whales were observed ($n = 26$ for southern Vancouver Island; $n = 48$ for all of western Vancouver Island). Thus, 6 of the 74 (8.1%) whales identified off Vancouver Island in the PNW catalog were known Sakhalin individuals. Given that the PNW catalog contains only a small fraction (1064) of the estimated total number of individuals (~19 000) in the ENP population, it is likely that more WNP/ENP exchange has occurred than was detected during this comparison.

The high match rate observed between the SAK and PNW catalogs suggests a spatio-temporal behavioral factor that makes Sakhalin whales more likely to have been identified in the small PNW spring sample. The fact that all the matches came from sightings made on only 2 days, mostly in the same groups and in localized areas, indicates that whales from the Sakhalin feeding ground associate, at least to some degree, even when utilizing migratory routes in the ENP. These 6 whales were sighted in an area where some whales tend to linger and feed during the northbound migration (Darling et al. 1998). Feeding whales are often found in more nearshore waters and over extended periods of time, potentially making them more likely to be photographed than animals rapidly migrating past the area (Darling et al. 1998,

Calambokidis et al. 2010). The long distance and potential open water crossing required for transit from the ENP to the WNP may make it advantageous for whales to spend time feeding in the Pacific Northwest (e.g. Vancouver Island) prior to undertaking a westerly passage to Sakhalin.

The preliminary comparison of the SAK and LSI catalogs revealed 4 additional matches. Since the SAK to LSI catalog comparison was conducted in a non-comprehensive manner, relying on long-term familiarity with whales in the WNP catalog, it is probable that additional matches exist. Given the importance of conducting further comparisons to the wintering lagoons of Baja California, Mexico, a systematic and comprehensive comparison of the SAK catalog to a recently compiled multi-year catalog from LSI and Laguna Ojo de Liebre (Scammon's Lagoon) is presently underway (see IWC 2011).

When the 10 WNP/ENP photo-identification matches reported here are combined with the 2 genetic matches noted by Lang (2010), a total of 12 gray whales (6 males, 5 females and 1 whale of unknown sex) identified in the WNP off Sakhalin Island have been matched to 3 locations in the ENP (Vancouver Island, Southern California, Laguna San Ignacio), providing evidence that both sexes, in approximately equal numbers, move between the WNP and the ENP. Despite this level of mixing, significant mtDNA and nuclear genetic differences between whales utilizing the Sakhalin feeding ground and those summering in the ENP support the continued recognition of Sakhalin animals as a distinct genetic unit (Lang et al. 2011).

Adding to the complexity of mixing between the WNP and ENP are contemporary records of gray whales off Japan and, to a lesser degree, China. As previously mentioned, there have been only 13 records of gray whales in Japanese waters since 1990 (Nambu et al. 2010). One of these reports includes a whale first identified as a calf accompanied by her mother on the Sakhalin Island feeding ground in July and August 2006 that was later fatally entrapped in a set net off the Pacific coast of Honshu (Area 5 in Fig. 1) in January 2007 (Weller et al. 2008). While observations of gray whales in Japan have been made between November and August, most of these records are concentrated between March and May. This March to May period coincides with the sightings in the ENP of the 10 matched whales described here. Observations of gray whales in China are exceptionally rare. Only 24 sightings and/or strandings have been recorded since 1933, including obser-

uations of 2 mother–calf pairs (Wang 1984, Zhu 2002). However, a 13 m female gray whale stranded in the Taiwan Strait near the town of Baiqingxiang (Pingtan County), China (Area 6 in Fig. 1), in November 2011 (Zhu 2012). These findings, in combination, suggest that not all gray whales identified in the WNP share a common wintering ground.

The use of photo-identification methods, together with genetic and telemetry techniques, is essential to furthering our understanding of gray whale population structure. We recommend that other existing photo collections and tissue samples of gray whales in the WNP and ENP (e.g. those from Sakhalin, Kamchatka, Chukotka, Mexico, and Japan) be used to further examine gray whale movement patterns and population mixing within the Pacific. Ideally, a collaborative Pacific-wide study should be undertaken, similar in scope to those conducted for humpback whales in the Atlantic and Pacific (Smith et al. 1999, Calambokidis et al. 2008).

Acknowledgements. We thank all who have contributed photographs and data to the WNP and ENP catalogs. D. DeMaster and R. Wulff were instrumental in securing funding for this comparison. J. Cooke, G. Donovan, R. Reeves, and W. Perryman provided valuable insight and encouragement throughout this project. The IWC granted permission for use of photographic data from 2010. The National Marine Mammal Laboratory provided support for portions of the PNW photo-identification studies. The Protected Resources Division, Southwest Fisheries Science Center, National Marine Fisheries Service, National Oceanic and Atmospheric Administration provided support for the participation of R.L.B., A.R.L., and D.W.W.

ABSTRACT

While recent observations have documented gray whales (*Eschrichtius robustus*) identified in the western North Pacific migrating to areas off the coast of North America (Vancouver, California, Mexico) during the winter/spring, the past and present occurrence of gray whales off Japan and China (and the Korean Peninsula historically) suggest that not all gray whales identified in the WNP off Sakhalin share a common wintering ground. Observed genetic differentiation between western and eastern gray whales, in combination with sighting/stranding records from Japan and China during the winter/spring cause us to believe that a relic WNP gray whale population still exists. Thus, the number of whales in the WNP population is substantially smaller than currently estimated and is therefore of increased conservation concern.

KEYWORDS: GRAY WHALE; PACIFIC OCEAN; POPULATION STRUCTURE; MIGRATION

INTRODUCTION

Gray whales (*Eschrichtius robustus*) are recognized as comprising two populations in the North Pacific Ocean. Significant mitochondrial and nuclear genetic differences have been found between whales in the western North Pacific (WNP) and those in the eastern North Pacific (ENP) (Lang *et al.*, 2011). The ENP population ranges from calving areas in Baja California, Mexico, to feeding areas in the Bering, Beaufort, and Chukchi Seas. The WNP population feeds in the Okhotsk Sea off Sakhalin Island, Russia, and in nearshore waters of the southeastern Kamchatka Peninsula (southwestern Bering Sea).

The historical distribution of gray whales in the Okhotsk Sea greatly exceeded what is found today (Reeves *et al.*, 2008). Whales associated with the Sakhalin feeding area can be absent for all or part of a given feeding season (Bradford *et al.*, 2008), indicating they probably use other areas during the summer and fall feeding period. Some of the whales identified feeding in the coastal waters off Sakhalin, including reproductive females and calves, have also been documented off the southern and eastern coast of Kamchatka (Tyurneva *et al.*, 2010). Further, whales observed off Sakhalin have been sighted off the northern Kuril Islands in the eastern Okhotsk Sea and Bering Island in the western Bering Sea (Weller *et al.*, 2003).

Recently, mixing of whales identified in the WNP and ENP has been observed. Lang (2010) reported that two adult individuals from the WNP, sampled off Sakhalin in 1998 and 2004, matched the microsatellite genotypes, mtDNA haplotypes, and sexes (one male, one female) of two whales sampled off Santa Barbara, California in March 1995. Mate and colleagues (Mate *et al.*, 2011) satellite-tracked a whale from the WNP to the ENP in 2010/2011. Finally, photographic matches between the WNP and ENP, including resightings between Sakhalin and Vancouver Island and Laguna San Ignacio, have further confirmed use of areas in the ENP by whales identified in the WNP (Weller *et al.*, 2011; Urban *et al.* 2012). Despite this level of mixing, significant mitochondrial and nuclear genetic differences between whales in the WNP and ENP have been found (Lang *et al.*, 2011).

Although it is clear that some whales feeding off Sakhalin Island during the summer/fall migrate to the west coast of North America during the winter/spring, observations of gray whales in the WNP off Japan, Korea and China during the winter/spring suggest that not all gray whales in the WNP share a common wintering ground. Little is known about the current migratory routes and wintering areas in the WNP, but historical evidence indicates that the coastal waters of eastern Russia, the Korean Peninsula and Japan were part of the migratory route and that areas in the South China Sea were used as wintering grounds (see review in Weller *et al.*, 2002). Summarized herein are relevant gray whale records from the WNP,

including two recent sightings from China in 2011 and Japan in 2012.

DATA RECORDS

Japan

Nambu *et al.* (2010) reported only 13 known sighting or stranding records in Japanese waters between 1990 and 2007. Between 2005 and 2007, four female gray whales were fatally entrapped in set nets along the Pacific coast of Honshu, Japan. One of these females, entrapped in January 2007, was matched to earlier photographs of it as a calf (with its mother) while on the Sakhalin feeding ground in July and August 2006 (Weller *et al.*, 2008). This match provided the most contemporary link between the summer feeding ground off Sakhalin and a winter location along the coast of Asia. More recently, the Japan Times (3 May 2012) reported that in March 2012 a gray whale was sighted and photographed in Mikawa Bay (Aichi Prefecture), east of Ise Bay near Nagoya on the Pacific coast of Honshu.¹

While observations of gray whales in Japan have been made between November and August, most records are concentrated between March and May. This March to May period coincides with when a majority of the whales matched between the WNP and ENP have been sighted in the ENP (Weller *et al.*, 2011), suggesting that not all gray whales identified in the WNP off Sakhalin share a common wintering ground.

China

Observations of gray whales in China are also exceptionally rare. Although 24 capture, sighting or stranding records exist since 1933 (Wang, 1984; Zhu, 2002), including observations of two mother-calf pairs, some of these (especially the sightings) have not been reported in sufficient detail to validate species identification. More recently, an 11.5 m female stranded live at Zhuanghe (Bohai Sea *ca.* 39°N) in December 1996 (Zhao, 1997) and a 13 m female gray whale was taken in fishing gear offshore of Baiqingxiang (Pingtan County), in the Taiwan Strait in November 2011 (Zhu, 2012). Henderson (1990) summarized information from the 1869 logbooks of the New Bedford whaleships *Cornelius Howland* and *Onward* while they were on the “Chinese whale grounds” (also see Reeves *et al.*, 2008). The *Cornelius Howland* reported gray whales being sighted in February at nearly an identical location (Pingtan County) as the aforementioned November 2011 Baiqingxiang specimen. The *Onward* reported gray whales off the northern coast of Taiwan, but no subsequent records are known from Taiwanese waters (Yang, 1964).

While the 2011 gray whale specimen confirms the continued occurrence of gray whales off China, the low latitude location (~25°30'N 119°47'E) of this record in November 2011 (equivalent to the latitude of the ENP wintering lagoons in Baja California, Mexico), is early for the southbound migration. In his summary of whaling in Chinese waters, Henderson (1990) noted that whalers recorded gray whales arriving to waters south of Hailing Island (near Yangjiang, Guangdong Province), China (north end of the island at 21°51'N 111°58'E) in January and February (before 1874). Wang (1984) reported fishermen noting a small number of gray whale sightings in June and July, but the method of species identification was not mentioned. Based on the varied timing of these observations, Henderson (1990) hypothesized that some gray whales may remain in Chinese waters all year and that the southern most whales occurred as far south as Hainan Island (between 18°30'N and 20° N).

Korea

Gray whales were once common and hunted off the coast of South Korea (Andrews, 1914; Mizue, 1951) and off Yushin (*ca.* 40°N 129°E), North Korea (Tago, 1922). The last reported commercial catches were in 1966 off Ulsan, South Korea (Brownell and Chun, 1977). Despite systematic annual sighting surveys conducted since 1999 during May and June when gray whales would be expected to be present off South Korea, no sightings have been reported (Kim *et al.*, 2002). In fact, there is no recent evidence from any source (stranding, sighting, bycatch) to confirm the occurrence of gray whales off the Korean Peninsula in the past 35 years. The last known sighting of a gray whale off Korea was in 1977 (Park, 1995; Kim, 2007). Given the absence of gray whales off the coast of Korea in recent times, we suggest that WNP gray whales have abandoned the once heavily used migration corridor along the Korean Peninsula or that the gray whale subpopulation using the Korean Peninsula is extinct.

CONCLUSIONS

The past and present occurrence of gray whales off Japan and China (and the Korea Peninsula historically) suggest that not all gray whales identified in the WNP off Sakhalin share a common wintering ground. Despite the recently documented interchange of whales between the WNP and ENP, showing that some whales identified off Sakhalin migrate to the ENP during the winter/spring, the observed genetic differentiation between western and eastern gray whales (Lang *et al.*, 2011) in combination with sighting/stranding records from Japan and China during the winter/spring migratory period leads us to conclude that a relic WNP gray whale population still exists. That being said, the number of whales in the WNP population is probably substantially smaller than the currently estimated ~150 whales that use the Sakhalin summer feeding area. Thus, the status of gray whales in the WNP may be of greater conservation concern than is currently recognized.

ACKNOWLEDGEMENTS

We thank the Southwest Fisheries Science Center for supporting this work and extend appreciation to our colleagues for many thought-provoking discussions about gray whales in the western North Pacific.

NOAA Technical Memorandum NMFS

The National Oceanic and Atmospheric Administration (NOAA), organized in 1970, has evolved into an agency that establishes national policies and manages and conserves our oceanic, coastal, and atmospheric resources. An organizational element within NOAA, the Office of Fisheries is responsible for fisheries policy and the direction of the National Marine Fisheries Service (NMFS).

In addition to its formal publications, the NMFS uses the NOAA Technical Memorandum series to issue informal scientific and technical publications when complete formal review and editorial processing are not appropriate or feasible. Documents within this series, however, reflect sound professional work and may be referenced in the formal scientific and technical literature.

SWFSC Technical Memorandums

SWFSC Technical Memorandums are available online at the SWFSC web site (<http://swfsc.noaa.gov>). Copies are also available from the National Technical Information Service, 5285 Port Royal Road, Springfield, VA 22161 (<http://www.ntis.gov>).

This **NOAA Technical Memorandum NMFS** issued by the Southwest Fisheries Science Center may be cited in following manner:

Weller, D.W., Bettridge, S., Brownell, R.L., Jr., Laake, J.L., Moore, J.E., Rosel, P.E., Taylor, B.L and Wade, P.R. 2013. Report of the National Marine Fisheries Service gray whale stock identification workshop. U.S. Dep. Commer., NOAA Tech. Memo. NMFS-SWFSC-507

Executive Summary

The Marine Mammal Protection Act of 1972 (MMPA) requires that the National Marine Fisheries Service (NMFS) and the Fish and Wildlife Service develop stock assessment reports for all marine mammal stocks in waters under U.S. jurisdiction. NMFS considers stock structure as part of these assessments and has developed guidance for delineating separate population stocks under the MMPA. A single population stock of gray whales (*Eschrichtius robustus*), referred to as the eastern North Pacific (ENP) stock, is presently recognized in U.S. waters (Carretta *et al.* 2013). New information, however, suggests the possibility of recognizing two additional stocks of gray whales in U.S. waters: the Pacific Coast Feeding Group (PCFG) and the western North Pacific (WNP) stock. To evaluate the currently recognized and potentially emerging characterization of gray whale stock structure, NMFS established a scientific Task Force (TF). The overarching objective of this TF was to provide an objective scientific evaluation of gray whale stock structure as defined under the MMPA and implemented through the NMFS Guidelines for Assessing Marine Mammal Stocks (GAMMS; NMFS 2005). More specifically, the TF was convened to provide advice on the primary question – “*Is the PCFG a “population stock” under the MMPA and GAMMS guidelines*”? In addition, the TF was asked to provide advice on a question of developing importance – “*Is the WNP stock a “population stock” under the MMPA and GAMMS guidelines*”?

Both of these questions have immediate management implications, including: (1) how future NMFS stock assessment reports will address gray whale stock structure in the North Pacific, and (2) how to interpret any new information in the context of the Makah Indian Tribe’s MMPA waiver request to resume hunting gray whales off Washington State, USA.

As the agency lead for gray whale science, the Southwest Fisheries Science Center convened a meeting of the aforementioned TF from 31 July to 2 August 2012. Using the best scientific information available at the time of the workshop, the TF worked to: (1) review new information relevant to gray whale stock structure, and (2) provide advice on revisions to stock structure so as to be available for management consideration. The TF conducted its work as an advisory rather than prescriptive body and therefore its conclusions should be viewed as scientific advice based on review and discussion of the available science.

The implications of new data pertinent to stock structure, including considerable information related to the PCFG and WNP gray whales, were thoroughly reviewed during the workshop. Evaluating the new findings relevant to the status of the PCFG proved particularly complex. After review of results from photo-identification, genetics, tagging, and other studies within the context of the GAMMS guidelines (NMFS 2005) there remains a substantial level of uncertainty in the strength of the lines of evidence supporting demographic independence of the PCFG. Consequently, the TF was unable to provide definitive advice as to whether the PCFG is a population stock under the MMPA and the GAMMS guidelines. Members of the TF ranged in their opinions from strongly agreeing to strongly disagreeing about whether the PCFG should be recognized as a separate stock.

In the case of WNP gray whales, the work of the TF was more straightforward. The mitochondrial DNA and nuclear DNA genetic differentiation found between the WNP and ENP stocks provided convincing evidence that resulted in the TF providing unambiguous advice that the WNP stock should be recognized as a population stock pursuant to the GAMMS guidelines and the MMPA.

Additional research may narrow the uncertainty associated with the question of whether the PCFG should be recognized as a population stock. To work towards this objective, the TF recommended further investigation of recruitment into the PCFG. Presently, both the photo-identification and genetics data indicate that the levels of internal versus external recruitment are comparable, but these are not quantified well enough to determine if the population dynamics of the PCFG are more a consequence of births and deaths within the group (internal dynamics) rather than related to immigration and/or emigration (external dynamics). The TF offered a number of research recommendations, using the existing photo-identification and genetics datasets, that could provide increased resolution on the issue of recruitment and, in turn, the question of stock identification.

While the need for additional data collection was apparent, especially with regard to recruitment into the PCFG, the purpose of the workshop was for the TF to determine whether the *existing* best available science was sufficient to advise that the PCFG be recognized as a population stock under the language of the MMPA and GAMMS guidelines. Therefore, the advice of the TF offered in this report should be viewed as a contemporary “snapshot” taken from an emerging and ever-changing body of knowledge regarding the PCFG.

The TF emphasizes that the PCFG is relatively small in number and utilizes a largely different ecosystem from that of the main ENP stock. While the status of the PCFG as a population stock has yet to be resolved, continued research on these whales should be undertaken with particular attention dedicated to collecting data relevant to the question of stock identification.

1. Introductory Remarks

Dr. Lisa Ballance, Director of the Marine Mammal and Turtle Division at Southwest Fisheries Science Center (SWFSC), welcomed the workshop participants. She noted that this workshop represented a significant event, in that it: (1) brings agency scientists together to review research that continues to evolve and reveal unexpected patterns, (2) provides results that will be relevant to management activities for the National Marine Fisheries Service (NMFS), and (3) typifies the ideal model for how NMFS works, illustrating science addressing management actions and highlighting the collaboration between NMFS scientists, regional offices, and headquarters.

The technical and scientific expertise required on the Task Force (TF) was determined by SWFSC in consultation with the NMFS Northwest Regional Office (NWR) and the NMFS Office of Protected Resources (OPR). TF members were experts in their respective fields with ample experience and ability to bridge scientific and policy issues related to marine mammal stock structure. Members of the TF included the following eight NMFS scientists:

Dr. Shannon Bettridge	NMFS – Office of Protected Resources
Dr. Robert L. Brownell, Jr.	NMFS – Southwest Fisheries Science Center
Dr. Jeffrey L. Laake	NMFS – Alaska Fisheries Science Center
Dr. Jeffrey E. Moore	NMFS – Southwest Fisheries Science Center
Dr. Patricia E. Rosel	NMFS – Southeast Fisheries Science Center
Dr. Barbara L. Taylor	NMFS – Southwest Fisheries Science Center
Dr. Paul R. Wade	NMFS – Alaska Fisheries Science Center
Dr. David W. Weller (Chairman)	NMFS – Southwest Fisheries Science Center

In addition to the TF, a number of agency scientists and NMFS affiliates (e.g., post-docs, contractors, etc.) attended the workshop to observe and provide information. These participants included: Eric Archer (SWFSC), Lisa Ballance (SWFSC), Laurie Beale (NOAA General Counsel), Jim Carretta (SWFSC), Donna Darm (NWR), Kirsten Erickson (NOAA General Counsel - by phone), Jason Foreman (NOAA General Counsel), Annette Henry (SWFSC), Aimee Lang (SWFSC), Karen Martien (SWFSC), Sarah Mesnick (SWFSC), Phil Morin (SWFSC), Vicki Pease (SWFSC), Bill Perrin (SWFSC), Wayne Perryman (SWFSC) and Steve Stone (NWR). At the request of the TF, several of these participants provided valuable information to the workshop in the form of expert knowledge, presentations and/or written documents. Aimee Lang and Annette Henry generously agreed to serve as workshop rapporteurs.

The agenda for the workshop was circulated amongst the TF for input in advance of the meeting (Appendix 1). It was agreed, however, that the agenda would serve to guide the workshop proceedings but be viewed as flexible so as not to constrain discussion. Documents for the workshop were made available on a file sharing website. Appendix 2 provides a list of the workshop documents available for review and consideration by the TF in preparation for the workshop.

1.1 Workshop objectives

NMFS presently recognizes a single stock of gray whales (*Eschrichtius robustus*) in U.S. waters that is referred to as the eastern North Pacific (ENP) stock (Carretta *et al.* 2013). New information, however, suggests the possibility of recognizing two additional stocks of gray whales in U.S. waters, including: (1) the Pacific Coast Feeding Group (PCFG) - defined as whales observed between 1 June to 30 November within the region between northern California and northern Vancouver Island (from 41°N to 52°N) and photo-identified within this area during

two or more years (see section 3.3), and (2) western North Pacific (WNP) gray whales - defined as whales observed feeding during summer and fall off Sakhalin Island, Russia, and other areas in the WNP (see section 3.2). The main objective of the TF was to provide scientific advice regarding gray whale stock structure using the definitions given in the GAMMS guidelines (NMFS 2005; see also Moore and Merrick 2011). More specifically, the TF was convened to provide advice on two questions: (1) *Is the PCFG a “population stock” under the MMPA and GAMMS guidelines?*, and (2) *Is the WNP stock a “population stock” under the MMPA and GAMMS guidelines?* Both of these questions have immediate management implications, including: (1) how future NMFS stock assessment reports (SAR) will address gray whale stock structure in the North Pacific, and (2) how to interpret any new information in the context of the Makah Indian Tribe’s MMPA waiver request to resume hunting gray whales off Washington State, USA.

1.2 Workshop relationship to stock assessment reports

At the request of the TF, Carretta (SWFSC) summarized the relationship of the workshop to future gray whale stock assessment reports (SARs). The current eastern North Pacific gray whale SAR (Carretta *et al.* 2013) provides a summary of present knowledge but is expected to evolve based on the input received at this workshop as well as from input from the scientific review groups (SRG)¹, NWR and OPR. The TF expected that the outcome of the workshop would influence how the SAR is structured in the future, including how various data sources (i.e., genetics, movements, distribution) are evaluated for future stock designation. The workshop report will also serve as a useful SRG background document on gray whale stock structure.

1.3 Workshop relationship to Makah waiver request

Newly available information from genetic, photo-identification and tagging studies suggests that more than one stock of gray whales may occur in U.S. waters (Lang *et al.* 2010; Frasier *et al.* 2011; Lang *et al.* 2011a; Lang *et al.* 2011b; Mate *et al.* 2011; Calambokidis *et al.* 2012; Weller *et al.* 2012). With that in mind, the TF requested that Darm (NWR) present a summary of the Makah Indian Tribe’s request to hunt gray whales off northwest Washington State, USA.

The Makah’s right to hunt whales is secured by the 1855 Treaty of Neah Bay, where the Makah ceded lands to the U.S. government but reserved the right to hunt, fish, seal and whale. The Ninth Circuit Court of Appeals decision in 2004 (Anderson v. Evans) held that for the Makah to exercise their right to hunt whales they must comply with the requirements of the MMPA. In 2005, the Makah requested authorization from NOAA/NMFS, under the MMPA and the Whaling Convention Act, to resume limited hunting of gray whales for ceremonial and subsistence purposes in the coastal portion of their usual and accustomed (U&A) fishing grounds off the coast of Washington State (NMFS 2008). The spatial overlap of the Makah U&A with the summer distribution of PCFG whales has management implications. The proposal by the Makah Tribe includes time/area restrictions designed to reduce the probability of killing a PCFG whale and to focus the hunt on whales migrating to/from feeding areas to the north.

The NWR was assigned responsibility for evaluating the Tribe’s request under the MMPA and National Environmental Policy Act (NEPA) process. Section 101(a) of the MMPA imposes a

¹ Pursuant to Sec. 117 of the MMPA, independent scientific review groups, representing Alaska, and the Pacific and Atlantic coasts, were established in 1994. These groups consist of individuals with expertise in marine mammal biology and ecology, population dynamics and modeling, commercial fishing technology and practices, and stocks taken under section 101(b).

moratorium on the take of all marine mammals, although the statute provides for certain exemptions allowing the take of marine mammals. Section 101(a)(3)(A) allows for a waiver of the take prohibition; this exemption applies to a specific stock and is only authorized to the extent provided for in the waiver. Determination of whether the waiver will be granted must be made based on the best scientific information, in consultation with the Marine Mammal Commission, and with due regard to the distribution, abundance, breeding habits, and movements of the stock in question. For the waiver to be granted there must also be a finding that the requested take is in accord with sound principles of resources protection and conservation as provided for in the MMPA.

Unlike most rulemaking by the agency, this determination will entail a formal rulemaking process in which the agency presents evidence before an administrative law judge (ALJ) to support the rule. This process may involve presenting evidence on the status of relevant stocks, including their optimum sustainable population level (OSP)², and whether the stocks are at or below that level (i.e., depleted).

Although the NWR made substantial progress in evaluating the waiver request during the past few years, this progress had been slowed by: (1) new information pertinent to the question of whether the PCFG is a separate stock, and (2) the potential implications of movements of whales between the WNP and ENP. Therefore, the advice of the TF will provide a collective “best professional judgment” useful to the ongoing evaluation of the waiver by the NWR.

In discussion, the TF asked Darm if there would be a potential need to get more than one waiver to the MMPA if it was determined that three stocks of gray whales occur in U.S. waters (i.e., ENP, PCFG and WNP stocks). In that case, Darm replied that there would be some possibility of needing to request multiple exemptions (waivers). However, the need for a waiver would be informed by the likelihood of take and obtaining a waiver for WNP gray whales (if the group is recognized as a stock) is highly unlikely given that they are listed as endangered under the Endangered Species Act (ESA) and as such, would be considered depleted under the MMPA.

2. Overview of MMPA Language, GAMMS Guidelines and Related Key Concepts

From the outset of the workshop, the TF concurred that it was important to review the existing language of the MMPA and GAMMS with regard to the definition of “population stock”. In addition, it was also agreed important to discuss three key concepts inherent to defining a population stock, including: (1) “demographic independence”, (2) “interbreed when mature”, and (3) “functioning element of the ecosystem”.

Under the MMPA, population stock (used interchangeably with “stock” and “population” hereafter) is the fundamental conservation unit. The MMPA (Sec. 3) defines population stock as: *“a group of marine mammals of the same species or smaller taxa in a common spatial arrangement, that interbreed when mature.”* The purposes and policies underlying the stated definition, as follows, are found in Sec. 2(2) and Sec. 2(6) of the MMPA:

² The maximum net productivity level is described in the National Marine Fisheries Service's definition of “optimum sustainable population” (OSP) (50 CFR 216.3) as the abundance level that results in the greatest net annual increment in population numbers or biomass resulting from additions to the population due to reproduction and/or growth less losses due to natural mortality. Under the U.S. Marine Mammal Protection Act, populations above MNPL are considered to be at OSP; populations below MNPL can be designated as ‘depleted’ and are afforded a greater level of protection.

(1) “[marine mammal] species and population stocks should not be permitted to diminish beyond the point at which they cease to be a significant functioning element in the ecosystem of which they are a part, and, consistent with this major objective, they should not be permitted to diminish below their optimum sustainable population.”

(2) “... the primary objective of their management should be to maintain the health and stability of the marine ecosystem.”

Acknowledging the above definitions and objectives of the MMPA, the TF then considered the related guidelines contained in the “Definition of Stock” section of the GAMMS guidelines (NMFS 2005):

(1) “For the purposes of management under the MMPA, a stock is recognized as being a management unit that identifies a demographically isolated biological population.”

(2) “Demographic isolation means that the population dynamics of the affected group is more a consequence of births and deaths within the group (internal dynamics) rather than immigration or emigration (external dynamics). Thus, the exchange of individuals between population stocks is not great enough to prevent the depletion of one of the populations as a result of increased mortality or lower birth rates.”

The TF noted that within the broader field of population biology, the term “isolation” generally implies little or no exchange (emigration or immigration of individuals) between stocks and is a criterion commonly used to distinguish taxonomic units higher than that of a population (e.g., species, subspecies). In contrast, the GAMMS guidelines and definition of stock clearly allow for the “exchange of individuals between population stocks” (NMFS 2005), a distinction more in line with use of the term “demographic independence” rather than “demographic isolation”. The use of the term “independence” as opposed to “isolation” is potentially confusing and has been noted by a number of NMFS reviewers and workshops (Eagle *et al.* 2008). To avoid this confusion, Eagle *et al.* (2008) suggested that the term “demographic isolation” be replaced by “demographic independence”.

Moore (SWFSC) provided the TF with an overview of the GAMMS III workshop, convened by NMFS in February 2011, which also noted the potential confusion over the use of “isolation” as opposed to “independence”. The GAMMS III workshop recommended revising the SAR guidelines to reflect that the intent of the GAMMS II guidelines (NMFS 2005) was to base stock identification on demographic independence as noted in Eagle *et al.* (2008) and proposed that the term demographic isolation be replaced with “demographic independence” as follows:

(1) “For the purposes of management under the MMPA, a stock is recognized as being a management unit that identifies a demographically independent biological population.”

(2) “Demographic independence means that the population dynamics of the affected group is more a consequence of births and deaths within the group (internal dynamics) rather than immigration or emigration (external dynamics). Thus, the exchange of individuals between population stocks is not great enough to prevent the depletion of one of the populations as a result of increased mortality or lower birth rates.”

In other words, the participants at the GAMMS III workshop viewed this as a semantic issue where the term demographic independence is a better description for the current GAMMS guidelines definition than is the term demographic isolation.

2.1 Discussion of “demographic independence”

This interpretation of “isolation” differs substantively from how it is used within the GAMMS guidelines definition above, wherein allowance is made for some level of exchange of individuals between stocks. The TF concurred that in spite of using the term “isolation”, the actual definitions under the current GAMMS guidelines (see above) are more consistent with MMPA objectives to protect population stocks than with the objective of protecting just subspecies and species.

Given that the draft GAMMS guideline revisions from the GAMMS III workshop have not yet been formally approved, the TF agreed to use the current GAMMS guidelines definition (NMFS 2005) for the purposes of their discussions and deliberations but noted that the actual definition used in the two versions (for demographic isolation and demographic independence) is essentially the same in that neither implies true “isolation” within the context of the MMPA.

2.2 Discussion of “interbreed when mature”

Bettridge (OPR) presented a brief overview of relevant language under the MMPA and GAMMS guidelines pertaining to NMFS interpretation of “interbreed when mature”. She explained that the draft second revision to the SAR guidelines (from the GAMMS II workshop held in Seattle in 2003) included a definition of interbreed when mature. This term was interpreted to mean cases in which either:

(1) *“mating occurs primarily among members of the same demographically isolated group”*

or

(2) *“the group migrates seasonally to a breeding ground where its members breed with members of the same group as well as with members of other demographically distinct groups which have migrated to the same breeding ground from a different feeding ground.”*

When comments were solicited on the draft GAMMS II guidelines (69 FR 67541, 18 November 2004), the Marine Mammal Commission (MMC) supported the aforementioned interpretations, but suggested that a more rigorous analysis was needed of how the revisions fit with the language of the MMPA. Additionally, the MMC stated that NMFS should develop criteria for applying the modified guidelines to determine when a population is demographically isolated to an extent that it is a discrete group that warrants recognition as a separate stock.

In its response to comments on this issue (70 FR 35397, 20 June 2005), NMFS stated that public comments were sufficient to raise questions about the proposed interpretation, and the agency removed the proposed text pertaining to “interbreed when mature” from the final GAMMS II guidelines.

Subsequent NMFS review and consultation with MMC staff and NOAA General Counsel suggest that the GAMMS II workshop definition of “interbreed when mature” is consistent with NMFS GAMMS guidelines and the review undertaken in Eagle *et al.* (2008, see below). In those forums NMFS has consistently interpreted a population stock not as one that is completely reproductively isolated but rather as something less restrictive.

Regarding the MMC request for scientific criteria for how much interbreeding would be consistent with the proposed GAMMS II guidelines definition, the TF noted that specific quantitative criteria would be impractical to apply consistently across all contexts of uncertain stock definition and that determining whether a population is demographically independent or an isolated unit would likely have to be conducted on a case-specific basis. Some TF members felt

that the “interbreed when mature” component of the MMPA definition of stock should merely be viewed as a necessary but not sufficient criterion for defining a stock. In other words, individuals “in a common spatial arrangement” would not constitute a stock unless there is some interbreeding (satisfying the need criterion), but this would not preclude individuals of a stock from also breeding with members of other stocks.

For the purposes of the workshop, the TF agreed they would continue to interpret “interbreed when mature” consistent with “demographic independence” as suggested by Eagle *et al.* (2008) and GAMMS II (NMFS 2005), with the minor change of “isolation” being replaced with “independence”.

2.3 Discussion of “functioning element of the ecosystem”

Sec. 2 of the MMPA states that marine mammals are “resources of great international significance, esthetic and recreational as well as economic” and “that the primary objective of their management should be to maintain the health and stability of the marine ecosystem”. The TF therefore considered whether the functioning element of the ecosystem criteria is aesthetically or ecologically based (or both) but no clear resolution on how to best define functioning element of the ecosystem was reached by the TF.

The TF then focused its discussion on defining the ecosystem and appropriate scale of management with respect to gray whales. The TF agreed the matter was complex given the species’ seasonal use of different ecosystems. In general, the TF agreed that the Chukotka Peninsula/Bering Strait feeding areas were not part of the same ecosystem as that found off the Pacific Northwest and used by the PCFG. In discussion of this concept, it was noted by some TF members that even for the largest-scale classification system for marine ecosystems (Longhurst 1998, discussed in Moore and Merrick 2011), it could be argued that the PCFG is in a different ecosystem than other gray whales. Other TF members pointed out, however, that this was only true for part of the year, and that the interpretation was complicated because non-PCFG animals migrate through the area defined for PCFG whales and, in some cases, may feed there in a given year but not return in a subsequent year.

2.4 Additional information on the definition of “population” for marine mammals

In addition to applying the MMPA language and GAMMS guidelines definitions, the TF considered two documents relevant to the question of stock definition under the MMPA. In the first (Taylor 1997), simulation analyses were used to explore the potential consequences, in terms of the risk of violating MMPA ecosystem function objectives, of defining a population stock as a unit akin to an evolutionarily significant unit or reproductively isolated group. Briefly, this analysis considered scenarios in which a single reproductively isolated population was distributed as a network of discrete groups occupying distinct habitat areas throughout its range, with some level of dispersal between discrete groups. The major analytical finding was that, if allowable human caused mortality (HCM) for the entire population (i.e., sum of all discrete groups) were to act disproportionately on certain groups, those groups could be extirpated, depending on whether the amount of immigration from other groups was below a certain dispersal rate threshold (which varied with simulation conditions). In conclusion, to achieve MMPA objectives of maintaining marine mammals as “functioning elements of their ecosystem”, distinct groups should be managed as separate stocks if their connectivity to other groups via dispersal is low, although how low is context specific.

Taylor (1997) provides several examples (Figure 1) where localized removals lead to local extirpation which arguably violates the ecosystem goals of the MMPA. For all of the models tested, when dispersal fell below a few percentage of the population per year, recruitment into the population with HCM was insufficient to compensate for removal, and population levels declined below those sought by management objectives. Therefore, populations should be managed separately if dispersal between them is less than several percent per year.

Taylor (SWFSC) cautioned the TF, however, that it is impossible to have a “one number fits all” criterion and that a better approach would be to have an objective that states what is important in

terms of maintaining the extent and connectivity of the range. There are some cases where it is obvious that a stock is no longer a functioning element of its ecosystem, such as example C in Figure 1 where the large central group is extirpated. Extirpation of the PCFG would be more analogous to removing one of the smaller groups outside of the main group (e.g., example B). Further discussion is needed to better define the intent of the MMPA with respect to maintaining marine mammals within different parts of their range.

The second document discussed by the TF, as pertains to the agency’s definition of population stock, was the report of a 2006 workshop entitled “Conservation Units of Managed Fish, Threatened or Endangered Species, and Marine Mammals” (Eagle *et al.* 2008). This workshop was convened by NMFS with the objective of bringing together scientists, managers and policy advisers to discuss differences and recommend revisions to how NMFS defines units to conserve under three statutes – the MMPA, ESA and Magnuson-Stevens Act (MSA). The workshop sought to address two overarching questions: (1) why are conservation units different under the three statutes? and (2) is there a biological paradigm that can be used to explain the differences?

In brief, it was agreed by the participants of the 2006 workshop that the differences in how NMFS defines conservation units under the three statutes are appropriate given the differing objectives of the three laws. Under the ESA, major objectives are to prevent *species* extinction and preserve evolutionary potential. Thus, conservation units under this Act should be substantially reproductively isolated. Under the MMPA, objectives correspond to maintaining population and ecosystem goals. Therefore, conservation units align with demographically independent units (DIPs), which are demographically discrete from other populations but not necessarily genetically discrete due to a low but sufficient degree of interbreeding between them. Participants of the 2006 workshop concluded that while the GAMMS guidelines “...clearly support the use of DIPs as stocks of marine mammals [...] the MMPA does not indicate to what extent breeding should occur within a stock instead of among stocks” and that future revisions to the GAMMS guidelines “should, therefore, include a rationalization for recognizing DIPs as stocks in cases where males from one stock may breed with females from the same and other stocks”.

There was discussion amongst the TF regarding where to reasonably draw the line in defining small stocks, given that for some marine mammal species very small groups of animals could be

Figure 1. Original figure from Taylor (1997).

considered DIPs. For example, individual pods of killer whales (*Orcinus orca*) could potentially be considered demographically independent. However, other TF members noted that the intent of the GAMMS guidelines was not to recognize very small population units – such as individual killer whale pods or a small group of animals occupying a small habitat fragment – as population stocks. It was similarly suggested that other criteria besides demographic independence, such as whether the unit can be considered a significant functioning element of the ecosystem, should also be considered in defining stocks. The TF understood that most biological “populations” and “stocks” do not exist as truly distinct groups, nor are individuals within the same population typically part of a truly panmictic group (Waples and Gaggiotti 2006). Rather, population differentiation occurs along a continuum, and placing discrete boundaries along this continuum for management purposes is a challenge. The TF acknowledged that marine mammal social structure can further complicate determining whether a unit should be considered demographically independent. In these areas of uncertainty, decisions will likely be case specific, and ultimately rely on scientific judgment and the factors identified for consideration in the MMPA and GAMMS guidelines.

The TF considered the report by Eagle *et al.* (2008) and the recommendations from that workshop as support for the NMFS interpretation of “interbreed when mature” as one that includes cases where individuals interbreed primarily within their stock but occasional interbreeding amongst stocks may occur and agreed to use such as the operational definition for the purposes of their work.

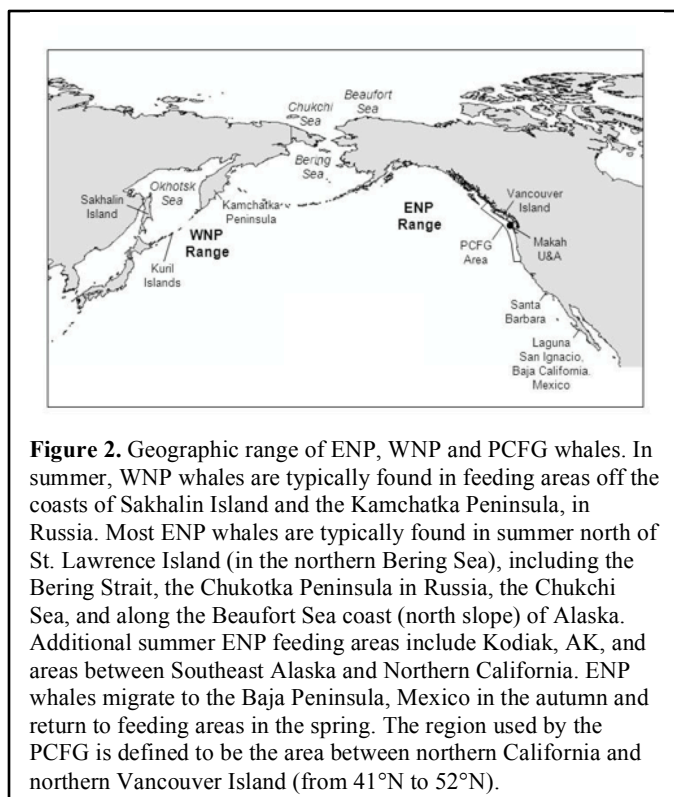

3. Overview of Eastern, Western and Pacific Coast Feeding Group Gray Whales

Like many species of baleen whales, gray whales exhibit seasonal movements between high-latitude summer feeding grounds and low-latitude wintering areas. The current distribution of this species is limited to the North Pacific, where a small western population (<150 individuals) and a much larger eastern population (~19,000 individuals) are recognized.(Reilly *et al.* 2008).

Lang (SWFSC) presented a brief overview of information on the biology of ENP, WNP, and PCFG gray whales. The purpose of this overview was not to discuss gray whale stock structure in detail but rather to provide a summary of relevant background information.

3.1 Eastern North Pacific (ENP) gray whales

During summer and fall most ENP whales feed in the Chukchi, Beaufort and northwestern Bering Seas (Figure 2). An exception is the relatively small number (100s) of whales that summer and feed along the Pacific coast between Kodiak Island, Alaska and northern California (Darling 1984; Calambokidis *et al.* 2002; 2012; Gosho *et al.* 2011). By late November, the southbound migration of the ENP stock is underway as whales begin to travel from summer feeding areas to winter calving areas off the west coast of Baja California, Mexico (Rugh *et al.* 2001; Swartz *et al.* 2006). The southbound migration is segregated by age, sex and reproductive condition (Rice and Wolman 1971). The northbound migration begins about mid-February and is also segregated by age, sex and reproductive condition.

Gray whale breeding and calving are seasonal and closely synchronized with migratory timing. Sexual maturity is attained between 6 and 12 years of age (Rice 1990; Rice and Wolman 1971). Gestation is estimated to be 13 months, with calving beginning in late December and continuing to early February (Rice and Wolman 1971). Some calves are born during the southbound migration while others are born near or on the wintering grounds (Shelden *et al.* 2004). Females produce a single calf, on average, every 2 years (Jones 1990). Calves are weaned and become independent by six to eight months of age while on the summer feeding ground (Rice and Wolman 1971). Three primary calving lagoons in the ENP are utilized during winter, and some females are known to make repeated returns to specific lagoons (Jones 1990).

The abundance of the ENP population, which includes the PCFG, is presently estimated to be about 19,000 whales (Laake *et al.* 2012). The potential biological removal (PBR) level for the ENP stock of gray whales is calculated as the minimum (20th percentile) estimate of population size, times one-half of the maximum theoretical net population growth rate ($\frac{1}{2} \times 6.2\% = 3.1\%$), times a recovery factor of 1.0 for a stock above its maximum net productivity level (MNPL) (Punt and Wade 2012). The minimum population estimate (N_{MIN}) for the ENP stock is calculated from Equation 1 from the PBR Guidelines (Wade and Angliss 1997): $N_{\text{MIN}} = N / \exp(0.842 \times [\ln(1 + [CV(N)]^2)]^{1/2})$. Using the 2006/07 abundance estimate of 19,126 and its associated CV of 0.071, N_{MIN} for this stock is 18,017. Therefore, PBR is 558 animals. A recent analysis conducted by Punt and Wade (2012) estimated a probability of 0.884 that the ENP gray whale stock is above its MNPL, which means there is a 0.884 probability that it is at its OSP as defined by the MMPA.

Genetic studies suggest some sub-structuring may occur on the wintering grounds, with significant differences in mitochondrial DNA (mtDNA) haplotype frequencies found between females (mothers with calves) utilizing two of the primary calving lagoons and females sampled in other areas (Goerlitz *et al.* 2003). Other research, employing both mtDNA and microsatellites, identified significant departure from panmixia between two of the lagoons using nuclear data, although no significant differences using mtDNA were observed (Alter *et al.* 2009). Significant mtDNA and nuclear (nDNA) genetic differences have been found between whales in the WNP and those in the ENP (LeDuc *et al.* 2002; Lang *et al.*, 2011b).

In discussion, the TF agreed that the information presented by Lang represented an up to date overview of the ENP population and had no follow up questions.

3.2 Western North Pacific (WNP) gray whales

Information on the distribution and migration patterns of gray whales in the WNP is incomplete. There is no doubt that the historical distribution of gray whales in the Okhotsk Sea once greatly exceeded what is found at present (Reeves *et al.* 2008). Today, the main feeding ground is in the Okhotsk Sea off the northeastern coast of Sakhalin Island, Russia (Figure 2) but some animals also occur off eastern Kamchatka and in other coastal waters of the northern Okhotsk Sea (Weller *et al.* 2002; Vertyankin *et al.* 2004; Tyurneva *et al.* 2010). Whales associated with the Sakhalin feeding area can be absent for all or part of a given feeding season (Bradford *et al.* 2008), indicating they probably use other areas during the summer and fall feeding period. For example, some whales observed off Sakhalin have been sighted off the northern Kuril Islands in the eastern Okhotsk Sea and Bering Island in the western Bering Sea (Weller *et al.* 2003).

The WNP migration route(s) and winter breeding ground(s) are poorly known (Weller *et al.* 2002; Weller and Brownell 2012). Information collected over the past century indicates that whales migrated along the coasts of Japan and South Korea (Andrews 1914; Mizue 1951; Omura 1984) to wintering areas somewhere in the South China Sea, possibly near Hainan Island (Wang 1984). At present, observations of gray whales off Japan are rare. Nambu *et al.* (2010) reported 13 known sighting or stranding records in Japanese waters between 1990 and 2007. Between 2005 and 2007, four female gray whales were fatally entrapped in set nets along the Pacific coast of Honshu, Japan. One of these females, entrapped in January 2007, was matched to earlier photographs of it as a calf (with its mother) while on the Sakhalin feeding ground in July and August 2006 (Weller *et al.* 2008). This match provided the most contemporary link between the summer feeding ground off Sakhalin and a winter location along the coast of Asia. More recently, in March 2012 a gray whale was sighted and photographed in Mikawa Bay (Aichi Prefecture), east of Ise Bay near Nagoya on the Pacific coast of Honshu (Japan Times, 3 May 2012).

Observations of gray whales in China are also exceptionally rare. Although 24 capture, sighting or stranding records exist since 1933 (Wang 1984; Zhu 2002), including observations of two mother-calf pairs, some of these (especially the sightings) have not been reported in sufficient detail to validate species identification. More recently, an 11.5 m female stranded live at Zhuanghe (Bohai Sea ca. 39°N) in December 1996 (Zhao 1997) and a 13 m female gray whale was taken in fishing gear offshore of Baiqingxiang (Pingtan County), in the Taiwan Strait in November 2011 (Zhu 2012). The last known sighting of a gray whale off Korea was in 1977 (Park 1995).

The WNP gray whale population is redlisted by the IUCN as Critically Endangered. The most recent population assessment (for 2012), using a Bayesian individually-based stage-structured model, resulted in a median 1+ (non-calf) estimate of 155 individuals, with 95% CI = 142-165 (IUCN 2012). A collaborative Russia-U.S. research program on WNP gray whales summering off northeastern Sakhalin Island, Russia, has been ongoing since the mid-1990s. When data collected between 1994-2011 are combined, a catalog of 200 photo-identified individuals has been compiled. Beginning in 2002, photo-identification studies off Sakhalin have also been conducted by Russia scientists working with oil and gas companies (Tyurneva *et al.* 2010). This research largely corroborates the work of the Russia-U.S. team and in some cases collaborative analyses utilizing combined datasets have been conducted.

Recently, results from photo-identification (Urbán *et al.* 2012; Weller *et al.* 2012), genetic (Lang 2010; Lang *et al.* 2011b), and telemetry studies (Mate *et al.* 2011) have documented spatial and

temporal overlap between WNP and ENP gray whales. Observations of such overlap include: (1) six whales photographically matched from Sakhalin Island to southern Vancouver Island, (2) two whales genetically matched from Sakhalin to Santa Barbara, California, (3) 13 whales photographically matched from Sakhalin Island to San Ignacio Lagoon, Mexico, and (4) 2 satellite tagged whales that migrated from Sakhalin Island to the west coast of North America. In combination, these studies have recorded a total of 23 gray whales observed in both the WNP and ENP. Despite this overlap, significant mtDNA and nDNA differences are found between whales in the WNP and those summering in the ENP (Lang *et al.* 2011b). Although it is clear that some whales feeding off Sakhalin Island during the summer/fall migrate to the west coast of North America during the winter/spring, past and present observations of gray whales in the WNP off Japan, Korea and China during the winter/spring suggest that not all gray whales in the WNP share a common wintering ground (Weller and Brownell 2012).

In discussion, the TF agreed that the occurrence of WNP gray whales in U.S. waters presented previously unexpected implications with respect to the SAR process and the Makah waiver request. More specifically, two questions were discussed at length, including: (1) given the occurrence of WNP gray whales in U.S. waters, is a WNP gray whale SAR required? and (2) given the potential occurrence of WNP gray whales in the proposed Makah hunt area, what are the implications regarding the existing waiver request?

TF members also noted that these new findings of gray whales moving between Sakhalin Island and the ENP had significance to our understanding of the status of gray whales in the WNP. That is, given that some of the whales sighted off Sakhalin appear to overwinter in the ENP, the number of animals remaining in the WNP year-round may be much smaller and of greater conservation concern than is currently recognized (Weller and Brownell 2012).

3.3 Pacific Coast Feeding Group (PCFG)

Gray whales using the Pacific Northwest area during summer and autumn include two components: (1) whales that return frequently and account for most of the sightings between 1 June and 30 November, and (2) whales that are sighted only in one year, tend to be seen for shorter time periods in that year, and are encountered in more limited areas. For the purposes of their work to evaluate the proposed Makah Indian Tribe gray whale hunt, the International Whaling Commission (IWC) defined PCFG gray whales as: whales observed between 1 June to 30 November within the region between northern California and northern Vancouver Island (from 41°N to 52°N) and photo-identified within this area during two or more years (IWC 2011; IWC 2012a). This same definition has been adopted in the analyses of Calambokidis *et al.* (2012). In this report, the TF defines “PCFG whales” following the IWC definition.

Recent research has provided new information on movements and habitat utilization of PCFG whales (for example Frasier *et al.* 2011; Lang *et al.* 2011a; Calambokidis *et al.* 2012). While PCFG whales are known to feed during summer and fall off the Pacific coast between northern California and southeastern Alaska, they also occasionally occur as far north as Kodiak (Gosho *et al.* 2011) and Barrow, Alaska (Calambokidis *et al.* 2012). The sighting from Barrow suggests that some PCFG whales (meaning whales seen in summer in the defined area used by the PCFG and in more than one year), at least occasionally occur in one of the most northern gray whale feeding areas in the ENP (Calambokidis *et al.* 2012). Similarly, of the 121 whales identified off Kodiak from 1998-2010, there have been 30 sightings of 17 individuals between June-November in areas extending from northern California to northern British Columbia (Table 9, Calambokidis

et al. 2012). These observations indicate that at least some PCFG whales have used both the Kodiak feeding area in addition to the 41°N to 52°N area defined for the PCFG.

Satellite tagging studies between 3 September and 4 December 2009 off Oregon and California provide additional movement data for whales considered to be part of the PCFG (Mate *et al.* 2010). While duration of tag attachment differed between individuals, some whales remained in relatively small areas within the larger PCFG seasonal range while others traveled more widely. All six individuals whose tags continued to transmit through the southbound migration utilized the wintering area within and adjacent to Laguna Ojo de Liebre (Scammon's lagoon). Three whales were tracked north from Ojo de Liebre and displayed the following movement patterns: (1) one whale traveled at least as far as Icy Bay, Alaska, and (2) two whales were tracked to coastal waters off Washington (Olympic Peninsula) and California (Cape Mendocino). In combination, satellite tag and photo-identification data suggest that the range of the PCFG may, at least for some individuals, exceed the pre-defined 41°N to 52°N boundaries that have been used in a number of PCFG-related analyses (e.g., abundance estimation).

Further support of the PCFG range extending beyond the pre-defined 41°N to 52°N boundaries comes from a study of six whales satellite tagged off the central west coast of Vancouver Island in March. This study was designed to determine northern migration routes in the greater Vancouver Island area (Ford *et al.* 2012). Three of the tagged whales had been previously sighted within the seasonal range used by PCFG whales (41°N to 52°N) and two had multi-year sighting histories there. These three whales moved north to between ~55°N to 57° N before their tags stopped transmitting. One of these whales was later observed in the seasonal range of the PCFG off southern Vancouver Island. These findings suggest that in the spring at least some PCFG whales may migrate northward, past the defined seasonal range used by the PCFG, along with the larger ENP stock before "circling back" to within the range of the PCFG summer feeding area.

It is unknown how long gray whales have used the PCFG area in summer and autumn; it may have been colonized as recently as the last century or during the Little Ice Age (~1540-1850) or other glacial periods when it was difficult or impossible for gray whales to feed further north. Records of gray whales feeding between northern California and Alaska during summer/fall date back to at least 1926 (Howell and Huey 1930), including reports of whales feeding on the southern feeding ground during the 1940s, 1950s, and 1960s (Gilmore 1960; Pike and MacAskie 1969; Rice and Wolman 1971). The consistent return of individuals to the southwestern coast of Vancouver Island, British Columbia, was first documented in the early 1970s (Hatler and Darling 1974).

A unique characteristic of PCFG whales is an apparent flexibility in their feeding habits. That is, whales summering in the seasonal range of the PCFG consume a varied diet including mysids, amphipods, crab larvae, and herring eggs/larvae. This is in contrast (generally speaking) to gray whales feeding in the arctic where they seem to be more focused on an amphipod food base (Nerini 1984). That being said, whales that utilize the seasonal range of the PCFG in only a single year (i.e., non-PCFG whales) must also be flexible, at least to some degree, in their feeding habits.

Abundance estimates of PCFG gray whales reported by Calambokidis *et al.* (2012) show a high rate of increase in the late 1990s and early 2000s, but have been relatively stable, albeit with some decline, since about 2003. No statistical analysis of trends in abundance is currently

available for this population. The PCFG is estimated to contain about 200 individuals (Calambokidis *et al.* 2012). As stated in the 2012 gray whale SAR “because the PCFG appears to be a distinct feeding aggregation and may warrant consideration as a distinct stock in the future, a separate PBR was calculated” (Carretta *et al.* 2013). Calculation of a PBR for the PCFG allows NMFS to assess whether levels of HCM are likely to cause local depletion of this group. In keeping with that management objective, NMFS used the 2008 abundance estimate of 194 (SE = 17.0)³ from Calambokidis *et al.* (2010) and the range of the PCFG (between 41°N to 52°N) as defined by the IWC to calculate a potential PBR for PCFG whales (Carretta *et al.* 2013). This calculation used the minimum population size (180 animals), times one half the maximum theoretical net population growth rate ($\frac{1}{2} \times 6.2\% = 3.1\%$), times a recovery factor of 0.5 (for a population of unknown status), resulting in a PBR of 2.8 animals (NMFS 2012). Further, a review of annual HCM in the PCFG between 2006 and 2010 was estimated and averaged 0.6 animals/year known deaths (Carretta *et al.* 2013).

In discussion, the TF asked Lang if there was any evidence that oceanographic changes have influenced the abundance or recruitment of whales into the PCFG. Lang replied that Calambokidis *et al.* (2012) reported a higher than usual “pulse” of animals recruited into the PCFG in the years following the 1999-2000 gray whale Unusual Mortality Event (UME). This UME has been theorized to be the result of limited food resources on the northern feeding grounds (see Gulland *et al.* 2005), and as such, this “pulse” of gray whale immigration⁴ into the PCFG could potentially be considered a response to oceanographic changes. Given that the photo-identification effort on PCFG whales expanded greatly in 1998 (data from years prior to 1998 exist but not at the same level of effort), coinciding closely in time with the UME, it makes it impossible to resolve with certainty the occurrence or magnitude of the hypothesized pulse recruitment.

In response to the observations of PCFG whales in northern areas such as Kodiak and Barrow, Alaska, some members of the TF asked why the boundaries of the PCFG area defined by the IWC were not extended further north? The TF noted that the IWC definition was not intended to define the stock but rather to provide a conservative basis on which to evaluate the gray whale hunt proposed by the Makah Indian Tribe. With respect to low survey effort north of 52°N, the TF agreed that the PCFG could have a higher abundance than currently estimated and that this might affect a number of analyses including determination of annual sighting patterns of individual whales (e.g., a PCFG whale may have been present in a larger area but not photographed because it was located in a region not surveyed). The TF concurred that these issues are important to assignments of PCFG whales (i.e., those seen in two or more years between 41°N and 52°N) and highlighted the importance of expanding the spatial and temporal coverage of the photo-identification effort. In addition, further satellite tagging of known PCFG whales would also help to better define habitat use and delineate the seasonal feeding range.

Additional discussion was devoted to addressing the possibility that HCM (e.g., ship strikes and commercial fisheries bycatch) for whales in the PCFG area could be higher than for whales that migrate through the area. That is, PCFG whales spend more time near shore where ship traffic and fishing gear are concentrated. Despite this concern, little information is available on where

³ This estimate will be updated in the 2013 SAR to include the now available 1999-2010 time series presented in Calambokidis *et al.* (2012).

⁴ Immigration, as used here, means a permanent change of feeding ground fidelity and is considered interchangeable with “external recruitment”.

HCM actually occurs. The TF asked Carretta how whales were classified as being PCFG in his analysis. He replied that the estimate was based on NMFS stranding data for the most recent 5-year period and included whales that stranded within the defined PCFG time period (1 June and 30 November) and range (41°N to 52°N). Carretta noted that his estimate of 0.6 animals/year, based on only the most current 5-year period (as per protocol of the SAR guidelines), is lower than the 20-year average of 1.5 animals/year reported elsewhere (IWC 2012a). The TF agreed that both of these estimates of HCM for the PCFG were likely to represent minimum estimates because there is no correction for incidents that go unobserved or unreported.

Related to the issue of HCM, the TF also discussed the results presented in Connor *et al.* (2011), which found that PCFG whales had higher rates of scarring than other gray whales. It was noted that crab pots are common off the Washington and Oregon coasts and as such may pose an increased threat in some parts of the PCFG range. Carretta noted that when looking through the HCM records, a fair number of southern California crab pot interactions were reported, which suggests that fisheries interactions of this nature could be a pervasive issue along the coast. The TF noted that PCFG animals could have more interactions (compared to non-PCFG whales) with crab pots and coastal fishing gear given their extended residency in nearshore areas. Therefore, the TF recommended that the existing photo-identification time series be used to examine scarring patterns of PCFG whales to possibly provide a better assessment of their interactions with fishing gear.

4. Population Dynamics of the Pacific Coast Feeding Group

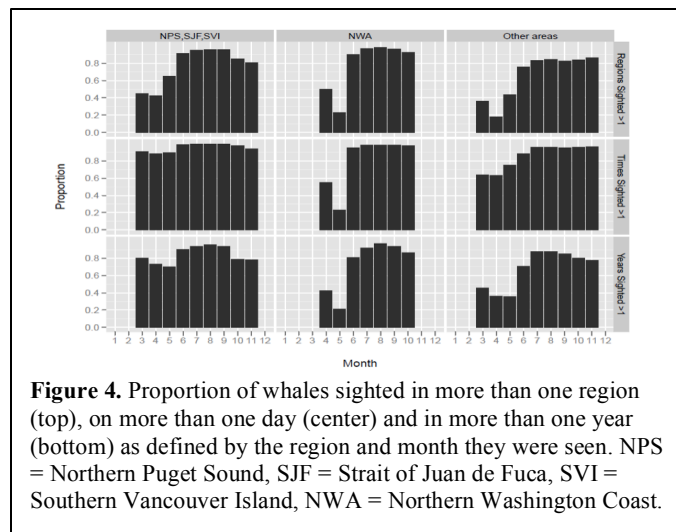

Laake (AFSC) provided a summary of information regarding the PCFG (following the IWC definition) based on photo-identification research as described in Calambokidis *et al.* (2012). Photo-identification studies from 1998 to 2010 between northern California and northern British Columbia have categorized gray whales using that region during summer and autumn in two components: (1) whales that frequently return to the area, are seen in more than one year between 1 June and 30 November, and account for most of the sightings during that time period, and (2) whales that are sighted only in one year, tend to be seen for shorter time periods in that year, and are encountered in more limited areas.

4.1 Definition of Pacific Coast Feeding Group whales based on timing and area

Defining the PCFG involves analysis that spans both time and space. The temporal component of the PCFG range is better defined than the spatial component, but neither can be considered absolute. As mentioned previously, the IWC defines the PCFG as: gray whales observed between 1 June to 30 November within the region between northern California and northern Vancouver Island (from 41°N to 52°N) and photo-identified within this area during two or more years (IWC 2012a). The spatial boundaries of the PCFG range under the IWC definition were chosen for the following reasons: (1) samples used for the genetic analyses were taken from whales across this range, (2) the work of Calambokidis *et al.* (2012) showed movements of whales throughout the area (Figure 3), (3) only a small number of PCFG whales have been observed north or south of the area during the 1 June to 30 November time period, and (4) few if any whales are still migrating north through the 41°N to 52° N region from 1 June to 30 November. The temporal definition (1 June to 30 November) was based, in part, on the disparity in sighting rates across months. Whales observed after 1 June were more likely to be sighted (i.e., photographed) more than one time, in more than one year, and in more than one region (Figure 4).

In discussion, the TF asked whether the results presented in Figure 3 were effort-corrected. Laake explained that the proportions are only dependent on the effort in the region from the Makah U&A to Southern Vancouver Island (SVI) and not in the other areas. Variation in effort in areas outside of the Makah U&A-SVI region will change the sample size that could be detected in the Makah U&A-SVI but not the proportion of individuals resighted in the Makah U&A-SVI.

The spatial range of PCFG whales was then discussed by the TF, including apparent gaps in survey coverage. Surveys in the seasonal range of the PCFG tend to focus on regions where gray whales have been seen and so the surveys are not randomly designed to cover the entire possible range. There is a large gap in survey effort north of 52° N (i.e., between northern Vancouver Island and Kodiak, Alaska). Because only a limited amount of gray whale survey effort has been undertaken in this region, it is unknown whether this area represents a true distributional gap. Even with this limitation, it is nevertheless possible to document observed movements of known individuals and estimate a related minimum range. Figure 5 presents the

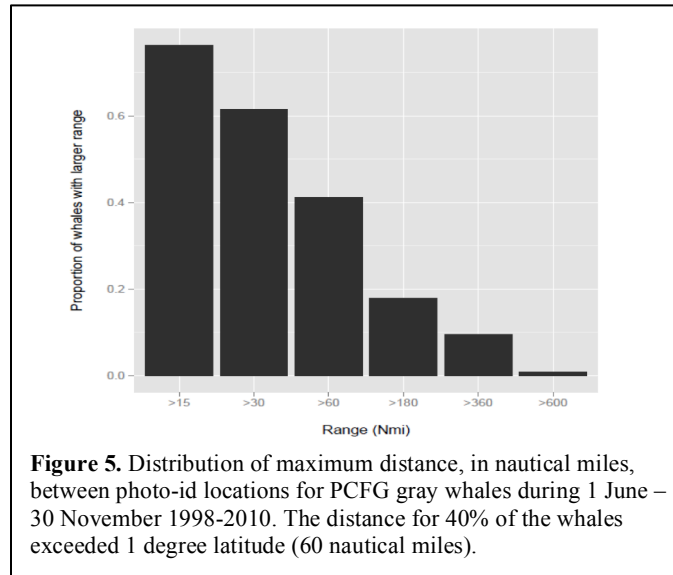

observed range of maximum distances between sighting locations for individual whales. Overall, approximately 40% of PCFG whales are known to have utilized areas spanning at least one degree of latitude. Further, there are documented movements of PCFG whales to Kodiak (Gosho *et al.* 2011) and Point Barrow, Alaska (Calambokidis *et al.* 2012), in years they were not seen in the PCFG area. Finally, information from tagging (see section above) also supports the idea that the range of some PCFG whales extends outside of the presently defined boundaries.

It was noted by the TF that site fidelity of known reproductive mothers to the WNP Sakhalin Island feeding area is very strong (Weller *et al.* 2002). The TF therefore recommended that the existing PCFG photo-identification data be examined to see if moms/calves demonstrate higher levels of fidelity than other whales.

4.2 Pacific Coast Feeding Group abundance and survival

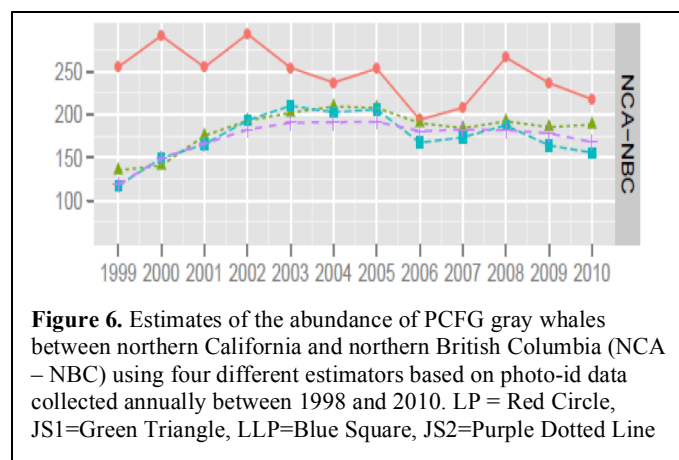

The photo-identification data collected annually in the seasonal range of PCFG whales (following the IWC definition) between 1998 and 2010 have been used to estimate abundance. In these analyses, the term “transient whale” was used to refer to whales seen in only one year and

never seen again in any other year, and “non-transient whale” was used to refer to whales seen in at least two years, such that an estimate of the number of non-transient whales would be equivalent to an estimate of the number of whales defined to be in the area used by the PCFG. The total number of gray whales in the area used by the PCFG in summer would include both transient and non-transient whales, and is therefore higher than the number of defined PCFG whales in the area. In the following discussion of abundance estimates, whether an estimate is biased or not is relative to the true number of defined PCFG whales (not to the total number of gray whales in the area).

A number of different estimators were used including: (1) Lincoln-Peterson (LP), (2) Limited Lincoln-Peterson (LLP), and (3) Modified Jolly-Seber (JS1). The first two estimators constructed estimates from consecutive years of data. The LP estimator assumes a closed population and is unbiased if there are only losses or only gains. There are both losses and gains to the PCFG due to transient whales and therefore induces a positive bias. The LLP estimator removes the positive bias of the LP estimator by restricting the data to whales seen during the 2-year period but also in another year prior or after the 2-year period. This restriction eliminates whales that were transients in either of the years. The JS1 estimator is an open population model that estimates the abundance of non-transient whales. A fourth estimator, JS2, is an alternate JS modification that produced similar results except at the end of the time series (Calambokidis *et al.* 2012).

Calambokidis *et al.* (2012) considered the JS1 estimator to be the best suited for analysis of the PCFG (Figure 6). The Jolly Seber 1 (JS1) estimator assumes that any gray whale joining the PCFG is seen the first year it enters. The assumption is made to model the data adequately with the strong relationship between minimum tenure (time between first and last sighting in the year) and the probability it remains in the PCFG. The magnitude and trend of the LP abundance estimates do not match up well with the limited LP and the JS1 estimates; this is due to the fact that the LP

estimator was positively biased and the bias was greater at the beginning of the time series when there was more immigration and emigration into and out of the area used by the PCFG.

In discussion, the TF focused on whether the increase in the JS1 abundance estimates from 1999-2002 (Figure 6) was real or a reflection of the discovery of “new” whales that were present in the area used by the PCFG but not observed (i.e., photographed). Some of that discussion also focused on the related topic of recruitment described below. Laake responded that there were 13 whales not sighted in 1998 that were seen after 1998 (most of them were sighted in 1999) and were in the catalog for sightings prior to 1998. These results indicate that the assumption of JS1 (i.e., that any gray whale joining the PCFG is seen the first year it enters) was not met entirely. That being said, Laake argued that the bias was small or negligible after 1999 for the following reasons: (1) values from the JS1 estimator correspond closely to the value from the limited LP estimator which does not make the same assumption, (2) simulation results using similar values for capture probability estimated from the data showed a minimal amount of bias after 1999, and (3) the UME in 1999-2000 provides a plausible explanation for the coincident increase in PCFG abundance.

4.3 Pacific Coast Feeding Group IWC implementation review

Wade (AFSC) presented a brief overview of the status of the Implementation Review (IR) process conducted by the IWC. The IR includes trials based on three hypotheses: (1) Hypothesis P (Pulse) assumes that there is no bias in the PCFG abundance estimates (but dropping 1998) and that a pulse of immigration occurred in 1999 and 2000; (B) Hypothesis B (Bias) assumes a strong time-varying bias in the abundance estimate but no pulse of immigration; and (3) Hypothesis I (Intermediate) includes a moderate time-varying bias in the abundance estimates and a pulse of 10 immigrants into the PCFG in both 1999 and 2000. These hypotheses were evaluated because the model used in the IWC IR trials could not produce simulated abundance trajectories that fit the abundance estimates without incorporating a pulse or a bias into their model. For these trials the IWC Scientific Committee agreed that a sufficient fit to the data could be achieved with maximum annual immigration of up to six animals.

Wade noted that for the most part there was broad similarity between the population trajectories in the IWC trials and the population trajectories in the OSP determinations performed by Moore and Punt (pers. comm.), which only use Hypothesis P (a pulse of immigrants in 1999 and 2000, see related item below). The IWC implementation trials produce final statistics related to conservation status and catches.

There was some discussion about the need to evaluate trials that produced worrying conservation statistics and that it would be valuable to look at what the depletion level could be in those trials. Wade noted that the trials incorporating a low growth rate with little immigration or the trials in which the probability of taking a PCFG whale were doubled were the trials which do not do well with respect to conservation statistics such as final depletion level. Note that “final depletion level” is defined by the IWC to be the final population level as a percent of K. This is related to, but can be slightly different from, the U.S. MMPA definition of “depletion”, which is defined to be a population level below the Maximum Net Productivity Level (MNPL). In U.S. MMPA depletion determinations, MNPL is generally assumed to either be a range from 50-70% of K, or a single value such as 50% or 60% of K. The only practical difference occurs when a range is used in MMPA determinations, where one calculates the probability a population is below MNPL over a range of percentages of K. If a single value is used for MNPL (e.g., 60%), then the IWC final depletion level is identical.

Some of the simulations conducted by the IWC with worrisome conservation performance (with respect to final depletion below 60%) are those using Maximum Sustained Yield Rate (MSYR) of 1% or 2%, implying a relatively low maximum population growth rate (Annex E, IWC 2012b). Note that the IWC Scientific Committee parameterizes population models with MSYR rather than R_{max} (used in U.S. MMPA calculations). MSYR is the population growth rate at the Maximum Sustained Yield level, which is equivalent to MNPL if human-caused removals are unbiased with respect to age. Therefore, if MNPL is 50% of K , a population with an MSYR of 2% has an R_{max} of 4%, and a population with an MSYR of 1% has an R_{max} of 2%. Taylor noted that although she would have initially thought population growth rates that low were unlikely, after seeing some of the results presented she felt that relatively low population growth rates cannot be ruled out. She also noted that all trials in the table (which was a summary of trials that performed poorly with respect to conservation statistics) have annual immigration = 0 to 2, at the low end of the range considered. It appears that rates of annual immigration higher than 2 provide just enough of an offset to low MSYR rates of 1 or 2%.

The TF asked how the rescaled final depletion level was related to final depletion level in the IWC results. The rescaled final depletion statistic is used by IWC in trials whose specifications cause the population to decline even in the absence of catches. To evaluate those trials, the final population level for the trial (with catches) is compared to the final population level that would have been obtained in the absence of catches. That ratio is termed the rescaled final depletion, and represents the fraction of the population size that would have been obtained in the absence of catches. Since a low MSYR rate results in low population growth, the IWC found it is useful to compare depletion levels both with and without catches. The rescaled final depletion results for the PCFG only differ from the final depletion statistic for trials with a low value for MSYR, where the PCFG would decline and become depleted regardless of whether a hunt occurred due to the combination of a low population growth rate and bycatch.

4.4 Pacific Coast Feeding Group recruitment

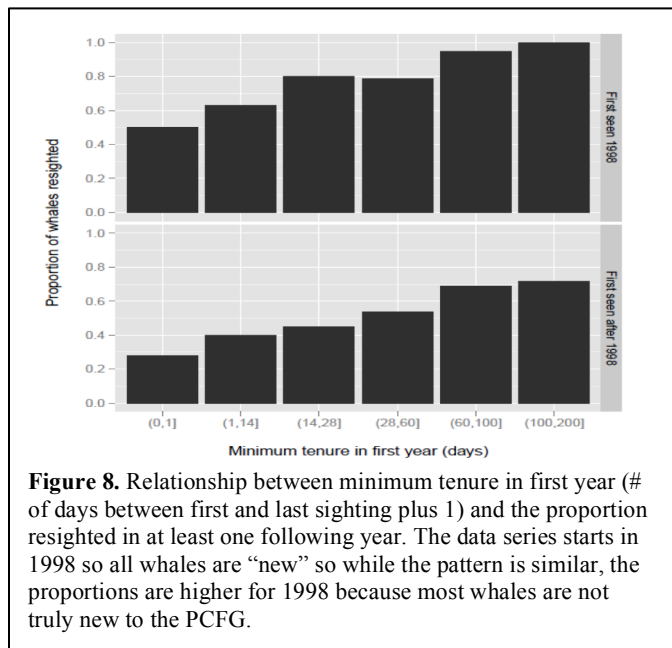

Although new whales are identified each year in the range of the PCFG, about 50% of these individuals are seen in only one year and considered “transients” or “visitors” (Figure 7). Other whales are resighted in subsequent years and are considered “recruits” into the PCFG. Whales with a longer minimum tenure in the first year they were sighted have higher first year apparent survival and higher probability of return (i.e., do not permanently emigrate). This relationship

might be expected given a hypothesis that whales are more likely to return if they find a suitable prey base during their first year in the seasonal range of the PCFG.

Whales that recruited into the PCFG in 1999 or a subsequent year had lower first year apparent survival than whales that were first identified in 1998.

Approximately 75% of the whales whose minimum tenure was 100 days or more in 1999 or later were resighted in a following year. For whales identified in 1998 (the first year of the study) whose minimum tenure was 100 days, nearly 100% were

resighted in a following year (Figure 8). This suggests that some of the animals that recruited into the PCFG in 1999 or later may have subsequently emigrated out; this could explain why the abundance has declined somewhat in the later years (Figure 6). The high number of new whales identified in the seasonal range of the PCFG between 1999 and 2002 is hypothesized to have been in response to the 1999-2000 UME.

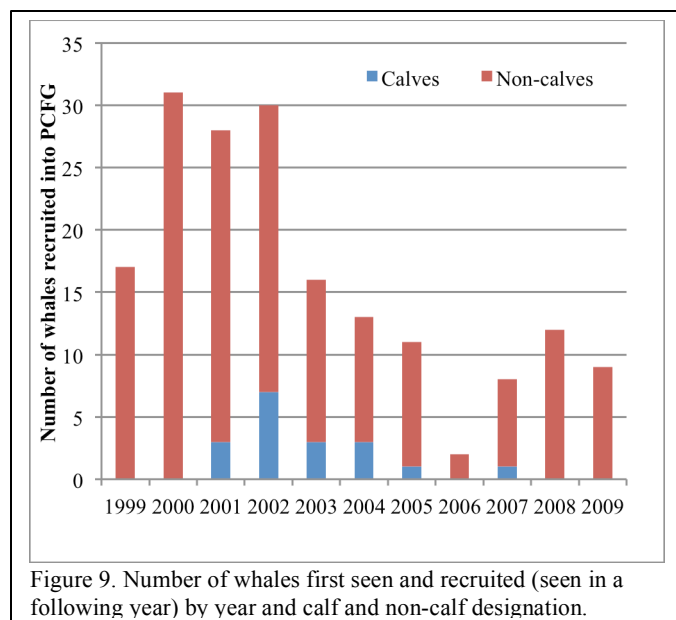

The TF discussed several alternative explanations for the relatively high numbers of recruits into the PCFG in the early part of the time series (1999-2002). For example, whether the increase in abundance during early years could be due to a “discovery” effect, such that it

took a number of years for all the whales which were part of the PCFG to be photographed and “discovered”. Alternatively, the heterogeneity in survey coverage over time and space could lead to some animals being considered “new” in a given year even if they had been utilizing areas with limited or no survey coverage in previous years. However, overall capture probabilities are high, suggesting it is unlikely a whale would be in the area for several years and not photographed. The TF concurred that on an annual basis, whales observed in the area used by the PCFG could be characterized as a collection of individuals whose residence patterns vary along a continuum such that some whales use the area for a single year (e.g., transients), some for a few years, and others on a consistent long-term basis.

By way of an analogy, Laake characterized the PCFG as a “leaky bucket”, in that some whales are immigrating in while others are emigrating out. The “leaky bucket” phenomenon is not a random process, however, because a “core group” of whales appear to stay in the bucket over time. The dataset cannot discriminate between PCFG whales that die versus those that emigrate. Animals that recruit into the PCFG as non-calves may be more likely to emigrate out of the area than calves recruited to the PCFG in the year they were born. That is, calves of the year have been taught to feed on prey types common to the PCFG area (various swarming prey for instance) by their mothers and may obtain “local knowledge” that allows them to be successful long-term inhabitants of the PCFG area. To evaluate this, the TF recommended that the existing PCFG photo-identification time series be examined to see if moms/calves demonstrate higher degrees of fidelity than other whales.

In thinking about the “core group” of PCFG whales that return to the area on a consistent basis, the TF questioned if biopsy efforts in the area could be potentially biased towards these whales. If sampling efforts are unintentionally concentrating on the “core group” of PCFG whales, then the results of genetic comparisons may be driven by matrilineal fidelity of this “core group”. In addition, the biopsy efforts are not spread evenly over time and space (more heterogeneity than the photo-identification survey efforts). If “core group” animals predominantly use the areas with high biopsy effort, then this potential bias could be magnified.

Some newly seen whales are calves with their mothers (Figure 9). As described in Calambokidis *et al.* (2012), much of the sighting effort occurs in August and later when many calves are likely to already be weaned and thereby more difficult to identify as a calf (versus a yearling). The TF noted that many of the whales identified as calves off Sakhalin Island in the WNP are not

resighted for many years subsequent to their birth year but eventually they are again resighted in the area. This pattern suggests that young animals (1+ years old) may use other areas to feed during their first several years. Therefore, in the case of the PCFG, if a whale was not seen as a calf but returned in a later year it would appear to be an external rather than internal recruit. With that in mind, the TF recommended that the existing PCFG photo-identification time series be examined following a protocol developed by Bradford *et al.* (2011) that uses barnacle and pigmentation characteristics on young gray whales to reliably distinguish calves of the year from yearlings.

In summary, the TF discussion about the magnitude and source of recruitment into the PCFG focused on: (1) incomplete survey coverage of the entire seasonal range used by the PCFG and the potential for whales to be missed and then “recruited” in a subsequent year, (2) the proportion of “recruited” whales that were calves of mothers from the PCFG that may have been missed as a calf or misidentified as an external recruit, (3) the potential of the 1999/2000 UME to create a pulse of immigration into the PCFG, (4) to what degree gray whales recruited in 1999 or later were either emigrating back to the northern feeding areas or experiencing higher mortality, and (5) whether the biopsy sampling effort was prone to sample whales that spent more time in the range used by the PCFG.

All of these issues are relevant to assessing the amount of external recruitment into the PCFG and thereby especially pertinent to determining if it should be recognized as a population stock under the MMPA and GAMMS guidelines. That is, if the PCFG experiences little external recruitment then it would be considered demographically independent and should be recognized as a stock. If most of the recruitment into the PCFG were external, however, then it would not be considered demographically independent and would not be recognized as a stock. The TF concurred that the resolution of the existing photo-identification data in combination with uncertainly surrounding the accuracy of assigning whales as external or internal recruits prevent this question from being fully resolved. Increased genetic sampling in tandem with increased photo-id effort over both space and time may be the only way to better address this question.

4.5 Pacific Coast Feeding Group trend and optimum sustainable population determination

Moore presented an update on work he conducted in collaboration with Andre Punt (University of Washington) to determine if the PCFG, as a putative stock, is at OSP. The OSP assessment is based on the two-stock population model that has been developed as part of the IWC gray whale

Implementation Review (see section 4.3). Both assessments use the same definition for a PCFG whale. There are some differences, however, between the IWC model framework and the one used for the OSP assessment. First, in the OSP analysis, a Bayesian approach is used in which prior distributions are specified for input parameters and the time series of abundance estimates (for the ENP and PCFG) are used to update priors and output posterior distributions. This contrasts with the IWC approach of generating outputs for many models each based on alternative fixed combinations of values for some parameters. Second, the IWC trials consider several hypotheses that attempt to explain the rapid increase in abundance estimates in the first few years of the time series; these include bias in the early abundance estimates, a pulse of immigration, and a combination of these two factors. In the OSP assessment, only the pulse immigration hypothesis is considered, based on work by Calambokidis *et al.* (2012) which suggested that the most recent abundance estimates should be fairly unbiased apart from the first estimate in 1998, which is not used in the OSP analysis.

At the time of the workshop, the OSP analysis considered two hypotheses pertaining to the regular annual immigration rate: one in which there is no immigration (PCFG is closed) and one in which the annual immigration rate is estimated, given a uniform prior distributed between 0 and 6 individuals per year. Different versions of the model allow the density-dependent (or inflection point) parameter θ to be estimated separately for each putative stock (PCFG vs. rest of the ENP) or to be constrained so that the two groups share a common θ . Outputs from both versions and immigration rate considerations (none vs. $U[0, 6]$) are similar in models run thus far. The primary parameter of interest in the OSP assessment is the probability that PCFG abundance is above MNPL (MSYL in IWC terms).

The analysis was not able to generate useful assessment results because, apart from the rapid population increase in the late 1990s attributed to an immigration pulse, the abundance time series is fairly flat and therefore not very informative for estimating *in situ* population growth parameters. The data have also not been informative for estimating population carrying capacity (K), a parameter necessary to determine whether current abundance is above MNPL. Posterior distributions for K have been strongly dependent on the upper bound used for the prior. Given that the abundance has been stable throughout most of the 2000s, it appears to be regulated at this level (of around 200 - 250 animals) by some factor, and thus it is somewhat puzzling that the data do not seem more informative with respect to estimating K . Moore suggested that annual levels of incidental take included in the model (about 2 animals per year) could be making it difficult to estimate whether the population is being regulated at K or some level below K , given that the data do not inform the estimates of MSYR (the population growth parameter in IWC models). For example, given annual bycatch mortality of 1%, a combination of being well below K and having a low MSYR may describe the data equally well as being close to K and having a high MSYR, since in both cases, the realized value for population growth would be low and potentially balanced by the additive mortality. It was also suggested that the population might be regulated at its current level as a result of emigration and bycatch offsetting the combination of immigration and *in situ* growth.

Moore and Punt were continuing to troubleshoot the problem by running alternative models that, for example, exclude incidental take from the model or constrain estimates of MSYR for the PCFG to be equal to those of the ENP. The goal of this troubleshooting is to explain why estimates of K and hence probability of being at OSP are elusive, which in turn may enable a decision as to whether an OSP assessment may be possible.

The TF thanked Moore and Punt for their work on this complicated matter and raised several points for clarification. It was asked where the estimates of incidental mortality for the model had come from. Moore reported that the bycatch estimate being used is based on a summary compiled at the 2011 IWC Aboriginal Whaling Management Procedure (AWMP) intersessional workshop (IWC 2012a). Carretta clarified that those estimates included data from over a 20-year period that tried to assign animals as being part of the PCFG (or not) based on time and space. Carretta also noted that the bycatch values used in the OSP analysis (as well as the SARs) account for only observed bycatch, which is likely to be an underestimate of actual bycatch.

It was also noted that emigration is a possible explanation for the difficulty in estimating K in spite of apparent PCFG population size stability. That is, all recruits are assumed in the model to have the same annual survival rate but as discussed above, whales that recruited into the PCFG in 1999 or later had lower first year survival than whales that were first identified in 1998. Not including this extra survival parameter may explain some of the lack of fit of the model to the abundance time series (plots show that the model underestimates abundance in the first half of the time series and overestimates abundance in the second half of the series).

The TF asked if the model assumed immigration was constant across years in the assessment given that in reality immigration into the PCFG is thought to vary across years. In the model, immigration to the PCFG occurs at a constant rate, with the number of immigrants being proportional to the northern stock (non-calf) abundance. The rate is equal to the estimated immigration parameter (I , specified with the uniform [0,6] prior) divided by 20,000. In other words, for recent abundance levels of the northern stock, annual immigration to the PCFG is approximately I individuals. Emigration from the PCFG group is similarly assumed to occur at a constant rate, specified by an additional survival parameter ($1 - S$), with the number of emigrants proportional to PCFG abundance. S is set so that when both stocks (northern and PCFG) are at carrying capacity, immigration and emigration to the PCFG is balanced, i.e., $IK_{\text{north}}/20000 = (1 - S)K_{\text{PCFG}}$.

Some members of the TF commented that based on this model it seems plausible that the pulse of immigration into the PCFG is larger than what the IWC is modeling or what the genetic simulations have modeled. If that were the case, then the estimates of regular annual immigration would be lower than estimated in the genetic simulations. In the light of this discussion, the TF noted that the genetic simulations should try pulses of 30 animals to see if that is consistent with the empirical genetic data. This line of thinking led to additional discussion as to how common pulse immigration events might be, and whether, for the purposes of the workshop and deliberations on internal versus external recruitment, the TF should be considering the pulse as part of the average level of immigration or if the pulse should be considered a one-time event and only annual immigration should be considered (in assessing how demographically independent the PCFG is).

It was further noted that if a UME event the size of the one in 1999-2000 had occurred previously, some record of it would be expected. Wade noted that it was due to this reasoning that they did not incorporate additional mortality events in the northern stock OSP analysis conducted by Punt and Wade (2012). Wade also noted, however, that there had been a drop in the northern stock abundance in earlier years of the time series but these were not accompanied by a record of increased strandings. The TF suggested that pulses could occur regularly on decadal time scales or as a result of a variety of other environmental or anthropogenic factors.

The TF discussed if the genetic data may reflect a sampling bias toward “core” PCFG animals. This follows other lines of evidence showing that there is a relationship between minimum tenure and probability of photographically capturing animals in the PCFG area (see section 4.4 above). If “core” PCFG whales are more approachable, then they are potentially more likely to be biopsied, meaning that these whales may be disproportionately selected for in the biopsy process.

Lang noted that she had looked at the current genetic sample set to see if the rare haplotypes found in the PCFG sample set came from animals that were sighted in 1999 or later, which might suggest that they were immigrants as the expectation would be that immigrants would be likely to bring in rare haplotypes. The results were mixed, with some rare haplotypes found in long-term PCFG whales while others were found in animals that came into the PCFG in 1999 or later.

This led to a discussion about what additional information might help the PCFG OSP assessment and improve inference generally about the level of internal versus external recruitment to the PCFG. The TF agreed that additional genetic sampling to improve estimates of immigration and residency times (emigration), and improved estimates of incidental mortality would be useful.

5. Probability of a Western North Pacific Gray Whale Being Taken by the Makah

Mixing of whales identified in the WNP and ENP has recently been reported (Weller *et al.* 2012). Lang (2010) reported that two adult individuals from the WNP, sampled off Sakhalin in 1998 and 2004, matched the microsatellite genotypes, mtDNA haplotypes, and sexes (one male, one female) of two whales sampled off Santa Barbara, California in March 1995. In 2010 and 2011, Mate and colleagues (Mate *et al.* 2011) satellite-tracked three whales from the WNP to the ENP (Mate *et al.* 2011; IWC 2012a; IWC 2012b). Finally, photographic matches between the WNP and ENP, including resightings between Sakhalin and Vancouver Island and Laguna San Ignacio, have further confirmed use of areas in the ENP by whales identified in the WNP (Urbán *et al.* 2012; Weller *et al.* 2012). Despite this level of mixing, significant mtDNA and nuclear genetic differences between whales in the WNP and ENP have been found (Lang *et al.* 2011b).

Observations of gray whales identified in the WNP migrating to areas off the coast of North America raise concern about placing the WNP population at potential risk of incurring mortality incidental to the ENP gray whale hunt proposed by the Makah Indian Tribe off northern Washington, USA (see IWC 2012a; IWC 2012b). Given the ongoing concern about conservation of the WNP population, in 2011 the Scientific Committee of the IWC emphasized the need to estimate the probability of a western gray whale being killed during aboriginal gray whale hunts (IWC 2012a). Additionally, NOAA is required by NEPA to prepare an Environmental Impact Statement (EIS) pertaining to the Makah’s waiver request. The EIS will need to include an analysis of the likelihood of a western gray whale being killed during the proposed Makah gray whale hunt.

Moore summarized the work that he and Weller (SWFSC) have done to estimate the probability that a WNP whale might be taken during the proposed gray whale hunt (Moore and Weller 2013). Four alternative models were evaluated; these models made different assumptions about the proportion of WNP whales that would be available for the hunt or utilized different types of data to inform the probability of a WNP whale being taken. The probability of striking at least one WNP whale over the course of five years was estimated to range from 0.034 – 0.058 across different scenarios of the preferred model, with upper 95% CI estimates ranging from 0.107 –

0.170. This result may be compared to an estimate of PBR. If the recovery factor for calculating PBR is set to 0.1, and discounting the estimate for the proportion of the population that may be migrating through U.S. waters and the proportion of time (months out of a year) they are in U.S. waters, then the 5-year PBR estimate is between 0.1 and 0.6 animals, depending on different assumptions about the amount of mixing between the WNP and ENP. Thus, if a WNP whale were to be struck during the 5-year period, PBR would be exceeded.

6. Status of Gray Whale Stocks as Defined by, MMPA, ESA and IUCN

At the request of the TF, Stone (NWR) provided a review of the status of ENP, WNP and PCFG gray whales under the MMPA, ESA, and the International Union for Conservation of Nature (IUCN) redlist.

(1) ENP – The ENP stock is not considered “*strategic/depleted*” under the MMPA and is listed as “*Least Concern*” by the IUCN. Gray whales in the ENP were delisted from the ESA in 1994. Although there have been two petitions (2001 and 2010) to relist the ENP stock under the ESA, both petitions were denied.

(2) WNP – The WNP stock is considered “*strategic/depleted*” under the MMPA and is redlisted as “*Critically Endangered*” by the IUCN. WNP whales are considered “*Endangered*” under the ESA, although there is no stand-alone SAR for WNP whales. Given that ENP whales were delisted in 1994, gray whales in the WNP would be considered a Distinct Population Segment (DPS) under the ESA. Use of the DPS terminology was not common at the time of the delisting and thus the listing documents do not describe the WNP as a DPS.

(3) PCFG - The PCFG does not have a formal status under the MMPA, IUCN nor ESA.

In addition to the above, the TF discussed the status of gray whale stocks as defined by the IWC. Under the IWC implementation review (IR) process, the IWC considers all plausible hypotheses of stock structure, and then determines which hypotheses have high or medium plausibility. Those stock hypotheses with high or medium plausibility are used to evaluate the management variants proposed by hunters. In the case of gray whales, the IWC traditionally considered only the hypothesis of a single ENP stock. New information presented to the IWC in 2010 (Frasier *et al.* 2011) suggesting that the PCFG could be a separate stock resulted in the IWC evaluating a two-stock hypothesis. Members of the TF reminded the group that the IWC does not have to decide if there are one or two gray whale stocks, but only if it is plausible that there is one stock and if it is plausible that there are two stocks (or three stocks). The objective of the IWC is to make sure that the stock or stocks are robust to the proposed hunt under all plausible scenarios. Thus, the IWC process is currently considering both stock hypotheses (1-stock and 2-stock). Future work by the IWC may need to incorporate a third stock (i.e., WNP) but for now the calculation of the probability of a WNP whale being killed during the Makah hunt (see section 5 above) is a stand-alone calculation.

7. Overview of Evidence Used in Recently Defined Population Stocks

Stone provided an overview of the lines of evidence used by NMFS to delineate stocks as inferred from the text of each SAR. It became clear during discussion of the summary that many of the SARs do not explicitly lay out the lines of evidence and justifications for originally delineating a stock but instead only present recent information. The killer whale SARs, for example, do not describe the acoustics data and other lines of evidence that were originally used

to identify the stocks. There was general agreement that an updated summary, in spreadsheet form, would be useful as it could capture the history and provide a long-term record of how each stock was delineated, but this would not be a trivial task. In the end, the TF concurred that agency practices for delineating stocks were not based on a set standard but were more variable and fact-specific so as to use the best available information.

8. Review of Stock Definition Cases Relevant to the Pacific Coast Feeding Group

The TF reviewed several examples of stock delineations for other species exhibiting some similar characteristics to the PCFG. Similar characteristics included: (1) use of mtDNA as the sole genetic marker necessary for stock structure determination and (2) mixing with individuals from other stocks during parts of the year.

8.1 Atlantic harbor porpoises

Rosel (SEFSC) presented an overview of stock structure in Atlantic harbor porpoises (*Phocoena phocoena*) with a focus on the Gulf of Maine/Bay of Fundy stock. A single stock was designated in U.S. waters of the Northwest Atlantic based on published literature of Gaskin (1984) who hypothesized four populations in the Northwest Atlantic (three in Canadian waters and one in U.S. waters). While following Gaskin (1984), the first SAR for U.S. Gulf of Maine/Bay of Fundy harbor porpoises stated “*Presently there is insufficient evidence to accept or reject this hypothesis*” (Blaylock *et al.* 1995). In subsequent years, mtDNA evidence supported four stocks in the Northwest Atlantic, including the Gulf of Maine stock, but nuclear microsatellite data did not (Rosel *et al.* 1999). Organopollutant levels (Westgate *et al.* 1997, Westgate and Tolley 1999) and life history characteristics (Read and Hohn 1995) also differed between the Gulf of Maine/Bay of Fundy and other populations in the Northwest Atlantic. The weight of evidence supported delineation of the Gulf of Maine/Bay of Fundy stock and the lack of nDNA differentiation between this stock and others in the Northwest Atlantic was taken to indicate female philopatry coupled with male-mediated gene flow. Microsatellite data indicated that porpoises from the Gulf of Maine/Bay of Fundy probably overlap in winter in the mid-Atlantic with porpoises from other regions of the Northwest Atlantic (Hiltunen 2006), but this is outside the breeding season.

8.2 Alaska harbor seals

Taylor summarized the history of recognizing stocks of harbor seals in Alaska. Harbor seals (*Phoca vitulina*) are continuously distributed throughout Alaskan waters, but mtDNA indicates that genetic differentiation among sampled sites increases with increasing geographic distance (O’Corry-Crowe *et al.* 2003). The continuous distribution implies that there will be movement of animals across stock boundaries drawn on a map, but if no stock boundaries are designated, there is the risk of local depletion and loss of portions of the species’ range. The first SARs for Alaska harbor seals comprised three stocks- Bering Sea, Gulf of Alaska and Southeast Alaska (Hill and DeMaster 1998). In 2011, the three stocks were changed to twelve (Allen and Angliss 2012). MtDNA, satellite telemetry, trend and distributional data were used to delineate these 12 stocks. At that time, nDNA data were not available and mtDNA analyses were considered sufficient to meet the criteria of demographic independence under the GAMMS guidelines.

8.3 Humpback whales

Lang presented a review of humpback whale (*Megaptera novaeangliae*) stocks, with a focus on the North Atlantic. There are multiple humpback whale feeding grounds in the Northwest Atlantic, but individuals from these different feeding grounds share one breeding ground in the

West Indies. Humpback whales throughout the Northwest Atlantic were originally classified as a single stock (Waring *et al.* 1999). However, genetic studies have revealed small but significant differences in mtDNA between animals sampled on different feeding grounds (Palsbøll *et al.* 2001) and photo-identification studies have documented strong site fidelity of individuals to the Gulf of Maine feeding area (Clapham *et al.* 1993). The 2000 SAR recognized whales utilizing the Gulf of Maine feeding area as a separate stock (Waring *et al.* 2000). Although this SAR covers only Gulf of Maine whales, individuals from other feeding areas have been identified in U.S. mid-Atlantic waters (Barco *et al.* 2002).

The stock structure of humpback whales in the Pacific is complex (Baker *et al.* 2008; Calambokidis *et al.* 2008) and differs from the western North Atlantic with respect to the “interbreed when mature” criteria. That is, humpback whales from different feeding grounds in the NW Atlantic have the opportunity to interbreed with each other in a single breeding area, while in the North Pacific not all animals have the opportunity to interbreed with each other because there are multiple breeding areas. There is some similarity between North Pacific humpbacks and those in the central and eastern North Atlantic, in that whales on the Norway and Iceland feeding areas may breed in different areas (Palsbøll *et al.* 1997; Stevick *et al.* 1998; Wenzel *et al.* 2009). Three humpback whale stocks are currently recognized in the North Pacific, based on three feeding areas (Allen and Angliss 2012; Carretta *et al.* 2013). The SAR for the Central North Pacific stock includes calculations of PBR for three different feeding areas (Allen and Angliss 2012), as is done for the PCFG in the current SAR (Carretta *et al.* 2013).

9. Review of Gray Whale Genetic Research on Population Structure

Lang provided a chronological summary of genetic research performed on North Pacific gray whales. Steeves *et al.* (2001) used mtDNA control region sequence data to compare 16 samples collected in summer in Clayoquot Sound, British Columbia, representing the PCFG, to 41 samples collected elsewhere in the ENP. Some haplotypes were shared between the two groups and no significant differentiation was found between them. Additional genetic analysis utilizing an extended set of samples (n=45) collected from whales within the seasonal range of the PCFG indicated that the genetic diversity and the number of mtDNA haplotypes identified among these samples were inconsistent with measures that would be expected (based on simulations) if recruitment into the group were exclusively internal (Ramakrishnan *et al.* 2001). Alternative scenarios, such as limited dispersal of whales from other areas into the PCFG, were not explored. LeDuc *et al.* (2002) examined mtDNA control region differences between ENP and WNP gray whales. The ENP sample consisted primarily of stranded animals along the migratory route with some samples from Chukotka, Russia (no distinctions between PCFG and non-PCFG whales were made). The WNP samples were collected off the northeastern coast of Sakhalin Island, Russia. Seven of the 36 identified haplotypes were shared between the two regions and significant genetic differentiation was found. In addition, haplotypic diversity of the WNP sample was lower than that seen for the ENP samples.

Within the ENP, Goerlitz *et al.* (2003) made comparisons between two wintering lagoons and between females sampled in wintering lagoons and those sampled outside the lagoons (in Clayoquot Sound and along the migration route- *i.e.*, “non-lagoon females”). They found small but significant differences in mtDNA data between Laguna San Ignacio cows (females with calves) and non-lagoon females and between Laguna Ojo de Libre cows and non-lagoon females but not when cows from the two lagoons were compared. Alter *et al.* (2009) compared both

mitochondrial and nuclear microsatellite markers across three wintering lagoons and found small but significant differences between only one of the three pairwise comparisons using the microsatellite data set only. Similar to Goerlitz *et al.* (2003), they did not find significant differentiation between Laguna San Ignacio and Laguna Ojo de Libre at mitochondrial or nuclear DNA.

More recently, Frasier *et al.* (2011) examined mtDNA differences between whales sampled in Clayoquot Sound, British Columbia (representing the PCFG) and a more carefully constructed data set of ENP whales from LeDuc *et al.* (2002) in which known PCFG whales were specifically removed. They found significant genetic differentiation between the two sample sets and high levels of haplotype diversity in the PCFG sample, comparable to samples thought to represent the larger ENP population. Using this dataset, Frasier *et al.* (2011) also performed a likelihood ratio test using Theta (Θ) as a proxy for effective population size to examine whether the two sample sets come from the same population. The likelihood ratio test indicated that Θ for the PCFG did not equal Θ for the ENP and the authors concluded that the two groups were demographically independent.

D'Intino *et al.* (2012) made a comparison of whales sampled off Vancouver Island and representing the PCFG to whales sampled at the calving lagoon at San Ignacio. Using 15 microsatellite loci, they found no evidence for population differentiation between these two areas and concluded that the two sampled groups come from the same interbreeding population and that maternally-directed site fidelity to different feeding areas leads to genetic differentiation at mtDNA among feeding areas. Lang *et al.* (2011a) expanded on this result and compared whales sighted over two or more years within the PCFG seasonal range to animals sampled on the feeding ground(s) north of the Aleutians using both mtDNA and nuclear microsatellite markers. Significant differentiation was seen for the mtDNA data but not the microsatellite data, supporting the conclusion of Frasier *et al.* (2011) that structure is present among different feeding areas and this structure may be directed by matrilineal fidelity⁵ to feeding grounds. Of note, when all samples collected on the PCFG seasonal range (including those collected from animals seen in only one year) were utilized in the mtDNA analyses, no significant differences were detected in the comparison to samples collected from whales off Chukotka. When all samples collected on the PCFG seasonal range were compared to all samples collected north of the Aleutians, the mtDNA F_{ST} comparison detected a significant difference although the χ^2 test did not.

Finally, Lang *et al.* (2011b) re-examined differences between ENP and WNP gray whales, expanding on the previous study of LeDuc *et al.* (2002) by using larger sample sizes, better characterized sampling and both mtDNA and nuclear microsatellite data. Comparisons of whales sampled off Sakhalin Island with whales feeding north of the Aleutians (i.e., ENP whales) and with the PCFG demonstrated significant differentiation at both nuclear and mtDNA markers. The extent of mtDNA differentiation between ENP strata (PCFG and whales feeding north of the Aleutians) and Sakhalin Island was higher than that observed in comparisons within ENP strata. As with previous studies, significant differentiation among ENP feeding areas was not seen in the microsatellite data. The Sakhalin stratum again displayed reduced haplotype diversity compared to the ENP strata. The authors conclude that the mtDNA data support demographic

⁵ Matrilineal fidelity as used here means the learned behavior of a calf (male or female) returning to the feeding ground of its mother.

independence for ENP and WNP gray whales. However, in examining the microsatellite genotypes, Lang *et al.* (2011b) found two individuals biopsied at the Sakhalin feeding ground and off the coast of southern California. These matches, in combination with recent photo-identification and telemetry data (Mate *et al.* 2011; Urbán *et al.* 2012; Weller *et al.* 2012), suggest that some animals summering off Sakhalin overwinter in the ENP in at least some years. Given that recent records document gray whales in the waters off Japan and China during winter and spring (see review in Weller and Brownell 2012) these results suggest that population structure in gray whales may be more complex than previously believed, such that not all of the animals that feed off Sakhalin share a common wintering ground, or that some animals may switch between wintering grounds.

In discussion, TF members suggested some further avenues for exploration including examining whether any microsatellite loci were out of Hardy-Weinberg equilibrium (HWE) for the Sakhalin samples, which might be an indication of mixing of multiple breeding populations on that feeding ground. It was noted that at the 2012 IWC Scientific Committee meeting a paper evaluating the use of HWE tests to look at mixing of stocks was presented and it might be worthwhile to see if the approaches in this paper could be applied to the Sakhalin dataset (IWC 2012b). There was also discussion regarding what proportion of mixing would have to take place before it would be detected by a relatively weak test like HWE.

9.1 Genetic modeling of immigration rates

Lang presented an overview of recent work utilizing a simulation-based approach to evaluate the plausible level of immigration (i.e., a permanent change of feeding ground fidelity, used interchangeably with external recruitment) that might be occurring into the PCFG. While the empirical studies summarized above have shown significant differences in mtDNA between the PCFG and other ENP gray whale feeding areas, suggesting that matrilineal fidelity is important in structuring feeding ground use, other evidence (some from genetics, mostly from photo-id) suggests that some immigration into the PCFG may be occurring. Lang and Martien (2012) used simulations to examine how much immigration into the PCFG could occur to produce results consistent with the empirical genetic (mtDNA) analyses. The results suggested that the plausible range of immigration is >1 and <10 animals/year on top of a two-year pulse of immigration (of 20 animals each year in 2000 and 2001). Annual immigration of 4 animals (with the 2 year pulse of immigration) produced simulated results that were most consistent with the empirical data. If the PCFG had been founded more recently or the abundance of the PCFG is greater than used in the simulations, it is plausible that no annual immigration could be occurring (still assuming the occurrence of a 2-year pulse of immigration).

In discussion of these results, the TF noted several important caveats to the approach used by Lang and Martien (2012), including: (1) the results may be overly precise because so many model parameters are set, and (2) the simulated abundance trajectories do not match well with the mark-recapture estimates (Calambokidis *et al.* 2012) when immigration is 4 immigrants/yr or more. The simulated population trajectories assumed that the PCFG split from the larger ENP population in 1930. Task Force members thought that the 1930 split might be unrealistic, as oceanographic conditions during the Little Ice Age (and earlier) would have limited access to the northern feeding ground(s) and thus may have caused some gray whales to utilize more southern waters for feeding. Lang commented that there were plans to model a split of the PCFG from the larger ENP in the Little Ice Age, but that this work is not yet complete. She also noted that there were many possible histories and it would be difficult to encompass all of them.

10. Discussion of Makah Documents Concerning the Pacific Coast Feeding Group

Weller introduced three documents drafted by or on behalf of the Makah Indian Tribe regarding the PCFG. These documents were provided to the TF in advance of the meeting for review and consideration. In combination, these three documents provided important summary information on the PCFG, including reviews of what is known about the history of the PCFG and summaries of the current status of the group.

The 2011 Makah document (Makah 2011) was drafted by the Tribe and their attorneys and provided to the Pacific and Alaska SRGs as a background paper to help inform their respective reviews of the draft 2012 gray whale SAR (NMFS 2012). This document provides the Makah perspective on whether the PCFG should be recognized as a stock and was therefore deemed important for the TF to review and consider. Information provided in Scordino *et al.* (2011) is largely the same as that presented in the Makah 2011 document.

The 2012 Makah document (Makah 2012) contains comments from the Makah Tribe and their attorneys on the 2012 draft gray whale SAR (NMFS 2012). This document was considered important for the TF to review. In response to the Tribe's request for government-to-government consultation, the SWFSC met with representatives from the Makah Tribe and their attorneys in person to review comments provided in the 2012 document. These comments, where appropriate, were incorporated as changes to the draft text of the SAR (NMFS 2012).

10.1 Discussion of genetics sections of Makah documents

In discussion of these documents, the TF agreed that it was most important to focus on the Makah comments and perspective regarding genetics research on the PCFG. Rosel agreed to lead the TF through the genetics sections of the Makah documents that called into question the strength of the genetic data presented with respect to demographic independence of the PCFG. These points were summarized as: (1) the samples used to represent the overall ENP stock may not be a random sample of the entire stock but could come from different and unknown feeding grounds. This calls into question what the PCFG is being compared to in the genetic analyses, (2) sample sizes from many locations are small relative to overall population size (i.e., relative to the size of the larger ENP population) and to the total level of genetic diversity and that this could cause misleading results, (3) many population comparisons of gray whales have yielded significant but low-level differences in haplotype frequencies; if this is considered sufficient evidence to classify the PCFG as a stock then every group of gray whales utilizing a particular feeding area should be considered a stock, and (4) the genetics results do not support reproductive isolation of the PCFG.

The first two points were related to sampling effects. In discussion, some members of the TF noted that it is not necessarily the sample size that is potentially problematic but rather if related animals are grouped together and multiple biopsies are taken from that "group" then the effective sample size is much smaller. It was further noted that small sample sizes may add variability, but it would only be a problem if there were additional (unrecognized) structure in the samples. From a genetic standpoint, many analyses rely on haplotype frequencies, but if a good sample relative to the genetic diversity of the group is not obtained then the genetic diversity may not be well characterized, especially if there are many rare haplotypes. Since haplotype frequency data also go into analyses for F_{ST} and Chi-square, then poor frequency estimates due to small sample size could affect the accuracy of the genetic differentiation results as well. Lang noted that there

is some evidence from North Atlantic humpbacks that the migration to the West Indies is segregated according to feeding ground origin (Stevick *et al.* 2003).

The TF noted, however, that the recent PCFG genetic analyses show high diversity indicating that sampled animals have different haplotypes and are thus not related (maternally). The TF asked if the question at hand is whether gray whales have feeding aggregations or whether the group that migrates north of the Aleutians is different from the group that does not migrate north of the Aleutians. Lang noted that the original intent of the project was to compare samples collected from different feeding areas north of the Aleutians to the area used by the PCFG but in the end sample sizes were insufficient for areas other than Chukotka. Nevertheless, although there could be multiple feeding aggregations north of the Aleutians, one of the comparisons conducted by Lang *et al.* (2011a) used only samples collected off Chukotka to try to avoid including unrecognized structure.

The TF recognized the continuing need for additional data to be collected, but for the purposes of the workshop the focus was whether the lines of evidence from existing genetic analyses are strong enough to counter lines of evidence that put the demographic independence of the PCFG into question. The primary question in the short-term is what can be done with the information that is currently available.

The TF noted that Frasier *et al.* (2011) compared animals from the PCFG with a sample set primarily derived from stranded animals along the U.S. west coast during migration. They agreed that these samples might not be a random representation of the larger ENP, as was also pointed out in the Makah documents.

Overall, the TF felt it was important to recognize that the current research questions being addressed center around feeding-ground-based groups of animals. The genetics work has already shown that when the PCFG is compared to a sample set from northern feeding area (Chukotka) animals or to the Sakhalin animals (also a feeding area) differences have been found (Lang *et al.* 2011b). That is, the PCFG has been shown to be different from two other well-characterized feeding grounds.

While interpretation of the currently available genetic results as relevant to the PCFG has led to debate amongst different groups, the TF concurred that it represents the best available science. In discussion, some members of the TF agreed that although more progress on this issue could be made over the next few years if resources were available for more intensive sampling, they did not think that the current interpretation of results would change much. That is, even if 1% of the 19,000 or so animals going through Unimak Pass were sampled, a mtDNA difference with the PCFG (as already observed) would remain. So far the PCFG has been compared to samples from feeding areas and from the migratory route and both comparisons detected a genetic difference. It was agreed that the critical issue for additional research to address was better determining the levels of internal versus external recruitment in the PCFG.

At this point the TF returned to discussing the remaining points raised by the Makah documents. The third point was that since multiple genetic comparisons have found low but significant differences, every group of gray whales should be considered a stock. The TF concurred and noted that there is nothing wrong with incrementally adding stocks as new evidence is uncovered, and that decisions have to be made based on the best available science.

The final point discussed was that the genetics results do not support reproductive isolation of the PCFG. The TF agreed in general that the pattern and timing of migration provide ample opportunity for breeding between PCFG whales and other ENP whales. Little is known about gray whale social and mating systems, however, and presently unrecognized mechanisms facilitating selective breeding could exist. If a form of selective breeding does exist, then it could be a long time before nDNA differences appear. A suggested approach to resolving this question is to look at the relatedness of animals in the PCFG. Despite this, the TF agreed that it is most likely that PCFG animals are interbreeding with animals coming from other areas.

11. Research Recommendations

The TF agreed that the following set of recommendations represent key research needs that could help provide additional insight regarding if the PCFG should be recognized as a population stock under the MMPA and GAMMS guidelines.

Given the limited photo-identification and biopsy effort north of 52°N but knowing that at least some observations of PCFG whales in northern feeding areas (e.g., Kodiak and Barrow, Alaska) have been recorded, the TF highlighted the importance of expanding the spatial and temporal coverage of the photo-identification and biopsy effort. In addition, the TF also recommended that further satellite tagging of known PCFG whales be conducted to better delineate habitat use and define the summer/fall feeding area boundaries.

The TF noted that PCFG animals might more regularly interact (compared to non-PCFG whales) with crab pots given their extended residency in coastal waters. Therefore, the TF recommended that the existing photo-identification time series be used to examine scarring patterns of PCFG whales to better understand the incidence of interactions with fishing gear.

Since much of the photo-identification sighting effort occurs in August and later, when many calves are likely to already be weaned and thereby more difficult to identify as a calf (versus a yearling), the TF recommended that the existing PCFG photo-identification time series be examined following a protocol developed by Bradford *et al.* (2011). This photo-based method uses barnacle and pigmentation characteristics on young gray whales to reliably distinguish calves of the year from yearlings.

Knowing that several lines of evidence demonstrate a relationship between minimum tenure and the probability of photographically capturing animals in the 42°N-52N° PCFG area, the TF recommended that the existing PCFG photo-identification time series be examined to see if moms/calves demonstrate higher degrees of fidelity than other whales.

Although photo-identification studies of the PCFG by Calambokidis and colleagues have been ongoing for over a decade, a relatively high number of "new" animals (not previously sighted in the area) are identified each year and subsequently show consistent return to the area (Calambokidis *et al.* 2012). These "new" animals could represent calves born into the group (i.e., internal recruitment) and not identified in their first year, or they could represent animals that traditionally feed in northern areas but now show fidelity to the seasonal range of the PCFG (i.e., external recruits). To better address this question, the TF recommended that relatedness analysis, in which microsatellite genotypes are used to identify animals that represent putative mother-offspring pairs, be used to assess the proportion of internal recruitment occurring within the PCFG. A sufficient understanding of recruitment to make a stock definition determination could

potentially be achieved with a concerted effort to sample known mothers and recruits and determine their relatedness.

Related to the recommendation above, some TF members felt that it was plausible that the pulse of immigration into the PCFG could be larger than what the genetic simulations have modeled. If so, then the estimates of annual immigration into the PCFG could be lower than that estimated in the genetic simulations. With this in mind, the TF recommended that the genetic simulations should try pulses of 30 animals and see if that is consistent with the empirical genetic data.

12. Structured Decision-Making Process

At the request of the TF, Bettridge provided an overview of the FEMAT-style structured decision-making process⁶. In some NMFS status reviews, Biological Review Teams (BRTs) formed pursuant to the ESA have adopted formal methods to express plausibility for use in guiding its analysis of DPSs and in assessing the risks to the population(s). These formal methods are important in a setting where quantitative measures of uncertainty derived from the empirical data are unavailable. This point allocation method is often referred to as the “FEMAT” method because it is a variation of a method used by scientific teams evaluating options under the Northwest Forest Plan (Forest Ecosystem Management Assessment Team). In this approach, for example, each expert is asked to distribute plausibility points among the choices/scenarios for a given decision, reflecting his or her opinion of how likely that choice or option correctly reflected the population status. If the expert is certain of a particular option, or feels it is the only plausible scenario, he or she could assign all points to that option. An expert with less certainty about which option best reflected reality or best reflected the population’s status could split the points among two or more options. This method has been used in all status review updates for anadromous Pacific salmonids since 1999, as well as in reviews of Southern Resident killer whales, West Coast rockfishes, Pacific herring (*Clupea pallasii*), Pacific groundfish, North American green sturgeon (*Acipenser medirostris*), black abalone (*Haliotis cracherodii*), Hawaii false killer whale (*Pseudorca crassidens*), and humpback whales.

In the humpback whale status review, BRT members distributed 100 likelihood points among the defined scenarios or options, reflecting their expert opinion of the relative likelihood that the status of a specific DPS falls into each of three risk categories. Then the team discussed how they had allocated points and subsequently had a chance to revise their scores. Scorer identity was known.

In the Hawaii false killer whale status review, BRT members distributed 10 points between the arguments for and against each factor. Team members agreed to view resulting scores with names associated to facilitate discussion and assure that linguistic uncertainty was not responsible for any disparate votes. The BRT discussed the scores and, in some cases, adjusted scores when prior articulation of the arguments had been unclear.

After presentation of the structured decision-making approach, Bettridge asked the TF the following questions: (1) Does the TF want to use this approach? (2) If so, how many points will each member allocate among scenarios? (3) Does the TF wish to disclose names, or keep scores anonymous? (4) Does the TF wish to allow for rescoring after discussion? The TF members agreed to employ the structured decision-making approach, allocating 100 points per person. The

⁶ The TF agreed that Bettridge, as leader of the decision-making process, should refrain from allocating points on the decision questions.

group agreed to disclose names with scores for the purposes of internal discussion and possible rescoring but to retain anonymity in the final report.

The TF further agreed that they needed to carefully formulate the questions to be addressed and clearly understand what it means to put likelihood points in one category or another so as to provide the necessary advice for management-related issues such as: (1) how future NMFS stock assessment reports will be drafted with regard to gray whale stock structure in the North Pacific and (2) how to interpret any new information in the context of the Makah Indian Tribe MMPA waiver request to resume hunting gray whales off Washington State, USA.

Some TF members with experience using this approach in other situations found that when one or a few members allocated points very differently it was often due to misunderstanding of the question or what the answers implied. Therefore, it was agreed that the questions and the categories of answers should be as clear as possible to make the process both efficient and transparent.

12.1 Question formulation

In keeping with the objectives stated above for developing questions, the TF dedicated significant time during day 2 of the workshop agreeing on questions to be considered during the decision-making process. A key objective of this exercise was to focus on existing lines of evidence to help create the questions while at the same time being mindful of the existing definitions of the terms (e.g., demographic independence, interbreed when mature, functioning element of the ecosystem) contained in the MMPA and GAMMS guidelines. For instance, a simple example of this might be; “*evidence of demographic independence is when the number of internal recruits is greater than the number of external recruits*”. In general, this philosophy of creating questions was adopted by the TF and maintained during its deliberations.

After considerable work, the TF agreed to 11 questions. Overnight, TF members privately completed their point allocations for each of the questions. Point allocations were tallied and ready for discussion on the final day of the workshop. Allocating points in this manner allowed individual TF members to express their level of certainty on each of the questions, such that placement of all points in a single category indicated relative certainty in the lines of evidence discussed during the workshop. The TF agreed to view resulting scores with names associated to facilitate discussion and assure that linguistic uncertainty was not responsible for any disparate votes. The TF discussed the scores and, in some cases, members adjusted them when prior articulation of the lines of evidence had been unclear. The final 11 questions and likelihood point allocations for each of the TF members (anonymous, labeled A – G), as well as the proportional distribution of points overall, are provided below.

Question 1.	Overall	A	B	C	D	E	F	G
	Does the ecosystem occupied by the PCFG when they are feeding differ from the ecosystems occupied by other ENP gray whales?							
Strongly Agree	53	100	0	80	100	90	0	0
Somewhat Agree	47	0	100	20	0	10	100	100
Neutral	0	0	0	0	0	0	0	0
Somewhat Disagree	0	0	0	0	0	0	0	0
Strongly Disagree	0	0	0	0	0	0	0	0

Question 2.	Overall	A	B	C	D	E	F	G
	If gray whales in the ENP continued to be managed as a single stock, would the future abundance of PCFG gray whales be maintained above 60% of their current abundance if annual HCM in the PCFG was 5?							
Strongly Agree	38	0	95	0	0	20	50	100
Somewhat Agree	23	20	5	5	0	80	50	0
Neutral	25	50	0	25	100	0	0	0
Somewhat Disagree	14	30	0	70	0	0	0	0
Strongly Disagree	0	0	0	0	0	0	0	0

Question 3.	Overall	A	B	C	D	E	F	G
	If gray whales in the ENP continued to be managed as a single stock, would the future abundance of PCFG gray whales be maintained above 60% of their current abundance if annual HCM in the PCFG was 10?							
Strongly Agree	10	0	50	0	0	0	0	20
Somewhat Agree	24	10	50	0	0	25	30	50
Neutral	21	40	0	0	0	25	50	30
Somewhat Disagree	17	40	0	10	0	50	20	0
Strongly Disagree	29	10	0	90	100	0	0	0

Question 4.	Overall	A	B	C	D	E	F	G
	If gray whales in the ENP continued to be managed as a single stock, would the future abundance of PCFG gray whales be maintained above 60% of their current abundance if annual HCM in the PCFG was 20?							
Strongly Agree	0	0	0	0	0	0	0	0
Somewhat Agree	4	0	25	0	0	0	0	0
Neutral	7	0	50	0	0	0	0	0
Somewhat Disagree	22	10	25	0	0	50	50	20
Strongly Disagree	67	90	0	100	100	50	50	80

Question 5.	Overall	A	B	C	D	E	F	G
	Given the lack of significant differences found in nuclear markers between PCFG whales and other eastern Pacific whales, how would you allot points to:							
There is complete random mating within the eastern NP	63	70	70	70	50	80	60	40
There could be some non-random mating within PCFG whales that is either too recent or at too low a level to be detected given current sample sizes and marker numbers	37	30	30	30	50	20	40	60
PCFG whales breed primarily with each other	0	0	0	0	0	0	0	0

Question 6.	Overall	A	B	C	D	E	F	G
	Based on the genetic data and simulations, how would you allot points to:							
Nearly all recruitment into the PCFG area results from external recruitment (immigration)	0	0	0	0	0	0	0	NA
Most recruitment into the PCFG area results from external recruitment	21	20	30	20	0	20	33	NA
Recruitment is about equal between internal (births) and external (immigration) recruitment	56	60	50	60	100	30	34	NA
Most recruitment into the PCFG area results from internal recruitment	24	20	20	20	0	50	33	NA

Question 7.	Overall	A	B	C	D	E	F	G
	Based on the photo-identification data, how would you allot points to:							
Nearly all recruitment into the PCFG area results from external recruitment (immigration)	0	0	0	0	0	0	0	0
Most recruitment into the PCFG area results from external recruitment	38	30	55	50	0	30	50	50
Recruitment is about equal between internal (births) and external (immigration) recruitment	48	40	35	35	100	50	35	40
Most recruitment into the PCFG area results from internal recruitment	14	30	10	15	0	20	15	10
Nearly all recruitment into the PCFG area results from internal recruitment	0	0	0	0	0	0	0	0

Question 8.	Overall	A	B	C	D	E	F	G
	Do the genetic and photo-identification data indicate that the PCFG is a demographically independent population?							
Strongly Agree	0	0	0	0	0	0	0	0
Somewhat Agree	35	25	10	80	100	30	0	0
Neutral	21	50	30	10	0	40	20	0
Somewhat Disagree	25	25	50	10	0	30	40	20
Strongly Disagree	19	0	10	0	0	0	40	80

Question 9.	Overall	A	B	C	D	E	F	G
	Given all lines of evidence, is the PCFG a “population stock” under the agency’s interpretation of the MMPA?							
Strongly Agree	14	0	0	0	100	0	0	0
Somewhat Agree	22	25	10	80	0	30	10	0
Neutral	21	50	30	10	0	40	20	0
Somewhat Disagree	24	25	50	10	0	30	35	20
Strongly Disagree	18	0	10	0	0	0	35	80

Question 10.	Overall	A	B	C	D	E	F	G
	Given that some whales identified in the WNP migrate through U.S. waters to Mexico, should a separate SAR be developed for the WNP?							
Yes	79	100	70	100	100	50	80	50
No	21	0	30	0	0	50	20	50

Question 11.	Overall	A	B	C	D	E	F	G
	Given the differences found in mtDNA and nDNA between Sakhalin Island (WNP) and ENP gray whales, is there a “population stock” within the WNP under the agency’s interpretation of the MMPA?							
Strongly Agree	100	100	100	100	100	100	100	100
Somewhat Agree	0	0	0	0	0	0	0	0
Neutral	0	0	0	0	0	0	0	0
Somewhat Disagree	0	0	0	0	0	0	0	0
Strongly Disagree	0	0	0	0	0	0	0	0

12.2 Question outcomes and discussion

The outcomes of each question above are discussed below and follow the convention of using “percentage of total points” to describe the results. For example, in Question 1 the “strongly agree” category was allotted 53% of the total available TF points (370 points allotted/700 total points = 53%).

Question 1

The TF expressed general agreement, by allocating 100% of the their combined points to the categories “somewhat agree” (47%) and “strongly agree” (53%) that PCFG whales seasonally feed in a unique ecosystem that differs from other gray whale feeding areas in the Pacific. Therefore, the TF concurred that it is reasonable to consider that if the PCFG no longer existed and the region was not reoccupied via immigration, summer feeding gray whales would no longer be a functioning element of the coastal Pacific Northwest ecosystem. Although such a circumstance is plausible, keeping all other things equal (e.g., habitat, prey availability), the current lines of evidence from photo-identification studies suggest it is unlikely that the level of annual immigration into the PCFG in the past decade would cease. Thus, the likelihood of gray whales not being found in the PCFG area seems low. However, the time it might take for “recolonization” of the PCFG via immigration is undetermined and thereby puts into question whether this scenario would meet the MMPA objectives of maintaining stocks not only for ecological purposes but also for aesthetic, recreational and economic reasons.

Questions 2, 3 and 4

These three questions were meant to address the MMPA objective of maintaining population stocks as significant functioning elements in the ecosystem of which they are part, and that population stocks should not be permitted to decline below OSP. GAMMS II state that where mortality is greater than a PBR level calculated from the abundance for the region where human caused mortality (HCM) occurs, serious consideration should be given to identifying an appropriate management unit in the region. While estimates of PBR and HCM for a putative PCFG stock have been generated (Carretta *et al.* 2013), there is uncertainty about both estimates, especially with respect to: (1) whether HCM (e.g., ship strikes and fisheries bycatch) for whales in the PCFG area is indeed higher than for whales that migrate through the area, and (2) where HCM actually occurs. In response to these questions, the TF expressed increasing concern about the ability of the PCFG to be maintained above 60%⁷ of its current abundance once HCM exceeded 5 whales per year.

The point allocation in Question 2 indicates that the TF overall tended to agree that the future abundance of PCFG gray whales would be maintained above 60% of their current abundance if annual HCM in the PCFG was 5. However, the relatively equal distribution of likelihood points in all categories except “strongly agree” indicates a high level of uncertainty among the TF.

For Question 3, points were allocated more broadly across categories, indicating a higher level of uncertainty among TF members as to whether the PCFG could sustain levels of HCM at 10 whales per year.

There was increased consensus among the TF for Question 4 in that none of them responded “strongly agree”. Overall, the TF concurred that it somewhat (22%) or strongly disagreed (67%) that the future abundance of PCFG gray whales would be maintained above 60% of their current abundance if annual HCM in the PCFG was 20.

Question 5

The TF found no evidence to suggest that PCFG whales breed primarily with each other. While there was general agreement (63%) that the lack of significant differences found in nuclear DNA markers between PCFG whales and other ENP whales suggests random interbreeding among all ENP whales, the allotment of 37% of the total points to the intermediate category suggests TF members thought it was possible that some breeding segregation may exist based on migratory timing (see Lang *et al.* 2011) but there is no direct evidence presently available to support or further test this theory.

Question 6

The TF found no evidence in the results from genetics studies to suggest that nearly all recruitment into the PCFG area results from external recruitment (immigration). Based on the genetic data and simulations discussed during the workshop, the highest average TF response (56%) indicates that TF members believe recruitment is most likely about equal between internal (births) and external (immigration) recruitment. That being said, the remaining 45% of the total points were split between most recruitment into the PCFG area resulting from either internal or

⁷ The management goal of the MMPA is to prevent populations from “depletion”. NMFS considers a population depleted if it fall below its Maximum Net Productivity Level (MNPL). For marine mammals, this level is thought to be between 50% and 85% of carrying capacity and is more likely to be in the lower portion of that range (Taylor and DeMaster 1993). Therefore, populations are considered depleted by the U.S. government if they are directly estimated to be below their MNPL, or if they are estimated to be below 50%-70% of a historic population size which it thought to represent carrying capacity (Gerrodette and DeMaster 1990).

external recruitment, indicating some overall uncertainty among members regarding the presently available lines of evidence about recruitment in the PCFG. It should be noted that one member of the TF refrained from assigning any points to this question, so these results represent 6 of 7 TF members actively involved in the point assignment process.

Question 7

Based on the photo-identification data, the TF found no evidence to suggest that nearly all recruitment was either external or internal, but rather some combination of the two. As with the genetics evidence, the highest average TF response (48%) indicates that the TF felt recruitment from internal (births) and external (immigration) sources are comparable. That being said, 38% of the total points were allocated to most recruitment into the PCFG area resulting from external recruitment. Therefore, a majority of the total points were allocated to either recruitment being about equal between internal (births) and external (immigration) recruitment (48%) or most recruitment into the PCFG area results from external recruitment (38%). As was also true with the genetic lines of evidence, these results from the TF suggest a fairly high level of uncertainty regarding recruitment into the PCFG.

Question 8

Based on the genetic and photo-identification data, the TF did not strongly agree that the PCFG is a demographically independent population. Although the highest average TF response (35%) was “somewhat agree” that the PCFG is a demographically independent population, the combined categories of “somewhat disagree” and “strongly disagree” elicited 44% of the total points allocated. Overall, these results from the TF suggest a high level of uncertainty regarding recruitment in the PCFG.

Question 9

Given all lines of evidence, the point allocation of the TF reflects broad uncertainty as to whether the PCFG should be regarded as a population stock under the MMPA and GAMMS guidelines. Perhaps more than all of the other questions considered, Question 9 reflects the highest degree of uncertainty. For instance, the “strongly agree” (14%) and somewhat agree (22%) categories are almost perfectly counter-balanced by the “somewhat disagree”(24%) and “strongly disagree” (18%) categories. An additional level of uncertainty is indicated by the “neutral” category (21%). Given these results, it seems clear that TF was unable to reach a definitive response with respect to the PCFG being a population stock. That is, members of the TF ranged in their opinions from strongly agree to strongly disagree as to whether the PCFG should be considered a separate stock.

Given that this question represents the primary purpose of the workshop, the following two sections provide insight into the deliberations of the TF with regard to arguments for and against the PCFG being a demographically independent unit.

❖ Arguments for the PCFG being a demographically independent unit

The return of individual whales to specific feeding areas for as long as the PCFG has been studied (30+ years) strongly suggests that site fidelity is key to maintaining gray whales as a functioning element of this ecosystem. There was agreement that this ecosystem differs from other feeding ecosystems occupied by gray whales. Gray whales are unique among the great whales in being found in only a single ocean basin. Within this ocean basin the PCFG is the only feeding group that does not rely on the dynamics of a sub-arctic ecosystem. As such, the PCFG deserves the protections afforded by being an MMPA stock because the ecosystem role of these

animals is unique and also because it provides gray whales, as a species, the flexibility they may need given potential challenges in a changing sub-arctic ecosystem.

Although there is evidence of recruitment from other feeding aggregations, there is also evidence of direct internal recruitment because calves have been shown to return to the PCFG area and reside there. Furthermore, because photographic efforts take place after most calves would be weaned, the recruits into the population not first seen as calves are actually of unknown origin and cannot be definitively assigned as external recruits.

PCFG whales show a low but significant level of genetic differentiation at the mtDNA control region when compared to samples collected in Chukotka [representative of the ENP population and sampled at a single feeding location in the Bering Sea], and when compared to a set of samples collected primarily from animals that stranded along the west coast of the U.S. [representative of a broader sampling of the ENP population]. The significant differences found when the mtDNA haplotype data from the PCFG is compared with that of groups representing the larger ENP population provide indirect evidence of internal recruitment and matrilineally-directed site fidelity to feeding grounds. The level of differentiation is on par with levels identified among humpback whales feeding in different areas of the western North Atlantic (Palsbøll *et al.* 2001) as well as humpback whales using different breeding grounds in the Southern Hemisphere (Rosenbaum *et al.* 2009), suggesting that the PCFG exhibits demographic independence similar to what has been inferred for other large whales. Within the western North Atlantic, humpback whales feeding in the Gulf of Maine are managed as a separate stock despite the fact that they share a common breeding ground with humpbacks feeding in other areas. Although evidence for nuclear DNA differentiation between PCFG whales and other areas has not been found, nuclear genetic differentiation has not always been required for stock delimitation. Pacific harbor seal stocks were delimited on mtDNA differentiation alone (nuclear data were not available at the time), while the Gulf of Maine/Bay of Fundy stock of harbor porpoises was delimited based on significant differentiation at mtDNA, contaminant loads, and life history differences, and despite a lack of differentiation at nuclear markers.

❖ *Arguments against the PCFG being a demographically independent unit*

The evidence that external recruitment is not a rare event is quite strong. The genetic data have numerous rare haplotypes that are not consistent with a small, closed population. Indeed, simulations are not consistent with a closed population. A sizable number of individuals seen in the main feeding season are identified as transients, which is consistent with an on-going level of the main ENP population investigating this new habitat but then moving on. Further, when all samples collected in summer in the PCFG area are used there is not a significant difference found in mtDNA frequencies compared to all samples collected north of the Aleutian Islands. The number of recruits into the PCFG has been estimated, through genetic data, to be 4 to as high as 8 individuals per year. Photo-identification data suggest similarly high numbers of non-calf recruits per year (8-11). These numbers exceed the estimated number of internal recruits and, given that PCFG numbers appear to be relatively stable, an addition of 4 or more external recruits per year cannot be considered trivial. These external recruitment rates suggest the PCFG is not demographically independent from the larger ENP population.

Furthermore, unlike other large whale populations, the annual coastal migration of the vast majority of ENP gray whales brings most individuals into contact with the habitat used by the PCFG. Should there be increased removals from this area, the continual visitation to this area by

a large number of gray whales would make it likely that external recruitment would increase to fill any voids. The apparent pulse recruitment in 1999-2000 when conditions in the sub-arctic feeding areas resulted in a large mortality event shows that gray whales can adapt to a new habitat when conditions dictate. Using data collected since 2002 (post-pulse recruitment event), an average of 29.3 new whales have been identified in summer in the area used by the PCFG, with 18.5 animals that are not seen in later years and 10.8 whales that are seen in later years. Given that an average of 18.5 new whales (at least, as this does not account for new whales not photographed) visit the PCFG area each summer but do not return, this suggests that something on the order of 10% of the whales that occur in the PCFG area each summer are transients that otherwise feed north of the Aleutians, and serve as a substantial and continuous source of potential recruitment into the PCFG.

To date, there is no evidence for nDNA differentiation between Chukotka and PCFG whales based on 8 microsatellite loci or between the PCFG and one Mexican calving lagoon based on 15 loci. These results may be interpreted as female directed site fidelity to the PCFG area coupled with random mating between PCFG and ENP whales on the breeding ground. Lack of nuclear differentiation diminishes support for demographic independence.

All lines of evidence (photo-identification and genetics) are consistent with ongoing external recruitment that could be at a magnitude that is not trivial to the persistence of the feeding aggregation (more than a percent or two per year). Uncertainty in the number of recruits per year and exactly who those recruits are (PCFG calves misidentified as recruits, true recruits of adults, temporary immigrants who do not stay more than a few years and may not even be contributing to the gene pool) creates significant uncertainty as to whether internal recruitment exceeds external recruitment. Given the high level of mtDNA haplotypic diversity, the precision of F_{ST} estimates is also uncertain. Taken together, the available evidence is weak for concluding the PCFG is demographically independent.

Question 10

Given that some whales identified in the WNP have been observed to migrate through U.S. waters to Mexico, in combination with the 1994 amendments to the MMPA requiring that SARs be published for all stocks of marine mammals in U.S. waters, the TF agreed to a high degree (79%) that a separate SAR should be developed in the future for the WNP stock of gray whales.

Question 11

Based on the differences found in mtDNA and nDNA between Sakhalin Island (WNP) and ENP gray whales, the TF unanimously (100%) agreed that it qualifies as a population stock under the MMPA and GAMMS guidelines.

13. Concluding Remarks

The implications of new data pertinent to stock structure, including considerable information related to the PCFG and WNP gray whales, were thoroughly reviewed during the workshop. Evaluating the new findings relevant to the status of the PCFG proved particularly complex. After review of results from photo-identification, genetics, tagging, and other studies within the context of the GAMMS guidelines there remains a substantial level of uncertainty in the strength of the lines of evidence supporting demographic independence of the PCFG. Consequently, the TF was unable to provide definitive advice as to whether the PCFG is a population stock under the MMPA and the GAMMS guidelines. Members of the TF ranged in their opinions from

strongly agreeing to strongly disagreeing about whether the PCFG should be recognized as a separate stock.

In the case of WNP gray whales, the work of the TF was more straightforward. The mitochondrial DNA and nuclear DNA genetic differentiation found between the WNP and ENP stocks provided convincing evidence that resulted in the TF providing unambiguous advice that the WNP stock should be recognized as a population stock pursuant to the GAMMS guidelines and the MMPA.

Additional research may narrow the uncertainty associated with the question of whether the PCFG should be recognized as a population stock. To work towards this objective, the TF recommended further investigation of recruitment into the PCFG. Presently, both the photo-identification and genetics data indicate that the levels of internal versus external recruitment are comparable, but these are not quantified well enough to determine if the population dynamics of the PCFG are more a consequence of births and deaths within the group (internal dynamics) rather than related to immigration and/or emigration (external dynamics). The TF offered a number of research recommendations, using the existing photo-identification and genetics datasets, that could provide increased resolution on the issue of recruitment and, in turn, the question of stock identification.

While the need for additional data collection was apparent, especially with regard to recruitment into the PCFG, the purpose of the workshop was for the TF to determine whether the *existing* best available science was sufficient to advise that the PCFG be recognized as a population stock under the language of the MMPA and GAMMS guidelines. Therefore, the advice of the TF offered in this report should be viewed as a contemporary “snapshot” taken from an emerging and ever-changing body of knowledge regarding the PCFG.

The TF emphasizes that the PCFG is relatively small in number and utilizes a largely different ecosystem from that of the main ENP stock. While the status of the PCFG as a population stock has yet to be resolved, continued research on these whales should be undertaken with particular attention dedicated to collecting data relevant to the question of stock identification.

14. Acknowledgements

The Task Force appreciates the dedication and hard work of Aimee Lang and Annette Henry. Their contributions to the workshop and related report were indispensable. We also thank Lisa Ballance, Donna Darm, Jeremy Rusin, and Wayne Perryman for their advice and support in bringing the workshop to fruition. Jim Carretta and Steve Stone provided astute summaries of information that greatly benefitted the work of the Task Force. Cisco Werner and Kristen Koch provided encouragement for the workshop to be held and made available the facilities of the Southwest Fisheries Science Center. Barb Taylor kindly hosted a wonderful social gathering at her home.

16. Appendix 1 – Workshop Agenda

GRAY WHALE STOCK IDENTIFICATION WORKSHOP AGENDA

Southwest Fisheries Science Center

La Jolla, California

31 July-2 August 2012

Day 1 (31 July 2012)

8:30-8:45

1. Introductory Items

- 1.1 Convenor's opening remarks (Ballance)
- 1.2 Arrangements for the meeting (Henry)
- 1.3 Appointment of chair, task force and rapporteurs
- 1.4 Adoption of agenda
- 1.5 Documents available

8:45-9:15

2. Workshop Objectives

- 2.1 Provide scientific advice on gray whale stock structure (Weller)
- 2.2 Workshop relationship to stock assessment reports (Carretta/Bettridge)
 - 2.2.1 Confirm current stock structure
 - 2.2.2 Assess new information on putative or prospective stocks
 - 2.2.3 Provide advice on necessary changes to stock structure
- 2.3 Workshop relationship to Makah waiver request (Darm/Stone)
 - 2.3.1 History
 - 2.3.2 Key considerations
 - 2.3.3 Current status of waiver request
 - 2.3.4 Need to know information

9:15-10:30

3. Working Group on Stock Identification (Bettridge and Moore)

- 3.1 Overview of MMPA language and GAMMS guidelines pertaining to stock definition (Moore)
 - 3.1.1 Existing GAMMS language
 - 3.1.2 Proposed GAMMS revisions from the GAMMS III workshop
- 3.2 Overview of recent history pertaining to NMFS interpretation of "interbreed when mature" (Bettridge/Beale)
 - 3.2.1 Draft GAMMS II language pertaining to "interbreed when mature"
 - 3.2.2 Status of current legal analysis of NMFS proposed definition
- 3.3 Additional relevant history concerning definition of "population" for marine mammals (e.g., Taylor 1997, excerpts from Eagle *et al.* 2008) (Moore/ Taylor)

BREAK 10:30-10:45

10:45-12:00

- 3.4 Current status of gray whale SAR development (Bettridge)
- 3.5 Discuss key concepts: interbreed when mature, population, demographic independence, functioning element of ecosystem
- 3.6 Proposed TF voting protocol and process: examples from FEMAT and the ESA (humpback whale BRT, false killer whale BRT) (Bettridge)

3.7. Proposed questions to be voted on by the Task Force

12:00-12:45

4. Working Group on Other Information (Weller and Brownell)

- 4.1 Overview of gray whale “population stocks” (Lang)
 - 4.1.1 Eastern North Pacific Stock
 - 4.1.2 Western North Pacific Stock
 - 4.1.2.1 Genetic lines of evidence as being a stock
 - 4.1.2.2 Movements of whales between the WNP and ENP
- 4.2 Brief overview of the Pacific Coast Feeding Group (PCFG) putative stock (Lang)
 - 4.2.1 History
 - 4.2.2 Range
 - 4.2.3 Abundance
 - 4.2.4 Diet
 - 4.2.5 Movements (tagging, photo-ID)
 - 4.2.6 Incidental Take (Carretta)
 - 4.2.7 Emerging issues and areas of uncertainty
 - 4.2.7.1 Probability of a WNP Being Taken by the Makah (Moore)
- 4.3 Status of the ENP, WNP and PCFG as stocks (NMFS/MMPA/ESA/IWC) (Stone)
- 4.4 Proposed questions to be voted on by the Task Force

LUNCH 12:45-1:30

13:30-14:15

5. Working Group on Genetic Population Structure (Taylor and Rosel)

- 5.1 Broad overview of evidence used in recently defined stocks (Stone)
- 5.2 Review of stock definition cases relevant to the PCFG case
 - 5.2.1 Atlantic harbor porpoises (Rosel)
 - 5.2.2 Alaska harbor seals (Taylor)
 - 5.2.3 Humpback whales (Lang)

14:15-15:00

- 5.3 Review of gray whale genetic research relating to population structure (Lang)
 - 5.3.1 Summary of early work (LeDuc, Ramakrishnan, Alter breeding lagoon)
 - 5.3.2 Summary of recent work
 - 5.3.2.1 Frasier and D’Intino
 - 5.3.2.2 Lang – empirical genetics
 - 5.3.2.3 Lang – modeling genetics
- 5.4 Proposed questions to be voted on by the Task Force

BREAK 15:00-15:30

15:30-17:00

6. Discussion of Documents Drafted by the Makah Tribe and Other General Matters (Task Force)

- 6.1 Makah Tribe documents (Weller)
 - 6.1.1 Introduce GWLJ33: “Is the Pacific feeding group of gray whales a “population stock” within the meaning of the Marine Mammal Protection Act?”
 - 6.1.2 Introduce GWLJ32: “Comments on Draft 2012 Stock Assessment Report for eastern North Pacific stock of gray whales”
 - 6.1.3 Introduce GWLJ34: “What is the PCFG? A review of available information”
 - 6.1.4 Discuss genetics sections of Makah Tribe document GWLJ33 (Taylor/Rosel)
- 6.2 General discussion of Day 1 information

Day 2 (1 August 2012)

9:00-10:30

7. Working Group on Population Abundance and Trends (Laake and Wade)

7.1 Photo-identification and population dynamics of the PCFG (Laake)

7.1.1 Definition of PCFG whales based on timing/area

7.1.2 Movements of known PCFG whales (photo-identification and telemetry)

7.1.3 Abundance/survival estimates

7.1.4 Trends (Wade)

7.1.5 Recruitment

7.1.6 PCFG Trend/OSP (Moore)

7.1.7 Discuss photo-identification and telemetry sections of Makah Tribe document GWLJ33 (Laake/Wade)

7.2 Proposed questions to be voted on by the Task Force

BREAK 10:30-11:00

11:00-12:30

8. Review and Agree on Workshop Questions for Voting

LUNCH 12:30-13:30

13:30-15:30

9. Description of Vote Procedure (Bettridge)

10. TF Voting on Workshop Questions (TF Only)

Overnight

11. Compile and Tally Votes (Lang/Henry)

Day 3 (2 August 2012)

9:00-12:00

12. Review of Vote Outcomes (Lang/Henry)

13. Discussion of Vote Outcomes

14. Revision of Questions for voting if Necessary

15. Revote if Necessary

LUNCH 12:00-13:30

13:30-16:30

16. Review of Revote Results if Necessary (Lang/Henry)

17. Other Business

18. Workplan for Workshop Report Completion

19. Adjourn

17. Appendix 2 - Workshop Document List

GWLJ01

Moore, J. E., and Merrick, R., eds. *Guidelines for Assessing Marine Mammal Stocks: Report of the GAMMS III Workshop, February 15 – 18, 2011, La Jolla, California*. Dept. of Commerce, NOAA Technical Memorandum NMFS-OPR-47.

GWLJ02

Andrews, K. R., Karczmarski, L., AU, W. W. L., Rickards, S. H., Vanderlip, C. A., Bowen, B. W., Grau, E. G., and Toonen, R. J. (2010), Rolling stones and stable homes: social structure, habitat diversity and population genetics of the Hawaiian spinner dolphin (*Stenella longirostris*). *Molecular Ecology* **19**: 732–748.
